◆ Listening and talking methods of addressing psychological and psychosomatic problems and change ◆ An unstructured and non-directive form of therapy, using the therapeutic relationship as an active ingredient in promoting change ◆ Counselling operates largely without medication or other physical interventions ◆ Counselling may be concerned not only with mental health but with social, spiritual, philosophical and other aspects of living ◆ Professional forms of counselling are based on formal training, accreditation and on-going supervision and professional development	◆ Support, psycho-education and guidance ◆ Insight and understanding ◆ Self actualization and personality change ◆ Adjustment, symptom reduction and 'cure' ◆ Problem-solving and decision-making ◆ Crisis intervention and management ◆ Risk management (e.g. genetic counselling)

Counselling and psychotherapy

Much of the above can also be applied to psychotherapy and parts of this chapter do indeed overlap significantly with psychotherapy. There may well be variation between countries in what is defined as counselling or psychotherapy. Counselling and psychotherapy each have distinct features including different historical roots. *Psychotherapy* arose from the seminal works of Freud in the late nineteenth and twentieth centuries, and in the past, psychotherapists tended to offer a long-term psychodynamic approach. Now, however, psychotherapy also includes interpersonal, humanistic, and cognitive models. In the United States, *counselling* was originally linked with vocational guidance, personnel management, and the workplace,[5] and as such was much more advisory and directive than the analytic processes of psychotherapy. Carl Rogers, the founder of non-directive counselling in the 1940s, initiated the movement away from practical guidance and problem-solving towards collaborative and person-centred models, forming the basis of counselling today.

Differences between psychotherapy and counselling tend to relate more to the individual psychotherapist's or counsellor's training and interests and to the setting in which they work, rather than to any intrinsic difference in the two activities. In medical and mental health settings, psychotherapists are more likely to work with patients with severe psychological disorders, offering long-term therapy, whereas counsellors may concentrate on difficulties amenable to short-term work—mild to moderate psychological disorders, relationship difficulties, or bereavement. Counsellors who work for voluntary agencies or in educational settings such as schools and colleges usually concentrate more on the 'everyday' problems and difficulties of life than on severe psychological disorders, although agencies such as MIND, Alcoholics Anonymous, or

Narcotics Anonymous offer counselling to people with serious mental illnesses. In private practice, however, a counsellor's work will overlap with that of a psychotherapist.

In a pragmatic vein, Feltham states that *practitioners and the public stand to gain much more from the assumption of commonality than from spurious or infinitesimal distinctions . . . little is to be gained practically from further controversy about professional titles and distinctions*.[5] In 2000, the British Association for Counselling lent weight to greater rapprochement by becoming the British Association for Counselling and Psychotherapy. On a practical level, it is interesting that many recipients of 'talking therapies' other than counselling, such as psychotherapies, cognitive-behaviour therapy and problem-focused discussions with GPs, psychiatrists, or nurses, say that they have received *counselling*, reinforcing Feltham's plea that the issue of definition and distinction is academic rather than of practical value.

Counselling skills and counselling practice

Counselling skills are integral to the practice of psychiatry and all the 'helping professions', as basic ingredients of effective interviewing, accurate history-taking, diagnosis, and treatment-planning.[6] The skills of listening, summarizing, reflecting, checking, understanding, gaining rapport, and communicating enable other people to feel understood. They are essential for engagement and eliciting information, especially when the person is afraid, in pain, or mistrustful. The health worker's counselling skills may influence the patient's collaboration with an active participation in treatment, and thereby the outcome of a wide range of medical and even surgical treatments. Many helping and health professionals such as social workers, occupational therapists, probation officers, and speech and communication therapists use counselling skills as an integral part of their work but would not be seen as primarily counsellors.

In contrast, counsellors as *professionals*, who use counselling as a specific intervention, work in many areas of mental health practice alongside psychotherapists, clinical and counselling psychologists, psychiatrists, psychiatric nurses, and social workers.[7] For professional counsellors, counselling skills are central to their work.

Counselling as a specific planned intervention in psychiatry can be differentiated into two broad and overlapping categories, defined by aims into *decision-making* and *treatment*:

- *Decision-making* is an important ingredient in many forms of therapeutic counselling but, conversely, some forms of decision-oriented counselling (e.g. genetic counselling) embody no explicit therapeutic intention.
- Counselling as a primary *treatment* for problems is used in the management of a range of conditions as an adjunct to other interventions including medication, as an integral component of a multimodal treatment method (e.g. crisis intervention), or as a specific treatment in its own right (e.g. for postnatal depression).

Counselling psychology

As well as professional counsellors, counselling psychologists have a particular role to play within counselling provision in mental health. The area of counselling psychology, now developing in the United Kingdom in line with other parts of the world, is a distinctive profession within applied psychology, which aims to foster the psychological development of the individual and help people develop more effective and fulfilled lives. It is based on the fundamental tenets of counselling, but in addition aims to integrate the application of psychological theory and research into its practice.[8] Counselling psychologists use a variety of therapeutic models, including person-centred, psychodynamic, and cognitive. Although the training of counsellors can be varied, as discussed below, counselling psychologists undergo standardized post-graduate doctorate training leading to chartered status within the British Psychological Society, or equivalent in other countries.

Is counselling an effective method of treatment?

Despite the proliferation of counsellors in many areas of medicine and psychiatry, counselling has tended to lag behind medicine and other health care professions in engaging in and promoting research to establish its effectiveness and efficacy.[9] The nature of counselling can mean that standard methods such as RCTs are not appropriate means of evaluation, whereas qualitative research methodology is better able to assess meaningful changes.[10] However, counselling as a profession is now engaging in better quality research, concentrating on outcomes in routine practice as well as qualitative analysis. New practice-based methods of evaluation, such as CORE (Clinical Outcomes in Routine Evaluation), and the aggregation of data across UK NHS counselling services can lead to national benchmarks. Methods of case-study research, and the development of measures of the client's perspective on psychological distress, PSYCHLOPS,[11] enable more client-focused research. Such emphasis on evidence-based practice will lead to more careful targeting of specific counselling approaches to specific problems,[3] clearer information for the public and will improve counselling's parity with other health care professions.

Currently, counselling has an image that it is more appropriate for people with mild to moderate difficulties. The Department of Health[4] recommends that counselling should not be the main intervention for people with severe and complex mental health problems or personality disorders. Patients who are adjusting to life events, illnesses, disabilities, or losses may benefit from brief therapies such as counselling. However, counsellors such as those in primary care and the voluntary sector are already offering an important and valued service. Although people with more serious and enduring mental health difficulties require primarily psychiatric and pharmacological intervention, offering emotional support, advice, and problem-solving can form an important, although under-researched, part of their care.

The core conditions of counselling and the therapeutic relationship

Counselling depends primarily on the interaction between the counsellor and client, what goes on in that interaction and the qualities of both client and counsellor. Carl Rogers'[12] definition of the conditions necessary for therapeutic change was a radical departure from traditional psychotherapeutic practice, in emphasizing the *qualities* and *attitudes* of the counsellor rather than specifying what the counsellor must *do*. His work led to the following as *necessary* and *sufficient* conditions for therapeutic change:

- The client is in a state of *incongruence*, being vulnerable or anxious.
- The therapist is *congruent* and *genuine* in the relationship with the client.

- The therapist experiences *unconditional positive regard* for the client.
- The therapist experiences an *empathic understanding* of the client's frame of reference or way of seeing things.
- The therapist feels *non-possessive warmth* towards the client.
- The client *perceives* the therapist's unconditional positive regard and empathic understanding.

These core conditions have been used and developed in many models of counselling and therapy; even therapies traditionally seen as more technical have always maintained their importance.[13] *Empathy*, for example, a core condition which is central to all good therapeutic relationships, enables clients to know that they are heard and understood. At its simplest, empathy is a simple restatement of someone else's words. At its richest, it involves ... *a fearless exploration of another's inner world, a sensing of meanings unspoken, a compassionate naming of pain ... the fullest empathy does not censor or discriminate. It sees the world as the other person sees it.*[14]

While Rogers took the view that such core conditions are both necessary and sufficient for therapeutic change to occur, other models of counselling have defined such conditions as necessary but not in themselves sufficient for change. However, the core conditions remain the bedrock upon which counselling is practised.

The therapeutic relationship

Across very diverse treatments, including cognitive and psychopharmacological,[15] measures of the strength of the relationship, or alliance, have been the strongest and most consistent process correlates of treatment outcome.[3,16] Clients who have strong alliances with their therapists tend to have better outcomes.

Although recognized as an essential component of change, different models have different conceptual and practical approaches to the relationship. Three examples illustrate the differences:

- Person-centred models take a here-and-now perspective, looking at the immediate interaction between client and counsellor. The client's perception of the therapist's empathy, unconditional positive regard, and congruence enables therapeutic change.
- Cognitive models regard the relationship as necessary but not sufficient for therapeutic change. The relationship is primarily collaborative, with an active, working bond formed between client and counsellor to facilitate the tasks of therapy.
- Psychodynamic models distinguish the real relationship between client and counsellor, and the transference relationship, consisting of both client transference and therapist counter transference. The working alliance therefore is only partly based in reality, also containing aspects of both parties' histories.

Counselling methods and techniques

There have always been many approaches to counselling and psychotherapy, and this diversity grew into a veritable 'multiverse' during which some authors estimated that there were over 400 brand therapies in existence. There are also different settings and agencies which offer counselling—clinics, institutes, health centres, or voluntary bodies, each with its own particular features. Within each model and setting, there are different formats of counselling including self-help materials on CD-rom and the Internet, as well as individual, couple, group, family, and organizational. Such a range can be confusing to potential clients and organizations, and the question of what works, for whom, and in which setting, has to be central in matching client, problem, therapy, and therapist.

Specific models of counselling are usually differentiated by a number of factors:

- Basic assumptions or philosophy
- Formal theory of human personality and development
- Clinical theory defining the goals, principles, and processes of change
- Therapeutic skills and techniques[17]

One useful distinction exists between *schools* of counselling and *theoretical approaches*.[18] A theoretical approach presents a single position regarding the theory and practice of counselling, whereas a school is a grouping of different theoretical approaches with common characteristics(see Table 6.3.1.2).

The three main schools are humanist-existential, psychodynamic, and cognitive behavioural. Humanistic-existential models will be described in detail, with briefer mention of psychodynamic and cognitive behavioural models, which are covered in other chapters. The section on methods also looks at the trend towards integration and eclecticism within counselling, whereby counsellors use a variety of methods and approaches adopted from different models. Although not clearly fitting into any one school, information-giving and *problem-solving* are counselling methods widely used in psychiatry, and are therefore described first.

Information-giving and problem-solving

Giving information is an important part of all medical and psychiatric practice, reflecting an open and collaborative approach to treatment, providing patients and their carers with the material necessary for informed decision-making. For example, for people with schizophrenia or those who misuse alcohol, the provision of information about the diagnosis, causes, and potential consequences of their condition is essential for mobilizing motivation and compliance with treatment. Giving information about the actions and potential side-effects of a prescribed medication enables people to

Table 6.3.1.2 Overview of counselling schools and main approaches (Reproduced from Nelson-Jones, R. *Theory and practice of counselling and therapy* (4th edn.), copyright 2006, Sage Publications.)

Psychodynamic school
Classical psychoanalysis (Sigmund Freud)
Analytical therapy (Carl Jung)
Humanistic-existential school
Person-centred therapy (Carl Rogers)
Gestalt therapy (Fritz Perls)
Transactional analysis (Eric Berne)
Existential therapy (Irvin Yalom and Rollo May)
Cognitive behavioural school
Behaviour therapy (Ivan Pavlov, BF Skinner and Joseph Wolpe)
Rational emotive behaviour therapy (Albert Ellis)
Cognitive therapy (Aaron Beck)
Multimodal therapy (Arnold Lazarus)

play an active role in pharmacological intervention. Information-giving is always crucial when communicating a diagnosis and fundamental to counselling for risk, as in genetic counselling, and to any intervention in which the individual is helped to make decisions.

Psycho-educative methods have a place in most models of counselling and psychotherapy, but have specific importance in problem-solving and cognitive behavioural models. For example, a psychologist or counsellor may describe to the client a psychological model of a specific condition, such as the cognitive model of panic, to help the client understand their particular symptoms.

Information-giving and psycho-education involves more than just giving information to a passive recipient. Wherever possible the individual's curiosity about their condition is promoted, encouraging them to ask questions and, when appropriate, to find their own answers. The Socratic method and guided learning are central to cognitive approaches. Information is not provided in a didactic fashion, but in response to the client's questions, as client and therapist are engaged in collaborative enquiry. Whatever the information given, the practitioner checks whether the client has understood the information and its meaning. Information-giving is rarely the endpoint of an intervention, serving instead as the basis for decision-making or continuing therapeutic work.

Problem-solving has been used and empirically validated as a specific treatment, particularly for depression, and is used by many cognitive behavioural and humanistic counsellors. Problem-solving forms a major part of brief solution-focused therapy.[19] From a problem-solving perspective, depression results from the interaction between negative life events, current problems, and deficient problem-solving abilities, and therefore facilitating solving problems is a means to alleviate depression.[20] Therapist and client work collaboratively to identify and prioritize key problem areas, break them down into specific manageable tasks, solve problems, and develop appropriate coping behaviours. The approach involves several stages:

- Identification and formulation of the client's problem(s)
- Setting clear and achievable goals
- Generation of alternatives for coping
- Selection and operationalization of a preferred solution
- Evaluation of progress, with further problem-solving as necessary

Research in the United Kingdom has shown that problem-solving delivered by general practitioners is as effective as pharmacological treatment for moderate and major depression in primary care.[21,22] The intervention can be extremely useful for clients who do not want or cannot tolerate pharmacological treatment and is recommended in NICE guidelines as a treatment for mild depression. It can be offered by counsellors, general practitioners, and nurses, and may be a means to improve treatment adherence for people with psychotic disorders, as part of a psycho-educational intervention including motivational interviewing.[23]

Brief solution-focused therapy developed from its roots in family therapy to applications in counselling, mental health, group work, education, drug and alcohol work, social work, and business. It is the preferred mode of working for counsellors in the workplace, given its brief and focused approach. The model arose from family therapists' observations that clients made significant changes when focusing on their preferred futures rather than on current problems. By articulating solutions, and building on existing skills and strengths, clients saw their problems in a different light and could effect change.

The 'miracle question' is a classic method of solution-focused therapy which is integrated into other models. The client is asked to think about and describe waking up one day to find that all problems have vanished. The counsellor explores the impact of the miracle on people and situations. The question enables the client to get into a problem-solving cognitive set, enabling identification of what needs to happen for the problems to change. The method has been studied in a range of client groups and settings, including with repeat offenders in the forensic service, and can produce positive outcomes.[19]

Humanistic and existential models

Humanistic and existential approaches include person-centred therapy, gestalt therapy, transactional analysis, and existential approaches. Of these, the person-centred model is the most well known, and the one that comes most readily to mind when describing the philosophy of counselling.

Client-centred, *or* ***person-centred*** as it is more often called, counselling originates from the work of Carl Rogers, whose emphasis on the recognition and empowerment of the help-seeker challenged the perceived authoritarianism of both the medical model and psychoanalysis. The model highlights respect for the person, and adopts the optimistic assumption that each person has an inner potential for healthy development and achievement, or 'self-actualization'. Person-centred approaches often use the analogy of a plant to describe the concept of growth and change. No one can make a plant grow, but if the plant is provided with the right conditions—water, light, soil, nutrients—then it will become the best plant it can be. Person-centred therapy assumes that people have an inbuilt motivation to change, and also have the skills necessary with which to effect changes. Rogers' model of counselling is non-directive. The counsellor's task is to create the core relationship conditions of empathy, warmth, unconditional positive regard, and genuineness, described above, in which the client's inner resources and potential will be unlocked, leading to the spontaneous resolution of problems and developmental growth.

The central features of person-centred counselling form the bedrock of other models of counselling, including cognitive approaches. Carl Rogers, in initiating the person-centred approach, has also had a wide influence in the helping professions—the term 'person-centred' is used frequently in policy documents and guidelines within health care organizations, as one of the standards of service and as a philosophy of health care.

While a non-directive and reflective approach has value, and may be useful for initial data-gathering and supportive work, caution must be applied to the use of Rogerian counselling in psychiatry. Resource constraints require practitioners to impose time limits on counselling, which therefore must be more focused and 'active'. Furthermore, very disturbed people may be unable to access an inner potential for spontaneous change and growth, implicit within the client-centred model. There are some for whom a reflective non-directive approach may be harmful, risking an overwhelming upsurge of avoided or forgotten memories of traumatic experiences without providing methods for coping with them.

Victims of childhood sexual abuse or other destructive experiences may be re-traumatized by unstructured reflective counselling.

It is likely that the person-centred approach will continue to form the basis of good counselling and psychotherapeutic practice regardless of the model used, with increased emphasis on more 'skills-based' approaches such as cognitive behavioural and other models that lend themselves more easily to measurement, structured working, and evidence-based practice.

Gestalt therapy was originated by Fritz Perls, who described his approach as dealing with the total existence of a person, rather than being primarily occupied with symptoms or character structure.[24] Gestalt therapy argues that the past is past and the future unknowable, therefore the focus of counselling should be the present moment—an approach, interestingly, espoused by the development of mindfulness in psychiatry and psychotherapy.[25] The goal of therapy is to put clients in touch with what they are thinking, feeling, and sensing, in the here and now, and how they restrict or limit themselves by continual focus on the past or future. Gestalt therapists regard the therapeutic relationship as a 'working' relationship, with client and counsellor taking responsibility for themselves. Attaining awareness is an essential aim within the relationship.

Gestalt therapy uses many techniques, including dream-work and psychodrama. The classic 'two chair' method of gestalt therapy enables clients to work with 'unfinished business' which may be influencing current problems. For example, a client with memories of a difficult relationship with a parent is encouraged to have a dialogue with the parent in the empty chair, to see both client and parent's point of view. The client may put themselves, metaphorically, in the empty chair, to enable greater understanding and acceptance of the self.

Research has only recently played a role in the development of gestalt theory and practice. Most of the studies concern the effectiveness of the two-chair method, an approach which is being integrated into other models, for example Greenberg's[26] emotion-focused psychotherapy, and cognitive approaches.[13]

Transactional analysis (TA) was founded by Canadian psychiatrist Eric Berne, and provides a theory of personality, child development, and psychopathology as well as a theory of counselling. The method assumes, as for other person-centred approaches, that people are born with a drive for growth and health—the 'I'm OK, you're OK' life position. TA characterizes the personality into three groups of 'ego states'—parent, adult, and child, each with behavioural, social, historical, and phenomenological aspects. Psychopathology arises from the repetition of unhelpful life scripts, or patterns of being, often learned early in life. Counselling enables the individual to identify and modify problematic patterns.

Very little research has been conducted into the effectiveness of TA as a therapy although many theoretical concepts and practical techniques have been assimilated into psychotherapy and counselling.[27] The method has also led to the concept of the 'reflective practitioner', a theme embodied by the BPS Division of Counselling Psychology.

Existential approaches originated in applied philosophy, and focus on helping people to come to terms with life in all its confusing complexity. Rather than curing people of pathology, the aim is to help people deal with the contradictions, dilemmas, and paradoxes of everyday existence.[28] Anxiety and depression, rather than to be avoided, are to be embraced and understood in order to live life to the full. The main method is conversational, enabling clients to confront rather than avoid the reality of situations.

Although existential approaches may sound idealized and unrealistic, much of existential therapy aims to help people build confidence and competence in tackling everyday problems. The methods and approaches have very little outcome research, because of the opposition of existential therapists to what is seen as the reductionist tendencies of research—i.e. what is effective in therapy is not open to evaluation using standard methodology. It may be that the approach offers a number of factors which can be usefully integrated into other, more evidence-based models, such as the focus on validating experience, creation of meaning to enable traumatic events to be processed, and authenticity.

Cognitive behavioural approaches

Cognitive behaviour therapy (CBT) is currently receiving excellent press internationally, and occupies a central place in the move towards evidence-based practice. NICE recommends CBT more often than other therapeutic approaches for many psychological problems. Despite its popularity and evidence-base, cognitive approaches have not been readily embraced by the counselling world.[13] The structured and focused approach, and use of techniques to promote change, rested uncomfortably with counsellors trained in client-centred approaches, and cognitive therapy was felt to pay insufficient attention to the therapeutic relationship and to the influence of past events on current problems. However, the last few years have seen a major change in the way cognitive therapy is being adopted within counselling, and a large proportion of counsellors integrate at least some of the approaches into their work.

The attraction of cognitive therapy to counsellors is increasing, with more overt focus placed on the therapeutic relationship, long-term approaches, and schema-focused work inherent in newer models, which enables counsellors to abandon their prejudices against CBT.[29] There is enormous scope for counsellors to adopt cognitive therapy in a more systematic and rigorous manner, particularly in light of the empirical evidence supporting its effectiveness and increasing demand for briefer interventions.[13] However, counsellors trained in different schools of counselling can be tempted to borrow specific methods from cognitive therapy, such as monitoring negative thoughts, and to use them in an eclectic way. The risk is that the effective components of the approach such as collaboration, structure, focus and homework, may be lost, thus diluting CBT's established effectiveness.

Psychodynamic counselling

Psychodynamic counselling[30] draws from the theoretical traditions of Alderian therapy, Jung's analytical psychology, Freudian psychoanalysis, and Kleinian psychodynamic therapy. Psychodynamic approaches pay particular attention to past experience, particularly adverse relationship experiences during early life, the continuing influence of which may be mediated by unconscious processes. These are seen to influence attachment patterns, psychosocial development, and later psychological functioning. Unconscious processes derived from early experiences contribute to the generation and maintenance of abnormal psychological states. In psychodynamic counselling and psychotherapy, these unconscious processes may be identified through examining

transference and counter-transference in the therapeutic relationship.

The search for the personal meaning of the client's problem or symptoms is central to psychodynamic counselling. The counsellor encourages clients to talk about their difficulties, but also to reflect and gain insight on spontaneous associations and attitudes towards the counsellor as potential sources of information about the presenting problems. Insight alone may be sufficient to enable clients to spontaneously bring about the required changes in their lives. Psychodynamic counselling may also use methods akin to problem-solving and behavioural experiments to facilitate identification and rehearsal of new and more adaptive interpersonal strategies.

Eclectic-integrative approaches

Many practitioners assimilate conceptual and practical way of working that can be attributed to more than one theoretical perspective, formulating the client's difficulties and choosing a mix of methods using more than one theoretical framework. Formally working with a variety of models and methods may be described eclectic or integrative.[31] Such generic therapies often emphasize non-specific factors such as building the therapeutic alliance and engendering hope. Whether this gives the best of each world, or risks the worst of all, is very much open to question, and by nature, eclectic therapy is difficult to standardize for RCTs. The worst kind of *eclecticism* may be an arbitrary pick-and-mix approach, whereby a generically skilled counsellor trains in a variety of approaches and applies these with clients in a way in which he or she deems best. There is little evidence that such an approach is any more effective than the core conditions of counselling allow. Lazarus[32] describes *technical eclecticism*, the drawing of interventions from different sources without necessarily subscribing to their founding discipline. Wherever possible, technically eclectic therapists use treatments based on empirical evidence and client need.

Integration, in contrast, combines identifiable and specific aspects of models in a predetermined way, allowing the evolution of a defined form of therapy such as *cognitive analytic therapy*.[33] *Psychodynamic interpersonal therapy* offers NHS counsellors a point of convergence between predominantly humanistic counselling and more clinically and dynamically orientated approaches often used within psychiatry.[34]

Integration and eclecticism in counselling and therapy will no doubt continue to develop as the nature of clients' problems and the ways of doing therapy evolve. Environmental and technological changes may lead to increasing use of the Internet in counselling and psychotherapy, with face-to-face interactions possible even when client and counsellor are in different locations. It is essential that new counselling approaches are thoroughly supported by empirical evidence so we do not see creeping eclecticism washing out the effectiveness of established methods.

Applications of counselling to specific conditions

Depending on the settings in which they work, counsellors need to be equipped to work with clients with a range of psychological difficulties. For example, the primary care counsellor's caseload is likely to include client difficulties ranging from mild to moderate anxiety or depression to bereavement and relationship problems. Whether or not counselling is an effective intervention for the range of problems seen in these settings has not yet been clearly established. The following looks at counselling for problems where there is good evidence for effectiveness.

Common psychological problems

A Cochrane systematic review[35] compared counselling with normal GP care for people suffering from anxiety, depression, or stress disorders. The authors concluded that overall, significant benefits were seen in mental health improvement from counselling compared with usual GP care, or GP care plus antidepressant treatment, in the short-term (up to 4 months). However these benefits were not maintained in the longer term, over 9 to 12 months. Counselling may be more effective for depression than as a treatment for anxiety. Barrowclough *et al.*[36] compared CBT with supportive counselling (SC) in the treatment of anxiety symptoms in older adults. The CBT group did better than the SC group following treatment, and at follow-up. Overall, cognitively orientated models of counselling and therapy are more effective for depression and anxiety in the long-term than generic counselling. However, counselling may enable people to recover more quickly from depression, and is therefore a valuable and valued intervention.

Counselling for adjustment disorder

Adjustment disorder is defined as a problematic response to a normal stressor, not caused by another mental health problem or bereavement. Such stressors include normal transitions such as leaving home, migration, adverse interpersonal experiences (e.g. relationship breakdown), and unexpected losses such as redundancy. Individual vulnerability can play a part in a person's reaction to life changes, such as previous losses or other adversity, social or cultural isolation, economic deprivation or physical illness.

Counselling is recommended as the first line of treatment for people having difficulty adjusting to life events, illnesses, disabilities or losses, including childbirth and bereavement.[4] The counselling relationship is an important source of security when much has changed in the person's life. The client is helped to identify the stressors, to explore the personal significance of the changes experienced, and to express the emotions generated. It can be necessary to examine unresolved past experiences which may impact on the current adjustment—for example, an individual may not begin to come to terms with redundancy until he recognizes and addresses his unresolved feelings about being abandoned by a parent in childhood. Problem-solving methods are used to identify adaptive goals and ways they may be achieved. The counsellor may encourage the client not to use unhelpful solutions such as denial, excessive use of alcohol, or emotional suppression. The aim is for the client to resolve the crisis themselves.

Relationship problems

Government statistics from both the United States and the United Kingdom show that an ever-growing proportion of marriages fail, with around one in two marriages ending in divorce and an even higher rate in other relationships. Many divorces and relationship problems involve children under the age of 16. A number of specialized services have evolved, including pre-marital counselling, counselling for sexual problems, infertility counselling, bereavement and divorce counselling, and counselling for those involved in

second and subsequent relationships.[37] Telephone counselling and drop in services are frequently used by individuals and couples aiming to clarify the problems and find appropriate help. The kind of issues couples bring to relationship counselling include:

- Communication difficulties
- Conflicts in need between different parties
- Extra-relationship affairs
- Sexual problems
- Conflicts as parents
- Gender role changes
- Violence
- Substance abuse
- Jealousy or possessiveness

Because of the wide range of difficulties, relationship counsellors tend to offer a variety of interventions rather than working within one therapeutic model, and it is unclear whether any one theoretical approach is generally more effective than another.[38] Brief, dynamic work can start the process of internal change, so that the couple is able to work on their own to practise new patterns of relating. Brief, focused work can offer immediate and early solutions to issues which might otherwise threaten the relationship. Longer interventions may be required for couples dealing with major life events and experiences, and offer the opportunity to look at childhood and other roots of persistent or destructive patterns of relating.

The effectiveness of counselling depends a great deal on the willingness of participants to engage in a process which can be painful, challenging often long-established patterns of relating, and one partner in the relationship may be more enthusiastic than the other to promote change. Research shows that many of those who experience relationship counselling understand themselves better, become less emotionally disturbed and understand their partner and relationships better.[39] In some cases, a good outcome is for the relationship to end, in a way which causes least disruption to all parties including children. In the latter case, referral to other agencies may be essential, such as when child protection issues are involved.

Grief counselling

Grief is not a pathological state in itself, and most people emerge from the natural grieving process in a healthy way. Counselling has a role both in facilitating grieving for those who experience difficulties in the process, and in helping those with complex grief reactions.[40] Counselling might involve more than one person in a bereaved family or other grouping, for example the college friends of a student killed in an accident.

In health settings grief counselling is undertaken by trained professionals or volunteers, and in the community by self-help voluntary agencies such as Cruse (in the United Kingdom) or groups attached to hospices.[41] Voluntary agencies are often staffed by people who have themselves experienced bereavement, and group counselling in this context provides a valuable opportunity for acceptance, sharing of experience, and the hope borne out of talking with others who have already come to terms with their loss.

The research on grief counselling[42] shows that professional services and professionally supported voluntary and self-help services can reduce the risk of psychiatric and physical problems following bereavement, and reduce the risk level of 'high-risk' widows to that of a 'low-risk' group. Reid *et al.*[43] found that support by hospice volunteers of high-risk bereaved relatives substantially reduced their levels of anxiety and need for medical care.

Drug and alcohol problems

Drug and alcohol dependence and related problems generate many controversies about their nature and treatment, such as whether people diagnosed as alcoholics can ever return to harm-free, controlled drinking, and the motivation and ability of those addicted to drugs and alcohol to change. Many volunteer agencies offer drug and alcohol treatments, advocating a multifaceted approach, with a combination of methods drawn from motivational interviewing, person-centred and cognitive behavioural therapy known as 'motivational enhancement therapy'. There are several different models of drug and alcohol use, including that of Narcotics Anonymous, similar to Alcoholics Anonymous, who view substance abuse as a pre-existing, biochemical abnormality, necessitating lifelong abstinence. Other views seek to minimize the harm caused by drugs and alcohol, by reducing risks, reducing intake, and possibly changing to another, less harmful substance. A third view sees addiction as a pattern of inappropriate coping: cognitive behavioural principles are used to recognize and deal with situations likely to lead to drug use.

A major trial in the United States randomized 487 patients to one of four, 6-month, treatments. All treatments included group drug counselling following a 12-step model, focusing on achieving abstinence. The group program was offered either alone, or in combination with individual drug counselling, CBT or individual supportive-expressive psychotherapy. Attrition rates in all groups were high, with only 28 per cent completing treatment. All interventions led to a reduction in drug use, but the greatest reduction was for individual plus group counselling.[44]

Counselling for recent and past trauma

Increased public awareness of global trauma arising from natural disasters, war, and terrorism, has led to the development of psychological interventions designed to prevent the onset of post-traumatic stress disorder (PTSD) in those exposed to traumatizing events. However, after many years of early interventions in the form of active single-session 'debriefing' for individuals and groups, there is no evidence for their effectiveness in preventing PTSD. One of the problems in the field is the tendency to 'medicalize' normal distress in traumatic situations, leading to the construction of 'disaster therapists', perhaps with limited understanding of the culture in which the disaster occurred, ready to offer advice and counselling to survivors who may not see themselves as having a mental health problem.[45]

There is also no evidence that non-directive counselling is effective in treating acute stress disorder, which itself constitutes a risk factor for PTSD.[46] Short individualized preventive interventions in the style of 'psychological first aid' may be most effective.

There is no evidence that non-directive or reflective counselling is effective in the treatment of post-traumatic stress disorder. The advocates of counselling for post-traumatic stress disorder describe active-focused methods such as cognitive behaviour therapy,[47]

and using debriefing, to enable people to build a cognitive and emotional account of their experiences. Given that many clients with PTSD are, understandably, mistrustful or avoidant, the methods have to be used within the context of a sound therapeutic relationship, meeting the core counselling conditions.

Postnatal depression

Postnatal depression is often mild and remits spontaneously for many women. However, effective treatment is important because of the potential adverse effect on the child's emotional and cognitive development. Home-based counselling is as effective as antidepressant medication in the treatment of postnatal depression, and is more acceptable to mothers.[48] Counselling can be delivered by health visitors trained in cognitive behavioural counselling methods.[49] The research suggests that depressed mothers benefit from an opportunity to talk about their concerns, not all of which necessarily focus on their baby, with a receptive and non-judgemental professional person. Counselling and other psychological interventions are highly acceptable to mothers with postnatal depression, and preferred over pharmacological treatment. If counselling and other forms of psychotherapy enable women to recover from postnatal depression more rapidly than usual care, this alone may be a valuable service to offer in addition to routine care.

Counselling settings

Counselling takes place in a large number of settings relevant to psychiatry. These include primary care, general medical settings, student counselling services, workplace counselling services, and the voluntary sector. These settings will be described below, aiming to discuss the ways in which counselling may be best adapted to the individual settings, with indications of outcome data on effectiveness.

Counselling in primary care

Primary care is one of the most conspicuous areas of growth in counselling, stimulated by greater demands for alternatives to medication for emotional problems, and by continuing debate about the most effective way of managing mental health problems in primary care. The Layard report on the need for CBT for depression and NICE guidelines stress the importance and effectiveness of psychological interventions including counselling, with a particular focus on CBT. It is likely that the number of counsellors who practice CBT will grow in order to meet demand.

In the United Kingdom, around half of general practices employ a qualified counsellor and the majority meet national criteria for good practice.[50] The development of UK primary care counselling is no doubt part of a wider international trend towards more accessible counselling services at the primary care level.

Counsellors in primary care are a diverse group, in the patients that they see, the counselling models used, and the length of counselling offered. Those identified as primary care counsellors include practice nurses, health visitors, and district nurses trained in counselling skills; clinical and counselling psychologists; community psychiatric nurses, and social workers, and qualified counsellors and psychotherapists. Counselling in primary care is usually provided through one of three main service delivery models[51]:

- Counsellors based in GP practices and provided by a local agency or cooperative
- Managed counselling services provided by the PCT or mental health trust, with counsellors based in GP practices or a central site
- Voluntary agencies (in cases where PCTs have contracts to refer to externally managed services in the voluntary sector)

Counsellors are valued in primary care for a number of reasons,[52] providing time for patients to talk through and reflect on problems, where general practitioners are unable to spend the necessary time on individual patients, as well as a valued alternative or addition to pharmacotherapy. Counselling in primary care also facilitates early identification and intervention for mental health difficulties.

Counsellors in primary care need to be flexible in the way that they work, using different models as appropriate to each client. They also need to be flexible about boundaries and confidentiality, communicating with general practitioners and other health professionals as appropriate. Counselling is generally six to eight 50-min sessions, with a maximum of 20 sessions, and therefore focusing on presenting difficulties rather than long-term issues. The role of the counsellor is varied, and may include offering individual or group counselling, offering advice or training to primary care staff on managing mental health problems, and general consultation.

Despite the growth and popularity of counselling in primary care, it is not clear how effective it is compared to other models such as CBT. Studies have shown mixed findings.[9] Trials comparing counselling for anxiety and depression with usual general practitioner care, CBT, and anti-depressant medication have shown significantly greater clinical effectiveness of counselling compared to usual general practitioner care in the short-term but not in the long-term.[53–55] For people with chronic depression, there were no significant differences between usual care, CBT and short-term psychodynamic counselling,[56] although at 12 months, both psychological therapies were superior to usual care. Counselling in primary care can be cautiously reported as a valuable service, particularly for people with mild to moderate emotional disturbance as well as bereavement and relationship difficulties. Clients improve in the short-term, and the service is appreciated and valued by general practitioners and patients. Primary care services are probably best offered as a range of mental health services, linking closely with community mental health services.

Counselling in general medical settings

Medical patients are understandably at higher risk of psychological difficulties compared to the general population, and many hospital departments and clinics employ counsellors as part of the multidisciplinary team to meet patients' psychosocial needs.[57] Counselling benefits patients in many hospital settings such as gastroenterology, cardiology, obstetrics, and gynaecology, the families of children with medical problems and disabilities and patients with diabetes, renal failure, disfigurement, cancer, head injuries, and chronic conditions such as multiple sclerosis.[58] Counsellors offer what is becoming increasingly limited in medicine—time. A large amount of psychosocial adjustment is needed in most serious illnesses and conditions, and counsellors in health care settings are assisting people cope with potentially life's most challenging moments.

For some conditions, such as HIV/AIDS and genetically transmitted illnesses, counselling forms an important aspect of treatment. From its outset, HIV/AIDS attracted the attention of psychological therapists, since at first there was little else to offer

to help people deal with a strange and potentially fatal illness. A range of professional and voluntary services grew to support those infected. The stages of the illness present different needs, from pre-testing counselling, dealing with the emotional, social, and physical consequences of a positive diagnosis, and managing the adjustment to living with a chronic condition. *Genetic counselling* is specialized branch of counselling practice with increasing applications within psychiatry. In the coming years, the expected identification of susceptibility genes for psychiatric disorders may bring new opportunities and expectations from patients and families for psychiatric genetics.[59]

Counselling is usually offered through referral to a specific hospital department or ward-based counsellor. Many health care workers and hospital chaplains use counselling skills, which are generally regarded as supportive and therapeutic for patients. This does not replace the need for managed counselling services delivered by trained and professional therapists.

Counselling in educational settings

Counselling services in college and university settings cater for students with a wide range of issues. Because of their age and developmental stage, many students have problems adjusting to the new freedoms and demands of college life and also face the developmental challenges of adolescence and young adulthood—conflicts between dependence and independence, psychosexual development, issues to do with self and body image and eating disorders. Other common difficulties include financial, study, and interpersonal problems. Mature students may also contend with the stress of juggling study with children and home-life, and being minorities within a younger peer group. With increasing admissions of overseas students, issues such as identity and loneliness will also arise.

Student counselling services are often arranged so that practical (e.g. financial guidance or careers counselling) and psychological help are offered separately to provide discreet and confidential access. Most clients refer themselves, but may be referred by staff or the student's doctor. Services need to include or work closely with psychiatrists and other mental health professionals in order to meet the needs of students with mental illness. The majority present with less severe emotional or psychological problems, but these may be highly disruptive to their studies and social integration.

Short-term counselling is usually appropriate for students, partly because of their urgency and the structure of the academic year, but also because their natural developmental potential enables most young people quickly to change. This process may be accelerated even more by the intelligence inherent in students, though emotional development can lag behind intellectual development. The task of counselling has been likened to helping the young person back on to the track of normal psychosexual development. More severe derailments, however, may require longer counselling, specialized psychotherapy, or psychiatric treatment.

Counselling in the voluntary sector

Counselling within the voluntary sector has vastly increased, with a growing number of support groups and voluntary organizations offering counselling, mainly on self-referral basis. The most well known in the United Kingdom include Alcoholics Anonymous, Cruse Bereavement Care, Relate for relationship difficulties, and the Samaritans, with equivalent organizations in other countries. Many mental health charities offer support, befriending, and counselling at a 'grassroots' level; some, such as MIND in the United Kingdom, are organized nationally, whereas others operate at a local level. These organizations contribute a great deal to mental health provision, offering the opportunity to talk through and reflect on problems, and in offering support to individuals with more severe mental health problems and their families.

The interface between voluntary and statutory services is varied and at times uncomfortable, with the two sharing different models of care, philosophies, and policies on issues such as confidentiality. There is less research on the effectiveness of counselling provision within the voluntary sector, although one study has shown it to be at least as effective as statutory provision and is often carried out by appropriately trained staff.[60]

Counselling in the workplace

Mental health and employment are known to be significantly related: satisfaction at work is positively correlated with mental health and the unemployed experience higher rates of mental health problems compared to those in employment. The provision of workplace counselling has steadily expanded over the past 20 years, with more than 75 per cent of medium and large organizations in Britain and North America making counselling available to their staff. Counselling may be part of a benefits package, occupational health, human resources or a service brought in to help with specific problems, such as redundancy. Workplace counselling can be viewed as the application of methods of brief psychological interventions that have been shown to be effective in other settings. However, a distinctive strength of seeing a counsellor in the workplace is that the counsellor will be sensitive to the combination of personal and work pressures that the person may present. Workplace counselling is a systemic, as well as individual, intervention in that the organization that pays the counsellor is always present, consciously or unconsciously, influencing the number of sessions and confidentiality boundaries.

Counselling for work-related difficulties is effective in reducing stress-related problems at work and sickness.[61,62] Those who receive counselling are highly satisfied, believing it helps them resolve their problems. Clinically significant improvement in levels of anxiety and depression are reported in 60–75 per cent of clients. Counselling is associated not only with reduction in sickness absence but also improvement in other organizational outcomes such as more positive work attitudes, fewer accidents, and enhanced work performance.

The main provision of counselling at work include employee assistance programmes (EAPs) and specialized staff counselling services.

Employee assistance programmes were first introduced in the United States after the Second World War, to rehabilitate oil-industry employees with alcohol problems. EAPs have become widespread in North America and are increasing in the United Kingdom. They are reported to achieve good results in terms of the percentage of employees who are rehabilitated for work, the reduction in alcohol consumption, improvement of work performance, and cost savings to the company.[63]

EAPs provide a comprehensive confidential counselling service to employees and their families, allowing employee's problems to be identified and resolved at an early stage, and are normally incorporated into the company's benefits package as a form of private emotional health care. EAPs include 24-h access, telephone

counselling, and helplines as well as individual counselling offered at short notice. One of the advantages of counselling organized through EAPs as opposed to in-house staff counselling is improved confidentiality: staff may be reluctant to use counselling services at work if they are not convinced of full confidentiality, and if they fear their career prospects may be adversely affected.

Staff counselling services: many private and public sector organizations now have in-house counselling services.[61] One of the first was set-up by the Post Office in the early 1980s, in recognition of the need to provide emotional and psychological support to employees. Mental health issues, mainly anxiety and depression, formed 46 per cent of the caseload, as well as relationship problems, alcohol problems, bereavement, assault, physical illness or disability, and social problems. Staff counselling schemes are now promoted by many health and education authorities, the Royal College of Nursing, the British Medical Association, and MIND at Work. Problem-solving and cognitive methods of counselling appear to be the most valuable models for workplace settings.[61]

Evaluation of the London Transport Counselling and Trauma Unit showed that the service made huge savings in its first year of operation, in terms of reduced sickness absence and other treatment costs. Research from the United States indicates a return for every dollar invested in Employee Assistance Programmes of between $3 and $7.[61,62] Other benefits may be less quantifiable but nevertheless valuable. For example, a qualitative study[64] of police officers and support staff who had received counselling for work-related difficulties, showed that many described themselves as learning something new and useful about themselves as a result of counselling. For example, an experienced detective stated, *I am 100 per cent better at listening now to a person.*

Telephone and electronically delivered counselling

The telephone is a valuable method of counselling, as shown by organizations such as The Samaritans. Telephone helplines respond to millions of calls each year, and offer a means of talking about feelings and gaining support, information, and advice. The telephone is excellent for crisis intervention and short-term work—one of the key reasons why people phone telephone helplines is because they are in crisis and want to talk anonymously and confidentially.

The telephone and teleconferencing can also be used to conduct some or all of a course of individual or group counselling, or as an adjunct to pharmacological treatment. Telephone advice and structured counselling improved outcome and satisfaction for clients starting antidepressant medication,[65] and also improved adherence to medication.[66]

Electronically delivered counselling: since the mid-1990s, new forms of text technology—the Internet, chatrooms, email, and mobile phone texting—are being developed to deliver counselling and psychotherapy. There is an increasing body of evidence that using text to conduct a therapeutic relationship is not only possible but also in many cases more desirable than face-to-face interaction. Electronically delivered counselling has been addressed by counselling organizations in the United Kingdom, United States and internationally, with published guidelines on issues such as confidentiality and data protection, contracting and informed consent, assessment of suitability of clients, boundaries, and practitioner competence.[67] The International Society for Mental Health Online (http://www.ismho.org/) was formed in 1997 to 'promote the understanding, use and development of online communication, information, and technology for the international mental health community'.

Working electronically has benefits those who cannot access therapy because of, for example, disability or geography. Communicating from a distance can make for a more honest and open relationship, clients diverging information or issues which they would find difficult to discuss face-to-face. Such disinhibition may be empowering—clients having a cathartic experience, so they can then disappear into cyberspace—or potentially hazardous, with traumatic issues remaining unresolved. Although the evaluation of such services is in its infancy, and there are many issues to be addressed, such as practitioner competence and confidentiality, electronic forms of mental health provision are likely to increase. They provide a means of providing help to clients who not only cannot but do not wish to meet with a helper, clients who have been traditionally excluded from mental health provision.

Counselling accreditation, training, and registration

The number of counsellors and psychotherapists in the United Kingdom and other countries is growing rapidly. Professional status and accountability are key concerns about counselling and counsellors, along with other providers of non-medical health care[68]—in the past, anyone could practise as a counsellor, with no standards of training, supervision, or attachment to a regulatory body. As a result, the vulnerable users of such practitioners are at risk. However, there is a strong move within counselling towards clear standards of training and accreditation, to be able to provide an effective and accountable service to the public.

For full *accreditation*, professional counsellors are required to follow, as a minimum, a 3-year full-time training course in the theory and practice of counselling. The standards required are covered by two main organizations in the United Kingdom, with equivalents in other countries:

- The British Association of Counselling and Psychotherapy, which offers accreditation for counsellors from a variety of disciplines, mainly humanistic and psychodynamic.
- The British Psychological Society, which offers accredited chartered status for counselling psychologists, trained to meet standards in applied psychology.

The requirements for accreditation or registration vary between organizations. Common requirements are a minimum of 450 taught contact hours and 450 h of supervised practice, evaluated via case studies and process reports; academic knowledge of counselling theory and research; personal counselling or psychotherapy; and, for the British Psychological Society, research skills and experience. The qualification requires that practitioners follow a code of practice and ethics, stipulating ethical practice, the need for supervision, appropriate confidentiality, and other standards for professional practice.

One of the problems in accreditation is ensuring that counsellors have followed a known and recognized training course. Alongside the expansion of interest in counselling, the number of counselling courses rises each year, ranging from short evening classes in active

listening and short courses in counselling skills for health professionals, to full-time training leading to professional accreditation or chartering. A recent review of UK training found that many psychotherapy and counselling organizations are small, and a significant number of training providers are linked to no external quality assurance systems, 63 per cent having no professional body recognition.[69] There are a large number of titles for both training courses and individual counsellors and psychotherapists, which can only cause confusion to both potential trainees and the public. The review[69] made a number of recommendations to improve the quality of training courses, to lead to greater standardization.

A further change within counselling is the move towards registration. Currently there is no statutory protection for using the terms 'counsellor' or 'psychotherapist', and therefore no means for the prevention of bad practice or abuse. Without registration through a professional body, clients may have no redress for incompetent practice. The National Service Framework for mental health, which sets clear standards for the delivery of effective services, emphasize the importance of 'talking therapies' but stresses the need to register counsellors, psychotherapists, and psychologists. The registering organizations are now moving towards statutory registration and legal protection for the terms counsellor, psychologist, and psychotherapist; and at the time of writing, definitive legislation is likely to be in place by 2008 or so. In the meantime, it is vital that the public and health professionals are aware of the need to seek help only from qualified practitioners of counselling.

Conclusions

For psychiatrists and other mental health care professionals, it can be difficult to make sense of the range of counselling models available, and it is therefore not surprising that potential purchasers and consumers are similarly confused about the nature and advisability of seeking counselling. Counselling has only recently been subject to the rigorous evaluation necessary to meet the standards of evidence-based practice. The most central aspects of counselling, the therapeutic relationship, and qualitative nature of the work, can be difficult to evaluate using established research methodology.

However, counselling is an evolving profession, moving away from, but not forgetting, its roots in Rogerian and psychoanalytic practice, and working hard to meet standards of effectiveness, evaluation, registration, and accountability.

Far more attention is being paid to evaluation, with the development of research paradigms suited to counselling. Systematic evaluation will eventually make it possible to identify, on the basis of clear evidence, the indications for specific models of counselling as well as their limitations. Issues of training, standards, ethics, and accountability are being addressed, to enable counselling to become fully consolidated and integrated within mental health services.

Counselling is a vital part of psychiatry for many reasons. There is a significant gap between the demand for psychological therapy and the available supply. One proposal to overcome this problem is to increase efficiency of provision through the adoption of briefer 'minimal interventions' within stepped care models.[70] Counselling is likely to play an increasingly important part of provision of psychological therapies, particularly for those with mild to moderate mental health problems and social and relationship difficulties. It makes sense for interventions to be offered at an early stage of difficulties: while many problems do resolve on their own, people welcome the support and understanding that counselling can offer, and it is valuable in hastening recovery from emotional distress. Counselling may be appropriate as part of the treatment for people with serious mental illness, offered by psychiatric nurses, social workers, occupational therapists, and workers in the voluntary sector.

Although CBT is being advocated as the treatment of choice for many psychological problems, there is a risk that over-enthusiastic endorsement of the benefits of CBT at the expense of other models may lead to a gap in care: not everyone responds to cognitive approaches, and even when they do, the level of recovery varies. Therefore, the breadth and repertoire of counsellors can add a variety and richness to mental health care provision. *It is this aspect of the human condition, the recognition that we must learn to 'weep for the plague, not just cure it', that is an essential component of meaningful therapy and meaningful relationships. When we experience what seems awful and horrible in our lives, we often take solace in knowing that another person understands, or, at least, is attempting to understand, our pain.*[71]

6.3.2 Cognitive behaviour therapy

Contents

6.3.2.1 Cognitive behaviour therapy for anxiety disorders

David M. Clark

Introduction

Cognitive behaviour therapy for anxiety disorders is a brief psychological treatment (1 to 16 sessions), based on the cognitive model of emotional disorders. Within this model, it is assumed that it is not events per se, but rather people's expectations and interpretations of events, which are responsible for the production of negative emotions such as anxiety, anger, guilt, or sadness. In anxiety, the important interpretations, or cognitions, concern perceived physical or psychosocial danger. In everyday life, many situations are objectively dangerous. In such situations, individuals' perceptions are often realistic appraisals of the inherent danger. However, Beck[1] argues that in anxiety disorders, patients systematically overestimate the danger inherent in certain situations, bodily sensations, or mental processes. Overestimates of danger can arise from distorted estimates of the likelihood of a feared event, distorted estimates of the severity of the event, and/or distorted estimates of one's coping resources and the availability of rescue factors. Once a stimulus is interpreted as a source of danger, an 'anxiety programme' is activated. This is a pattern of responses that is probably inherited from our evolutionary past and originally served to protect us from harm in objectively dangerous primitive environments (such as attack from a predator). The programme includes changes in autonomic arousal as preparation for flight/fight/fainting and increased scanning of the environment for possible sources of danger. In modern life, there are also situations in which these responses are adaptive (such as getting out of the path of a speeding car). However, when, as in anxiety disorders, the danger is more imagined than real, these anxiety responses are largely inappropriate. Instead of serving a useful function, they contribute to a series of vicious circles that tend to maintain or exacerbate the anxiety disorder.

Two types of vicious circle are common in anxiety disorders. First, the reflexively elicited somatic and cognitive symptoms of anxiety become further sources of perceived danger. For example, blushing can be taken as an indication that one has made a fool of oneself, and this may lead to further embarrassment and

blushing; or a racing heart may be taken as evidence of an impending heart attack and this may produce further anxiety and cardiac symptoms. Second, patients often engage in behavioural and cognitive strategies that are intended to prevent the feared events from occurring. However, because the fears are unrealistic, the main effect of these strategies is to prevent patients from disconfirming their negative beliefs. For example, patients who fear that the unusual and racing thoughts experienced during panic attacks indicate that they are in danger of going mad and often try to control their thoughts and (erroneously) believe that if they had not done so, they would have gone mad.

Within cognitive models of anxiety disorders, at least two different levels of disturbed thinking are distinguished. First, negative automatic thoughts are those thoughts or images that are present in specific situations when an individual is anxious. For example, someone concerned about social evaluation might have the negative thought, 'They think I'm boring', while talking to a group of acquaintances. Second, dysfunctional assumptions are general beliefs, which individuals hold about the world and themselves which are said to make them prone to interpret specific situations in an excessively negative and dysfunctional fashion. For example, a rule involving an extreme equation of self-worth with social approval ('Unless I am liked by everyone, I am worthless') might make an individual particularly likely to interpret silent spells in conversation as an indication that others think one is boring.

Cognitive behaviour therapy attempts to treat anxiety disorders by (a) helping patients identify their negative danger-related thoughts and beliefs, and (b) modifying these cognitions and the behavioural and cognitive processes that normally maintain them. A wide range of procedures are used to achieve these aims, including education, discussion of evidence for and against the beliefs, imagery modification, attentional manipulations, exposure to feared stimuli, and numerous other behavioural assignments. Within sessions there is a strong emphasis on experiential work and on working with high affect. Between sessions, patients follow extensive homework assignments. As in cognitive behaviour therapy for other disorders, the general approach is one of collaborative empiricism in which patient and therapist view the patient's fearful thoughts as hypotheses to be critically examined and tested.

Background

Historical development of cognitive behaviour therapy

Modern cognitive behaviour therapy for anxiety owes its development to pioneering work since the 1950s and 1960s in which the principles of classical conditioning were applied to the understanding and treatment of phobias.[2] It was argued that (a) phobic stimuli are conditioned stimuli that acquired their aversive properties by being paired on one or more occasions with a traumatic event, and (b) avoidance is the main reason why phobias fail to extinguish. This suggestion led naturally to the development of various forms of exposure therapy, in which patients were systematically exposed to phobic stimuli. Initially therapists were concerned that elicitation of strong anxiety responses would be counter-therapeutic so exposure was very gradual, often starting with brief, imaginal presentations, followed by relaxation. Subsequent research showed that such a gentle approach was unnecessary and relatively rapid, *in vivo* exposure became the norm. By the mid-1970s, it was clear that up to 70 per cent of phobics obtained worthwhile improvements from *in vivo* exposure.[3] However, many were less than fully recovered and it was not clear how exposure therapy could be applied to non-phobic anxiety states (such as panic disorder and generalized anxiety disorder). In an attempt to enhance treatment effectiveness further, researchers attempted to identify additional factors that might maintain anxiety. Several cognitive processes outlined below received empirical support. As a consequence, more comprehensive cognitive behavioural treatments that attempt to modify a range of maintaining factors were developed. This chapter describes these treatments.

Cognitive content of anxiety disorders

Although there is no substitute for a careful assessment of each patient's ideation, research shows that most anxiety disorders are characterized by a specific type of fearful ideation and successful therapy generally focuses on such ideation.[4]

(a) Panic disorder

Panic disorder is characterized by a fear of an immediately impending internal disaster (e.g. heart attack, cessation of breathing, mental derangement) and a sense of loss of control over physical and mental functions. Many of panic patients' negative thoughts can be viewed as misinterpretations of normal bodily sensations (such as palpitations or a slight feeling of breathlessness). Indeed, cognitive theorists[5] argue that panic attacks result from a vicious circle in which catastrophic misinterpretations of body sensations lead to an increase in anxiety and associated sensations, which are in turn interpreted as further evidence of impending, internal disasters (e.g. heart attack, fainting, going mad). Panic disorder with agoraphobia is often also accompanied by fear of the interpersonal consequences of attacks (e.g. 'I'll make a fool of myself').

(b) Social phobia

Social phobia is characterized by exaggerated fears of being evaluated, of having one's weaknesses exposed, and of being judged adversely by other people. While in feared social situations, the social phobic continually monitors his or her performance, fears that this performance will be viewed as evidence that he or she is inept, boring, or stupid, and expects that such judgements will have dire long-lasting implications (loss of status or worth and failure to achieve key goals such as friendship, marriage, promotion). Often social phobics have excessively high standards for social performance (e.g. 'My speech must be perfectly fluent', 'I must always appear intelligent and witty'). Typically, social anxiety is triggered when individuals have a strong desire to convey a particular, favourable impression of them and have marked insecurity about their ability to do so.

(c) Generalized anxiety disorder

Generalized anxiety disorder is characterized by excessive worry about a number of life circumstances (e.g. finance, health, work, children, etc.) and the subjective impression that the worry is difficult to control.[6] Beck *et al.*[7] suggested that generalized anxiety disorder patients are anxious about many topics because their beliefs about themselves and the world make them prone to interpret a wide range of situations and circumstances in a threatening fashion. Although their beliefs are quite varied, Beck suggested that they mainly revolve around issues of acceptance, competence, responsibility, and control, as well as the symptoms of anxiety. Borkovec *et al.*[8] have shown that, compared with non-patients,

the worry of general anxiety disorder patients involves less imagery about specific feared outcomes and more verbal rumination in which problems are cast in a more abstract, more difficult to solve, form. Wells[9] has highlighted the importance of positive and negative beliefs about worry (meta-cognition).

(d) Obsessive–compulsive disorder

Obsessive–compulsive disorder is characterized by intrusive and distressing thoughts, impulses, or images about possible harm coming to oneself or others. Thoughts with a similar content to the intrusions of obsessional patients (e.g. a young mother having an intrusive thought about dropping her baby) are common in the general population.[10] For this reason, it has been suggested that the key cognitive abnormality in obsessive–compulsive disorder is not the content of obsessional thoughts, but rather the way the thoughts are interpreted.[11] In particular, it would appear that obsessional patients interpret recurrent obsessional thoughts and impulses as a sign that something terrible will happen, for which they will be responsible. For example, the young mother mentioned above may think that because she had a thought of dropping her baby, she is very likely to do so, despite finding the idea repugnant. In order to prevent the feared consequences of their obsessional thoughts, patients engage in a wide range of 'putting right' acts including (when relevant) washing and checking.

(e) Post-traumatic stress disorder

Surveys[12] indicate that unwanted, intrusive, and distressing memories and the other symptoms of post-traumatic stress disorder (avoidance of reminders and hyperarousal/numbing) are common immediately after traumatic events. Over the next few months many people recover but in a subgroup post-traumatic stress disorder becomes chronic. It is the latter group that normally present for treatment. Research indicates that chronic post-traumatic stress disorder is associated with appraising the traumatic event and/or its sequelae in a manner that would produce a sense of serious current threat to one's view of oneself and/or the world.[13] Examples are given in Table 6.3.2.1.1. There is also evidence that chronic post-traumatic stress disorder tends to be associated with a fragmented memory for the traumatic event and that recovery is associated with developing a more coherent narrative.[14,15]

Why do negative thoughts and beliefs persist?

If the world is not as dangerous as anxiety disorder patients assume, why do they not notice this and correct their thinking? For many patients with chronic anxiety disorders, the persistence of their fears can seem strangely irrational, at least at first glance. Consider, for example, panic disorder patients who think during their panic attacks that they are having a heart attack. Before they come for treatment they may have had several thousand panic attacks, in each one of which they thought they were dying, but they are not dead. Despite what might appear to an outsider as stunning disconfirmation of their belief that a panic attack can kill, their thinking has not changed.

Several factors that appear to prevent patients from changing their negative thinking are outlined below. Such factors are important because reversing them is likely to be a particularly efficient way of treating anxiety disorders.

(a) Avoidance, escape, and safety-seeking behaviours

Early conditioning theorists identified avoidance of, and escape from, feared stimuli as important factors in the maintenance of anxiety disorders. It is easy to see how avoidance of a feared situation (e.g. a supermarket for an agoraphobic) or escape from the situation before a feared event (e.g. a panic attack) occurs could prevent phobics from disconfirming their fears. However, situational avoidance/escape is not so obviously relevant to non-phobic anxiety and some phobics regularly endure feared situations without marked improvement in their fears. Salkovskis[16] introduced the concept of in-situation safety behaviours to deal with this problem. In particular, Salkovskis suggested that while in feared situations most patients engage in a variety of (often subtle) behaviours that are intended to prevent, or minimize, a feared outcome. For example, cardiac concerned panic disorder patients may sit down, rest, and slow down their breathing during attacks and believe, erroneously, that performing these safety behaviours is the reason why they did not die. Experimental studies have confirmed that (a) anxious patients engage in safety behaviours while in feared situations, and (b) dropping these behaviours facilitates fear reduction.[4]

Recent work[17] has highlighted several other important features of safety behaviours. First, although termed 'behaviours', many are internal mental processes. For example, patients with social phobia who are worried that what they say may not make sense and will sound stupid, often report memorizing what they have said and comparing it with what they are about to say, whilst speaking. If everything goes well, patients are likely to think 'It only went well because I did all the memorizing and checking; if I had just been myself people would have realized how stupid I was'. In this way their basic fear persists. Second, it is common for patients to engage in a large number of different safety behaviours while in a feared situation. Table 6.3.2.1.2 illustrates this point by summarizing the safety behaviours used by a patient who had a fear of blushing, especially while talking to men whom she thought other people would think were attractive. Third, safety behaviours can create some of the symptoms that patients fear. For example, responding to a feeling of breathlessness in panic attacks by breathing more quickly and deeply (hyperventilating) can enhance the feeling of being short of breath. Similarly, post-traumatic stress disorder patients who are concerned that unwanted intrusive recollections of the trauma mean they are going mad and often try hard to suppress such recollections. Unfortunately, active suppression increases the probability that the intrusion will occur. Fourth, some safety

Table 6.3.2.1.1 Some examples of idiosyncratic negative appraisals leading to a sense of current threat in post-traumatic stress disorder

What is appraised?	Negative appraisal
Fact that trauma happened	'Nowhere is safe'
One's behaviour/emotions during trauma	'I cannot cope with stress'; 'It was my fault'
Initial post-traumatic stress disorder symptoms	
Irritability, anger outbursts	'My personality has changed for the worse'
Flashbacks, intrusive recollections, and nightmares	'I'm going mad'; 'I'll lose control of my emotions'
Other people's reactions after trauma	
Positive responses	'They think I am too weak to cope on my own'
Negative responses	'Nobody is there for me'; 'I can't rely on other people'

Table 6.3.2.1.2 Safety behaviours associated with a fear of blushing

Feared outcome	Safety behaviour intended to prevent feared outcome
'My face (and neck) will go red'	Keep cool (open windows, drink cold water, avoid coffee, wear thin clothes) Avoid eye contact. If in a meeting, pretend to be writing notes Keep topic of conversation away from 'difficult' issues Tell myself the man is not really attractive. He's no more than a 2 (out of 10)
'If I do blush, people will notice'	Wear clothes (scarf, high collar) that would hide part of the blush Wear make-up to hide the blush Put hands over face. Hide face with long hair Stand in a dark part of the room
'If people notice, they will think badly of me'	Provide an alternative explanation for the red face, e.g. 'it's hot in here'. 'I'm in a terrible rush today', 'I'm recovering from flu', etc.

behaviours can draw other people's attention to problems that patients wish to hide. For example, a secretary who covered her face with her arms whenever she felt she was blushing discovered that colleagues in her office were much more likely to look at her when she did this than when she simply blushed. Finally, some safety behaviours influence other people in a way that tends to maintain the problem. For example, the tendency of social phobics to monitor continually what they have said, and how they think they come across, often makes them appear distant and preoccupied. Other people can interpret this as a sign that the phobic does not like them and, as a consequence, they respond to the phobic in a less warm and friendly fashion.

(b) Attentional deployment

Selective attention plays an important role in maintaining some anxiety disorders. Patients with panic disorder or hypochondriasis fear certain bodily sensations and symptoms, believing they indicate the presence of a serious physical disorder (heart attack, cardiac disease, cancer, etc.). Such patients have often had several medical investigations that indicate they do not have the physical illness(es) they fear, but they are not convinced. One reason appears to be that their fears lead them to focus attention on relevant parts of their bodies and, as a consequence of this attentional deployment, they become aware of benign bodily sensations that other people do not notice.[5] The presence of such sensations is then taken by the patient as evidence that a serious physical illness has been missed. (Hypochondriasis is classified as a somatoform disorder in DSM-IV[6] and as a somatization disorder in ICD-10.[18] However, it has many features in common with anxiety disorders and can be conceptualized as such for the purposes of psychological treatment).

Social phobia appears to be associated with two attentional biases. First, when in feared social situations, patients with social phobia report becoming highly self-focused, constantly monitoring how they think and feel they are coming across, and paying less attention to other people.[17] Reduced processing of other people means that social phobics have less chance to observe other people's responses in detail and, therefore, are unlikely to collect from other people's reactions information that would help them to see that they generally come across more positively than they think. Second, there is some evidence that when social phobics do focus on other people, they are particularly good at detecting negative reactions[19] and are poor at detecting positive reactions.

(c) Spontaneously occurring images

Spontaneously occurring images are common in anxiety disorders and also appear to play a role in maintenance. Patients with social phobia often report 'observer-perspective' images in which they see themselves as if viewed from outside.[20] Unfortunately, in their images they do not see what a true observer would see, but rather their fears visualized. For example, a teacher who was anxious about talking with colleagues in coffee breaks noticed that before speaking she felt tense around her lips. The tension would trigger an image in which she saw herself with a twisted and contorted mouth, looking like 'the village idiot'. At that moment, she was convinced everyone else thought she was stupid. Negative images are also used as information in other anxiety disorders. For example, obsessional patients who have images of committing a repugnant act (e.g. stabbing one's child) take the occurrence of the image as evidence that they are in danger of performing the act. Similarly, patients with post-traumatic stress disorder report that flashbacks increase the perceived likelihood of a future trauma.

(d) Emotional reasoning

A further source of misleading information that can enhance patients' perception of danger is anxiety itself.[21] For example, social phobics often think they look as anxious as they feel, but in general this is not the case.[22] Similarly, generalized anxiety disorder patients often take feeling on edge as a sign that something bad is about to happen.

(e) Memory processes

Some anxiety disorders are associated with a tendency for the selective recall of information that would appear to confirm the patient's worst fears. For example, high socially anxious individuals selectively recall negative information about the way they think they have appeared to others in the past when anticipating a stressful social interaction.[22] Similarly, patients with hypochondriasis selectively recall illness-related information. In post-traumatic stress disorder, a failure to elaborate memories at the time of the trauma and enhanced associative learning appear to play a key role in maintaining the re-experiencing symptoms.[13]

(f) Rumination

Anxious patients often spend protracted periods of time ruminating about negative things that could happen in the future and about how bad they would be. They may also ruminate about things that they feel have gone wrong in the past. Studies by Davey and Matchett[23] indicate that such rumination can enhance fear. There are several ways in which rumination might operate. First, thinking about an event may directly increase its subjective probability. Second, selectively focusing on past negative events, feelings, and impressions may further enhance the perceived likelihood of future danger. Third, rumination is rarely focused on constructively processing perceived threats, but instead often seems to elaborate the

threats or make them more abstract and hence difficult to deal with. For example, patients with post-traumatic stress disorder often ask themselves 'Could I have done something different?' during their traumatic event without thinking through in detail what their alternative options might have been, and how feasible they would have been at the time.

Treatment

Assessment interview

Table 6.3.2.1.3 summarizes the main topics covered in the assessment interview. The aims of the interview are as follows: (a) to obtain a detailed description of the patient's fears and behaviour; (b) to identify maintaining factors; (c) to normalize the problem; (d) to develop a model of the problem that can be used to guide treatment.

The interview would start by asking the patient to provide a brief description of the main presenting problem(s). For example, intense anxiety attacks, anxious apprehension, and avoidance of places where the attacks seem particularly likely or would be embarrassing. The interviewer then obtains a detailed description of a recent occasion when the problem occurred or was at its most marked. This would include the situation ('Where were you?', 'What were you doing?'), bodily reactions ('What did you notice in your body?', 'What sensations did you experience?'), thoughts ('At the moment you were feeling particularly anxious, what went through your mind? What was the worst that you thought might happen? Did you have an image/mental picture of that? How do you think you looked?'), behaviour ('What did you do?'), and the behaviour of others ('How did X react?', 'What did X say/do?'). Having obtained a detailed description of a recent occasion, the interviewer should check whether the occasion was typical. If not, further descriptions of other recent occasions should be elicited to provide a complete picture.

Table 6.3.2.1.3 Summary of topics to be covered in assessment interview

Brief description of presenting problem(s)
For each problem
Detailed description of a recent occasion when problem occurred/was at its most marked
Situation
Bodily reaction
Cognitions
Behaviour
List of situations when the problem is most likely to occur/be most severe
Modulators (things making it better or worse)
Possible maintaining factors
Avoidance of situations/activities
Safety behaviours
Attentional deployment
Faulty beliefs
Attitudes and behaviour of others
Medication
Beliefs about cause of the problem
Previous treatment (types, whether successful)
Onset and course
Personal strengths and assets
Social and financial circumstances

Next a list of situations in which the problem is most likely to occur or is most severe is elicited ('Are there any situations in which you are particularly likely to have a panic attack?'), together with information about modulators ('Are there any things that you notice make the symptoms stronger/more likely to occur?', 'Are there any things that you've noticed make the symptoms less likely/less severe/more controllable?').

Possible maintaining factors should be identified, including the following:

- avoidance of situations or activities ('What situations/activities do you avoid because of your fears?')
- safety behaviours ('When you are afraid that X might happen, is there anything you do to try to stop it happening?')
- attentional deployment ('What happens to your attention when you are worried about X? Do you focus more on your body? Do you become self-conscious?')
- faulty beliefs (e.g. an obsessive–compulsive disorder patient, believing that thinking something can make it happen)
- attitudes and behaviour of significant others ('What does Y think about the problem?'; 'What does Y do when you are particularly anxious?')
- current medication

There are several ways in which excessive use of both prescribed and non-prescribed medications can maintain anxiety disorders. For example, painkillers and tranquillizers can cause derealization and sleep disturbance respectively, and drinking before social occasions prevents disconfirmation of one's social fears.

It is also important to assess patients' beliefs about the cause of their problems as some beliefs may make it difficult for patients to engage in therapy. For example, patients with post-traumatic stress disorder who think the best way of dealing with a painful memory is to push it out of their mind are unlikely to engage in imaginal reliving of the event until this belief is dealt with.

Finally, a brief description of the onset and subsequent course of the problem should be obtained. This description should particularly focus on factors, which may have been responsible for initial onset and for fluctuations in the course of the symptoms and is primarily used to make the development of the problem seem understandable to the patient.

It is not always possible to obtain all the information needed for a cognitive behavioural formulation in an assessment interview. Sometimes it is necessary to follow-up the interview with homework assignments in which the patient collects more information to clarify the formulation. For example, a hypochondriacal patient who was concerned that palpitations meant that she had cardiac disease was asked to record what she did each hour and how many palpitations she experienced. To her surprise, palpitations were not associated with exercise, as she expected, but rather were most common when she was sitting quietly, reading, watching television, or studying. This realization helped convince her that her problem may be disease preoccupation rather than a faulty heart.

Developing an idiosyncratic model of the patient's problem

Assessment ends with the development of an idiosyncratic version of the cognitive model. In particular, therapists aim to show patients

how the specific triggers for their anxiety produce negative automatic thoughts relating to feared outcomes and how these are maintained by safety behaviours and other maintenance processes. The model is usually drawn on a whiteboard, so that patient and therapist can look at it and discuss it together. Figure 6.3.2.1.1 shows an example for a panic disorder patient. His panic attack started with a twinge in his chest muscles, and he then had the thought, 'There is something wrong with my chest area, maybe I am having a heart attack'. This interpretation made him start to feel anxious, his chest muscles tightened up more, he started to feel dizzy, his heart raced more, and he then thought, 'I'm dying, I'm having a heart attack', and also, interestingly, 'If I don't die, people will notice I'm anxious and think it is odd'. He then engaged in a series of safety behaviours to try to prevent himself from dying. He thought he had read somewhere that paracetamol (aminacetophen) is good for people with heart problems and so he took a paracetamol. This is incorrect information, but the key point is that he believed it. He also sat down and rested, took the strain off his heart, and took deep breaths, trying to slow down his heart rate. He believed that the main reason he had not died was that he had engaged in the safety behaviours. The reader will also notice that some of the safety behaviours (taking deep breaths and monitoring the heart) will also have augmented his feared symptoms.

Figure 6.3.2.1.2 shows a further example with a social phobic patient. The patient's main fear was that other people would think she was stupid and boring. The situation used to develop the model was a recent coffee break at work during which the patient had difficulty joining a conversation with colleagues. When attempting to join the conversation she had the thought, 'I'll sound stupid and everyone will think I am dumb'. In order to prevent herself from sounding stupid, she engaged in an extensive set of safety behaviours which (a) prevented her from discovering that her spontaneous thoughts are interesting to other people, (b) made her appear preoccupied and uninterested in her colleagues, and (c) made her excessively self-conscious. While self-conscious, she became particularly aware of anxiety symptoms (sweaty palms, stiff muscles around her mouth) that she thought other people might see, and indeed, had an image of herself in which she looked very strange, with a twisted and rigid mouth and appeared stupid.

Normally idiosyncratic models of the form illustrated in Figs 6.3.2.1.1 and 6.3.2.1.2 will be developed at the end of the first interview, and certainly not later than the second session. Such models are used as blueprints to help therapist and patient organize and develop the rest of therapy.

Monitoring progress

Once treatment has started, it is important to monitor progress continually in order to decide whether a particular treatment procedure is working or whether the case needs reformulating and new treatment procedures need to be implemented. Usually patients are asked to complete a small number of self-report questionnaires before each therapy session. Typically, these include frequency and severity ratings for the main anxiety problems (often using simple 0–8 Likert-type scales), a measure of negative thoughts, and general measures of anxiety and depression (such as the Beck Anxiety Inventory[24] and the Beck Depression Inventory[25]). Table 6.3.2.1.4 summarizes some of the most commonly used weekly measures. In some instances these are supplemented by more individualized diaries and ratings. More global standardized measures of symptom severity are also often administered at the beginning, middle, and end of therapy in order to provide normative data (see Table 6.3.2.1.4).

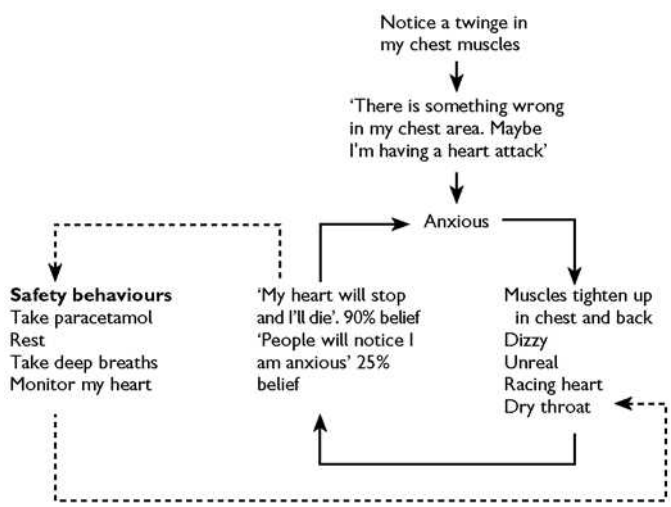

Fig. 6.3.2.1.1 A cognitive model of a patient's panic attacks. (Reproduced from Clark, D.M., Panic disorder: from theory to therapy. In *Frontiers of cognitive therapy* (ed. P.M. Salkovskis), pp. 318–344, Copyright 1996, Guildford Press, New York.)

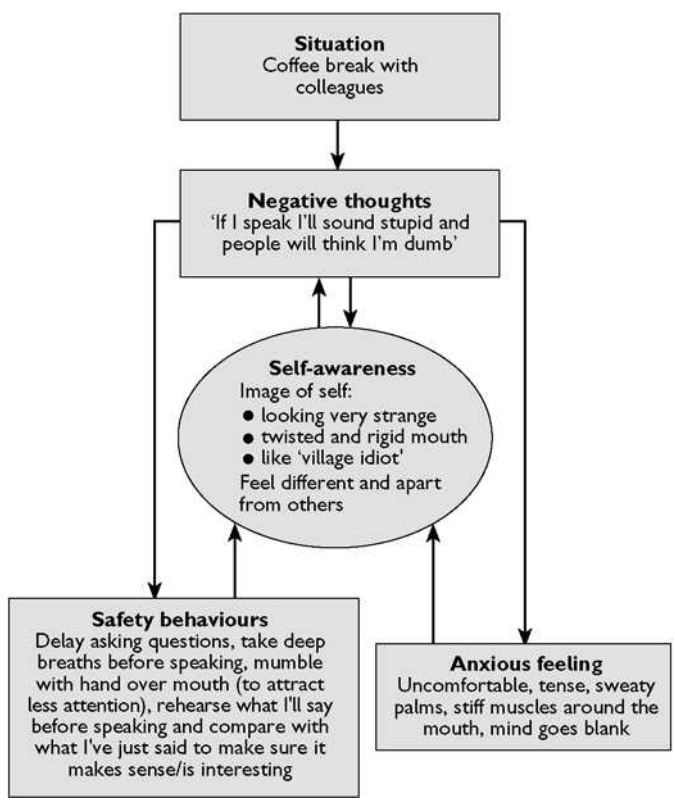

Fig. 6.3.2.1.2 A cognitive model for a patient with social phobia.

Treatment procedures

A wide range of procedures can be used to modify patients' negative beliefs and linked maintenance processes. For clarity the procedures are described separately. However, in practice the techniques are closely interwoven. Within a given session, therapists will usually use a mixture of discussion and experiential techniques to help patients to challenge convincingly their negative beliefs. As with cognitive behaviour therapy for other disorders, patients are given extensive homework assignments and it is assumed that a sizeable amount of therapeutic change is the result of homework assignments.

(a) Identifying patients' evidence for their negative beliefs

Anxiety disorder patients usually have reasons for believing that the things they fear are dangerous, however strange their fears may seem. The therapist, therefore, tries to 'get inside the patient's head' and see what the evidence is. Often the evidence is an event or piece of information that the patient has misinterpreted. Identifying and correcting such misinterpretations can be helpful. For example, a panic disorder patient believed that experiencing high anxiety could kill her. When asked by the therapist what her evidence was, she explained that she had seen it happen. Further enquiry revealed she had entered Dresden the day after the fire bombing of that city by the allies during the Second World War and had helped search for survivors. When opening up cellars below demolished houses, she repeatedly observed that the occupants were either dead or behaved in a dazed confused manner, even though the fire had not entered their cellars. She concluded that fear had killed the occupants or sent them mad. However, further questioning from the therapist revealed that the cellar occupants all had bright cherry-red lips. This allowed the therapist to explain that they were suffering from carbon monoxide poisoning, not the effects of intense fear. This correction considerably reduced the patient's fear of anxiety.

(b) Education

Education about the symptoms of anxiety is often helpful, especially if it directly targets patients' idiosyncratic fears and concerns. For example, post-traumatic stress disorder patients often think their flashbacks and emotional outbursts mean they are going mad or have permanently changed for the worse. In such cases, detailed assessment of the patient's post-traumatic stress disorder symptoms and explanation that each are common reactions to a trauma can greatly help. Similarly, panic disorder patients with cardiac concerns often cite left-sided chest pain as evidence for their belief that they have a cardiac disorder. In such cases discussion of Fig. 6.3.2.1.3 (from a study of chest pain in patients referred to a cardiac clinic[26]) is useful. In particular, the patient discovers that left-sided chest pain is more characteristic of non-cardiac chest pain than of either confirmed angina or myocardial infarction. Further questioning helps patients to see that the association between left-sided pain and attacks is probably a consequence of their fears. That is to say, they can experience pain on either side of the chest but only panic when it is on the left side. Finally, patients with obsessive–compulsive disorder who are perturbed by the apparently repulsive and unusual nature of their intrusive thoughts often benefit from reviewing Rachman and De Silva's classic

Table 6.3.2.1.4 Commonly used measures for monitoring progress

Anxiety disorder	Measure		
	Symptoms	**Thoughts**	**Global severity**
Panic disorder	Panic Rating Scale[63] Panic Diary[63] BAI[33] BDI[2]	Agoraphobic Cognitions Questionnaire[65]	Fear Questionnaire[64] Mobility Inventory[66]
Social phobia	Social Summary Scales (Table 4) BAI[33] BDI[2]	Social Cognitions Questionnaire[53]	Liebowitz Social Anxiety Scale[67] Social Performance Scale[68] Social Interaction Anxiety Scale'[68]' Social Phobia and Anxiety Inventory[69]

paper[10] which demonstrated that thoughts with identical content to obsessional intrusions are common in the general population.

(c) Identifying observations that contradict patients' negative beliefs

As anxiety disorder patients' beliefs about the dangerousness of feared stimuli are generally mistaken, patients have often experienced a number of events that contradict their beliefs before they come into therapy. Therapists can make considerable progress, even in an assessment interview, by spotting these events and helping patients understand their significance. For example, panic disorder patients who are worried that their symptoms mean they are about to have a heart attack, often report that in some attacks something unexpected happened to distract them (e.g. a telephone call) and then their symptoms went away. Therapists could then pause and help the patient understand what this means, perhaps asking, 'Would a cardiologist prescribe telephone calls as a treatment for a heart attack?' The patient would probably answer 'No', to which the therapist might reply, 'If telephone calls would not stop a heart attack, how might they work? If the problem was the negative thought, could they help (by distracting one from the thoughts)?'

(d) Imagery modification

Images play an important role in many anxiety disorders. Most images represent feared catastrophes and can be treated as predictions to be tested (see behavioural experiments below). However, when the images are stereotyped and repetitive it is often also necessary to work directly with the images and to restructure them explicitly.

The problem with anxiety-related images is that they seem very realistic at the time they occur and, as a consequence, greatly enhance fear. A common restructuring technique involves discussing with the patient whether the image is realistic. Once it is intellectually agreed that the image is an exaggeration, patients are asked to recreate intentionally the negative image and to hold it in mind until they start to feel anxious. They are then asked to transform it into a more realistic image, or an image, which convincingly indicates that the original image was unrealistic. A common observation is that patients' spontaneous images generally stop at the worst moment. For example, agoraphobic patients who fear fainting in a supermarket might see themselves collapsed on the floor, but not see themselves getting up, recovering, and going home. A useful transformation in such cases is to 'finish out' the image by asking patients to run it on until they see the positive resolution. Of course, sometimes simply running on an image does not produce a positive resolution. For example, a patient who feared she would go mad frequently experienced an image of two men in white coats entering her house to take her away to a locked ward. In the image, the men were extremely powerful and she felt powerless. Transformation, following suggestions from her, involved shrinking the men and then turning them into ridiculous looking (and hence non-threatening) white poodles.

An interesting observation about spontaneous imagery is that it often fails to incorporate positive information that would seriously undermine the impact of the image, even when the patient has such information. For example, a mother whose children died in a house fire, repeatedly experienced intrusive flashbacks in which she saw the house going up in flames and smelled burning flesh, despite having seen her children in the mortuary, knowing that they had not been burnt, but instead were rapidly overcome by fumes.

For imagery restructuring to be effective it is important that it is not done as a cold, intellectual exercise, but instead includes eliciting the affect normally associated with the image. Transformation may have to be done in several steps. It is often best to start with the

most threatening aspect of the image. Possible alternative images should be generated by patients, rather than simply imposed by the therapist.

(e) Cognitive restructuring

All the above techniques are examples of cognitive restructuring in which the therapist provides information and asks a series of questions to help the patients challenge their fearful thoughts and images. A list of some of the questions that can be particularly useful for helping anxiety disorder patients challenge their negative thoughts is given in Table 6.3.2.1.5. Further useful questioning techniques can be found in Chapter 6.3.2.3.

It is sometimes helpful to use graphical methods for discussing alternatives to negative thoughts. In situations where there are several non-threatening alternative explanations for a feared event, pie charts are particularly useful. When constructing a pie chart the therapist draws a circle which is meant to represent all the possible causes of a particular event and asks the patient to list all the possible non-catastrophic causes of the event and allocate a section of the circle to each cause. At the end of the exercise, there is often very little of the circle left for the patient's negative explanations. Figure 6.3.2.1.4 illustrates the use of a pie chart to challenge a generalized anxiety disorder patient's belief that he would be 100 per cent responsible for people not enjoying themselves at his dinner parties. The belief was preventing him from making new social contacts after a painful divorce. Pie charts are particularly helpful for dealing with distorted beliefs about responsibility and hypochondriacal concerns (e.g. 'Headaches mean I have a brain tumour').

When considering the worst that could possibly happen in a feared situation patients frequently ignore the fact that there are many intermediate events, each with a probability of less than 1, which have to occur for the catastrophe to be realized. The inverted pyramid can be a good way of representing this. Figure 6.3.2.1.5 shows an example with a patient who was afraid of blushing. His worst fear was that other people would think they were greatly superior to him if he blushed. Whenever he felt his face becoming hot, he was convinced other people were thinking they are superior to him and gloating. However, careful discussion helped him to see that there were many intermediate steps between him feeling hot and the feared outcome. Once the conditional probabilities were taken into account, there was only a minute chance that his worst fear would be correct.

Table 6.3.2.1.5 Useful questions for challenging anxiety-related thoughts

What is the evidence for this thought?
Is there any alternative way of looking at the situation?
Is there an alternative explanation?
How would someone else think about the situation?
Are you focusing on how you felt, rather than on what actually happened?
Are you setting yourself an unrealistic or unobtainable standard?
Are you forgetting relevant facts or overfocusing on irrelevant facts?
Are you thinking in all-or-nothing terms?
Are you overestimating how responsible you are for the way things work out?
What if the worst happens? What would be so bad about that? How could you cope?
How will things be x months/years afterwards?
Are you overestimating how likely the event is?
Are you underestimating what you can do to deal with the problem/situation?

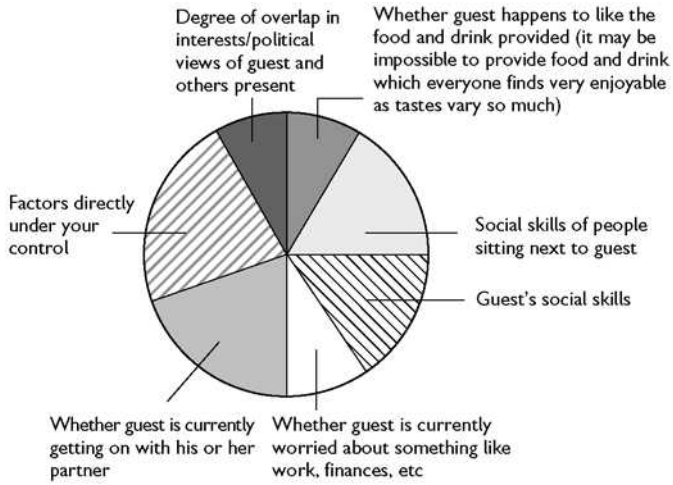

Fig. 6.3.2.1.4 A pie chart representing factors that might contribute to guests enjoying themselves at a dinner parties to challenge a generalized anxiety disorder patient's belief that he would be 100 per cent responsible for people not enjoying themselves. (Reproduced from Clark, D.M., Anxiety states: panic and generalized anxiety, In *Cognitive therapy for psychiatric problems: a practical guide* (ed. K. Hawton, *et al.*), pp. 52–96. Copyright 1989 with permission from Oxford University Press.)

It is important to remember that anxiety results from overestimating the cost of feared events as well as their probability. Discussions aimed at modifying perceived cost are often helpful. This can be true even in cases where it might seem obvious that the feared event is objectively costly. For example, in hypochondriacal patients who are worried about dying, therapists may be tempted to focus exclusively on whether or not the patients are likely to die from the symptoms they are concerned about. Accepting that dying is a bad thing, the therapist may not be inclined to ask, 'What would be so bad about dying?' However, Wells and Hackmann[27] found that many hypochondriacal patients have distorted beliefs and images about death and the process of dying. For example, they think that when they die they will remain conscious and will continue to experience all the pain they had up to that point. Such people can benefit greatly from discussion of their beliefs about the cost of dying.

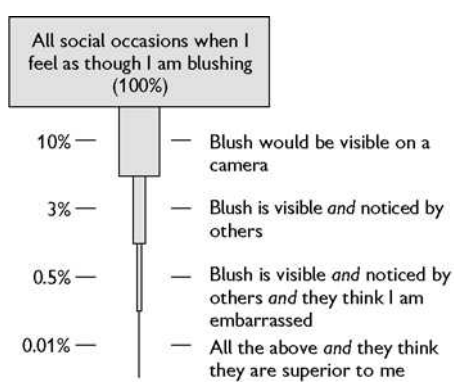

Fig. 6.3.2.1.5 An inverted pyramid representing conditional probabilities between 'feeling hot' and 'others thinking they are superior to you' constructed for a patient who was afraid of blushing.

(f) *In vivo* exposure to feared situations, activities, and sensations

Systematic exposure to feared and avoided situations has a long history in cognitive behaviour therapy and is one of the most effective ways of helping patients to discover that the things they are afraid of will not happen or are more manageable than they anticipate. Initially, exposure was often conducted in imagination but it is now known that *in vivo* exposure is a more effective way of dealing with situational fear.[3] During the 1970s and 1980s the dominant framework for exposure was habituation. It was assumed that repeated prolonged exposure was required to achieve fear reduction. More recent cognitive formulations have suggested that exposure is likely to be optimally effective when set-up in a way that maximizes the extent to which patients are able to disconfirm their fears, and considerable attention is now devoted to setting up exposure assignments in a way that will maximize cognitive change. Before entering a feared situation, patients are asked to specify what is the worst they think could happen, how likely they think it is, and what they would normally do to prevent the feared catastrophe (safety behaviours). They are then asked to enter the feared situation while dropping their safety behaviours and to observe carefully whether the feared outcome occurs. Afterwards, discussion focuses on whether the feared catastrophe occurred. If it did not, how does the patient explain its non-occurrence? Was it because the patient now thinks the feared outcome is unrealistic or does the patient think it was because of 'luck' or the continued use of safety behaviours? In the latter two instances, further exposure assignments with further encouragement to drop safety behaviours are required.

In addition to avoiding feared situations, anxiety disorder patients can also avoid feared sensations. Such avoidance is particularly prominent in panic disorder. For example, because of their fears about the meaning of increases in heart rate, dizziness, sweating, and other autonomic cues, panic disorder patients often avoid exercise. Increasing exercise can be an excellent way of helping them to challenge their negative beliefs, as can other ways of inducing bodily sensations such as ingesting caffeine, and hyperventilating. In each instance, the key point is to help patients discover that they can experience intense physical sensations without dying, losing control, or experiencing some other catastrophe.

Table 6.3.2.1.6 shows a record sheet that can be useful for planning and summarizing the results of exposure assignments, with illustrations from patients with social phobia and agoraphobia. Because of the intensity of patients' fears, and their tendency to attribute good outcomes to 'luck', it is often necessary to move up a hierarchy of feared situations and to consolidate successes by repetition.

In obsessive–compulsive disorder, the compulsive rituals act as safety behaviours and it is necessary to ensure that patients refrain from engaging in rituals (which are often also termed 'putting right' acts) during exposure assignments. This procedure is called 'exposure and response prevention'. For example, obsessional washers would be asked to 'contaminate' themselves by touching feared objects and then not put things right by washing. Similarly, obsessional checkers may be asked to expose themselves to activities that would normally provoke their checking (e.g. turning on the gas cooker) and then refrain from checking more than would be normal. In both instances, patients usually find that although exposure initially provokes considerable distress, the distress systematically declines during prolonged response prevention.[28]

Unlike most phobic fears, the fears of obsessive–compulsive disorder patients (e.g. developing a fatal disease from touching an object that is believed to be contaminated) often cannot be disconfirmed during a single or indeed multiple, exposure assignments. Discussing this issue, Salkovskis[11] has suggested that exposure and response prevention may work by providing patients with a different understanding of their problems. In particular, the decline

Table 6.3.2.1.6 Record sheet for noting behavioural experiments

	Situation	Prediction	Experiment	Outcome	What I learned
		(What exactly did you think would happen? How would you know?) (Rate belief 0–100%)	(What did you do to test the prediction?)	(What actually happened? Was the prediction correct?)	(1) Balanced view (rate belief 0–100%)? (2) How likely is what you predicted to happen in future (Rate belief 0–100%)
Social phobic patient	Coffee break; sitting with other teachers; trying to join in the conversation	If I just say things as they come into my mind, they'll think I'm stupid (50%)	Say whatever comes into my mind *and* watch them like a hawk; don't focus on myself; this only gives me misleading information (such as images of myself as the 'village idiot'), and means I can't see them	I did it and I watched the others; one of them showed interest and we talked; she seemed to quite enjoy it	I am probably more acceptable than I think (70%)
Agoraphobic patient	Shopping in a supermarket	I will feel dizzy and have a panic attack (90%). Unless I grip the trolley tightly or sit down at that moment, I collapse (80%)	Go into the supermarket. When I start to feel dizzy, remind myself it is just anxiety, my heart rate is up and I can't faint. Then move away from the trolley and stand unsupported	I felt dizzy but didn't faint, even though I didn't sit down or hold on to the trolley	Feeling dizzy in anxiety attacks will not make me faint (60%)

in distress during exposure and response prevention helps the patient to discover that they are suffering from a worry problem, rather than being in objective danger.

(g) Imaginal exposure in post-traumatic stress disorder

Although imaginal exposure is rarely used in most anxiety disorders, it plays an important role in the treatment of post-traumatic stress disorder. It is known[29] that avoidance of thinking about the traumatic event is an important predictor of persistent post-traumatic stress disorder. In the light of this finding, clinicians have attempted to treat post-traumatic stress disorder by repeated, imaginal reliving of the traumatic event, and controlled trials[30] have shown that this technique is effective. At this stage it is not known why reliving works. One suggestion is that the intrusive symptoms of post-traumatic stress disorder are the result of a fragmented and disorganized memory for the trauma that is poorly integrated with other autobiographical information. Reliving might, therefore, facilitate the production of a more organized narrative account of the event that can be placed in the broader context of the individual's life.[13,31] Two types of imaginal reliving have been used in controlled trials: writing out details of the event and reliving the event in imagery. In either case, it seems important to focus not only on what happened, but also on patients' feelings and thoughts, both at the time and now, looking back at the event. Problematic idiosyncratic meanings that can be addressed with cognitive restructuring are often identified during reliving exercises.

(h) Behavioural experiments

Behavioural experiments play a central role in the treatment of anxiety disorders. In a behavioural experiment, therapist and patient plan and implement a behavioural assignment that will provide a test of a key belief. The *in vivo* exposure assignments outlined above are examples of behavioural experiments. Several further examples are given to illustrate the technique.

Patients with post-traumatic stress disorder often think their intrusive recollections mean they are going mad or losing control in some way, and as a consequence, try to push the intrusions out of their mind. If this problem is identified during the first session of therapy, therapists often conduct an experiment to illustrate the undesired consequences of thought suppression. For example, the therapist might say to the patient, 'It doesn't matter what you think about in the next few minutes as long as you don't think about one particular thing. The thing is a fluorescent green rabbit eating my hair!' Most patients find they immediately get an image of the rabbit and have difficulty getting rid of it. Discussion then helps them to see that an increase in the frequency of target thoughts is a normal consequence of thought suppression. This result can then be used to set-up a homework assignment in which the patient is asked to collect data to test the idea that thought suppression may be enhancing intrusions. The experiment involves not trying to push the intrusions out of one's mind, but instead just letting them come and go, watching them as though they were a train passing through a station. Often patients report this simple experiment produces a marked decline in both the frequency of intrusions and the belief that they are a sign of impending insanity or loss of control.

Patients with social phobia often overestimate the significance of their anxiety symptoms for other people. A useful behavioural experiment to illustrate this point involves having either the patient or the therapist conduct a survey in which other people are asked for their views about the feared symptom. For example, in the case of fear of blushing, other people might be asked:

Why do you think people blush?
Do you notice other people blushing?
Do you remember it?
Do you think badly about people who blush?
If you do, what do you think about them?'

A further helpful experiment can involve intentionally displaying a feared symptom (e.g. handshaking or forgetting what one is talking about) and closely observing other people's responses. A particularly effective behaviour experiment for modifying social phobics distorted self-images involves the use of video feedback. Patients are asked to engage in a difficult social task while being videotaped. Afterwards they are asked to describe in detail how they think they appeared. They are then asked to view the video, watching themselves as though they are watching a stranger, ignoring memories of how they felt and simply focusing on how they would look to other people. In this way they often discover that they come across better than they would expect on the basis of their self-imagery. This experiment is often a powerful way of correcting distorted self-images.

Patients with panic disorder or hypochondriasis persistently think that normal bodily signs and/or symptoms are caused by a serious physical disorder. Numerous behavioural experiments can be used to demonstrate the correct, innocuous causes of their symptoms. For example, reading pairs of words which represent patient's illness interpretations (e.g. palpitations-dying, breathlessness-suffocate) has been shown to induce feared sensations.[5] Similarly, reproducing patients' fear-driven behaviours can produce the very symptoms the patients take as evidence for a serious physical illness. For example, patients who feel short of breath in a panic attack often respond by breathing quickly and deeply (hyperventilation), which paradoxically produces more breathlessness. Similarly, patients who are concerned about cancer may palpate body parts and then take the resulting soreness or discomfort as evidence of the presence of cancer.

(i) Therapy notes

Over a series of sessions therapist and patient will generate a substantial number of arguments against the patient's fearful beliefs. In order to maximize the impact of this accumulation, patients are asked to keep a running record of evidence against their beliefs in a notebook that can easily be consulted at times of doubt. Table 6.3.2.1.7 shows an illustrative example from a panic disorder patient's notebook. At the start of therapy, the patient had been concerned that there was something seriously wrong with his heart.

(j) Anger management

Although anxiety is the predominant problematic emotion in anxiety disorders, some patients also report significant problems with other emotions such as depression and anger. Techniques for dealing with depression can be found in Chapter 6.3.2.3. Some empirically validated techniques for dealing with anger are described here. Although presented in the context of anger accompanying anxiety disorders, these techniques are also relevant to anger in other disorders and to people without an Axis I disorder.

Table 6.3.2.1.7 A panic disorder patient's notebook: evidence for the two alternative explanations for chest pains

'There is something seriously wrong with my heart'	'My problem is my belief that there is something wrong with my heart'
1 *I hear my heart thumping sometimes, even in my ear.* But because of my fears I focus on my body and that makes me notice it. When I notice it I get anxious and that makes it louder because my heart beats are bigger	1 I think I am dying in a panic attack and that thought makes me anxious, producing many more sensations and setting up a vicious circle
2 *I have chest and rib tightness throughout the day.* But cardiac patients don't. They get chest pain (often crushing and more localized) during heart attacks. It is muscle tension due to work stress. It is mild after a good night's sleep and easier at weekends. It is worst after a stressful day at work	2 Distraction sometimes helps. That makes sense if the problem is my thoughts. It does not make sense if the problem is a heart attack. The same argument applies to leaving the situation. That would not stop a heart attack but it makes me feel more comfortable and undermines the negative thoughts
3 *I occasionally get tingling in my fingertips.* But this is a common symptom of anxiety. Also deep breathing—which I do when I think there is something wrong—causes tingling	3 I get symptoms most often at the end of the day, when I have come to expect them and have time to dwell on them
	4 I have proved to myself that there is nothing wrong with my heart with vigorous exercise. All that happens is that my heart beats faster and pumps harder, as it should do in order to supply my muscles with the energy they need

(k) Cognitive content and other assessment issues

Anger is triggered when other people are seen to have broken one's personal rules about what is right and fair.[1] Angry individuals invariably think that they have been badly treated and ascribe their perceived ill treatment to intention or unacceptable neglect on the part of others. A key first step in assessment is to help patients become aware of their automatic thoughts during periods of anger. It is also helpful to keep a record of the situations and behaviours of other people that routinely trigger anger. Review of such triggers often reveals a particular theme and an implicit rule that the patient thinks other people should abide by. A detailed description of how the person behaves when angry and what effect the behaviour has on others is also essential.

(l) Intervention

As patients' rules about the way that others should behave are often highly idiosyncratic, a useful tactic involves asking patients to consider whether the problem is assuming that others hold the same rule as them when they do not. This can help reduce the conviction that others' actions are actively malicious. Other useful questions include the following.

- Is there any other explanation for what happened?
- Did the other people know that their actions would harm me?
- Am I mind-reading?
- Am I over-applying the 'shoulds'?
- What are the advantages and disadvantages of responding with anger?
- Are there other ways I could behave which will be more likely to put things right/help me to get over it?

Although identifying and changing anger-related thoughts is a useful tactic, it is important to remember that anger is an action-orientated emotion. When angry, patients have a strong compulsion to hit out verbally or physically, and have great difficulty in thinking rationally. For patients with recurrent anger problems, it is often useful to teach them first to pause and relax or remove themselves from the anger-provoking situation before trying to challenge their thoughts and to delay-taking action (such as writing angry letters to others) until they have calmed down and had time to consider the appropriateness/usefulness of the action. To enhance further the generalizability of thought-challenging work, it is often useful to summarize the answers to typical anger-related thoughts on a flash card that patients can carry around and consult whenever they become angry.

Anger can sometimes be the result of chronic under-assertiveness, with patients' fears preventing them from making their point of view known until they feel overwhelmed and irritated by the demands placed on them. In such cases, discussion of the fears that prevent earlier and more appropriate assertion and role-playing in which the patients try out and evaluate ways of communicating their views to others in a prompt and constructive fashion can be helpful.

Indications and contraindications

Cognitive behaviour therapy is suitable for most patients with anxiety disorders and the low dropout rates reported in many controlled trials[4,32] suggest that it is well tolerated. In cases with additional severe comorbid problems (e.g. alcohol dependence, depression) it is sometimes necessary to bring these problems under control before starting cognitive behaviour therapy for anxiety. Concurrent use of prescription anxiolytic medication (benzodiazepines, tricyclics, selective serotonin reuptake inhibitors) is not a contraindication. At one time it was thought that anxiolytics may facilitate treatment by helping patients to confront their fears more quickly. However, there is little evidence that concurrent medication enhances initial response.[32] In addition, combining medication (alprazolam or imipramine) with cognitive behaviour therapy has been shown to produce poorer long-term outcome than cognitive behaviour therapy alone in panic disorder.[33] The latter result suggests that if a patient is not already taking anxiolytic medication, it is probably best to start treatment with cognitive behaviour therapy alone. Medication might then be added at a later stage, if response to cognitive behaviour therapy alone is poor.

Efficacy

Controlled trials involving comparisons with other psychological interventions and waiting-list control groups indicate that cognitive

behaviour therapy is an effective and specific treatment for panic disorder, social phobia, specific phobia, generalized anxiety disorder, hypochondriasis, obsessive–compulsive disorder, and post-traumatic stress disorder.[4,32] Results comparing immediate response to cognitive behaviour therapy alone and pharmacotherapy alone have been mixed, with superiority for cognitive behaviour therapy, equivalence for cognitive behaviour therapy, and superiority for pharmacotherapy all being reported. In contrast to the immediate response data, the follow-up analyses after medication discontinuation that are currently available favour cognitive behaviour therapy.[34] However, the database is modest and further research is required. For anger problems, controlled trials have shown that the cognitive behavioural procedures described here are effective.[35]

Training and supervision

Most controlled trials have used therapists who have received specialized training in cognitive behaviour therapy and there is some evidence that deviation from therapy protocols and/or poor implementation is associated with less good outcome.[36] For these reasons, clinicians are likely to benefit from specialized training and supervision. Where local training institutes exist, it is wise to take advantage of their expertise. Even when no local institute is available, expert cognitive behaviour therapists from established centres often travel internationally to deliver workshops and supervision. Several professional organizations run regular training workshops and can be contacted through the Internet. The organizations include the British Association of Behavioural and Cognitive Psychotherapies (http://www.babcp.org.uk), the Association of Behaviour and Cognitive Therapies (www.abct.org), the International Association of Cognitive Psychotherapy (http://www.cognitivetherapyassociation.org), the American Psychological Association (http://www.apa.org), and the American Psychiatric Association (www.psych.org). A comprehensive list of the competencies required for the main cognitive behaviour therapies for anxiety disorders can be found at: http://www.ucl.ac.uk/clinical-health-psychology/CORE/CBT_Framework.htm

Further information

A number of texts describe the theory and practice of cognitive behaviour therapy for specific anxiety disorders[37–39] and for anger problems[40] in considerable detail. Texts are frequently updated. Readers interested in the latest therapy guides are recommended to visit the following websites: www.oup.com, www.oup.com/us/ttw, www.guilford.com, www.wiley.com. Video illustrations of therapy sessions are also available for some anxiety disorders (see ABCT, American Psychological Association, and Guilford Press websites).

6.3.2.2 Cognitive behaviour therapy for eating disorders

Zafra Cooper, Rebecca Murphy, and Christopher G. Fairburn

Introduction

The eating disorders provide one of the strongest indications for cognitive behaviour therapy. This bold claim arises from the demonstrated effectiveness of cognitive behaviour therapy in the treatment of bulimia nervosa and the widespread acceptance that cognitive behaviour therapy is the treatment of choice.[1] Cognitive behaviour therapy is also widely used to treat anorexia nervosa although this application has not been adequately evaluated. Recently its use has been extended to 'eating disorder not

otherwise specified' (eating disorder NOS),[2] a diagnosis that applies to over 50 per cent of cases,[3] and emerging evidence suggests that it is just as effective with these cases as it is with cases of bulimia nervosa.

In this chapter the cognitive behavioural approach to the understanding and treatment of eating disorders will be described. The data on the efficacy and effectiveness of the treatment are considered in the chapters on anorexia nervosa and bulimia nervosa (see Chapters 4.10.1 and 4.10.2 respectively), as is their general management.

The cognitive behavioural account of the maintenance of eating disorders

Although both the DSM and ICD schemes for classifying eating disorders encourage the view that anorexia nervosa and bulimia nervosa are distinct clinical states, consideration of their clinical features and course over time does not support this.[4] Patients with anorexia nervosa, bulimia nervosa, and eating disorder NOS have many features in common, most of which are not seen in other psychiatric disorders, and studies of their course indicate that most patients migrate between these diagnoses over time. This temporal movement, together with the fact that the disorders share the same distinctive psychopathology, has led to the suggestion that common 'transdiagnostic' mechanisms are involved in the persistence of eating disorder psychopathology.[5]

Anorexia nervosa, bulimia nervosa, and most cases of eating disorder NOS are united by a distinctive core psychopathology: patients over-evaluate the importance of their shape and weight and their ability to control them. According to the cognitive behavioural view it is this dysfunctional scheme of self-evaluation that is of central importance in maintaining these disorders. Whereas most people evaluate themselves on the basis of their perceived performance in a variety of domains of life, people with eating disorders judge themselves primarily in terms of their shape and weight and their ability to control them. Most of their other clinical features can be understood as stemming directly from this 'core psychopathology', including the extreme weight-control behaviour (i.e. the dieting, self-induced vomiting, laxative misuse, and over-exercising), the various forms of body checking and avoidance, and the preoccupation with thoughts about eating, shape, and weight. Fig. 6.3.2.2.1 provides a 'transdiagnostic' representation (or 'formulation') of the main processes involved in the maintenance of eating disorders.

The only feature that is not obviously a direct expression of the core psychopathology is binge eating, present in all cases of bulimia nervosa, many cases of eating disorder NOS and some cases of anorexia nervosa. The cognitive behavioural theory proposes that binge eating is largely a product of attempts to adhere to multiple extreme, and highly specific, dietary rules. These patients' tendency to react in a negative and extreme fashion to the (almost inevitable) breaking of these rules results in even minor dietary slips being interpreted as evidence of poor self-control. Patients respond to this perceived lack of self-control by temporarily abandoning their efforts to restrict their eating. This produces a highly distinctive pattern of eating in which attempts to restrict eating are repeatedly interrupted by episodes of binge eating. The binge eating maintains the core psychopathology by intensifying patients' concerns about their ability to control their eating, shape, and weight. It also encourages further dietary restraint, thereby increasing the risk of further binge eating.

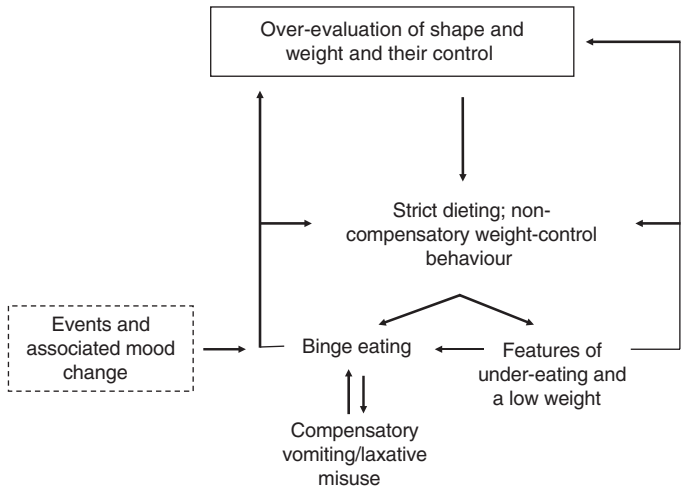

Fig. 6.3.2.2.1 The transdiagnostic 'template' formulation of the maintenance of eating disorders. (Reproduced from Fairburn, C.G., *Cognitive behavior therapy and eating disorders*, Copyright 2008, Guilford Press, NY).

Three further processes also maintain binge eating. First, difficulties in the patient's life and associated mood changes increase the likelihood that they will break their dietary rules. Second, binge eating temporarily ameliorates such mood states and distracts patients from thinking about their difficulties. Third, if the binge eating is followed by compensatory vomiting or laxative misuse, it is also maintained because patients' mistaken belief in the effectiveness of such 'purging' undermines a major deterrent to their binge eating. They do not realize that purging has little effect on energy absorption.[6]

Patients with anorexia nervosa share the distinctive core psychopathology of those with bulimia nervosa and eating disorder NOS. The major difference between patients with anorexia nervosa and those with other eating disorders lies in the fact that in anorexia nervosa under-eating predominates and therefore patients become extremely underweight. This has certain physiological and psychological consequences (see Chapter 4.10.1) that contribute to the persistence of the eating disorder.[7] For example, delayed gastric emptying results in a sense of fullness even after eating modest amounts of food and secondary social withdrawal magnifies patients' isolation from the influence of others.

The composite 'transdiagnostic' formulation shown in Fig. 6.3.2.2.1 represents the core processes that maintain any eating disorder. The specific maintaining processes operating in any patient depend upon the nature of the eating disorder psychopathology present. In some cases only certain of the processes are active (for example, in most cases of binge-eating disorder), but in others (for example, cases of the binge eating/purging subtype of anorexia nervosa) most are operating. The formulation highlights the maintaining processes that need to be addressed in treatment, thereby allowing the clinician to design a bespoke treatment to fit the individual patient's psychopathology.

Evidence for the cognitive behavioural account

There is a sizeable body of research that supports the cognitive view of the maintenance of eating disorders.[8] This includes descriptive and experimental studies of the clinical characteristics of these

patients and the research on dietary restraint and 'counter-regulation' (a possible analogue for binge eating).[9] There is also strong indirect support from a large body of research indicating that cognitive behaviour therapy based on this model has a major and lasting impact on bulimia nervosa (see Chapter 4.10.2) and emerging evidence that this is also true of eating disorder NOS. Further support comes from the finding that 'dismantling' the cognitive behavioural treatment for bulimia nervosa by removing those procedures designed to produce cognitive change attenuates its effects and results in patients being markedly prone to relapse.[10] Direct support comes from studies that have shown that dietary restraint appears to mediate this treatment's effect on binge eating[11] and that continuing over-evaluation of weight and shape in those who have recovered in behavioural terms is predictive of subsequent relapse.[12,13]

Transdiagnostic cognitive behavioural treatment of eating disorders

There follows a brief description of cognitive behaviour therapy for eating disorders. Full details are provided elsewhere.[14] The treatment is outpatient-based and, as applied in research settings, involves 20 individual treatment sessions over 20 weeks for the 80 per cent or more of patients who are not significantly underweight (body mass index over 17.5). The remaining patients with a body mass index of 17.5 or below receive 40 sessions over 40 weeks. The indications for the treatment are the presence of an eating disorder of clinical severity. It is not appropriate for those whose psychiatric state, general physical health, or degree of weight loss is such that they cannot safely be treated on an outpatient basis.

The treatment has four stages.

(a) Stage one

The aims of the first stage are as follows: to educate patients about treatment and the disorder; to engage the patient in treatment and change, and to introduce and establish a pattern of regular eating and weekly weighing. This stage comprises approximately eight sessions which are held twice weekly over 4 weeks.

(i) Jointly creating the formulation

This is usually done in the first treatment session. The therapist draws out the relevant sections of Fig. 6.3.2.2.1 incorporating the patient's own experiences and terms. This helps patients to realize both that their behaviour is comprehensible and that it is maintained by a variety of self-perpetuating mechanisms which are open to change. The formulation provides a guide to what needs to be targeted in treatment if patients are to achieve a full and lasting recovery.

(ii) Establishing real-time self-monitoring

This is the ongoing 'in-the-moment' recording of eating and other relevant behaviour, thoughts, feelings, and events (see Chapter 4.10.2 for an example monitoring record). Self-monitoring is initiated in the first session and continues throughout treatment. It serves two purposes: it assists in the identification of the patient's problems and progress and, more importantly, it facilitates change by helping patients address problems as they occur.

(iii) Establishing 'weekly weighing'

The patient and therapist check the patient's weight once a week and plot it on an individualized weight graph. Patients are strongly encouraged not to weigh themselves at other times. Weekly in-session weighing has several purposes: first, it provides patients with accurate data about their weight at a time when their eating habits are changing; second, it provides an opportunity for the therapist to help patients interpret the numbers on the scale, which otherwise they are prone to misinterpret and, third, it addresses the important maintaining processes of excessive body weight checking or its avoidance.

(iv) Providing education

From the second session onwards, an important element of treatment is education about weight and eating since many patients have misconceptions that maintain their eating disorder. The following topics need to be covered:

- Body weight and its regulation: the body mass index and its interpretation; natural weight fluctuations; and the effects of treatment on weight.
- Physical complications of binge eating, self-induced vomiting, the misuse of laxatives and diuretics, and the effect of the eating disorder on hunger and fullness.
- Ineffectiveness of vomiting, laxatives, and diuretics as a means of weight control.
- Adverse effects of dieting: the types of dieting that promote binge eating; dietary rules versus dietary guidelines.

To provide reliable information on these topics, patients are asked to read relevant sections from one of the authoritative books on eating disorders[6,15,16] and their reading is discussed in subsequent treatment sessions.

(v) Establishing 'regular eating'

The establishment of a pattern of regular eating is fundamental to successful treatment whatever the form of the eating disorder. It addresses an important type of dieting ('delayed eating'); it displaces episodes of binge eating and, for underweight patients, it introduces regular meals and snacks that can be subsequently increased in size. Early in treatment (usually by the third session) patients are asked to eat three planned meals each day, plus two (or if underweight three) planned snacks and they are asked not to eat between them. Patients may choose what they eat at these times with the only conditions being that the meals and snacks are not followed by any compensatory behaviour and that there should rarely be more than a 4-hour interval between these occasions of eating. The new eating pattern should take precedence over other activities but should not be so inflexible as to preclude the possibility of adjusting timings to suit the patients' commitments each day.

Patients should be helped to adhere to their regular eating plan and to resist eating between the planned meals and snacks. Two rather different strategies may be used to achieve this: the first involves helping patients to identify activities that are incompatible with eating or make it less likely, and the second is to help patients to recognize that the urge to eat is a temporary phenomenon. Through using these strategies patients learn to distance themselves from the urge to eat which they find gradually fades with time.

(vi) Involving significant others

The treatment is primarily an individual treatment for adults and hence it does not actively involve others. Despite this, it is our

practice to see 'significant others' with the patient if this is likely to facilitate treatment and the patient is willing for this to happen. There are two specific indications for involving others: if others could help the patient in making changes or if others are making it difficult for the patient to change by, for example, commenting adversely on eating or appearance.

(b) Stage two

Stage two is a transitional stage which generally comprises two appointments, a week apart. Whilst continuing with the procedures introduced in stage one the therapist and patient conduct a joint review of progress to date, identify problems still to be addressed, revise the formulation if necessary, and design stage three.

(c) Stage three

The aim of this stage is to address the key mechanisms that are maintaining the patient's eating disorder. The order in which these mechanisms are addressed depends upon their relative importance in maintaining the particular patient's psychopathology. There are generally 8-weekly appointments.

(i) Addressing the over-evaluation of shape and weight

The first step involves explaining the concept of self-evaluation and helping patients identify the life domains which contribute to their judgement of themselves. The relative importance of these domains can be visually represented on a pie chart, which for most patients is dominated by a large slice representing shape and weight and controlling eating.

The patient and therapist then identify the problems inherent in this scheme for self-evaluation. Briefly there are three related problems: first, the over-evaluation of shape and weight tends to marginalize other domains and thus self-evaluation is overly dependent on performance in one area of life; second, the area of controlling shape and weight is one in which success is elusive, thus undermining self-esteem; and third, the over-evaluation leads to behaviour which is unhelpful and which itself maintains the disorder.

The final step in educating about self-evaluation involves identifying its three main expressions which occur to varying degrees in different patients. These are body checking, body avoidance, and feeling fat. The therapist explains how these behaviours and experiences serve to maintain and magnify the patient's concerns about shape and weight and it is agreed therefore that they need to be addressed in treatment.

(ii) Addressing body checking and avoidance

Patients are often not aware that they are engaging in body checking and that it is maintaining their body dissatisfaction. The first step in addressing body checking involves obtaining a detailed account of the behaviour by asking patients to record it. An example monitoring record is shown in Fig. 6.3.2.2.2. Patients are then helped to realize that body checking is not a helpful way of assessing their

Day ……Friday…….. Date …..6th Sept ……..

Time	Food and drink consumed	Place	*	V/L	Checking (what done, time taken)	Place	Context and comments
7.45	1 piece of toast with butter and marmite. 1 cup of tea	Kitchen					Not hungry but know I should have breakfast
8.15					Looking at stomach and thighs in bedroom mirror while getting dressed (2 mins)	Bedroom	Depressing. Can't see any muscles – only fat.
10.30	1 apple & diet coke	Office					
11.15					Scrutinisng stomach in mirror standing sideways (1 min)	Office toilet	Ok
			*				How can it be so fat?? Have hardly eaten anything today!
12.30	Cheese and tomato sandwich & banana and kit kat	Canteen					Chocolate was too much. Feel too full.
1.30					Feeling and pinching stomach while sitting at desk (10mins)	Office	myself sick.
							Fat disgusting flesh. Feel massive.
3.10	Cup of coffee and 1 yoghurt	Office					Had planned to have other 1/ 2 of chocolate bar. Can't do it, am already too fat!
3.30	Water				Assessing shape of woman on street (10secs)	Office – through window	Feel unhappy. Wish I was as thin as her. Can't accurately compare myself to others – never really sure what my shape is. Frustrating.
6.45	Salad with tuna 1 glass of red wine	Living room					
7.30					Looking at reflection in window while doing dishes (5mins)	Kitchen	Still want more food but won't let myself since might lose control.
						Bathroom	
8.10			*	V	Touching and pinching stomach and thighs while having a bath (15mins)		I'm so huge! Wish I was tall and elegant. How depressing.
9.30	1 kit kat and half a crunchie 1 glass of red wine	Living room					Feel disgusted. Am I ever going to get rid of this fat?
							Feel fat! Too much chocolate today. Have to get rid of the food. Go to bed to stop thinking about it.

Fig. 6.3.2.2.2 An adapted monitoring record illustrating body checking.

shape or weight as it provides unreliable and biased information. Certain forms of body checking are best stopped altogether. In the case of more normative checking such as mirror use, education should stress that, as with other forms of body checking, what one finds depends to an important extent upon how one looks (e.g. scrutiny of perceived flaws tends to magnify them). For patients who avoid seeing their bodies, the therapist needs to explain that this too maintains dissatisfaction. Patients need to be encouraged to get used to the sight and feel of their body. Participation in activities that involve a degree of body exposure can be helpful, for example, swimming.

(iii) Addressing 'feeling fat'

'Feeling fat' is an experience reported by many women but the intensity and frequency of this feeling appears to be far greater among people with eating disorders. Feeling fat is a target for treatment since it tends to be equated with being fat (irrespective of actual shape and weight) and hence maintains body dissatisfaction. Although this topic has received little research attention, clinical observation suggests that in many patients feeling fat is a result of mislabelling certain emotions and bodily experiences. It may be addressed by helping patients appreciate that feeling fat tends to be triggered by the occurrence of certain negative mood states (e.g. feeling bored or depressed) or by physical sensations that heighten body awareness (e.g. feeling full, bloated, or sweaty). Patients can then be encouraged to question the feeling when it occurs and correctly label and address the underlying triggering state using a problem-solving approach.

(iv) Developing marginalized domains for self-evaluation

Tackling the expressions of the over-evaluation of shape and weight will gradually reduce it. At the same time, it is also important to encourage the patient to increase the number and significance of other domains for self-evaluation. Although this is an indirect means of diminishing the over-evaluation of shape and weight, it is nevertheless a powerful one.

(v) Exploring the origins of the over-evaluation

Towards the end of stage three it is often helpful to explore the origins of the patient's sensitivity to shape, weight, and eating. An historical review can help to make sense of how the problem developed and evolved, highlight how it might have served a useful function in its early stages and help patients distance themselves from the past. If a specific event appears to have played a critical role in the development of the eating problem, the patient should be helped to reappraise this from the vantage point of the present.

(vi) Addressing dietary restraint

A major goal of treatment is to reduce, if not eliminate altogether, strict dieting. This dieting has two aspects: an attempt to limit eating termed 'dietary restraint' and actual under-eating in physiological terms termed 'dietary restriction'. 'Regular eating' will already have addressed one form of dietary restraint (delayed eating). Patients need to recognize that their multiple extreme and rigid dietary rules lead to preoccupation with food and eating, encourage binge eating and impose practical and social restrictions. It should therefore be agreed that dietary restraint needs to be addressed. To do this, the patient's various dietary rules should be identified together with the beliefs which underlie them. The patient should be helped to break the rules in order to test the beliefs in question and to learn that the feared consequences that maintain the dietary rule (typically sudden weight gain or binge eating) are not an inevitable result of breaking it. With patients who binge eat it is important to pay particular attention to food avoidance and to help them systematically reintroduce such foods into their diet.

(vii) Addressing event-triggered changes in eating

Among patients with eating disorders, eating habits may change in response to outside events. The change may involve eating less, stop eating altogether, overeating or binge eating. If these changes persist into stage three, they should be addressed by helping patients to tackle the triggering events using a problem-solving approach and by helping patients to accept the occurrence of intense-mood states and identify ways (that are not harmful) of modulating their moods.

(d) Stage four

The aims in stage four are to ensure that the changes made in treatment are maintained over the following months and that the risk of relapse is minimized in the long term. There are three appointments, each 2 weeks apart. During this stage, as part of their preparation for the future, patients discontinue self-monitoring and transfer from in-session weighing to weighing themselves at home.

To maximize the chances that progress is maintained the therapist and patient jointly devise a specific plan for the patient to follow over the following few months until a post-treatment review appointment. Typically this includes further work on body checking, food avoidance, and perhaps further practice at problem-solving. In addition, the therapist encourages patients to continue their efforts to develop new interests and activities.

There are two elements to 'relapse prevention'. First, patients must have realistic expectations regarding the future. A common problem is that many hope never to experience any eating difficulties again. It needs to be explained that this makes them vulnerable to relapse since it encourages a negative reaction to even minor setbacks. Patients should be told to expect lapses with the eating problem continuing to be their Achilles' heel. The goal is for patients to identify setbacks as early as possible, view them as a 'lapse' rather than a 'relapse', and use a well-developed plan to deal with them. Thus, the second element of relapse prevention is the construction of such a plan. The therapist and patient should review the components of treatment with the aim of identifying the principles and procedures that were most relevant and helpful and devise a plan for the future incorporating this information.

Underweight patients

When treating patients who are underweight (most are cases of anorexia nervosa but some are cases of eating disorder NOS) three main modifications to the treatment are required: the motivation of these patients needs to be enhanced, their state of starvation needs to be corrected, and significant others are more likely to be involved. As a result treatment needs to be considerably longer.

(a) Enhancing motivation to change

The poor motivation of these patients needs to be addressed from the outset of treatment. There are various ways of enhancing motivation[17] including focusing on establishing a sound therapeutic relationship, ensuring that the patient feels understood, making it clear that one is working on behalf of the patient and not their

relatives or concerned others, accepting the patient's beliefs and values as genuine and comprehensible, and adopting an experimental approach in which the therapist and patient together explore the advantages and disadvantages of making changes. This includes educating the patient about the physiological and psychological effects of starvation; for example, impaired concentration, preoccupation with food and eating, sleep disturbance, sensitivity to cold, ritualistic eating, social withdrawal, and enhanced fullness secondary to delayed gastric emptying.[7] It is best to focus particularly on those features that the patient views as a problem and explain how they tend to perpetuate the eating disorder. In addition, an exploration of the broader impact of the eating problem on the patient's life is important. When exploring the advantages and disadvantages of change, it is important to draw a distinction between the short-term and long-term consequences of change since patients tend to focus on the immediate present rather than the future.

(b) Restoring a healthy weight

Unless the weight loss is rapid or extreme, or the patient's health is endangered by physical complications, weight restoration can usually be accomplished on an outpatient basis. Before focusing on weight gain, however, it is best to devote several sessions to establishing a collaborative working relationship and to developing a joint formulation and treatment plan. Thereafter, weight gain and the subsequent maintenance of a healthy weight must be an integral part of treatment. A target weight range should be identified in excess of a body mass index of 19.0.

The weight gain should be gradual and steady (at an average rate of about 0.5 kg/week). This requires an energy surplus to be established. This can be achieved by providing patients with energy-rich drinks to supplement their food intake (which should be increased such that it is sufficient to maintain their current weight). The energy-rich drinks may be viewed as weight restorative 'medicine' designed to produce the energy surplus. The drinks should be phased out once the target weight range has been reached. Whilst regaining weight patients should be helped to address their shape and weight concerns and dieting in much the same way as described above. Once a satisfactory weight has been reached patients need time to learn how to maintain their weight in a normal manner.

(c) Involving the significant others

Weight regain is a protracted process that takes considerable time and effort on the part of the patient. If the patient lives with others it can be helpful to involve them if doing so is consistent with the nature of their relationship. Significant others can help the patient choose what to eat and provide guidance concerning portion sizes. This is likely to be especially important with younger patients (many underweight patients are adolescents) who are still living at home with their parents.

6.3.2.3 Cognitive behaviour therapy for depressive disorders

Melanie J. V. Fennell

Introduction

This chapter describes A.T. Beck's cognitive behaviour therapy (CBT) for depression.[1] Beck's is probably the most fully developed, comprehensively evaluated, and widely disseminated cognitive behavioural approach to depression. Additionally, CBT is an effective treatment for a range of acute psychiatric disorders, shows promise for severe mental illness and personality disorder, and is thus helpful not only with primary depression, but also with a range of comorbid conditions.

Central characteristics of CBT

The general principles and nature of CBT are described elsewhere. Two specific points relate to depression:

(a) Demands of CBT

Given the nature of depression, CBT challenges both therapist and patient. It requires **active engagement** (e.g. willingness to carry out self-help assignments), yet depressed patients often lack motivation and energy. It is based on a **friendly collaboration**, yet depressed people often find it hard to talk and clinicians may find their negativity aversive. It is an **educational approach**, using written materials and record sheets, yet depressed patients often have concentration and memory difficulties. Its stance is **optimistic**, yet depressed patients are often afraid (or convinced) that change is impossible. Therapists should be alert to these difficulties, understand them as aspects of depression rather than blaming the patient ('She must want to be depressed') or themselves ('I'm no good at this'), and maintain a persistent, problem-solving stance.

(b) Advantages of CBT

Nonetheless, CBT has real advantages for depressed patients. Its **structure** discourages rumination, and helps patients to focus systematically on their difficulties. Its emphasis on a warm **therapeutic relationship** encourages empathy, while its **goal orientation** implies that change *is* possible. The **coherent model** of human functioning, on which it is based, allows it to address many issues, including depression itself, comorbid conditions, problems in living, long-standing difficulties (such as low self-esteem), patients' responses to therapy and therapist, and therapists' responses to patients. Its **emphasis on collaboration and on transfer of knowledge and skill** empowers patients to become their own therapists and to take control of their lives.

Background

Beck's interest in the role of cognition grew out of his practice as a psychoanalytical therapist. Dissatisfied with analytical understandings of depression, he became curious about the role of the negative thinking he observed in depressed patients.[2–4] Beck's clinical observation and research consistently showed the thinking of depressed people to be dominated by self-derogation, negative expectations, overwhelming problems and responsibilities, deprivation and loss, and escapist and suicidal wishes, themes fuelled by systematic biases in information processing. He suggested that patients could recover from depression by learning to re-evaluate everyday cognitions, and to understand the long-standing idiosyncratic schemas under lying them.

This early scientist–practitioner stance has remained central CBT, stimulating an integrated flow of experimental investigation, practice development, and research into treatment efficacy, which has continued to the present day. The first successful outcome trial of CBT for depression appeared in 1977.[5] A detailed treatment manual emerged shortly afterwards.[1] Thirty years of randomized controlled trials now support the treatment's effectiveness.[6] Like other short-term focused psychological treatments, it has consistently proved as effective as antidepressant medication post-treatment. It reduces the likelihood of relapse by about 50 per cent, and this effect endures,[7] and can be enhanced by booster sessions in the months following treatment.[8] Thus CBT emerges as surprisingly cost-effective.[9] With adequate training and supervision equivalent results can be achieved even with severe depression and high comorbidity.[10,11]

Technique

Cognitive case conceptualization

(a) Enduring cognitive vulnerability to depression

The **cognitive model of depression** proposes that enduring cognitive structures and processes shape how everyday experience is interpreted, and are in turn reinforced by these interpretations. This model (Fig. 6.3.2.3.1) forms the basis for an **individualized conceptualization**, developed and shared with the patient, which informs and guides therapy. It suggests that **experience** (loss, events with lasting implications for self-worth)[12,13] leads people to reach **fundamental conclusions** about themselves, others, and the world ('basic' or 'core' beliefs, or schemas). They devise **guidelines for living** ('conditional assumptions'), which allow them to operate in the world, assuming the truth of those conclusions. Using schemas and rules to organize experience and guide behaviour is a normal part of human functioning. However, where schemas are globally negative (e.g. 'I am inferior') and assumptions extreme and resistant to change (e.g. stringent perfectionism), they become counterproductive. Evidence for **cognitive vulnerability** to depression prior to first onset is now emerging,[14] as is evidence that recurrent episodes leave an tendency to re-experience depressogenic processing patterns in the presence of mild, normal depressed mood ('cognitive reactivity').[15,16]

(i) Relationship between thinking and other aspects of depression

Dysfunctional beliefs and assumptions are **activated by events** that match the person's particular sensitivities. So a person with negative beliefs about the self whose psychological well-being depends on love and approval might become depressed after experiencing rejection. Activation of the system results in an upsurge of '**negative automatic thoughts**'—'negative' in that they are associated with painful emotions, and 'automatic' in that they pop into the person's mind rather than being a product of reasoned reflection. Such thoughts reflect **processing biases** such as overgeneralization. Depression is characterized by biased negative thoughts about the self (e.g. 'I'm useless'), the world (e.g. 'My situation is intolerable'), and the future (e.g. 'Nothing will ever change'). The latter (hopelessness) is central to suicidality.

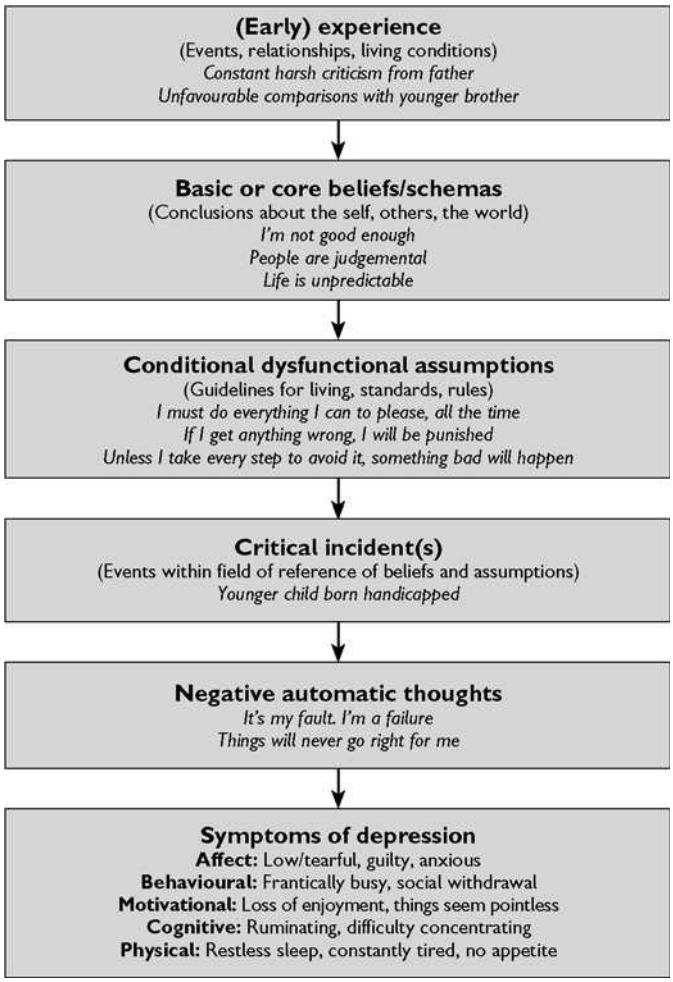

Fig. 6.3.2.3.1 Cognitive model of depression.

The more depressed people become, the more negative thoughts they think, and the more they believe them. The more negative thoughts they think and the more they believe them, the more depressed they become. Thus depression is maintained by **vicious circles** in which negative thinking and other symptoms reinforce one another. Experimental and clinical research reflects this **reciprocal relationship between affect and cognition**: modifying depressive thinking modifies depressed mood, while modifying depressed mood modifies depressive thinking.

(ii) Objectives of CBT for depression

The first goal is to **break the vicious circle** described above by teaching patients to work effectively with negative automatic thoughts. Attention then turns to cognitive predisposing factors (beliefs, assumptions) in order to **reduce vulnerability** and decrease the likelihood of future episodes. The aim is not to teach realistic thinking *per se*, but rather to help patients to resolve their problems by teaching them cognitive behavioural skills.

(iii) Overview of CBT for depression

Treatment usually proceeds through the following **stages**:

- diagnosis, assessment, problem identification
- cognitive interventions designed to reduce the frequency of negative thoughts
- behavioural assignments intended to tackle behavioural and motivational deficits
- monitoring, questioning, and testing negative automatic thoughts (the main body of therapy)
- relapse prevention.

Patients usually move from one stage to the next as each is mastered. The **starting point varies**: severely depressed patients often begin with simple behavioural interventions, whereas relatively mild depressions may immediately be amenable to cognitive work. At each stage, **cognitive and behavioural interventions are closely integrated**.[17] Thus behavioural interventions such as activity scheduling present opportunities to identify, question, and test negative thoughts, while work on thoughts and assumptions is closely linked to changes in behaviour.

Traditionally, **up to 20 sessions** of therapy are offered, twice weekly for 4 weeks and once weekly thereafter. Most patients respond within about 15 sessions. Some do well with 4–6 sessions, but severe chronic depressions may require more than 20 sessions, as well as shorter, more frequent sessions early on. Post-treatment boosters help to increase confidence and consolidate and extend skill. Sessions start with agenda-setting (prioritizing what to work on), homework review, and feedback on the previous session. After the day's main topics have been discussed, more homework practice is agreed to ensure generalization and reinforce new learning. Key points are summarized, and the therapist asks for reactions to the session, including anything that has been uncomfortable or unclear.

Indications and contraindications

CBT was developed as a treatment for moderate-to-severe unipolar depression,[1] and has been consistently effective with this population. However, good average results in outcome trials conceal wide variations in responsiveness.[18] Consistent predictors of treatment response remain elusive.

Patients presenting with endogenous symptoms are as likely to respond well as non-endogenous patients. However, results for severe depression[19] and bipolar disorder[20] remain somewhat conflicting.

Some factors may facilitate a positive response; well-developed pre-existing cognitive and behavioural coping skills, acceptance of the cognitive model, willingness to engage in self-help assignments, an early focus on teaching specific cognitive-therapy skills, ease of access to thoughts and feelings, problem specificity, and ability to form a collaborative alliance. Such criteria can be explored at assessment, especially if it is divided into two sessions with a simple intervening homework assignment.

Patients who are unsuitable for short-term CBT[21] may nonetheless respond to a modified approach with:

- greater emphasis on socialization and on cultivating a solid working relationship
- more extended behavioural work
- more work on enduring depressogenic schemas in the later stages of treatment
- more emphasis on integration with antidepressant medication
- more careful attention to environmental factors (including not only life stresses and family relationships, but also the ward and health-care team)

Finally, given that CBT and antidepressant medication generally produce similar results, the patients' wish for psychological treatment should also be taken into account.

Selection procedure

Diagnosis: recognizing and labelling depression

CBT was designed for moderate-to-severe major unipolar depression. The diagnostic criteria for major depressive episode,[22] remarkably consistent for over 30 years, describe a symptom pattern (including cognitive features) that has been recognized throughout history, and appears basically consistent across age, gender, race, and culture. However, the relative emphasis on different symptoms and the manner in which distress is expressed varies, and assessment procedures should be adapted to explore cultural context. Additionally, sociocultural factors necessarily influence belief systems, and therapists should be sensitive to such differences, rather than assuming that their own assumptions are shared by their patients.

Severity

Severity should be taken into account when deciding whether concurrent (or alternative) physical treatments or hospitalization are necessary, and in determining where to begin within CBT. Severity can be assessed through clinical interview (e.g. intensity, pervasiveness, and reactivity of depressed mood; extent of behavioural and interpersonal deficits). The **Beck Depression Inventory** (BDI-II)[23] a well-established self-report measure of depression, provides a rapid overview of symptoms. Weekly completion allows clinicians to observe overall progress, as well as tracking scores on particular items, e.g. hopelessness. Hopelessness and suicidality should be routinely assessed[24] and any sign of suicide risk investigated in-depth.[25]

Clinical interview

Interview assessment for CBT includes the following:

(a) Symptoms and associated cognitions

Negative automatic thoughts both trigger and enhance symptoms of depression (Table 6.3.2.3.1). Identifying meanings attached to symptoms prepares the ground for more helpful perspectives (e.g. 'These are symptoms of depression, not a reflection of my worth as a person').

(b) Impact on functioning

It is important to establish how depression affects relationships, work performance, and leisure time. It may be necessary to take practical steps to improve the patient's situation (e.g. gradual reintroduction to work).

(c) Coping strategies

The more depressed the patient, the more likely that she/he has adopted coping strategies which help in the short-term, but are in the longer-term self-defeating (e.g. alcohol or drugs, social withdrawal, bed). Therapist and patient can discuss the pros and cons of these, and how cognitive behavioural strategies might be more beneficial. The aim is for patients to reach the point of trying more adaptive coping strategies for themselves.

Table 6.3.2.3.1 Negative automatic thoughts and symptoms of depression

Symptoms	Negative automatic thoughts
Behavioural	
Lowered activity level	I can't do it. It won't work.
Procrastination	I'll never get it done. It's too much for me.
Motivational	
Loss of energy	It's too much effort. I'll wait till I fell better.
Loss of pleasure, interest	I won't enjoy it. What's the point? I can't be bothered.
Affective	
Sadness	I've lost everything important to me.
Guilt	I'm letting everybody down.
Anger	Why can't people just leave me alone?
Shame	What must everyone think?
Anxiety	I'm not going to be able to cope.
Cognitive	
Indecisiveness	Whatever I do will go wrong.
Poor concentration	I must be going senile.
Physical	
Loss of sleep	If this goes on, I won't be able to function.
Loss of appetite	I'm going to make myself ill.
Loss of sexual appetite	Our marriage is at an end.
Other	
Suicide	This is unbearable. There is no other way out.
Problems in living	There's nothing to be done.

(d) Onset of current episode

Information about the onset of episodes may provide valuable clues about beliefs and assumptions. For example, a young woman became depressed when her husband took a job abroad, and was away for long periods. She believed that he would not have done so if he truly loved her. In fact, he had taken the job because it paid exceptionally well and the savings they could make would allow them to start the family they had been planning. The therapist noted the patient's interpretation of her husband's behaviour, and later in therapy used this clue as a starting point to identify long-standing doubts about her attractiveness, and a linked dysfunctional assumption: 'If someone is not there for me all the time, it means they don't care about me'.

(e) Background

(i) Previous treatment

Many depressed patients presenting for CBT have already received other treatment (most commonly antidepressant medication and counselling). The therapist should inquire about the **outcome** of such treatment, and **what the patient makes of it**. Depressed patients often conclude that the incomplete success of prior treatment means that they will also be unable to benefit from this new approach. Such thoughts can be worked with using straightforward cognitive behavioural methods (identify, question, test). When the patient has received psychological therapy, it is often helpful to ask **what they learned** from it. If they feel they learned nothing, this may predispose them to approach CBT with pessimism.

Alternatively, if they learned something of value, CBT can build on this positive experience.

(ii) Expectations of CBT

These may reflect general pessimism about change, especially if patients know nothing about the approach. Those who have heard or read about CBT, and are aware of outcome data, may be more optimistic, although still anxious lest it fail to help *them*. Others may have heard negative reports (e.g. that it is mechanistic and fails to address deep issues). **Non-defensive discussion** of expectations allows doubts and misconceptions to be addressed, as well as encouraging open-mindedness and continued frank feedback from the patient.

(iii) Early experience and resultant beliefs and assumptions

CBT is **conceptualization driven**,[26] **closely based on the cognitive model of depression**. In order for patients to understand how their problems developed, and that current beliefs are learned opinions rather than reflections of fact, it is helpful to know about relevant formative experiences. This is particularly true when working with severe, chronic problems, and personality disorders. However, **obtaining historical information is often not an immediate priority**. It is more important initially to convey the hopeful message that something can be done to change things for the better. Therefore details about history, beliefs, and assumptions may not be explored until work on behavioural deficits and negative automatic thoughts has produced a reduction in hopelessness and depressed mood. That said, where patients are relatively mildly depressed, psychologically minded, and able to articulate their difficulties with ease, a draft conceptualization incorporating historical information, beliefs, and assumptions sometimes emerges even from the initial assessment.

Managing treatment

(a) Starting treatment

The **first treatment interview has four main objectives**:

- to establish a warm, collaborative therapeutic **alliance**
- to list specific **problems and** associated **goals**, and select a first problem to tackle
- to educate the patient about the **cognitive model**, especially the vicious circle that maintains depression
- to give the patient first-hand experience of the focused, workman-like, empirical **style** of CBT.

These convey two important messages: (1) it is possible to make sense of depression; (2) there is something the patient can do about it. These messages directly address hopelessness and helplessness.

(i) Identifying problems and goals

The **problem list** usually includes symptoms of depression. It may also contain aspects of other disorders (e.g. panic attacks), problems in living (e.g. family conflicts), and, in some cases, long-standing psychological problems (e.g. fear of intimacy). Developing the list provides the therapist with a 'map of the territory', which suggests possible targets for intervention, as well as an opportunity to foster the therapeutic relationship by demonstrating empathy. It suggests that apparently chaotic experience can be broken down into manageable problem areas. **Goal identification** then implies that progress is possible.

(ii) Introducing the cognitive model of depression

The therapist's next task is to demonstrate **how negative thinking influences emotion and behaviour**, relating this to the patient's experience using material derived from the session. The therapist explains that the patient will learn to notice negative automatic thoughts, to stand back, question them, and develop more realistic and helpful perspectives. Patients are often doubtful about their ability to do this. It is important therefore to present **CBT as a learning opportunity** during which skills can be acquired, step by step, with the therapist's guidance. The therapist is not obliged to convince patients that CBT will work for them, but a willingness to try it in practice is essential.

(iii) Where to start?

A **first treatment target** is chosen towards the end of the first session, and an appropriate **homework** task agreed upon. Suitable homework tasks include: observing a recording of the session and noting important points (this assignment follows every session), reading assignments,[27] and self-monitoring assignments. The initial target varies. Where patients are only relatively mildly depressed, and remain active and capable of experiencing interest and pleasure, monitoring negative automatic thoughts can begin right away. Where the depression is more severe, with significant behavioural and motivational deficits, it is best to begin with behavioural interventions.

(b) Behavioural interventions

(i) Reducing rumination

In severe depression, access to more positive perspectives may be blocked by depressed mood, making modifying negative automatic thoughts difficult or impossible. At the same time, depressed patients spend a great deal of time ruminating about their difficulties and shortcomings.[28] Learning to **direct attention elsewhere** reduces the frequency of negative thoughts and hence improves mood. This palliative measure will not resolve the patient's problems, but its impact reinforces the model, and feeling somewhat better can facilitate more constructive thinking.

(ii) Monitoring activities

Lowered activity levels and loss of interest and pleasure are often central to depression, and interventions designed to address them are known to be powerful in their own right.[19] Early behavioural interventions serve to **maximize engagement in activities providing a sense of pleasure and mastery**. This has a direct impact on mood, and provides opportunities to test negative thoughts that block engagement and, in a more global sense, prevent recovery (e.g. 'I can't do anything to change how I feel').

Patients record what they do, hour by hour, on a Weekly Activity Schedule (Fig. 6.3.2.3.2). Each activity is rated **0–10 for Pleasure (P) and Mastery (M)**. P ratings indicate how enjoyable the activity was, and M ratings how much of an achievement it was. 'P' is usually easily understood, but M can present difficulties. Depressed people often feel that nothing they do is an achievement, perhaps because most of their activities are routine ('What's so special about that?') or do not meet their standards ('I should have done more'). M should therefore be explained as 'an achievement, *given how you felt at the time*'. Thus even simple activities (e.g. making a cup of tea) are real achievements when patients are hampered by low mood and loss of energy. Ratings should be made immediately

Name _____ Week beginning _____

	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
9–10			Bed (P5, M0)	Take kids to school (P0, M9)	Bed (P4, M0)		
10–11			Bed (P4, M0)	Shopping with friends	Bed (P0, M0)		
11–12			Bed (P2, M0)	↓ (P6, M7)	Bed (P0, M0)		
12–1			Bed (P1, M0)	Lunch with friend (P7, M3)	Up, shower, dress (P2, M7)		
1–2			Bed (P0, M0)	Went for a walk (P7, M5)	Lunch, read paper (P3, M4)		
2–3			Up, shower, dress (P0, M5)	Gardening (P4, M7)	Therapy Session		
3–4			Pick up kids from school (P3, M7)	Pick up kids from school (P1, M3)			
4–5			Tea with friends (P4, M9)	Tea & TV with kids (P5, M2)			
5–6			Tea with friends (P6, M7)	Ironing (P0, M5)			
6–7			Get supper (P2, M5)	Get supper (P1, M5)			
7–8			Read with kids (P8, M3)	Read with kids (P7, M3)			
8–12			TV (P3, M1) Bed (P8, M0)	TV (P4, M0) Bed (P9, M0)			

Fig. 6.3.2.3.2 Weekly activity schedule. P, pleasure; M, mastery.

after each activity, since retrospective ratings may be distorted by negatively biased recall. In addition, it is helpful for patients to **review each day**, asking questions like: 'What worked for me?' 'What did not work?' 'What do I need more of? Less of? Different?'

(iii) Planning activities

Once self-monitoring is mastered, **each day is planned in advance** on an hour-by-hour basis. This:

- provides a structure and helps with setting priorities
- averts the need to keep making decisions about what to do next
- reduces what may seem like chaos to a manageable list
- increases the chances that activities will be carried out
- enhances patients' sense of control.

A pattern of activities is sought in which **mastery and pleasure are balanced and maximized**. The plan is likely to contain a blend of obligations (e.g. the ironing) and pleasures (e.g. listening to music). Avoided tasks can be included, broken down into manageable steps ('graded task assignment'). Again, it is helpful for patients to review each day in detail, identifying unhelpful thoughts to be worked on in the next therapy session (e.g. 'If I can't complete the task, I might as well not bother at all'). Thus the cognitive element is present even when behaviour change is the primary target.

(c) Working with negative automatic thoughts

Once behavioural methods have been mastered, patients learn to **identify, question, and test negative automatic thoughts**. The main tool here is the Dysfunctional Thoughts Record (Fig. 6.3.2.3.3). The example summarizes a lengthy discussion that took place when a patient experienced a serious setback midway through treatment.

(i) Identifying negative automatic thoughts

Patients learn to **record upsetting incidents** as soon as possible after they occur (delay makes it difficult to recall thoughts and feelings accurately). They learn:

1 **To identify unpleasant emotions** (e.g. despair, anger, guilt), signs that negative thinking is present. Emotions are rated for intensity on a 0 to 100 scale. These ratings (though the patient may initially find them difficult) help to make small changes in emotional state obvious when the search for alternatives to negative thoughts begins. This is important, since change is rarely all-or-nothing and small improvements may otherwise be missed.

2 **To identify the problem situation**. What was the patient doing or thinking about when the painful emotion occurred (e.g. 'waiting at the supermarket checkout', 'worrying about my husband being late home')?

3 **To identify negative automatic thoughts associated with the unpleasant emotions**. Sessions direct the therapist towards asking: 'And what went through your mind at that moment?' Patients become aware of thoughts, images, or implicit meanings that are present when emotional shifts occur, and record them word-for-word. Belief in each thought is also rated on a 0 to 100 per cent

Date	Emotion(s) *What did you feel? How bad was it (0–100%)?*	Situation *What were you doing or thinking about?*	Automatic thoughts *What exactly was running through your mind? Write your thoughts down, word for word. How far did you believe each of them (0–100%)?*	Alternative views *What alternatives are there to the automatic thoughts? How far do you believe each of them (0–100%)?*	Outcome *1. How far do you now believe the original thoughts (0–100%)? 2. How do you now feel (0–100)? 3. What can you do now (action plan, experiment)?*
Thurs	Depressed (95%) Hopeless (90%)	Three terrible days	I'm back to square one—I've lost everything I learned (100%)	Not true — even now, I'm not as bad as when I came into hospital (100%)	1. (60%)
				I am doing my housework, looking after the children, doing my job. I am getting some satisfaction out of it — it's not a total failure (75%)	2. Depressed (70%) Hopeless (35%)
			There's no point in doing anything. Nothing will work (100%)	I've been feeling very bad, but setbacks are to be expected — disappointment at the contrast with last week makes it worse (100%)	3. Accept setbacks as part of recovery, not the end of the world.
			I've tried everything now, and nothing has changed (100%)	I've been getting this therapy for 7 weeks — I've been depressed for 3 years. It's not surprising I haven't got over it completely. Already I can manage 75% of my depression, as opposed to 25% (100%)	Make a detailed plan to help me deal with these feelings if they come again.
			I've failed again (100%)	This setback is not my failure —it is part of the problem (80%)	Keep using what I have learned to deal with my depression
			I will always be like this (100%) The only solution is to kill myself (95%)	Suicide is not the answer. Keep working on your thoughts. The past 7 weeks, and today, show it can work (100%)	

Fig. 6.3.2.3.3 Dysfunctional thoughts record.

scale (100 per cent represents complete belief, 50 per cent a moderate degree of belief, and so on). Again, this helps to make small changes in conviction evident at the next stage.

The skill of identifying painful emotions and associated thoughts is best learned if therapist and patient **work through examples on the sheet** before the patient self-monitors independently. Therapists can make sure that patients understand what is required, and are prepared for possible difficulties. For example, patients sometimes avoid recording thoughts because doing so is upsetting. Therapists can reassure them that this phase will pass once they learn to answer their thoughts, and suggest that they follow recording by engaging in an absorbing and pleasurable activity. Sometimes thoughts recorded do not seem to 'fit' the emotion experienced; in this case, therapists may need to help patients to **'unpack' the meaning of the thought** (for example, 'That didn't go too well' may turn out to mean 'I'm a total failure'). Time taken to learn accurate self-monitoring varies; many patients acquire the skill within a few days, but others take much time and coaching.

(ii) Questioning negative automatic thoughts

Once patients can record thoughts and feelings, they learn to **search for alternative views**, writing these in the fifth column of the Dysfunctional Thoughts Record. There is no such thing as a 'right' answer to a negative thought; the 'right' answer is the one that helps the patient to feel better and handle the situation more constructively. Accordingly, the therapist's task is not to suggest alternatives, but rather to elicit them through '**guided discovery**', a process of sensitive questioning, which allows patients to reach new interpretations independently. It is helpful for therapists to develop a personal 'library' of questions, through discussion with colleagues, observation of other therapists, attendance at workshops, and reading. Productive areas of inquiry include:

1 **What is the evidence?** Processing biases in depression mean that patients give weight to information consistent with prevailing perspectives at the expense of information, which suggests that they may not be wholly true. The therapist thus needs to examine 'evidence' believed to support the thought, and also to seek information that might contradict it.

2 **What alternative views are there?** Questions such as the following can prompt alternative perspectives: 'How would you have reacted to this before you became depressed?' 'What is your perspective on this when you feel relatively well?' 'What might someone whose views you trusted make of this?' 'If someone you cared about came to you with this problem, what would you say?'

3 **What are the advantages and disadvantages of this way of thinking?** This approach is particularly helpful with self-critical thinking. Patients often believe that self-criticism is an effective way of bringing about change; in fact, it only intensifies depression. Patients who habitually self-criticize can be helped to draw

up an analysis of pros and cons. Apparent advantages (e.g. 'It keeps me on my toes') may in fact be outweighed by disadvantages (e.g. 'It paralyses me').

4 **What are the biases in my thinking?** The tendency to make inferential errors such as overgeneralization has already been mentioned. Learning to recognize these can be helpful, especially when patients regularly make the same mistake.

Alternatives reached by questioning negative automatic thoughts are recorded on the Dysfunctional Thoughts Record. The patient rates them for degree of belief, to ensure that they are *sufficiently* convincing (they do not require belief ratings of 100 per cent). If alternatives are not at all convincing, they will have no impact on the strength of the original automatic thoughts or associated emotions. These are now re-rated in the final column as a check that plausible alternatives have been found.

As with self-monitoring, these skills are **best learned by working through examples in session** before the patient attempts to answer thoughts independently. Even then, patients are sometimes unable to find alternatives, especially if emotion is high. This is quite normal, given that questioning one's thoughts is a complex skill. It may be helpful to leave searching for alternatives until the storm is past. Sometimes alternatives make no difference to the original thoughts or emotions. This may be because the patient has reservations about their validity ('Yes, but . . . '), which can dealt with like other negative thoughts. Alternatively, it may be that non-verbal methods (e.g. imagery work, experiential learning) are necessary to facilitate emotional change, or that the resistant thought is a more or less direct statement of an underlying belief of much longer duration, which will take longer to change.

(iii) Testing negative automatic thoughts: what can I do now?

It is important that cognitive changes brought about by questioning are consolidated through **behavioural experiments**.[17] These are often designed to test out the validity of the new perspective by seeking further information or acting differently and observing the results. They may also include practical plans to solve genuine life problems and to deal with the trigger situation differently should it occur again.

(d) Ending treatment

Although most episodes of depression are time-limited, **relapse and recurrence are common**—the more so, the more episodes a person has experienced. CBT therefore emphasizes working on cognitive vulnerability factors, summarizing and consolidating learning, and preparing for possible setbacks. A new approach, *Mindfulness-Based Cognitive Therapy*,[29] which integrates elements of CBT with intensive meditation practice, has been developed specifically to tackle this problem. Its effectiveness with patients who have experienced three or more episodes of depression has been demonstrated in two clinical outcome trials.[30,31]

(i) Re-evaluating dysfunctional assumptions

Once patients are skilled at answering negative automatic thoughts, attention turns to dysfunctional assumptions that make them vulnerable to depression. Often these emerge from information gathered earlier, for example repeating themes in Dysfunctional Thoughts Records. They may also be identified using a 'downward arrow' technique, which involves identifying situations that typically distress the patient, and associated thoughts. Instead of responding directly to these, the therapist asks: 'If that was true, what would it mean to you?' This question (or variants) is repeated until a general assumption or rule, relevant to a range of situations, emerges. The validity of the rule is then questioned and tested. This process normally takes several sessions to complete. A helpful sequence of questions is given below (these are not exhaustive:

1 **Where did this rule come from?** Identifying the source of a dysfunctional assumption (e.g. parental criticism) often helps to encourage distance by suggesting that its development is understandable, though it may no longer be relevant or useful.

2 **In what ways is the rule unrealistic?** Dysfunctional assumptions do not fit the way the world works. They operate by extremes, which are reflected in their language (always/never rather than some of the time; must/should/ought rather than want/prefer/would like).

3 **In what ways is the rule helpful?** Dysfunctional assumptions are not usually wholly negative in their effects. For example, perfectionism may lead to genuine high-quality performance. If such advantages are not recognized and taken into account when new assumptions are formulated, the patient may be reluctant to move forward.

4 **In what ways is the rule unhelpful?** The advantages of dysfunctional assumptions are normally outweighed by their costs. Perfectionism leads to rewards, but it also undermines satisfaction with achievements and stops people learning from constructive criticism.

5 **What alternative rule might be more realistic and helpful?** Once the old assumption has been undermined, it is helpful to formulate an explicit alternative (e.g. 'It is good to do things well, but I am only human-sometimes I make mistakes'). This provides a new guideline for living, rather than simply undermining the old system.

6 **What needs to be done to consolidate the new rule?** As with negative automatic thoughts, re-evaluation is best made real through experience: behavioural experiments. These encourage patients to challenge specific examples of old rules, as well as testing out the validity of new ones by acting as if they were true and observing the results This systematic work may need to continue for weeks or indeed months, given that assumptions have often been in place for many years.

(ii) Re-evaluating negative core beliefs

Negative thoughts often disappear as patients recover, whether the depression is treated by psychological means or not. Sometimes, however, they reflect enduring beliefs about the self, the world (including other people), or the future, which if left untouched may predispose the patient to become depressed again. Methods for dealing with these have primarily been developed in the context of CBT for personality disorder,[32,33] but can often be used within short-term CBT. This is important, given limited resources.

The cognitive model suggests that negative beliefs contributing to vulnerability to depression are (like dysfunctional assumptions) based on early learning, and maintained by a consistent bias in favour of information, which confirms them, and against information, which contradicts them. Therapists help patients to become aware of this bias, to question the 'evidence' that upholds

the negative beliefs (much as the 'evidence' in favour of negative automatic thoughts is questioned), and to search actively for information which contradicts it. Once a relevant belief has been identified (e.g. 'I am no good') and rated for degree of belief (0–100 per cent), the suggestion is introduced that this may be more of an opinion than a fact (work at the level of automatic thoughts should have prepared the ground for this idea). If possible, the patient is asked to suggest a more positive alternative (e.g. 'If you were not 'no good', how would you like to be?'), and belief in the alternative (which is likely to be low) is also rated. The alternative provides a new 'address' at which to store information inconsistent with the old belief. However, it is not always possible to find one at this stage (e.g. when the patient has predicated his or her life on the belief and accumulated a large body of supporting evidence). In this case, an alternative may only become available once the old belief has been systematically weakened.

Supporting 'evidence' may include events from the distant past, which have been interpreted in a self-derogatory way (e.g. childhood abuse), as well as later experiences (e.g. a broken marriage) and everyday events of the kind already recorded on the Dysfunctional Thoughts Record. Each item is questioned, and new and more adaptive interpretations arrived at. In addition, patients are asked to record evidence that would support a more positive alternative to the old belief (e.g. examples of their strengths and skills). The success of these interventions is assessed by repeatedly rating the degree of belief in the old system, as well as in the new alternatives. This work too may take a considerable time, especially if negative beliefs have had a sizeable impact on the person's life. Where treatment time is limited for practical reasons, clinicians may find it helpful to space out later sessions, ensuring that intervening weeks are used to consolidate and extend within-session work.

(iii) Consolidating learning: 'blueprints'

Preparation for ending treatment begins with the treatment contract. The implication of offering a limited number of sessions is that treatment will end, and that patients will acquire the skills necessary to deal with depression independently. Throughout therapy, they are encouraged to take increasing responsibility for determining session content, making practical suggestions, devising homework assignments, summarizing learning, and applying new skills in fresh areas. Written session summaries and therapy tapes encourage reflection and consolidation.

At the end of treatment, gains are summarized in a personal action plan or 'blueprint for the future'. The blueprint is confined to one or two sheets of paper, guides continued learning, and helps deal with relapse or recurrence. It draws on the case conceptualization, session notes, homework records, reading materials, and the like. The therapist should examine sessions, records, etc. independently, so that the plan is drawn up jointly, nothing important is forgotten, and the patient goes away with as full a summary as possible. The following questions provide a useful framework:

1 **How did my problems develop?** (unhelpful beliefs and assumptions, the experiences that led to their formation, events precipitating onset)

2 **What kept them going?** (maintenance factors)

3 **What did I learn from therapy that helped?** (techniques (e.g. activity scheduling) and ideas (e.g. 'I can do something to influence my mood'). Techniques should be detailed so that patients know exactly what to do should depression recur. Examples of handouts and record sheets can be included.)

4 **What were my most unhelpful negative thoughts and assumptions? What alternatives did I find to them?** (summarized in two columns)

5 **How can I build on what I have learned?** (a solid, practical, clearly specified action plan)

(iv) Preparation for setbacks

The blueprint should also be used to plan for relapse. It is helpful right at the beginning of treatment to tell patients that, however well they do, they may well experience a setback at some point, not least because periods of low mood are a normal part of human experience. CBT will not prevent the patient from ever having another moment's distress; it will provide tools for dealing with distress more effectively. This information can help patients to respond with less fear and despair when they do encounter setbacks.

Preparation for setbacks can be framed by the following questions:

1 **What might lead to a setback for me?** For example, future losses (e.g. children leaving home) and stresses (e.g. financial difficulties), i.e. events which impinge on patients' vulnerabilities and are thus liable to be interpreted negatively. For people who have experienced recurrent depression, mild normal low mood (without any major environmental stimulus) can act as a trigger for negative thinking which, if unchecked, can spiral down into clinical depression.

2 **What early warning signs do I need to be alert for?** Feelings, behaviours, and symptoms that might indicate the beginning of another depression are identified and listed, using careful analysis of this and previous episodes and of fluctuations in mood occurring during treatment.

3 **If I notice that I am becoming depressed again, what should I do?** Clear simple instructions, which will make sense despite low mood, are needed here. Specific ideas and techniques summarized earlier in the blueprint should be referred to. General encouragement can also be included (e.g. 'Don't panic'), as well as a specific plan for what to do if cognitive behavioural methods do not lift mood within a specified period (e.g. contact the general practitioner about medication, contact the therapist for telephone discussion or booster sessions, contact emergency services or telephone helplines in the event of serious suicidal thoughts). Recontacting therapists is often difficult, as patients may feel that they have failed or them down. Therapists should make it clear that they consider it a sign of courage to ask for further help, not a sign of weakness.

(e) Training

Cognitive behaviour therapy for depression is a sophisticated treatment, requiring theoretical knowledge, research familiarity, and clinical expertise. The latter is best developed through practical training and close supervision. Core skills have been operationalized in measures of therapist competency, such as the *Cognitive Therapy Scale*,[34] which allow practitioners to judge for themselves whether they are indeed practising cognitive behaviour therapy and to monitor skills development.

Treating depressed patients with cognitive behaviour therapy is a challenge, especially with severe, chronic, and relapsing depressions

and depression comorbid with other conditions. Therapist competency (the ability to carry out the treatment as intended and to an adequate standard) has a direct impact on outcome. Thus the need for experienced therapists, and for adequate training and ongoing supervision, especially with more difficult groups, cannot be overemphasized.[10,11]

Where established training institutes exist, it is wise to take advantage of their expertise. Even where no local institute is available, expert therapists from established centres often travel internationally to deliver conferences, workshops, seminars, and supervision—notably the triennial World Congress of Cognitive and Behaviour Therapies.

However, novice therapists will sometimes have little option but to supervise themselves, using clinical texts as a knowledge base. Therapists at all skill levels will benefit from regularly monitoring audio or video recordings of their treatment sessions, using the *Cognitive Therapy Scale* to identify strengths and areas in need of improvement. Even if no more experienced practitioner is available, peer supervision with interested colleagues is helpful. It provides external feedback on clinical practice, and makes other forms of learning possible (role play, study groups, etc.).

(f) Self-care

Depression is an infectious disease. It is easy for psychological therapists (especially if relatively inexperienced) to become contaminated by patients' hopelessness. Therefore supervision should include a focus on the therapist's own thoughts and feelings. Therapists with a substantial proportion of depressed clients should also ensure that they leaven their day by planning life-enhancing and pleasurable experiences, and should be prepared to use cognitive behavioural methods to address their own negative thoughts.

Training and supervision

The Beck Institute for Cognitive Therapy and Research in Philadelphia, Pennsylvania, runs extramural courses and training programmes (www.beckinstitute.org), as does the Oxford Cognitive Therapy Centre (www.octc.co.uk), who also offer a selection of CBT oriented booklets for patients and clinicians. The Academy of Cognitive Therapy offers information about CBT, training in CBT, certification as a cognitive therapist, and (once a member) access to a ListServe on which issues relating to theory, research, and clinical practice can be discussed with experienced cognitive therapists (www.academyofcognitivetherapy.org) The International Association of Cognitive Psychotherapy (www.cognitivetherapyassociation.org) also has a ListServe and hosts regular conferences in member countries. Different countries also have their own national organizations promoting CBT, for example, the American Association for Behavioural and Cognitive Therapies (www.aabt.org), the Australian Association for Cognitive and Behavioural Therapies (www.aabct.org), and the British Association for Behavioural and Cognitive Psychotherapies (www.babcp.com). These will be able to offer information about training opportunities.

Further information

A number of texts describe the theory and practice of CBT for depression in some detail.[1,17,21] Practical ideas can also be found in self-help texts for patients.

6.3.2.4 Cognitive behaviour therapy for schizophrenia

Max Birchwood and Elizabeth Spencer

Introduction

Cognitive behaviour therapy (**CBT**) for schizophrenia focuses on the core psychotic symptoms of hallucinations and delusions. Other psychosocial approaches to psychosis (e.g. intervention with families and to promote medication compliance) also frequently use CBT techniques. In this chapter, however, we focus on CBT for delusional beliefs and other psychotic phenomena and review evidence for its efficacy.

Background: assumptions and common components

The CBT approach to psychotic symptoms comprises two different strands each with their own theoretical basis, although of late these two approaches have become conjoined in practice.

Coping strategy enhancement

The first approach is inspired by the stress-vulnerability model of schizophrenia. Vulnerability here is viewed as a 'black box', drawing mainly on the biomedical tradition. It is assumed that stressors capable of triggering or exacerbating symptoms may be generated or modulated by the individual. For example, stressors emanating from the social environment are modulated by the patient's own appraisal of their stressfulness and his or her coping strategies.

Another class of stressors consists of the symptoms themselves. It is assumed that certain strategies used to cope with symptoms are unhelpful and generate stress in the individual, in turn, exacerbating symptoms. These strategies are conventionally divided into affective strategies (e.g. relaxation, sleep, etc.), behavioural strategies (being active, drinking alcohol, etc.), and cognitive strategies (distraction, challenging voices, switching attention away from voices, etc.). This underpins the approach known as Coping Strategy Enhancement[1] whereby patients are offered a range of strategies which are implemented in an empirical fashion to determine their effectiveness in symptom control. For example, Falloon and Talbot[2] documenting the coping strategies used by voice-hearers, concluded that those who had multiple strategies available

to them were more able to cope with their voices. Tarrier[3] on the other hand, focusing on a wider range of psychotic symptoms, concluded that those who applied strategies consistently tended to fare the best. This approach views the individual as an active agent who attempts to reduce the threat or distress posed by psychotic symptoms, but does not concern itself with the content or meaning that psychotic symptoms may have to the individual. There is also, in this approach, assumed to be a fundamental discontinuity between normal and abnormal functioning that comes about once the biological vulnerability is 'online'.

CBT for delusions and hallucinations

The second CBT strand draws its theoretical strength from the cognitive therapy approach.[4] Early work in this area focused on the similarity between normal (but strongly held) beliefs and delusions, in terms of the psychological processes at play in their maintenance. For example, Brett-Jones *et al.*[5] showed that delusions, like everyday beliefs, lead the individual to recruit evidence to support them and to de-emphasize or dismiss contradictory evidence. Continuing the exploration of the continuity between normal and delusional beliefs, Birchwood and Chadwick[6] argued that certain beliefs about voices' power may be considered as a quasi-rational response to anomalous experience, with the meaning attributed to them in terms of identity, power, and the consequence of disobedience determining distress and behaviour in relation to the voice. Other work has drawn on the cognitive therapy approach in depression, which emphasizes the importance of evaluative beliefs about the self (e.g. self-worth) in the genesis and maintenance of depressed mood.[7] The application of this to psychosis also emphasizes evaluative beliefs about the self. The precise relationship between self-evaluative beliefs and delusional thinking is a much debated issue of the present time. It has been argued, for example, that delusions may serve the function of defending the individual from the full impact of low self-worth through blaming others for negative events rather than the self. This is the so-called 'paranoid defence'.[8] The content of psychotic thinking often reflects such personal issues. For example, for the patient who has been sexually abused, this theme tends to crop up in the content of voice activity or in the supposed identity of the voice.[6]

This early work has been elegantly drawn together in a cognitive model of psychosis by Phillipa Garety and her colleagues. In a seminal paper[9] they propose a model of the cognitive processes leading to the positive symptoms of psychosis. In brief, positive symptoms in psychosis are hypothesized to begin with basic cognitive disturbances with lead to ambiguous sensory input, the intrusion into consciousness of unintended material from memory, or to difficulties with the self-monitoring of intentions and actions, such that they are experienced as alien. This result in anomalous conscious experiences such as actions being experienced as unintended, racing thoughts, thoughts appearing to be broadcast, and thoughts experienced as voices.

However, the authors argue that such anomalous experiences alone do not develop into full-blown psychotic experiences unless an individual appraises them as externally caused and personally significant. Such appraisals are the results of particular reasoning processes (e.g. data gathering bias or externalizing attributional style), dysfunctional personal schemas (e.g. low self-esteem born of adverse social experience), emotional states (e.g. anxiety and depression), and appraisal of the experience of illness.

This model integrates the two strands of cognitive therapy. It suggests, for example, that the reduction in dysfunctional emotional states through, for example, coping strategy enhancement, will contribute to alterations in the attributions, which are important in the formation and maintenance of the positive symptoms. Similarly, it provides a theoretical basis for the basic techniques traditionally used in the second strand of CBT. Such techniques encourage the individual to weigh evidence that contradicts a delusion as a strategy to compensate for the basic information-processing abnormality, challenge negative self-schemata, and combat depression.

Evaluation

In recent years the volume of trials evaluating CBT for psychosis has greatly expanded, with approximately 20 such studies now reported. Most of these have been conducted in the United Kingdom among patients with chronic schizophrenia. The strength of the data is now sufficient for The UK National Institute for Clinical excellence to state that cognitive behavioural therapy should be available as a treatment option for people with schizophrenia.[10]

An up-to-date review[11] reporting the analysis of 19 studies of CBT for positive symptoms in schizophrenia, found a mean effect size of 0.37. The authors concluded that 74 per cent of these studies achieved small effect sizes, 32 per cent moderate effect sizes, and 16 per cent large effect sizes in improving positive psychotic symptoms, relative to standard psychiatric care. Furthermore, they argued that this is unlikely to be due to publication bias. The effect sizes for CBT versus standard treatment among patients with chronic illness were greater than those among acutely ill patients. This may have been due to a ceiling effect caused by the effectiveness of medication in reducing symptoms in floridly ill inpatients. Similarly, the better the design of the trial, the smaller the treatment effect size, suggesting that CBT is not the panacea for all psychotic ills that it may have originally appeared.

With regard to relapse prevention, CBT appears to be more successful when the intervention is focused on relapse prevention, rather than relapse prevention being one of a series of components.[11] For example, Gumley and his colleagues[12] were able to demonstrate that a group of patients with psychosis receiving targeted CBT for relapse prevention had almost half the rate of relapse over a 12-month period compared with a similar group receiving treatment as usual (18.1 versus 34.7 per cent). In this study, the CBT treatment consisted of an engagement phase, early signs of relapse monitoring with a personalized questionnaire, and targeted CBT at the first sign of impending relapse.

While large, pragmatic trials of CBT treatment packages have yielded the above favourable results, investigating the active elements of the interventions is difficult because CBT for psychosis now refers to a wide range of treatments.

Furthermore, although the conceptual basis of CBT emphasizes the link between emotion, cognition, and behaviour, modifying emotion in psychosis has been relatively neglected in CBT trials, in favour of outcomes based on modification of delusions and hallucinations themselves.

It has been proposed that CBT should be focused into more targeted interventions aimed at emotional dysfunction or distress and/or behavioural anomaly in psychosis that is directly or indirectly linked to psychosis symptoms.[13] This approach recognizes

that while changing the psychosis symptoms might not always be possible, it may well be feasible to change the affective consequences of the symptoms or the diagnosis. This affective change may have further benefits in reducing the severity of the psychosis experience *per se*.

For example:

1 CBT can be used to reduce distress, depression, and problem behaviour associated with commanding voices, without changing the frequency or content of the voices themselves.[14]

2 CBT can focus on anxiety, depression, and interpersonal difficulty in individuals at high risk of developing psychosis.[15]

3 CBT can focus on the relapse prodrome to prevent relapse in psychosis.[12]

4 CBT can focus on 'comorbid' depression and social anxiety, including the patient's appraisal of the diagnosis and its stigmatizing consequences.[16]

5 CBT can be used to reduce stress reactivity, thereby increasing resilience to life stress and preventing psychotic relapse.[17]

6 CBT can be used to increase self-esteem and social confidence in people with psychosis.[18]

Management

Coping strategy enhancement

Coping strategy enhancement involves developing a coping repertoire and over-rehearsing it to facilitate an automatic coping response.[19] It can either be used to improve an individual's attempts to cope with his or her voices by developing an understanding of factors that trigger or improve the voices, or to test the reality of thoughts about the voices.

For example, therapy with a patient who hears threatening and frightening voices exacerbated of being alone might involve: An explicit congratulation on the strength involved in withstanding the voices' incessant activity; strengthening of coping strategies involving seeking company and social support; and the use of a personal stereo for distraction.

Cognitive therapy to challenge delusions and dysfunctional assumptions

The application of cognitive therapy in challenging of delusions and dysfunctional beliefs draws upon the approach described by Chadwick *et al.*[20] and builds upon the pioneering work of Chadwick and Lowe.[21]

Engaging patients is perhaps the greatest challenge facing a therapist. It is noticeable that many individuals either never attend or do so for a few sessions and then stop. Once individuals get past the opening strategies of cognitive therapy they usually see therapy through. Careful attention to appropriate therapeutic technique can maximize client engagement. Similarly, Kuipers *et al.*[22] report that a response to CBT in their study was associated with greater cognitive flexibility concerning delusions at baseline. This suggests that the sufferer may need some small degree of insight into the fact that he might be mistaken, to benefit from cognitive therapy for delusions.

The process involves six basic steps as summarized in Table 6.3.2.4.1.

Table 6.3.2.4.1 A summary of the steps in cognitive therapy for delusions

1 Viewing delusions as beliefs, not facts
2 Developing a rationale for questioning the delusion
3 Weakening delusions
4 Utilizing inconsistency and irrationality
5 Reformulating delusions as reactions to, and attempts to make sense of, specific experience
6 Assessing the delusion and alternative, and empirical testing

(a) Viewing delusions as beliefs, not facts

The first technical difficulty to be encountered is the necessary move to aid the client in conceptualizing a delusion as a belief and not a fact. This move is an essential part of CBT for all emotional problems, but is difficult at the best of times. With depression, for example, patients often struggle to appreciate that their sense of worthlessness, which is so concrete to them, is actually a belief they hold and is different from a knowledge of events and facts. With delusions there is the added complication that the therapist might be perceived as being just another person who disbelieves the patient.

There are two central points to bear in mind when seeking to reconceptualize delusions as beliefs, not facts—why it is being done and how it is done.[20]

The purpose of clarifying that delusions are beliefs, not facts, is to empower the patient and offer a way of easing his or her distress. If the patient really is being persecuted by a powerful organization, or has a radio transmitter and receiver in his head, neither he nor the therapist can actually change this. The patient feels that he knows this as a fact, with the consequence that he feels frustrated and helpless as well as distressed. However, if the patient only believes this to be true, then he gains the freedom to examine his beliefs and perhaps change his distressing feelings and behaviour and experiences himself. In this sense it is in his best interest for the delusion to be false.

How this process takes place is critical. The process of Socratic questioning is not one of persuading a patient that he is wrong and that you, the therapist, are right. This mistake is made all too often. Rather, in Socratic dialogue the therapist helps the patient to draw on his own doubt and experience in order to realize that there are other ways in which he is able to make sense of his experience. So, when the therapist pursues the conceptual step of clarifying that a delusion is only a belief, the patient's own doubt, past or present, his own contradictory experience and behaviour, and concern about the possibility that the delusion is wrong are accessed. Many patients have 'double awareness' of delusions—on the one hand they believe them firmly and are distressed and disturbed by them, yet on the other hand they behave in ways that contradict the delusion, and they believe that working with a therapist might ease the problem. Finally, the therapist must accept that it is acceptable if the patient does not alter his belief. The process is 'collaborative empiricism, not indoctrination'.[17]

(b) Developing a rationale for questioning the delusion

Patients are usually used to being told by family and carers that their beliefs are wrong, that they are deluded. It is easy for a therapist to

prepare the intervention well and embark on it before the patient is clear of the purpose and possible benefit, thus causing early loss of engagement. It is revealing to turn the engagement question on its head and to consider why a patient should ever wish to engage in therapy. With emotional problems patients identify their problems as depression, anger, anxiety, guilt, etc.; with delusions and hallucinations this is not so—patients predominantly present problems which they believe are actual events (persecution, voices, passivity). This means that they have no clear objective and therefore have no particular motivation to engage. The key reason for a patient to reconsider delusional beliefs is that it will help him feel less distress and it will free him to behave differently and to pursue the things he wants more directly. What the therapist does gradually through the unfolding cognitive assessment is to clarify with the patient that he is experiencing emotional and behavioural problems, and that these are tied to his beliefs (delusional and evaluative). The therapist then needs to explore with the patient how the delusion affects his life and how his life would be different (i.e. better or worse) if the delusion were false.[20] In this way, the therapist slowly encourages the patient to view the delusion not as an important discovery but as a belief that results in distress (e.g. fear, anxiety) and causes him to behave in ways which he would rather not (e.g. avoid things he would otherwise like to do).

(c) Weakening delusions

Disputing comprises four elements:[20]

- The evidence for the belief is challenged, in inverse order of its importance to the delusion.
- The internal consistency and plausibility of the delusional system is questioned.
- Following Maher,[23] the delusion is reformulated as being an understandable response to, and way of making sense of, specific experience, and a personally meaningful alternative is then constructed.
- The individual's delusion and the alternative are assessed in the light of the available information.
- Challenging the evidence for the belief.

Watts *et al.*[24] argued that a danger when trying to modify delusions, indeed, all strongly held beliefs, was psychological reactance, whereby too direct an approach served only to reinforce the belief. They offered two principles to minimize this possibility: begin with the least important belief, and also work with the evidence for the belief rather than the belief itself.

Accordingly a 'verbal challenge' of delusions begins by questioning the evidence for the belief, and this process begins with the least significant item of evidence and works up to the most significant one. Our preferred approach is that with each item of evidence the therapist questions the patient's delusional interpretation and puts forward a more reasonable and probable one. The customary approach in CBT is for the patient to be asked to generate the alternative interpretation(s), rather than the therapist supply one, but we have found that for certain patients this conventional tactic is a weak intervention.

When the therapist questions the evidence for a delusion there are two distinct but related objectives. One is to encourage the patient to question and perhaps even to reject the evidence for his or her belief, and in this way perhaps to undermine the patient's conviction in the delusion itself. For some individuals challenging the evidence is a very powerful intervention and one that produces a substantial reduction in delusional conviction. However, more commonly this does not happen, but challenging evidence is still valuable in that it does impart insight into the connection between events, beliefs, affect, and behaviour. This is the second objective of challenging evidence, namely to convey the essentials of the ABC approach, i.e. that strongly held beliefs influence affect, behaviour, and cognition (i.e. interpretation) for all people. Core beliefs recruit or bias everyday inferences and automatic thoughts. However, this means that people often impose an interpretation on to events, which is unwarranted, and because we are prone towards selectively processing information that confirms our beliefs, this goes undetected. In other words, it is understandable that a patient should interpret a particular event in line with his delusion because this is merely one occurrence of a general tendency, and confirmation bias, common to all of us. In therapy, it is helpful to convey the ordinariness and normality of this process with everyday examples.

Having considered the alternatives, the patient is then asked to rate his conviction about each; regardless of how convinced he remains that the delusional interpretation is correct, it is usual to move on to the next piece of evidence. The therapist does not have to change what the patient thinks, but only to offer a fresh insight into the way he is thinking.

(d) Utilizing inconsistency and irrationality

Although delusions contain differing degrees of inconsistency and irrationality, they all seem to contain some. For example, Margaret believed that she could not act or make a decision without reference to her voice; however, she described periods when she was relaxed and the voices quiescent where she would be making decisions. Such inconsistencies can be therapeutically useful.

(e) Reformulating delusions as reactions to, and attempts to make sense of, specific experience

We always construe a delusion as both a reaction to and an attempt to make sense of certain puzzling and often threatening experience. It is an understandable and reasonable attempt to find meaning at a time when the individual is bewildered, anxious, and frightened. But, the delusion carries a cost in terms of distress and disturbance, which the individual might not otherwise experience. This is how delusions may be explained to patients.[23]

At this stage the therapist has commenced the process of challenging the delusional belief, re-formed the delusion as an attempt to make sense of certain experiences (e.g. primary symptoms, trauma) and raised the idea that the delusion is psychologically functional (i.e. it eases puzzlement) and perhaps linked to evaluative beliefs.

(f) Assessing the delusion and alternative, and empirical testing

Finally, the patient and therapist need to assess the delusion and alternative in the light of the available evidence and previous discussion. The therapist may spell out the advantages of the alternative interpretative framework, which can also be discussed by relating it to the patient's experiences.

It is an integral part of CBT that the belief or assumption under consideration be tested empirically. Such reality testing involves planning and performing an activity that validates or invalidates a belief, or part of a belief.

When working with delusions, we set up a clear alternative belief in opposition to the delusion, clarifying with the patient in advance precisely what has to happen for each to be supported and refuted. For example,[20] Alison believed that by repeating her voice's command (e.g. 'The price of milk *will* rise a billion times') it would actually happen by transmitting the thought to a member of the government who would act upon it. The empirical test involved repeating the voice and purchasing milk before and after doing so, predicting that within 2 weeks the price of milk would at least double. If it did not, the alternative (that the power to change events was very weak) would be strengthened.

Cognitive therapy for beliefs about auditory hallucinations

The above techniques can be applied to challenge beliefs about 'voices' using the following three steps:

(a) Assessment

Assessing the personal meaning a voice has for a person is the defining feature of the cognitive approach to assessing auditory hallucinations. The delusional beliefs found to be most significant are those relating to a voice's identity, purpose, power, knowledge, and the consequences of compliance and resistance. The semi-structured interview schedule developed by Chadwick and Birchwood[6,25] is recommended.

(b) Disputing beliefs about voices

The thrust of the therapist's challenge is that the beliefs are reasonable and understandable reactions to, and attempts to make sense of, the auditory hallucinations. The therapist reviews evidence and inconsistency, and plans tests, with the aim always of evaluating two possible meanings: that the beliefs are true, a discovery, or that they are reasonable and understandable, but mistaken. As ever, it is vital that the therapist really practises Socratic questioning and works collaboratively. This involves drawing out patients' own doubts, puzzlement, double awareness, critical faculty, etc., rather than forcing a contradiction on them.

The major piece of evidence for the delusional beliefs is always the actual voices, especially their content—these are, after all, the activating events that the delusions are invoked to explain. The role of beliefs is critical because individuals usually attribute voices with a power and knowledge that goes well beyond what they have actually said. Several examples of challenging follow.

It is really quite common for beliefs about compliance (e.g. 'If I don't do what my voice says I will be punished') not to fit patients' experiences, and perhaps it is only their emotional impact which prevents patients from abandoning them. Kate, for example, believes 'If I drop my guard the voices will kill me', but in fact she has dropped her guard on many occasions without consequence. This might be pointed out as follows. 'Kate, you say that the voices have the power to kill you and you must be on your guard constantly. I certainly appreciate the fear that this must create. What puzzles me though is that your guard is often down, like when you are asleep. How is it that they have not succeeded in all these years?'

The appearance of being all knowing (omniscience) is a vital aspect of many voices[22] and often features as a key piece of evidence that the identity of the voice is superhuman. It leaves individuals feeling exposed and vulnerable and very prone to guilt and shame. Alice believes that her voice is a prophet endowed with the ability to foretell the future. In particular, the voice anticipates exactly the arrival of her husband home from work each day. To begin the process of questioning she was asked: 'Let's suppose for a moment that the voice cannot foretell the future; can you think of any other possible explanations for last night's prediction?' One such possibility was that the voice was making a very safe guess.

(c) Testing beliefs about control

A useful strategy is to use a procedure whereby the patient and therapist learn to engineer situations to start or increase the probability of hearing voices, and then to stop or reduce them. In this way the patient gains a surprising degree of control over the voice. The initial assessment provides information about cues that provoke voices for a particular individual; concurrent verbalization is known to stop or diminish voices temporarily. This information is combined in the following five steps.

- Identify cues that increase and decrease voices.
- Practise the use of 'increasing' and 'decreasing' strategies within a session.
- Propose the notion that 'control' requires the demonstration that voice activity can be turned up/on or down/off.
- In sessions encourage the patient to initiate or increase voice activity for short periods then reduce or stop it.
- Elicit changes in the patient's belief about his control over the voices.

The above process has been applied in a targeted way to the special case of beliefs about command hallucinations. These are high-risk, distressing, and relatively common symptoms of schizophrenia.

For example, Byrne and her colleagues[26] have developed a specific cognitive therapy for command hallucinations, which draws on the above techniques. Using the methods of collaborative empiricism and Socratic dialogue, the therapist seeks to engage the client to question, challenge, and undermine the power beliefs, then to use behavioural tests to help the client gain disconfirming evidence against the beliefs. These strategies are also used to build clients' alternative beliefs in their own power and status, and finally, where appropriate, to explore the origins of the schema so clients have an explanation for why they developed those beliefs about the voice in the first place. They were able to show that this process produce significant reductions in compliance behaviours and favourable changes in beliefs about the power, superiority and need to comply with the voices, despite the frequency, loudness, and content of the voices staying the same.[14]

Conclusion

CBT for psychosis is a rapidly developing field, and one that has borne considerable fruit in terms of providing effective treatments and a basis upon which a dialogue between the patient and the professional can take place about matters of great concern and a source of much distress.

6.3.3 Interpersonal psychotherapy for depression and other disorders

Carlos Blanco, John C. Markowitz, and Myrna M. Weissman

Introduction

Interpersonal psychotherapy (IPT) is a time-limited, diagnosis-focused therapy. IPT was defined in a manual. Research has established its efficacy as an acute and chronic treatment for patients with major depressive disorder (MDD) of all ages, as an acute treatment for bulimia nervosa, and as adjunct maintenance treatment for bipolar disorder.[1–9] The research findings have led to its inclusion in treatment guidelines and increasing dissemination into clinical practice.

Demonstration of efficacy in research trials for patients with major depressive episodes (MDEs) has led to its adaptation and testing for other mood and non-mood disorders. This has included modification for adolescent and geriatric depressed patients[10,11] patients with bipolar[12] and dysthymic disorders;[13,14] depressed HIV-positive[15] and depressed pregnant and postpartum patients;[16,17] depressed primary care patients;[18] and as a maintenance treatment to prevent relapse of the depression.[5] Most of the modifications have been relatively minor and have retained the general principles and techniques of IPT for major depression.

Non-mood targets have included anorexia, bulimia, substance abuse, borderline personality disorder, and several anxiety disorders. In general, outcome studies of IPT have suggested its promise for most psychiatric diagnoses in which it has been studied, with the exceptions of anorexia, dysthymic disorder, and substance use disorders.[14,19,20]

IPT has two complementary basic premises. First, depression is a medical illness, which is treatable and not the patient's fault. Second, depression does not occur in a vacuum, but rather is influenced by and itself affects the patient's psychosocial environment. Changes in relationships or other life events may precipitate depressive episodes; conversely, depressive episodes strain relationships and may lead to negative life events. The goal of treatment is to help the patient solve a crisis in his or her role functioning or social environment. Achieving this helps the patient to gain a sense of mastery over his or her functioning and relieves depressive symptoms.

Begun as a research intervention, IPT has only lately started to be disseminated among clinicians and in residency training programmes. The publication of efficacy data, the promulgation of practice guidelines that embrace IPT among antidepressant treatments, and economic pressures on length of treatment have led to increasing interest in IPT. This chapter describes the concepts and techniques of IPT and its current status of adaptation, efficacy data, and training. The chapter provides a guide to developments and a reference list, but not a comprehensive review.

Background

IPT traces its theoretical and clinical origins to the interpersonal psychoanalytic theory of Meyer and Sullivan and builds on work of other relational theory including object relations, particularly with regard to attachment. However, it applies this theory within a conceptual and clinical framework that differs significantly from that of Sullivan and much of relational theory. In contrast with psychoanalytically inspired schools of thought, IPT sees its goals in treating depression and other medical disorders, rather than trying to change overall personality. Pragmatically, IPT opts to narrow its focus to address the area of interpersonal life that seems to require the most immediate attention.

Acknowledging the importance of personality and early experience, IPT emphasizes the role of recent stressful events in triggering depression and other psychiatric disorders in vulnerable individuals, while it also recognizes the protective role social supports play against psychopathology. Nevertheless, IPT is less interested in discerning the *cause* of a depressive episode (since it assumes the aetiology of depression to be multifactorial) than in using the connection between current life events and the onset of depressive symptoms to help the patient understand and combat the episode of illness.

Compared to other psychotherapies, such as psychoanalytic psychotherapy or even cognitive behavioural therapy, IPT is relatively young. It is less concerned about maintaining an established orthodoxy than about adapting itself to the needs of the patient. Although IPT theorists have taken into account theoretical developments in psychiatry and related fields, much of IPT's evolution has been based on the results of clinical trials. As investigations continue into IPT as a treatment for different disorders and populations, further modification of its theoretical aspects as well as techniques are likely.

Indications

IPT research has demonstrated its efficacy for major depressive disorder across a range of patient ages and contexts, and for bulimia nervosa. One large trial indicates its efficacy (modified as interpersonal social rhythms therapy, or IPSRT) as an adjunctive treatment for bipolar disorder. [6] Lesser evidence suggests the potential benefits of IPT for several anxiety disorders. [21,22] IPT has shown no advantages over control psychotherapies for dysthymic disorder or substance abuse disorders. [14,20] For depressed adolescents, IPT has shown not only efficacy but effectiveness in a school-based programme. [10,11]

Both the physician and patient guides in primary care guidelines for depression list IPT, cognitive behavioural therapy (CBT), behavioural, brief dynamic, and marital therapy as treatments for depression. IPT is spreading from its initial research base in the United States. The IPT manual has been translated into Italian, German, Japanese, Spanish, and French, and is being used ever more widely around the world. Descriptions of IPT have appeared in Spanish, Norwegian, Finnish, and Dutch journals. An International Society for Interpersonal Psychotherapy, established at the American Psychiatric Association Annual meeting in May 2000 in Chicago, has a growing membership and biennial international meetings in 2004 and 2006, and maintains a bibliography of studies.

Because IPT focuses clinically on the social context of the depressive episode, researchers have sometimes adapted IPT when applying it to different treatment populations, developing manuals for different age groups or subpopulations, and occasionally adding focal problem areas. IPT has also been used at different lengths, in different formats, in one pilot couple's adaptation, and as a telephone intervention. Nonetheless, all these adaptations involve the basic principles that constitute IPT: a no-fault definition of the patient's problem as a medical illness, excusing the patient from blame for his or her symptoms; and a continual focus on the relationship between the patient's moods and life situation. The continuing growth of IPT research precludes an exhaustive description of studies. This chapter presents a selection of key research trials of IPT for mood and other disorders (see **Efficacy**) and offers selected references for further reading.

Contraindications

Although formal contraindications (i.e. situations in which IPT would worsen the patients' situation) are not known, IPT was never intended to function as a monotherapy for patients with psychotic depression or bipolar disorder. In addition, three controlled trials have found no benefit of IPT as a treatment for substance use disorders.

Conducting IPT

Each of the four IPT interpersonal problem areas has discrete goals for therapist and patient to pursue. The therapist helps the patient relate life events to mood and other symptoms. In this section we outline the phases of IPT, as well as common strategies and techniques used in IPT treatment. We also outline some differences with cognitive behavioural therapy, to which it is often compared.

Phases of treatment

As an acute treatment, IPT has three phases. The *first phase*, generally covering sessions 1–3, includes diagnostic evaluation,

psychiatric history, and setting the treatment framework. The therapist reviews symptoms, diagnoses the patient as depressed according to DSM-IV (or ICD-10) criteria, and gives the patient the sick role. The psychiatric history includes the 'interpersonal inventory', which is not a structured instrument but a careful review of the patient's past and current social functioning and close relationships, their patterns, and mutual expectations. The relationships are examined to see to what extent they are satisfactory, whether there have been recent changes in those relationships, or whether the patient desires to change them. As part of this review, the therapist commonly links the main social and interpersonal situations of the patient's life to the onset of depressive symptoms.

During the opening phase the therapist also sets a time limit for the acute treatment, generally between 12 and 16 sessions. The optimal number of sessions for IPT requires further research. One study suggests that as few as eight sessions may be effective for some patients, but similar to pharmacological treatment, different doses (i.e. number of IPT sessions) might be necessary for different patients. Sessions are generally scheduled weekly. This allows sufficient time to pass that things will happen in the patient's outside life, on which the treatment focuses. Yet it is frequent enough to maintain momentum and thematic continuity. However, in certain cases logistical difficulties (e.g. due to a general medical illness) might require less frequent sessions.

At the end of the first phase, the therapist links the depressive syndrome to the patient's interpersonal situation focusing on one of the four interpersonal problem areas: (1) *grief*; (2) interpersonal *role disputes*; (3) *role transitions*; or (4) *interpersonal deficits*. Once the patient explicitly accepts this formulation as the focus for treatment, IPT enters its middle phase.

It is important to keep treatment focused on a simple theme. Any formulation necessarily simplifies a patient's life narrative. Although some patients may present with multiple interpersonal problems, the goal of the formulation is to isolate one or, at most, two salient problems related to the patient's mood disorder (whether as precipitant or consequence). More than two foci would risk diffusing the treatment and diluting its efficacy. Sometimes a number of interpersonal problems contribute to the depressive episode, making it apparently difficult to choose a focus. However, research has shown that IPT therapists agree in choosing foci, and patients find those foci credible. Moreover, resolution of the interpersonal treatment focus appears to correlate with symptomatic improvement.

An important task of the initial phase requires deciding whether or not to use medication. A growing literature suggests that combined treatment with antidepressants and IPT works at least as well as, but is not always superior to IPT alone. Thus, except for very severe cases or possibly the elderly, the choice between IPT alone or combined with medication relies more on cost, availability of resources, and patients' preference than on existing empirical evidence.

The *middle phase* involves approaches specific to the chosen interpersonal problem area. For **Grief**—complicated bereavement following the death of a loved one—the therapist facilitates mourning and helps the patient find new activities and relationships to compensate for the loss. **Role disputes** are conflicts with significant others: a spouse, a child, other family members, co-workers, or a close friend. The therapist helps the patient explore the relationship, the nature of the dispute, and available options to negotiate its resolution, including ending the relationship. **Role transition** includes change in life status: for example, beginning or ending a relationship or career, moving, promotion, demotion, retirement, graduation, having a baby, or diagnosis of another medical illness. The patient learns to manage the change by mourning the loss of the old role, recognizing positive and negative aspects of the new role, and taking steps to master this new role.

Interpersonal deficits are used as a focus for patients who lack any of the first three focal life situations. Such patients are isolated or lack social skills, have problems in initiating or sustaining relationships. The goal is to help the patient to develop new relationships and skills. Some patients who fall into this category may in fact suffer from dysthymic disorder or social anxiety disorder, for which separate strategies have been developed.

The *final phase* of IPT, occupying the last 2–4 sessions of acute treatment, builds the patient's newly acquired sense of independence and competence by recognizing and consolidating therapeutic gains. Compared to psychodynamic psychotherapy, IPT de-emphasizes termination: it is a bitter–sweet graduation from successful treatment. The sadness of separating from the therapist is contrasted with depressive feelings.

If the patient has not improved, the therapist emphasizes that the *treatment* has failed, not the patient, and that alternative effective treatments, such as medication or other psychotherapies exist. If the treatment has succeeded, the therapist underscores the patient's competence to function without further therapy by emphasizing that the depressive episode has improved because of the patient's actions in changing a life situation. The therapist also helps the patient to anticipate triggers for and responses to depressive symptoms that might arise in the future.

Patients with multiple prior MDE's or significant residual symptoms, who successfully complete acute treatment but remain at high risk for relapse or recurrence, may contract for maintenance therapy as acute treatment draws to a close. At the end of the treatment (acute or maintenance, depending on the case) the patient is also explicitly told that, should depression recur, the patient should immediately seek treatment, just as the patient would do if any other medical illness recurred.

Techniques

Readers new to IPT will find that much of what we describe below sounds familiar and overlaps with other psychotherapies. Thus, on one level, IPT demands few novel skills from therapists and is relatively easy to learn.

The challenges of IPT lie not in the use of any individual technique, but in organizing these approaches to establish and maintain a coherent primary treatment focus and to resist the temptations of digressing into clinical material outside that focus. Additional challenges may arise from 'unlearning' reflexive responses from prior training experiences such as making transference-focused interventions (for psychodynamic therapists) or identifying automatic cognitions and schemas (for cognitive therapists). In our exposition of strategies and techniques, we focus on major depressive disorder, the first and still best tested indication for IPT, although the same principles may apply to other disorders.

(a) General strategies

IPT is organized around four important concepts.

(i) Psychoeducation

The therapist helps the patient to recognize that the problem is a common medical illness, a mood disorder, with a predictable set of symptoms, not the personal failure or weakness of the patient. IPT therapists define depression as a treatable condition that is not the patient's fault. This definition displaces guilt from the patient to the illness, decreases the patient sense of isolation by feeling part of a larger group (those with depression), and provides hope for a response to treatment.

Underscoring this approach, IPT therapists give depressed patients the 'sick role'. This role temporarily excuses them from what their illness prevents them from doing while assigning them the task of working as patients in order to recover their previous healthy role. The resolution of the sick role is to regain the healthy, euthymic role by the end of treatment. The time-limited structure of IPT also energizes patients and protects against regression during treatment.

(ii) Focusing on the positive

IPT therapists take an empathic, supportive, and encouraging stance. They emphasize their patients' successes, although they also commiserate on their difficulties. 'Focusing on the positive' means underscoring positive events; it does *not* mean ignoring negative affect. By doing this, IPT therapists may facilitate the therapeutic alliance that is crucial to good outcome. By solving an interpersonal crisis—a complicated bereavement, a role dispute or transition, or an interpersonal deficit—the IPT patient has the dual opportunity to improve his or her life situation and simultaneously relieve the symptoms of the depressive episode.

This coupled formula, validated by randomized controlled trials in which IPT has been tested, can be offered with confidence and optimism. Symptomatic relief may correlate with the degree to which the patient solves his or her interpersonal crisis. This therapeutic optimism, while not specific to IPT, very likely provides part of its power in remoralizing the patient.

(iii) Focus on the present, not the past

IPT deals with current rather than past interpersonal relationships, focusing on the patient's immediate social context. The IPT therapist attempts to intervene in depressive symptom formation and social dysfunction rather than addressing enduring aspects of personality, which are difficult to assess accurately during an episode of an Axis I disorder. However, IPT does build new social skills such as self-assertion and increased ability to understand interpersonal exchanges, which may be as valuable as changing personality traits.

(iv) Link mood to life events

A core strategy of IPT is constant attention to the link between the patient's current mood state and recent interpersonal experiences. Stressful life events and negative interpersonal encounters trigger lower mood and can lead to depressive episodes in vulnerable individuals. Conversely, depressed mood impairs social functioning, which can lead to further negative life events. IPT is postulated to work by helping the patients manage interpersonal relationships more effectively, which leads to improved mood. Improved mood then allows patients to more effectively manage interpersonal experiences in an iterative fashion.

Unlike psychodynamic psychotherapy, IPT *does not* focus on early childhood experiences and long-standing familial dynamics. Thus, the patient's current mood state is linked to recent experiences rather than those rooted in the distant past. Nor does IPT focus on transferential material, except in the relatively rare instance when problems arise in the therapeutic alliance. Thus the treatment highlights recent experiences outside the office.

(b) Specific techniques

To achieve the general goals of IPT, the following techniques are frequently used:

1 *An opening question*: 'how have things been since we last met?', which leads the patient to provide an interval history of mood and events. The therapist begins each session after the first one with this tactic. It is common, particularly at the beginning of the treatment that the patient will focus exclusively either on the mood or on a recent event. When that occurs, the therapist gently asks about the other aspect and helps the patient connect mood and recent events.

2 *Communication analysis*, a detailed recreation of recent, affectively charged circumstances. This detailed analysis often helps the patient uncover nuances of the interpersonal exchanges that had been missed prior to the session.

3 An exploration of the patient's wishes and options, to help the patient realize and voice the desired outcomes.

4 *Decision analysis*, to help the patient integrate communication analysis, the wishes and options and the constraints of the situation and decide on a specific course of action.

5 *Role-playing*, to help the patient rehearse that course of action before implementing in real life.

Similarities and differences with other psychotherapies

Because IPT and CBT are the two best empirically supported psychotherapies, they are often compared. [23] IPT shares with CBT an orientation towards making the patient feel understood, a 'here and now' focus, a general feeling of hope and optimism, psychoeducation, and the use of role-playing to favour the acquisition of new skills. It addresses interpersonal issues in a manner familiar to marital therapists. Although like CBT a time-limited treatment targeting a syndromal constellation (e.g. major depression), IPT is considerably less structured, and focuses on interpersonal problem areas rather than automatic thoughts. IPT overlaps to some degree with psychodynamic psychotherapies, yet IPT also meaningfully differs from them: in its focus on the present, not the past; its focus on practical, real-life change rather than self-understanding; its medical model; and its avoidance of the transference and of genetic and dream interpretations.

Efficacy

Research findings: IPT for mood disorders

IPT outcome research is ongoing, with new studies published every year. What follows is a selection of key research trials of IPT for mood and other disorders. For some of these trials, IPT was adapted in a separate treatment manual, but in all cases the general principles of the treatment remained the same.

(a) Acute treatment of major depression

IPT was first tested as an acute antidepressant treatment in a four-cell, 16-week randomized trial. This compared weekly IPT, amitriptyline (AMI), their combination, and a monthly supportive psychotherapy treatment for 81 outpatients with major depression.[24,25] The outcome of patients receiving amitriptyline and IPT was similar and superior to that of supportive psychotherapy. Patients who received both amitriptyline and IPT had better depression outcomes and better scores on a range of social adjustment measures including overall adjustment, work performance, and communication than those on amitriptyline alone, suggesting an additive effect of IPT on medication treatment. At 1-year follow-up, many patients sustained improvement from the brief IPT intervention, and IPT patients had developed significantly better psychosocial functioning whether or not they received medication. This effect on social function was not found for AMI alone and had not been evident for IPT at the end of the 16-week trial.

Still probably the most important study to date involving IPT is the National Institute of Mental Health Treatment of Depression[24,25] Collaborative Research Program (TDCRP), investigators randomly assigned 250 outpatients with major depression to 16 weeks of IPT, CBT, or either imipramine (IMI) or placebo with clinical management.[2] Most subjects completed at least 15 weeks or 12 treatment sessions. Patients with milder depression (defined as a 17-item Hamilton Depression Rating Scale [HDRS] score <20) improved equally in all four treatments. For more severely depressed patients (HDRS>20), IMI worked fastest and most consistently better than placebo. IPT and IMI were comparable on several outcome measures, including HDRS, and superior to placebo for more severely depressed patients. In some analyses, IPT appeared to be slightly superior to CBT. CBT was not superior to placebo among the more depressed patients.

A follow-up study of TDCRP subjects 18 months later found no significant difference in recovery among remitters (who had minimal or no symptoms after the end of treatment, sustained during follow-up) among the four treatments.[26] Thirty per cent of CBT, 26 per cent of IPT, 19 per cent of imipramine, and 20 per cent of placebo subjects initially randomized to those treatments remitted and remained in remission during that time span. Among acute remitters, relapse over the 18-month follow-up was 36 per cent for CBT, 33 per cent for IPT, 50 per cent for imipramine (medication having been stopped at 16 weeks), and 33 per cent for placebo. The authors concluded that, for many patients, 16 weeks of specific treatments were insufficient to achieve full and lasting recovery.

Special populations and settings

(a) Depressed primary care patients

There has been a study comparing IPT and nortriptyline with usual care for depressed patients in a primary care setting. If patients were hospitalized for a general medical condition, IPT was continued in the hospital when possible. Depressive symptom severity declined more rapidly with either nortriptyline or IPT than in usual care. Approximately 70 per cent of treatment completers receiving nortriptyline or IPT, but only 20 per cent in usual care, had recovered after 8 months. Subjects with a lifetime history of comorbid panic disorder had a poorer response across treatments, compared to those with major depression alone.

(b) Depressed HIV-positive patients (IPT-HIV)

IPT has also been investigated for depressed HIV patients (IPT-HIV), emphasizing common issues among this population including concerns about illness and death, grief and role transitions. A randomized study echoing the TDCRP of 101 HIV-positive patients with depressive symptoms found IPT and imipramine each superior to CBT and supportive therapy. Many patients reported improvement in depressive physical symptoms that they had mistakenly attributed to HIV infection. IPT may have been a better fit than CBT for these patients due to the extreme life events they faced at the height of the HIV epidemic.

(c) Peripartum depression

Pregnancy and the postpartum also provide natural role transitions as an IPT focus. Exploring these role transitions addresses the depressed pregnant woman's self-evaluation as a parent, physiologic changes of pregnancy and postpartum, and altered relationships with the spouse or significant other and with other children. Timing and duration of sessions are adjusted in response to bedrest, delivery, obstetrical complications, and childcare. Postpartum mothers may bring children to sessions. As with depressed HIV-positive patients, telephone sessions, and hospital visits are sometimes necessary. A controlled clinical trial comparing IPT to a didactic parent education group in depressed pregnant women showed advantages for IPT. A study of depressed postpartum women found superiority of IPT over a wait-list control group. A small randomized trial has also suggested the possibility that group IPT may serve to prevent MDD relapse during the postpartum period.

(d) Conjoint IPT for depressed patients with marital disputes (IPT-CM)

Marital conflict can precipitate or complicate depressive episodes. Some clinicians believe that individual psychotherapy for patients in marital disputes may lead to premature rupture of marriages. Researchers at Yale University developed a manual for conjoint therapy of depressed patients with marital disputes (IPT-CM). IPT-CM includes the spouse in all sessions and focuses on the current marital dispute. Eighteen patients with major depression linked to the onset or exacerbation of marital disputes were randomly assigned to 16 weeks of either individual IPT or IPT-CM. Patients in both treatments showed similar reductions in depressive symptoms, but patients receiving IPT-CM reported significantly better marital adjustment, marital affection, and sexual relations. These pilot findings require replication with a larger sample and other control groups.

(e) Depressed adolescents (IPT-A)

IPT has also been modified to incorporate adolescent developmental issues. Three randomized trials, one of them conducted in Puerto Rico, have shown the efficacy of IPT-A. It is important to note that in the Puerto Rico study, the only one that also included CBT in the design, IPT appeared superior to CBT in certain measures (e.g. self-esteem and social adaptation), consistent with the findings of the TDCRP and the study of depressed HIV-positive patients.

(f) Maintenance treatment

Based on the success of IPT as acute treatment for MDD, the recurrent nature of mood disorders, and the efficacy of medication in preventing relapse and recurrence, IPT was adapted as a once

monthly maintenance treatment for MDD (IPT-M). This was a novel development and allowed the first real testing of psychotherapy as a maintenance treatment for patients who had remitted from acute depression. Since IPT-M begins with patients who have remitted, its goal is to maintain the remitted state. Both patient and therapist are vigilant for early signs of interpersonal problems similar to those of which the patient and therapist previously identified as associated with the onset of the patient's most recent depressive episode. At the same time, the therapist works to enhance strengths that appear to have been present prior to the patient's illness or began to emerge as the most recent depressive episode remitted. In contrast with the acute phase application of IPT, which usually focuses on one or at most two interpersonal problem areas, IPT-M may shift problem areas over time. Three studies have compared medication and IPT as maintenance treatment for MDD.

In the first study, 128 outpatients with recurrent depression initially treated with combined high dose (>200 mg/day) imipramine and weekly sessions of IPT. [4,5] Responders remained on high-dosage medication while IPT was tapered to a monthly frequency during a 4-month continuation phase. Patients who remained remitted were then randomly assigned to 3 years of either: (1) imipramine plus clinical management; (2) imipramine plus monthly IPT; (3) monthly IPT alone; (4) monthly IPT plus placebo; or (5) placebo plus clinical management.

Both IPT and imipramine were significantly superior to the placebo group in delaying MDD relapse. Imipramine was superior to IPT-M in the ability to prevent relapse. The group that received IPT with imipramine had a numerically lower rate of recurrence at 1 year (16 per cent) than the group on imipramine alone (40 per cent), but those results were not statistically significant. Two different studies have had very similar findings in comparisons of IPT and nortriptyline for geriatric patients with recurrent major depression. [7, 27]

Further study is required to determine the efficacy of IPT relative to newer medications (e.g. selective serotonin-reuptake inhibitors), and the efficacy of dosages other than once monthly maintenance IPT. A study of differing doses of maintenance IPT for depressed patients in Pittsburgh has not found differences in outcome based on frequency of sessions.[28] Perhaps optimal dosing of maintenance IPT depends on individual patients' needs.

The success of IPT in treating MDD has led researchers to investigate its efficacy in bipolar and dysthymic disorder.

(i) Bipolar disorder

The modification of IPT used as an adjunct to medication in the treatment of bipolar disorder is called interpersonal and social rhythm therapy (IPSRT). Its use rests on the hypothesis that disruptions of social rhythms are destabilizing for bipolar patients and contribute to trigger their relapse. By decreasing the number and intensity of those disruptions, IPSRT should improve the course of bipolar disorder. The behavioural component helps to protect sleep patterns and limit the disruptions that may provoke mania; the IPT approach to depression remains largely the same.

After stabilizing bipolar I patients with appropriate pharmacotherapy and either IPSRT or intensive clinical management, patients were randomized again to either IPSRT or clinical management for preventive treatment.[6] They found that participants assigned to IPSRT acutely had longer survival times to a new affective episode, irrespective of maintenance treatment assignment. Participants in the IPSRT group had higher regularity of social rhythms at the end of the acute treatment, and this increased regularity of social rhythms during the acute treatment mediated the reduced likelihood of recurrence during the maintenance treatment. Further research appears necessary to more firmly establish the optimal timing and treatment duration of IPSRT.

(ii) Dysthymic disorder

A modification of IPT for dysthymic disorder[29] encourages patients to reconceptualize what they have considered their lifelong character flaws as ego-dystonic, chronic mood-dependent symptoms: as chronic but treatable 'state' rather than immutable 'trait'.

Three randomized trials have examined the efficacy of IPT in dysthymic disorder. In the first study, 35 patients with an ICD-10 diagnosis of dysthymia with or without comorbid MDD were randomized to moclobemide alone ($n = 19$) or moclobemide plus IPT ($n = 16$). Patients were assessed with the 17-item Hamilton Rating Scales for Depression (HAM-D), the Global Assessment Scale (GAS), and the Quality of Life and Satisfaction Questionnaire at baseline, 12, 24, and 48 weeks. Both groups showed statistically significant improvement in all measures across time. There were no differences between the two treatments at week 12. However, patients in the combined group had statistically better scores than the patients in the moclobemide group on all outcome variables at weeks 24 and 48.

In the second study, 707 adults in primary care clinic with DSM-IV dysthymic disorder were randomized, with or without past and/or current MDD (15 per cent of the sample had current MDD), to treatment with sertraline alone (50–200 mg), IPT alone (10 sessions), or sertraline with IPT combined.[30] At the end of treatment, response rates were 60 per cent for sertraline alone, 47 per cent for IPT alone, and 58 per cent for sertraline with IPT. After an additional 18-month naturalistic follow-up phase, there were no statistically significant differences in symptom reduction between sertraline alone and sertraline with IPT. However, both were more effective than IPT alone in reducing depressive symptoms. It is important to note, though, that IPT was given as a brief treatment, while sertraline was generally continued for the full 2 years of the study.

A third study compared IPT adapted for the treatment of dysthymia (IPT-D), brief supportive psychotherapy, sertraline, and combined IPT-D/sertraline for patients with pure dysthymic disorder (i.e. without 'double' depression) in 94 subjects treated over 16 weeks.[14] Patients improved in all conditions, with the cells including sertraline pharmacotherapy showing superiority over psychotherapy alone in response and remission. The results of this study are consistent with an emerging literature suggesting that pharmacotherapy may acutely benefit patients more than psychotherapy. In conjunction with the other studies in patients with dysthymic disorder, it suggests that IPT alone may not be an efficacious treatment for dysthymic disorder.

IPT for non-mood disorders

The efficacy of IPT as an antidepressant treatment has led to its adaptation as a treatment for other psychiatric disorders, based on the premise that life events are ubiquitous.

(a) Bulimia

Fairburn *et al.* modified IPT for the treatment of bulimia, eliminating the use of the sick role and of role-playing in order to contrast

distinct therapeutic strategies in comparing IPT and CBT. Initial trials showed that although CBT worked faster to relieve bulimic symptoms, IPT had longer-term benefits comparable to CBT and superior to a behavioural control condition.[1] A subsequent multisite trial found CBT superior to IPT.[9]

Following a model closer to the original IPT principles, Wilfley *et al*. modified IPT in a group format (IPT-G) and compared it to group CBT and a wait-list control for 56 women with non-purging bulimia.[8] The initial IPT phase was conducted individually. The interpersonal area for almost of all subjects was formulated as 'interpersonal deficits'. At termination, binge eating decreased in the IPT-G and CBT groups, but not in the control condition. Results persisted at 1-year follow-up. A randomized clinical trial of 162 women, comparing group IPT, and CBT for 20 sessions over 20 weeks, yielded similar results.

A research group in Christchurch, New Zealand studied the application of IPT to anorexia nervosa.[19] In their trial, neither IPT nor CBT showed efficacy as an outpatient treatment, consistent with the general anorexia outcome literature.

(b) Anxiety disorders

IPT has not yet been tested in controlled studies for anxiety disorders. Promising results have been found in for social anxiety disorders, PTSD, and panic disorder.[22, 31–33] Several groups are currently conducting controlled trials for these disorders.

(c) Substance abuse

IPT has failed to demonstrate efficacy in three clinical trials for patients with substance dependence.[20, 34, 35] These negative studies suggest limits to the range of utility of IPT as a main treatment for substance use disorders, but do not necessarily preclude its use to treat MDD comorbidity in those patients.

(d) Other applications

Research groups are testing the applicability of IPT to body dysmorphic disorder, chronic somatization in primary care patients, depressed patients postmyocardial infarction, depressed cancer patients, borderline personality disorder, insomnia, and other disorders. The IPT focus on life events suggests its potential applicability to patients with medical illness.

(e) IPT by telephone

Because many patients avoid or have difficulty reaching an office for face-to-face treatment, IPT and IPC are being tested as a treatment delivered over the telephone. Weissman and Miller conducted a successful pilot feasibility trial comparing IPT by telephone to wait-list control in 30 patients with recurrent major depression, and found IPT to be the superior control condition in reducing depressive symptoms and improving psychosocial functioning.[36] Neugebauer and colleagues found telephone IPC a helpful intervention for women with subsyndromal depression following a miscarriage.[37, 38]

(f) Interpersonal counselling (IPC)

Many patients presenting for treatment, particularly outside mental health settings, report psychiatric symptoms but do not meet threshold criteria for a psychiatric disorder. Nonetheless, their symptoms can be debilitating, interfering with their daily functioning, and often result in increased use of general medical services. Interpersonal counselling (IPC), based on IPT, was designed to treat distressed primary care patients who do not meet full syndromal criteria for psychiatric disorders. IPC is administered for a maximum of six sessions by health care usually by professionals who lack formal psychiatric training such as nurse practitioners. The first session can last up to 30 min; subsequent sessions are briefer.

IPC therapists assess the patient's current functioning, recent life events, occupational and familial stressors, and changes in interpersonal relationships. They assume that such events provide the context in which emotional and bodily symptoms occur. Klerman and colleagues studied 128 patients in a primary care clinic who scored 6 or higher on the Goldberg General Health Questionnaire (GHQ), randomizing them to IPC or to usual care without psychological treatment.[39] Over an average of 3 months, often receiving only one or two IPC sessions, IPC subjects showed significantly greater symptom relief on the GHQ than controls, especially mood improvement. IPC subjects were more likely to subsequently make use of mental health services, suggesting a new awareness of the psychological aspect of their symptoms.

Predictors of response to IPT

Five studies have examined predictors of response to IPT. Analyses of the TDCRP data identified general predictors of response to MDD treatment, as well as predictors for specific treatment modalities.[40,41] Seven patient characteristics predicted outcome across treatments: social dysfunction (higher social function predicted better response), cognitive dysfunction (better cognitive function predicted better response, particularly to CBT), expectation of improvement (higher expectation predicted better response), therapeutic alliance (a stronger alliance predicted better response), endogeneity of depression (endogenous depression tended to have better response, a finding supported by another study examining the relationship between EEG patterns and response to IPT in depressed patients[42]), double depression (its presence predicted poorer outcome), personality traits (their presence predicted worse response), and duration of current episode (longer duration was associated to worse response). In addition prior social adjustment, as measured by previous attainment of a marital relationship and higher satisfaction with social relationships in general, differentially predicted good response to IPT. This finding is consistent with reports in the general psychotherapy literature documenting that various indicators higher baseline psychosocial functioning predict good psychotherapy response. Two other studies suggest that comorbidity tends to worsen the prognosis of treatment with IPT alone, but not the prognosis of combined treatment.[43,44]

Summary of research findings

IPT has demonstrated efficacy as an acute and maintenance monotherapy and as a component of combined treatment for major depressive disorder. It also appears to have utility for other mood and non-mood syndromes, although the evidence for these is sparser. It has not shown benefit for substance use disorders or as a monotherapy for dysthymic disorder. Since monotherapy with either IPT or pharmacotherapy is likely to suffice for most patients with major depressive disorder, combined treatment is probably best reserved for severely or chronically ill patients. How best to combine time-limited psychotherapy with pharmacotherapy—for which patients, in what sequence, etc.—is an exciting area for future research.

Training

Until recently, IPT therapists were few, and practiced almost exclusively in research studies. Publications supporting its efficacy have led to clinical demand for this empirically supported treatment. IPT training is now increasingly included in professional workshops and conferences, with training courses conducted at University centres in Canada, the United Kingdom, continental Europe, Asia, New Zealand, and Australia. IPT is taught in a small but growing minority of psychiatric residency training programmes in the United States and as well as some family practice and primary care training programmes.

Although the principles and practice of IPT are relatively straightforward, any psychotherapy requires innate therapeutic ability, comfort with the so-called common factors of psychotherapy: tolerating and exploring affect, helping the patient to feel understood, engendering hope, etc. IPT training requires more than reading the manual: psychotherapy is learned by doing. Most IPT training programmes are designed to help experienced therapists refocus their treatment by learning new techniques, not to teach novices psychotherapy. Candidates should have a graduate clinical degree (MD, Ph.D., MSW, RN), several years of experience conducting psychotherapy, and clinical familiarity with the diagnosis of patients they plan to treat.

The IPT training in the TDCRP became the model for subsequent research studies. It included a brief didactic programme, reading the manual, and a practicum in which the therapist treated 2–3 patients under close supervision monitored by videotapes of the sessions. For research certification, we continue to recommend at least two or three successfully treated cases with hour for hour supervision of taped sessions.

Although many clinicians would like a formal certificate or diploma in IPT, there is no gold standard of IPT proficiency and no accrediting board. When IPT practice was limited to research settings, this posed no problem: one research group taught another, in the manner described above. As IPT spreads in clinical practice, the educational and accreditation process for IPT requires further study. The newly created International Society for Interpersonal Psychotherapy (ISIPT) may provide an appropriate forum in which to discuss these increasingly important issues.

Future directions

The history of IPT has been a succession of outcome trials. These studies have helped to define diagnostic indications for this treatment, but we know far less about the dosage and indications of IPT than about antidepressant medication. Future outcome trials may continue to define the scope of efficacy (response to treatment under ideal conditions) and effectiveness (response to treatment in more general clinical settings) of IPT. These should include both tests for different diagnoses, such as the anxiety disorders, testing of dosage—optimal frequency and duration of IPT sessions—and also studies of the sequencing of IPT with other treatments. Other research may help to determine the cost-effectiveness and potential cost-offset of IPT as a treatment that improves both symptoms and social functioning.

Most of the work on IPT to date has focused on treatment outcome. By contrast, little is known about the process aspects in IPT such as the specific value of many IPT interventions. Although it appears that solving an interpersonal problem area correlates with treatment outcome, it is unclear, for example, whether the choice of a particular treatment focus over other makes a difference for patients, or whether particular sorts of life events are helpful or unhelpful foci. Patient and therapist characteristics may also potentially influence treatment outcome.

Finally, while the initial work on IPT was conducted in the United States, over the last few years, IPT trials have also been conducted in other countries. As those studies continue to be conducted, it will become easier to discern to what extent IPT addresses topics are universal across cultures.

In summary, IPT is a time-limited, forward-looking, pragmatically focused psychotherapy that defines psychiatric disorders as treatable medical illnesses and links them to the patient's current social situation. This strategy has proved efficacious for patients with major depression and bulimia, and shows promise for other mood and non-mood disorders.

6.3.4 Brief individual psychodynamic psychotherapy

Amy M. Ursano and Robert J. Ursano

Introduction

Interest in brief dynamic psychotherapy has flourished in recent years. The psychodynamic psychotherapies, including brief psychodynamic psychotherapy, aim to change behaviour through new understanding and the recognition of maladaptive patterns of behaviour enacted since childhood but not previously observed. Through this process, perceptions, expectations, beliefs, and, therefore, behaviours and feelings are altered.[1]

Historically, 'brief psychotherapy' and 'long-term psychotherapy' were used synonymously with 'supportive' and 'explorative' psychotherapy, respectively. However, brief and long-term describe only the duration rather than the technique, focus, or goal of treatment.[2] The time limits of brief dynamic psychotherapy give it a unique character and distinguish it from long-term psychotherapy and psychoanalysis. Because of its limited goals, the brief dynamic psychotherapist must confront his or her ambitiousness and perfectionism as well as any exaggerated ideal of personality structure and function.

Psychotherapy in general, and brief individual psychodynamic psychotherapy in particular, is perhaps the most elegant form of micro-neurosurgery. Psychotherapy strives to alter behaviour (i.e. cognitions, affects, and actions) with verbal interchange—fundamentally to change neurone A that used to connect to neurone B so it will now connect to neurone C. Although the therapist in the individual psychodynamically derived psychotherapies does not 'require' behavioural change, the end result of the therapist's technical expertise is to achieve behavioural change, including changes in well-being, physical health, social supports, and societal productivity as well as symptomatic relief. As in all of medicine, both non-specific and specific curative factors affect the outcome of this work. The non-specific curative factors—abreaction, the provision of new information, and maximizing success experiences—are present in all forms of medical treatment including brief psychotherapy. Brief individual dynamic psychotherapy also has specific technical interventions and procedures above and beyond the non-specific curative factors. As in other medical therapies, there are contraindications and dangers in the use of this treatment.

Background

Evolving from psychoanalysis in the mid-twentieth century, brief individual psychodynamic psychotherapy, like other psychodynamic treatments, is based on the principle that meanings and past experience play an important role in behaviour and illness. Although psychoanalysis is now a lengthy procedure usually requiring a number of years to complete, the early psychoanalytic literature, including Freud's first cases, contain histories of successful short analyses. During the first 30 years of psychoanalysis, it was unusual for treatments to extend beyond 1 year.[3] Ferenczi was the first analyst to advocate shortening psychoanalysis. He advocated 'active therapy' a more directive, focused, and briefer treatment. Rank was the first one to explicitly to set a time limit on treatment. Ferenczi and Rank[4] articulated the advantages of brief dynamic psychotherapy.

Following the Second World War, the interest in psychoanalysis resulted in greater demand for psychotherapy and increased pressure to develop briefer treatments. In the mid-1940s, Alexander and French advocated shortening treatment by decreasing the frequency of sessions in order to minimize regression. They proposed to focus treatment on the present rather than the past, using historical conflicts to inform the therapist in providing the best corrective emotional experience for the patient in the present.

The community-based mental health treatment movement, the increasing cost of mental health care, and the rise of managed care in the United States; have stimulated efforts to find briefer forms of psychotherapy. Contemporary brief individual psychodynamic psychotherapy is heavily influenced by the British School's development of brief focal psychotherapy. Balint sponsored a workshop of experienced psychoanalytic psychotherapists, which focused on clinical evaluation and attempted to understand which patients might be suitable for briefer treatment. After Balint's death, Malan carried on the work of the group. At the Tavistock clinic, Malan developed and applied the principles of psychodynamic treatment to brief treatment, delineating methods for evaluating process and outcome variables. He emphasized the importance of therapeutic planning and the identification of a focal conflict.

Concurrently, Sifneos, at the Massachusetts General Hospital, was studying brief psychotherapy.[5,6] Sifneos developed 'short-term anxiety-provoking psychotherapy' as a technique and theory with strict inclusion and exclusion criteria for choosing patients. Davanloo broadened the focus of the brief psychodynamic psychotherapies to include more than one conflict. He also expanded the inclusion criteria to individuals with character pathology and chronic phobic and obsessional neuroses, and advocated actively confronting resistances. Mann's time-limited psychotherapy identified a central issue related to the meaning of time, as the focus of the treatment. Mann related this to the patient's difficulties in confronting loss and separation and the reality of time and death.

In recent years, brief psychotherapy has become increasingly research based. Strupp, Luborsky, and Horowitz have all introduced manualized focused psychodynamic treatments which substantially contribute to our research understanding of this treatment modality.

Brief dynamic psychotherapy technique

(a) Evaluation and setting

The evaluation is particularly important in brief individual psychodynamic psychotherapy because of the need for rapid and accurate assessment. In contrast to longer term treatments, brief individual psychodynamic psychotherapy does not offer the luxury of time to re-evaluate and correct mistakes. Although at times we think of psychotherapy as beginning as soon as the doctor sees the patient, this is a hyperbole, used to underscore the importance of interpersonal and transferential elements in the initial meeting with the patient. In fact, it is extremely important, particularly in brief individual psychodynamic psychotherapy, to distinguish the diagnostic interviews from the ongoing treatment.

The interventions and technical procedures performed during the evaluation phase, usually one to four sessions, are substantially different from the technical aspects of brief individual psychodynamic psychotherapy itself. The evaluation phase includes the diagnosis, consideration of the interaction among the patient's ego strength, physical health, and selection variables, and the treatment recommendation, including considering the option that no treatment is indicated.

As in all medical treatments, brief individual psychodynamic psychotherapy is given to patients rather than to diseases. The ability to participate in brief individual psychodynamic psychotherapy process requires the patient to be able to access his or her fantasy life in an active and experiencing manner (i.e. psychologically minded) and, importantly, is able to get up and leave this process behind at the end of a session and not be lost in reverie or uncontrolled fantasies or fears. Note that this does not mean the patient requires a 'high IQ'. In fact, a high IQ, when accompanied with rigidity, intellectualization, and rumination, as is often seen, can be a contraindication to a brief psychodynamic treatment since these defences can be quite formidable. The availability of interpersonal support in the patient's real environment and the patient's ability to experience and simultaneously observe highly charged affective states are necessary to a successful treatment. Individuals who are in an emergent crisis (e.g. imminently suicidal, psychotic, recent major life trauma) and therefore are very concerned and focused on the real events in their life cannot enter into a brief psychodynamic psychotherapy without first having a period of supportive treatment. A true life crisis does not allow the patient the opportunity to explore fantasies.

Negotiation with the patient is an important part of reaching a treatment decision in brief individual psychodynamic psychotherapy. The patient must rapidly feel a part of the treatment and committed to the process. The process of setting a time limit at the beginning of the treatment can be an important element in decreasing the dropout rate from this form of treatment,[7] particularly with the patient who is concerned about dependency, 'becoming addicted' to the therapist, or who needs to maintain a substantial sense of control. What is dealt with in treatment can only be what the patient is able to bring into focus, what the patient can tolerate talking about, and what he or she can tolerate the therapist talking about.[8] Although this is not different than other psychodynamic treatments, the limited time of brief individual psychodynamic psychotherapy means that there is limited ability to interpret multiple defences that might open new areas of exploration.

(b) Technique

The rapid establishment of the therapeutic alliance is critical to brief individual psychodynamic psychotherapy.[9] Identifying the patient's initial anxieties related to beginning therapy is an important technique in the early sessions of brief individual psychodynamic psychotherapy in order to assure the alliance and to establish the conditions under which the patient can favourably hear and respond to the interpretations that the therapist will later give. As the therapy unfolds, the therapist operates on the hypothesis that each session is related to the previous one. The therapist strives in each session to identify the continuity of meaning related to the treatment focus that is present but hidden.[10] This continuity is driven by the 'experience bias' of the patient, and his or her tendency to experience the world in a certain way due to unique developmental experiences that have moulded his or her perception, interpersonal beliefs, and expectations.[11]

Brief individual psychodynamic psychotherapy is more focused, and more 'here and now' oriented with fewer attempts to reconstruct the developmental origins of conflicts than the extensive reworking of personality undertaken in longer term psychotherapies. Through the exploration of the patient's metaphors and symbols, both defensive patterns and disturbances in present interpersonal relations are identified in the treatment setting as well as in the patient's life. The importance of being able to hear what the patient has to say and to understand its meaning remains central as in other psychoanalytically oriented treatments.

Free association and inquiry: Free association is part of the technique of brief individual psychodynamic psychotherapy. But what constitutes free association—as in all dynamic therapies—requires thoughtful consideration. In its most basic form, and particularly highlighted in brief individual psychodynamic psychotherapy, free association means that the patient is free to choose what they wish to talk about. This rather direct definition emphasizes that free association is always relative. In addition, in brief dynamic psychotherapy, the patient is always somewhat more task focused that in open-ended treatments or psychoanalysis and this focus should not be discouraged by the therapist. Rather it is the therapist's task to hear the themes in the patient's concerns. The therapist asks questions, directs the patient's attention, and uses benign neglect, i.e. avoids some areas of conflict that cannot be dealt with at this time or in a short period of time. The therapist identifies those spots at which free association breaks down (the presence of a defence) or at which the narrative is carrying a single emotional story out of the patient's awareness. As in all dynamic treatments, often when the patient is able to talk freely and with a coherent narrative about their conflicts, the work of the treatment is completed.

Defence and transference: Brief individual psychodynamic psychotherapy emphasizes understanding (a) the mechanisms of defence used by the patient to decrease anxiety and other uncomfortable feelings associated with areas of conflict which are out of awareness, and (b) the characteristic transference relationships which distort the patients response to their adult world. Typically these two areas, defence and transference, create the world of meaning and expectations in which the patient lives. The techniques of the brief psychodynamic psychotherapy are directed towards clarifying these areas and presenting them to the patient to increase understanding and in this manner change symptoms and behaviour. Often only one defence is concentrated on in a given brief treatment. As the defence is clarified, the transference relationship may become evident. The developmental narrative of how the patient came to see the world in the way he or she does, provides the 'glue' through which the patient can integrate this knowledge into their life experience and behaviours, and recall it for practice and future use.

The brief individual psychodynamic psychotherapy therapist, similar to longer term psychodynamic work, must both enhance the patient's observing capacity in order that the transference can be observed by the patient and therapist, and create the therapeutic situation in which the patient can hear the therapist's interpretations in a useful manner. Dreams, as well as slips of the tongue and symptoms, can provide an avenue to the understanding of unconscious conflict which can be taught and explored with the

patient. The therapist strives to interpret both the triangle of anxiety (wish-defence-anxiety) and the triangle of insight (transference figure in the present—the therapist/patient interaction—transference figure from the past).

Frequently, when the transference is most evident, other elements of the past are simultaneously experienced in the patient's life. In brief individual psychodynamic psychotherapy these can be particularly important to the patient's understanding the feeling elements of the transference in a mutative manner since the depth and intensity of the transference is much less and much briefer than in long-term work. In contrast, however, the presence of a recent precipitant to the patient's problems, as is usually the case in brief psychodynamic psychotherapy, can considerably intensify transference responses and be a central element in developing the psychodynamic understanding for the patient. The transference experience—the transference, the life experiences being relived, and particularly the precipitant—provide the web of meaning that is the focus of interpretation and the mutative force in brief individual psychodynamic psychotherapy.

Often the transference in brief individual psychodynamic psychotherapy is paternal or maternal, but it has also been noted that, perhaps due to the time-limited nature of the work, sibling and transference figures from adolescence may more often be recalled in brief individual psychodynamic psychotherapy. The transference is rarely as deep as that seen in long-term treatment. It requires a skilled eye to note and bring the transference to the attention of the patient in a manner that is neither intrusive nor offensive.[12] Interpretations usually occur over several sessions, in the middle or later third of the treatment, during which past, present, and transference experiences are linked together. In the context of the affective arousal associated with this transference experience and the simultaneous understanding of the experience, behavioural change occurs and the patient's ability to perceive previously hidden feelings and relationships as well as his or her view of the future and the past can change.

Countertransference: Countertransference is also an important element in brief individual psychodynamic psychotherapy as in other psychodynamic treatments.[13] Analysis of countertransference reactions can allow the therapist to recognize subtle aspects of the transference relationship and to understand the patient's experience better. Because of the more active stance, the brief psychodynamic psychotherapist can be particularly prone to countertransferences that show up as over-involvement or aggression. In addition, the brief time available for treatment can make recovery from countertransference errors quite difficult.

(c) Medication

Medication is frequently used in conjunction with brief psychodynamic psychotherapy. This can complicate the treatment and its progress as well as aid in symptom recovery. The therapist must explore the meaning of the medication and its role in the patient's view of himself or herself and interpersonal strengths and vulnerabilities. At times, brief individual psychodynamic psychotherapy can also serve as an alternative to medication treatment for less severe symptoms or when medication is contraindicated. Medication may have also begun during the initial brief psychodynamic psychotherapy and then continued after the psychotherapy has formally stopped and the patient is followed with less frequent meetings to monitor medication. This sequence has many advantages including resolving present stressors and precipitants, encouraging medication compliance, and ongoing medical follow-up after therapy either in maintenance or intermittent frequency. Another course of brief dynamic therapy may be indicated at a later date if the response to combined treatment is ineffective or if new problems appear. Greater education of clinicians and research on this combined and sequential treatment is needed.

Comparison of the brief psychodynamic psychotherapies

The work of Malan, Sifneos, Mann, and Davanloo shows substantial overlap in each author's goals, selection criteria, technique, and duration of treatment.[14] The goals of all of these models of brief psychotherapy include facilitating health-seeking behaviours and mitigating obstacles to normal growth. From this perspective, brief psychotherapy focuses on the patient's continuous development throughout adult life and the context-dependent appearance of conflict, depending on environment, interpersonal relationships, biological health, and developmental stage. This picture of brief psychotherapy supports modest goals that require the therapist to refrain from perfectionism. Malan, Sifneos, Mann, and Davanloo also seem to agree with Stierlin's[15] contrast between brief psychotherapy's use of the 'propitious moment' and long-term treatment's use of 'a shared past' between therapist and patient. Both the propitious moment and the shared past carry psychotherapeutic advantages and disadvantages, emphasizing certain technical possibilities and limiting others.

Selection criteria: Many of the selection criteria emphasized by Malan, Sifneos, Mann, and Davanloo are common to all kinds of psychodynamic psychotherapy. However, unique selection criteria are required due to the brief duration of treatment. Patients in brief psychodynamic psychotherapy must be able to engage quickly with the therapist, terminate in a short period of time, and be able to carry on much of the working through and generalizing of the treatment effects on their own.

The necessity for greater independent action by the patient requires that the patient have high levels of ego strength, motivation, and responsiveness to interpretation. Sifneos's rather unique emphasis on intelligence as a criterion may be related to his anxiety-provoking interpretations, which require a broader educational context in order to be understood. The importance of the rapid establishment of the therapeutic alliance underlies a substantial number of the selection and exclusion criteria.

Focus of brief psychotherapy: All authors mention the central importance of the focus in brief psychotherapy, and therefore the evaluation sessions to determine this focus. Mann formulates the focus to the patient in terms of the patient's fears and pain. However, he would probably agree with Malan, Davanloo, and Sifneos in the importance of constructing the psychodynamic focus at a deeper level in one's own understanding of the work being done. Maintaining the focus is the primary task of the therapist. This enables the therapist to deal with complicated personality structures in a brief period of time. Resistance is limited through benign neglect of potentially troublesome but non-focal areas of the personality. The elaboration of techniques for establishing and maintaining the focus of treatment is critical to all brief individual psychodynamic psychotherapies.

Transference: The manner and rapidity in which transference is dealt with vary considerably among proponents of brief individual psychodynamic psychotherapy. Malan takes a more typical psychoanalytic approach of waiting for transference to become resistance before it is interpreted. Sifneos, in his emphasis on the Oedipal relationship, is more aggressive in handling the deep conflictual areas of transference material. Davanloo is confrontational in developing a transference experience. This confrontational style may at times confuse the patient's experience of the real and the transferential therapist. However, Davanloo often treats severe obsessional disorders. In these cases, the need to increase the patient's affective awareness is high. These may be the patients in which this particular technique is most useful. Aggressive, competitive, and hostile feelings, which might otherwise remain firmly defended, may thus become available to these patients.

Countertransference: The role of countertransference in brief psychotherapy is as complicated as it is in long-term treatment. Countertransference issues related to the aggressive techniques used by Sifneos and Davanloo have been observed. Countertransference experiences related to termination and loss can also be prominent.[16] The goal-directed techniques of brief psychotherapy limit the development of regressive countertransference responses.[13]

Duration of treatment: There is remarkable agreement on the duration of brief psychotherapy. Although the duration ranges from 5 to 40 sessions, authors generally favour 10 to 20 sessions. The duration of treatment is critically related to maintaining the focus within the brief psychotherapy. Shlien *et al.*[17] have found in Rogerian therapy, a correlation between the number of sessions and recovery. In general, they report an increasingly successful outcome (measured by the patient's self-concept) up to about 20 sessions. Howard *et al.*[18] using a meta-analytical technique, found 75 per cent of patients showing some improvement by 26 sessions. However, this study includes a wide range of types of treatment. When treatment extends beyond 20 sessions, the therapist frequently may find himself or herself enmeshed in a broad character analysis without a focal conflict. Change after 20 sessions may be quite slow. Clinical experience generally supports the idea that brief individual psychodynamic psychotherapy should be between 10 and 20 sessions although more complicated cases will require greater length of treatment. Often extending treatment beyond 20 sessions is recognition that treatment will be beyond 40 or 50 sessions.

Brief psychodynamic psychotherapy for depression, narcissistic disturbances, panic disorder, substance abuse, and post-traumatic stress disorder have been described.[14,19] Horowitz *et al.*[20] have described brief psychotherapy focused on the stress responses evidenced by various personality styles. He emphasizes that this psychotherapy is directed towards dealing with the process of the stress response and not character change. However, his outcomes indicate that selected character changes are possible in some areas. The distinction between recovery from a disruption in homoeostatic balance, reconstitution of self-esteem and self-concept, and changes in character structure require further exploration.

Critical points: The identification of critical points during brief psychotherapy, when the 'danger' of becoming a long-term treatment is most acute, clarifies the technical handling of brief psychodynamic psychotherapy. At these points, the therapist often notes an increasing vagueness of the goals of the treatment, decreased activity by the therapist, and the emergence of the transference as the central element. These variables indicate the potential of a short-term psychotherapy becoming a long-term treatment. The fourth to sixth hour of weekly 12-session therapy is often a point at which incipient or potential regression may suddenly appear. The patient at this time is testing the boundaries of the treatment. Action by the therapist is required if a brief psychotherapy is to remain exactly that—brief. The study of technical interventions, which occur at these critical moments, will further elucidate the technical handling of limited regression in brief psychodynamic psychotherapy.

Malan and the Tavistock group: focal psychotherapy: Developed from the workshops of Balint and Malan, focal psychotherapy is an example of applied psychoanalysis.[21] Malan has carried on Balint's earlier work.[22,23] Previous attempts to develop brief forms of psychoanalytic psychotherapy primarily involved the use of 'activity' which was frequently equated with manipulation. On the contrary, Malan emphasized the importance of choosing and maintaining a narrow focal area to be dealt with in a brief period of time. He stresses the importance of finding the appropriate focus in the patient's story and consistently interpreting the focal problem area.[23] Through selective attention and neglect, the therapist maintains the focus and completes a brief psychotherapy. The importance of determining the focus underscores the value of the diagnostic process, including the psychodynamic assessment of the patient prior to the initiation of psychotherapy.[24]

Malan identifies the following factors as leading to the lengthening of treatment: resistance, overdetermination, a need for working through the roots of conflict in early childhood, transference, dependence, negative transference connected with termination, and the transference neurosis. In addition, some therapist characteristics may lengthen treatment. These include a tendency towards passivity, a sense of timelessness conveyed to the patient, therapeutic perfectionism, and a preoccupation with deeper earlier experiences. All of these factors must be dealt with in order to maintain a brief therapy. For Malan, identifying a focal conflict acceptable to the patient is critical to a successful outcome (Table 6.3.4.1). In addition, the patient must have the capacity to think in feeling terms, demonstrate a high motivation, and exhibit a good response to trial interpretations made during the evaluation phase. Patients who have had serious suicidal attempts, drug addiction, long-term

Table 6.3.4.1 Brief psychodynamic psychotherapies

Goal of treatment
Identify the defence, the anxiety, and the impulse
Link the present, the past, and the transference
Focus of treatment
Internal conflict present since childhood
Selection criteria
Patient is able to think in feeling terms
Highly motivated
Good response to trial interpretation
Duration of treatment
Up to 1 year
Mean 20 sessions
Termination
Set definite termination date at beginning of treatment

hospital stays, more than one course of electroconvulsive therapy, chronic alcoholism, incapacitating severe chronic obsessional symptoms, severe chronic phobic symptoms, or gross destructive or self-destructive acting-out are excluded from treatment. The patient is also excluded from focal psychotherapy if the therapist anticipates any of the items in Table 6.3.4.2.

For Malan, the criteria in Table 6.3.4.2 represent specific dangers. If the therapist cannot make contact with the patient, or low motivation or rigid defences are present, it will be difficult to form an effective therapeutic working alliance within a short time. Complex or deep-seated issues, which must be dealt with to resolve a conflict area, require a longer period of treatment. Difficult transference relationships may also prevent timely termination or lead to premature termination. The occurrence of severe depressive or psychotic episodes during treatment can be a danger to the patient and require adjunctive treatments. Thus, Malan takes seriously the time limitation in brief therapy, which requires the rapid establishment of a therapeutic alliance and the ability to terminate therapy without the development of unexpected serious symptoms.

Malan, in contrast with other practitioners, does not automatically exclude patients with serious psychopathology. He sees the balance between motivation and focality as the primary criteria. A patient with only moderate motivation but a highly focal conflict might be accepted into treatment. Similarly, a patient with high motivation but not as focal a conflict might also be accepted into treatment with the hope that clarification of the focus would occur in a short period of time.

Identifying the precipitating factors, early traumatic experiences, or repetitive patterns can indicate the area of internal conflict present since childhood and the possible focus of treatment. The therapist should assess the congruence between the current conflict and the 'nuclear' or childhood conflict during the evaluation phase. The patient's response to interpretations about aspects of this conflict may lead to acceptance into treatment. According to Malan, the greater the probability that the conflict area will manifest itself in the transference, the more positive the outcome will be.

Malan is less concerned with technique than with the importance of choosing the focus. He employs the usual technical procedures of psychoanalytic psychotherapy and emphasizes the importance of making interpretations of the transference and connecting these to current and past relationships. This 'triangle of insight' (the transference, the current relationship, and the past relationship) leads to the patient's cure. Overall, the goal is to clarify the nature of the defence, the anxiety, and the impulse, which the patient is experiencing, and to link these to the present, the past, and the transference. Once the defence and the anxiety are clarified, the link to the past can be made. The interpretation that links to the past may be experienced as reassuring by the patient because of its emphasis on the conflict belonging to the world of fantasy rather than to the world of the present. Malan emphasizes transference interpretations as the most therapeutically effective interpretations because of their 'here and now' character.

In the brief therapy unit at the Tavistock Clinic, a time limit was almost always given at the beginning of treatment. For trainees this was usually 30 sessions. However, in his publications, Malan indicates a mean of 20 sessions for those cases with favourable outcomes. The longer time for trainees gives the opportunity to correct mistakes that might occur. In some published cases, therapy was extended up to 1 year (46 sessions). In general, Malan advocates the importance of a definite date rather than a number of sessions. Practically speaking, this eliminates the need for the patient and therapist to keep count of the number of sessions and eliminates complications related to whether or not to make up sessions that the patient has missed. Such a time limit gives a definite beginning, middle, and end to the therapy. It helps to concentrate the patient's material and the therapist's work, to maintain the focus, and decrease the diffuseness that might lead into long-term work.

Sifneos: short-term anxiety-provoking psychotherapy: Sifneos emphasizes the importance of patient selection because of the anxiety-provoking nature of his brief psychotherapy techniques (Table 6.3.4.1). He distinguishes anxiety-provoking therapy from anxiety-suppressing therapy, commonly referred to as supportive psychotherapy. For short-term anxiety-provoking psychotherapy, the patient must be of above average intelligence and have had at least one meaningful relationship with another person during his or her lifetime. The patient who has had such a relationship will be able to withstand the anxiety produced by the therapy and to develop rapidly a mature collaborative relationship with the therapist. This criterion tends to exclude narcissistic disorders. In addition, the patient must be highly motivated for change, not only for symptom relief. Sifneos also identifies several criteria for the patient selection based on the presentation of the patient during the evaluation. The patient must have a specific chief complaint. If the patient has a number of complaints, Sifneos asks the patient which complaint is of top priority. The patient's ability to identify one conflict area and to postpone work on others is taken as an indication of the patient's ability to tolerate anxiety. Sifneos looks for patients with anxiety, depression, phobias, conversion, and mild obsessive-compulsive features or personality disorders involving clear-cut interpersonal difficulties. During the evaluation, the patient must show an ability to interact with the evaluating psychiatrist, to express feelings, and to show some flexibility.

Sifneos is one of the few authors who clarifies his assessment of motivation. He defines motivation as including the patient's ability to recognize symptoms as psychological, a tendency to be introspective and honest about emotional difficulties, and a willingness to participate in the treatment situation. In addition, motivation includes curiosity, willingness to change as well as a willingness to make reasonable sacrifices, and a realistic expectation of the results of psychotherapy.

Sifneos focuses on the Oedipal conflict and does not expect a good outcome in dealing with other than Oedipal conflict areas.

Table 6.3.4.2 Exclusion criteria for Malan's and the Tavistock group's brief focal psychotherapy

1. Therapist is unable to make affective contact with the patient during the evaluation
2. Therapist anticipates that extended work will be needed
   To generate motivation
   To decrease rigid defences
   To reach complex or deep-seated issues
   To resolve unfavourable, intense transference, or dependence which may develop
3. Depressive or psychotic disturbance may intensify and place the patient at risk

The majority of failures using short-term anxiety-provoking psychotherapy have occurred in patients who complained of reactive depression following the loss of a loved one. He believes that this failure is due to the non-triangular (non-Oedipal) origins of the ambivalent feelings in some patients. In such cases, when the issue of termination arises, the patient regresses and an impasse is reached.

During the initial phase of psychotherapy, the therapist must establish good rapport with the patient in order to create a therapeutic alliance. The therapist uses anxiety-provoking confrontations in order to clarify issues around the patient's early life situation and present-day conflict. The therapist avoids areas such as passivity, dependence, and acting-out, which might lead to extensive regression. The use of anxiety-provoking confrontations in a direct attack on the patient's defences distinguishes short-term anxiety-provoking psychotherapy from other brief psychotherapies. Although it is made clear to patients during their evaluation that the psychotherapy is expected to last only a few months, no specific number of sessions or termination date is given. Interviews are held weekly and last for 45 min. The vast majority of treatments last from 12 to 16 sessions, and none go beyond 20 sessions. The aggressive confrontational style of this treatment underscores the importance of excluding pre-Oedipal problems and the importance of countertransference reactions in the therapist related to being too aggressive.

Mann: time-limited psychotherapy: Mann has focused on the specific limitation of time in brief psychotherapy. Mann sees the variable of time as a specific operative factor in psychotherapy as well as an element in its curative effect.[25,26] The experiences of the timelessness of treatment and of the treatment's termination are significant elements in Mann's view of the psychotherapeutic process.

Usually there are two to four evaluation meetings prior to beginning psychotherapy. Mann limits psychotherapy to a total of 12 treatment hours, distributed according to patient need. This may result in weekly 30-min sessions for 24 weeks or twice weekly hour-long sessions for 6 weeks. In practice, however, nearly all patients are seen in once-weekly 45- or 50-min sessions for 12 weeks. Mann admits having chosen the number 12 somewhat arbitrarily; however, his clinical experience indicates that somewhere between 10 and 14 sessions is a sufficient number. Mann emphasizes the importance of a uniform number of sessions for evaluating the psychotherapeutic process among different therapists. In this way, the relationship between the patient's presenting problems and psychotherapeutic technique can be more easily studied. Also, the provision of a specific number of sessions can be more easily accepted by the patient as a typical medical 'prescription'. Finally, the setting of a specific last session in the initial contract with the patient allows the therapy to have a clear beginning, middle, and end (see Table 6.3.4.1).

Mann indicates a number of exclusionary criteria: serious depression, acute psychosis, borderline personality organization, and the inability to identify a central issue. Mann sees Sifneos' criteria as primarily excluding borderline patients. He does not agree with Sifneos' emphasis on superior academic or work performance.

To some extent, Mann initially minimized selection as a central issue for brief psychotherapy. Later, Mann expanded his selection criteria by emphasizing the importance of the patient's ego strength as measured by prior work performance and past relationships.[26] Patients who may have difficulty engaging and disengaging rapidly from treatment are excluded. This includes schizoid patients, certain obsessional patients, patients with strong dependency needs, some narcissistic patients, some depressive patients who will not be able to form a rapid therapeutic alliance, and some patients with psychosomatic disorders who do not tolerate loss well.

According to Mann, the selection of the central issue for the psychotherapy is the critical event. It is the vehicle through which the patient is engaged in the work of therapy and on which a successful outcome depends. Mann looks for a central issue that is developmentally and adaptively relevant and has been recurrent over time. He describes this issue as the patient's 'present and chronically endured pain' and characterizes it as preconscious. Mann has further described the central issue as including a particular image of the self.[25] The central issue formulated in terms of time, affect, and an image of the self is the 'paradigm of the transference' expected to emerge in treatment. The therapist's statement of the central issue is a clarification, which can be readily recognized, felt, and held onto by the patient. Time-limited psychotherapy is intended to resolve this present and chronically endured pain and the patient's 'negative self-image'. The therapist frames the central issue to the patient in terms of a general statement about feelings.

Mann and Goldman[26] described in detail the phrasing of the central issue to the patient. It is the central issue that specifies the therapeutic contract and the goal of the therapy. In the case of a 41-year-old depressed woman who was preoccupied with her husband and children being even a minute late, Mann suggested the central issue: 'You've encountered extreme life situations and have managed them remarkably well ... yet you fear and have always feared that despite your best efforts you will lose everything'. In a 31-year-old married man attempting to gain a college degree who was consumed with a fear of failing, Mann suggested the central issue: 'Because there have been a number of sudden and very painful events in your life, things always seem uncertain, and you are excessively nervous because you do not expect anything to go along well. Things are always uncertain for you'.[26]

Mann uses the usual psychoanalytic psychotherapy techniques: defence analysis, transference interpretation, and genetic reconstruction. Transference is interpreted from within the central identified conflict area and in terms of the adaptive processes of the patient. However, Mann does not confront the patient. In general, his interventions are very close to the conscious material provided by the patient. Mann identifies specific dynamic events that unfold during the 12 sessions. The opening sessions are understood as filled with the unconscious magical expectation that past pains will now be resolved. During the initial phase, the therapist makes few comments and accepts the positive transference of the patient. Important aspects of the current problem, defence mechanisms, coping styles, and genetic roots of the central issue become clearer during this phase. In the middle four sessions, resistance is likely to appear, as well as the negative transference. The patient experiences the frustration that all of the wished for changes may not occur. In the ending phase of treatment, termination and the patient's resistances to termination in the face of unresolved problems in other areas of life are prominent.

Mann sees the importance of confronting separation and termination issues as critical to the success of brief psychotherapy. Frequently, the patient unconsciously reveals an awareness that the mid-point of treatment has come. The patient experiences

separation from the transference-invested therapist as a separation from an ambivalently experienced person from the past, without having achieved the fantasized magical resolution. The goal is to enable the patient to separate from the transference-invested therapist less ambivalently than he had done from this earlier important figure. Consequently, both the resolution of the central issue and the unfolding of an attachment-separation process in the 12-session treatment contract are intimately related through the development and interpretation of the transference.

Davanloo: broad-focus short-term dynamic psychotherapy: Davanloo writes about broad-focus short-term dynamic psychotherapy.[27] His selection criteria include patients with an Oedipal focus, those with a loss focus, and those with multiple foci. Davanloo is particularly interested in patients suffering from long-standing obsessional and phobic neuroses. His research data indicate that 30 to 35 per cent of the psychiatric outpatient population can benefit from this mode of therapy. Most information about his technique is derived from the publication of cases, presentations, and brief descriptions of his research that accompany case presentations.

The initial evaluation is a specific focused interview in which the patient's defences against 'true' feelings are gently but consistently confronted. Davanloo says that this is not a universal technique for the initial interview and cautions on its use with patients with severe psychopathology. Selection is based on psychological mindedness, the quality of the patient's interpersonal relations, and, in particular, on the presence of at least one meaningful relationship in the patient's past. The patient's ability to tolerate and experience anxiety, guilt, and depression are important (Table 6.3.4.1). The patient must be motivated to complete the treatment process and to resolve neurotic problems. His or her ability to respond to interpretation is an important selection criterion. In particular, response to transference interpretations, which link the transference with the present and the past, is a critical feature in the assessment for broad-focus short-term dynamic psychotherapy. Davanloo finds no value in criteria based on severity and duration of illness. Finally, the presence of flexibility in the ego's defensive pattern and a lack of use of the primitive defences of projection, splitting, and denial are important factors in selecting patients.

The technique Davanloo uses in therapy is a continuation of that used in the initial interview. The emotional experience of the patient in the transference is emphasized. The patient is 'gently but relentlessly' confronted about his defences against feelings in the transference relationship and in the past. All the usual techniques of psychoanalytic psychotherapy are employed: defence analysis, transference interpretations, and genetic reconstruction. Dreams and fantasy materials are also used. Transference interpretations tend to be made early. Because of the confrontive style, a strong therapeutic alliance is necessary. Patients frequently experience hostile, angry feelings towards the therapist because of being confronted. Davanloo actively pursues the patient's defences against recognizing the anger and its transference elements. Davanloo warns therapists that passive dependent and obsessional characters may develop a symbiotic transference relationship. This may be avoided through active confrontation and selection of patients. The active confrontation of defences and early transference interpretations tend to mobilize powerful affects and memories early on in treatment.

Davanloo recommends from 5 to 40 sessions, depending on the patient's conflict area (Oedipal versus multiple foci) and other selection criteria. In general, his treatments fall between 15 and 25 sessions. He does not recommend setting a specific termination date but rather makes clear to the patient that treatment will be short. Shorter time periods (5–15 sessions) are chosen for patients with a predominantly Oedipal focus, longer durations (20–40 sessions) for the more seriously ill group.

Comparison of psychodynamic, cognitive, and interpersonal brief psychotherapies

Interpersonal psychotherapy[28,29] and cognitive behavioural psychotherapy[30] derive from the psychodynamic model and therefore share many common elements with brief psychodynamic psychotherapy but with distinct approaches and interventions. All three modalities, interpersonal psychotherapy, cognitive behavioural therapy, and brief individual psychodynamic psychotherapy, are complex methods of treatment that must be custom-tailored to the individual patient. Brief by definition, they all lack the extended working through and application period of psychoanalysis and intensive (long-term) psychodynamic psychotherapy. All demand a high degree of clinical judgement and considerable experience to acquire competency. The relationship between the therapist and patient and the establishment of a therapeutic alliance are essential (Table 6.3.4.3).

Table 6.3.4.3 Comparison of the brief dynamic psychotherapy with cognitive psychotherapy and interpersonal psychotherapy

	Brief dynamic psychotherapy	Cognitive psychotherapy	Interpersonal psychotherapy
Free association	++	+	+
Directiveness	+	+++	++
Neutrality	+++	+++	+++
Time-limited	+++	+++	+++
Defence analysis	+++	+++ Schema/distortions	+
Transference	+++ Interpersonal	+	+++ patterns
Behavioural interventions	—	+++	+
Published manuals	+	++	++
Concurrent use of medication	++	+++	+++
Empirical research indicates efficacious treatments	+	+++	+++
Training in long-term dynamic psychotherapy helpful	+++	+	+++

While sharing many similarities, it is ultimately in the conception of the problem, the goals, and therapeutic interventions that these treatments differ. It is unclear to what extent behavioural changes may be attributed to the similarities or differences between treatments. All psychotherapies, including brief individual psychodynamic psychotherapy, interpersonal psychotherapy, and cognitive behavioural therapy teach new skills-problem-solving skills directed at how to resolve interpersonal and emotional problems when they arise. Differences among these psychotherapies in their interventions are more striking than the differences in their goals or the problem areas they identify for therapeutic work. In psychodynamic psychotherapy the structure of the session is determined by the flow of the patient's thoughts and their interaction with the therapist's interpretive comments. In contrast, cognitive and interpersonal psychotherapies use more directive, structured, and behavioural interventions. Whereas the brief individual psychodynamic psychotherapy like other psychodynamic psychotherapies relies on the patient to activate and practice new behaviours without direction. The therapist remains an empathic interpreter, a sharer of the patient's experience and perspective. While in other therapies, especially cognitive, the therapist may direct, prescribe, enjoin, educate, or role play.

Practical problems in brief psychodynamic psychotherapy

The choice of focus is perhaps the most important and the most difficult aspect of brief individual psychodynamic psychotherapy. It is helpful to identify several foci during the evaluation process, recognizing that there are inevitably several conflict areas active at any one time in a patient's life. Then the therapist can begin the process of thinking through what the treatment of each focus would entail (Table 6.3.4.4).

The therapist can begin to decide which focal conflict will be more difficult to reach in a brief period of time, which will threaten the therapeutic alliance more and therefore require a deeper working relationship that may take more time, and which focus requires interpreting more primitive defences and therefore may be more complicated.

Choice of a particular focus can also create more family or external disruption or support which can aid or disrupt the treatment.

Use of medication requires carefully explaining to the patient the relationship of the medication to the psychotherapy. Often the medication treatment will continue beyond the psychotherapy.

Table 6.3.4.4 Identifying and selecting the focal conflict in brief dynamic psychotherapy

Identifying the focal conflict
Explore
Precipitant of symptoms
Early life traumas
Repetitive patterns of behaviour
Listen for inhibitions/avoidance
Watch for conflicts about success as well as loss/failure
Selection among several foci
Choose the focus that is presently active
Use trial interpretation to identify active focus
Select focus related to only one transference figure

If repeated complicated medication alterations are needed or if serious side effects of the medication occur, the psychotherapy plan may have to be altered to allow time to understand them from the patient's perspective.

New therapists are often concerned about setting the date of termination at the time of the evaluation, fearing that they may not be able to complete the work by the deadline. Supervision with an experienced colleague can be very helpful to assure confidence and avoid mistakes that may lengthen the treatment. Alternatively, the new therapist may feel too much relief in setting the termination date when treating a very dependent patient and therefore miss the intensity with which the patient is attached and experiencing the therapist as an important, needed, or feared figure from the past.

The management of missed sessions should be made clear at the beginning of treatment. Usually it is best not to 'make up' the sessions, but to keep to the termination date. If the therapist is concerned about this as a potential issue in the treatment, the therapist may wish to plan several additional sessions in the overall treatment to assure this can be discussed and understood therapeutically. Of course if an emergency arises it is always appropriate to schedule appointments as needed for the health and safety of the patient.

The patient who 'divulges' new 'secret' information near the end of the treatment is a challenge to all therapists. Understanding to what extent this represents narcissistic, or sociopathic issues, fear of the therapist or the treatment, or the emergence of hope for the future or a transference enactment will determine how to respond.

Brief individual psychodynamic psychotherapy is best learned in conjunction with the skills of longer term psychodynamic psychotherapy. In the longer work, the therapist will be able to see more easily the possible conflict areas and think about the sequencing of the treatment of these, i.e. which is closer to the patient's awareness or which is more defended. In addition there is more time to correct errors and repair untoward events in the therapeutic relationship. The brief individual psychodynamic psychotherapist will have less time to correct mistakes and must more quickly identify conflict areas and assess their relative importance and potential for resolution through treatment.

Efficacy: research and evaluation

The brief psychodynamic treatments have a small empirical database. Much further research is needed.[31] In general, studies have supported the efficacy of this treatment approach. However, methodological issues are prominent in most research in this area. The development of handbooks for treatment has gone far in improving research in the psychoanalytically oriented brief treatments.[19,32–34]

The effectiveness of psychotherapy in general, is not argued as in the past.[8,35–37] Brief psychodynamic psychotherapy has been shown to have an effect size similar to many other medical treatments. Short-term psychodynamic psychotherapy has shown modest to moderate, often sustained gains for a variety of patients.[38] However, the question of which psychotherapy is suitable for which patient and by which therapist is still unclear. The cost-effectiveness of psychotherapeutic treatment remains hotly debated and is a focus of substantial research.[9,39,40] Individual psychotherapy has been shown to result in fewer days of hospital stay for patients on medical or surgical services of a general hospital. In health clinics

or health maintenance organizations, brief psychotherapy decreases the number of visits to primary health care providers, reduces the number of laboratory and radiographic studies, decreases the number of prescriptions given, and, overall, reduces direct health care costs. Recently summaries of the cost-offset effects of outpatient mental health treatment, the majority of which were short-term are hopeful but not unambiguous. One study found outpatient psychotherapy resulted in a 33 per cent average reduction in medical care utilization. Furthermore, these reductions occurred mostly in the more expensive, inpatient medical services. In another study, 72 patients with significant emotional problems and treated only by internists in a general medical clinic were compared with 62 patients who, in addition to being treated by internists for medical problems, received 10 weekly psychotherapy visits. Both groups had approximately an equal degree of emotional disturbance. At 4-month and 1-year follow-ups, the brief psychotherapy group reported significantly more global improvement than the non-psychotherapy group. Also, more patients in the brief psychotherapy group became employed at 1-year follow-up than in the non-psychotherapy group. This study suggests specific beneficial effects of brief psychotherapy when used in a medical setting by skilled psychotherapists. Combining psychotherapy with antidepressant medication has also been shown to give the best outcome at 1 year when compared to either treatment alone. Whether a therapist keeps to a consistent frame of reference in the treatment may also be a predictor of success if brief individual psychodynamic psychotherapy, regardless of what that perspective is.[41]

Malan's finding of the importance of making the transference-parent link for the successful outcome of treatment is significant and requires further exploration.[2] One reanalysis of Malan's data confirmed his finding and one did not.[42] In addition, one replication of this finding has been published.[43] Importantly, more recently, the overuse of transference interpretations has been shown to lead to poorer outcome. The therapeutic alliance, particularly when measured from the patient's perspective, has a consistent although modest contribution to outcome.[9,44] It has been shown that independent of the type of treatment and early clinical improvement, the therapeutic relationship contributes directly to the positive therapeutic outcome.[45]

The quality of the therapeutic interaction and the handling of the transference and countertransference appears to be critical to success or failure in brief individual psychodynamic psychotherapy.[34] Patients treated by therapists who have not been professionally trained, may, on average, be as improved as patients treated by professional brief dynamic therapists. However, such non-experienced therapists run out of relevant material and are unwilling to continue to treat patients over an extended period of time.[46] One of the important tasks of training in psychotherapy may be the development of the ability to 'endure' with the patient and, over time, with numbers of patients. Technical training and a theoretical framework may allow the therapist to maintain a sense of competence, direction, and interest in the work which the non-professional therapist cannot.

Interpersonal psychotherapy and cognitive-behavioural therapy have been much more extensively studied than dynamic psychotherapy, particularly in combination with medications. Recently, telephone psychotherapy with cognitive behavioural therapy in primary care settings when initiating antidepressant medication has been shown to improve clinical outcome.[47,48] To the extent that these treatments share techniques and outcomes, similar results might be expected with brief dynamic psychotherapy; however, this still needs to be shown. Focal directive psychotherapies generally appear to be more effective than traditional unstructured psychodynamic psychotherapy for a number of types of patients, but a delineation of which psychotherapy for which patient over what time and with which medication remains to be demonstrated. Good clinical sense dictates combined treatments with matching the patient's cognitive and affective style with treatment type and making medication compliance a focus of any psychotherapy. Additionally, further research of brief psychodynamic psychotherapies in specific psychiatric disorders as well as across the life span are needed.[49,50]

Conclusion

Brief dynamic psychotherapy is an important treatment for numerous disorders, primarily the adjustment, anxiety, and mood disorders. Both alone and in combination with medication brief dynamic psychotherapy is an effective part of the treatment armamentarium. Clinicians should be trained in the brief as well as the longer term treatments and their use as brief, intermittent, and maintenance treatments. Skill in the longer term psychotherapies is important to developing skill in the brief dynamic psychotherapy where the needs for rapid establishment of the therapeutic alliance and the accurate assessment of transference and defence patterns are important.

Empirical studies comparing well-defined brief dynamic psychotherapy with cognitive and interpersonal psychotherapies are limited. Future research must address which form of brief psychotherapy may be most helpful for which patient. An individual's preferred learning path-what he or she may see and observe most easily such as thoughts or feelings or interpersonal relations-may be an important variable in determining which brief psychotherapy for which patient. State, trait, and contextual variables will influence this learning modality. The process of change in brief individual psychodynamic psychotherapy, a process of altering neuronal organization through verbal means, is influenced by the patient's diagnosis, medications, past history, cognitive style, developmental stage, and affective availability, as well as the doctor–patient match.

6.3.5 Psychoanalysis and other long-term dynamic psychotherapies

Peter Fonagy and Horst Kächele

Introduction

Basic assumptions

The term psychodynamic psychotherapy has no specific referent. It denotes a very heterogeneous range of psychological treatment approaches which arguably have in common an intellectual heritage of psychoanalytic theory. Psychoanalytic theory itself is no longer based on a unitary body of ideas[1] but a number of ideas appear to be core to most psychodynamic approaches. These notions are:

(a) A shared notion of psychological causation, that mental disorders can be meaningfully conceived of as specific organizations of an individual's conscious or unconscious beliefs, thoughts, and feelings.

(b) Psychological causation extends to the non-conscious part of the mind, and to understand conscious experiences, we need to refer to other mental states of which the individual is unaware.

(c) The mind is organized to avoid unpleasure arising out of conflict[2] in order to maximize a subjective sense of safety.[3]

(d) Defensive strategies are a class of mental operations that seem to distort mental states to reduce their capacity to generate anxiety, distress, or displeasure. Individual differences in the predisposition to specific strategies have often been used as a method for categorizing individuals or mental disorders.[4,5]

(e) Varying assumptions are made concerning normal and abnormal child and adolescent development but therapists are invariably oriented to the developmental aspects of their patients' presenting problems.[6]

(f) Relationship representations linked with childhood experience are assumed to influence interpersonal social expectations including the transference relationship with the therapist[7] and to shape the representations of the self.[8–11]

(g) These relationship representations inevitably re-emerge in the course of psychodynamic treatments.[12]

Brief overview of theories

Psychoanalytic theory has evolved from the work of Freud following two broadly separate paths which converged over the past 25 years only to separate again. In the United States followers of the Vienna school in the 1950s and 1960s evolved a systematic psychology of the ego, a conflict-oriented complex psychological model of the mind and its disturbances.[13] In Europe, only Anna Freud and her followers in London pursued this tradition of psychoanalytic thought.[14] Based on the Berlin school of Karl Abraham, Melanie Klein and her followers established a distinct approach focusing on the understanding of disturbance rooted in infantile destructiveness and sadism.[15] Some psychoanalysts, influenced by Klein and the idea of the pathogenic nature of the experiences of infancy, gradually discarded the mechanistic psychology of drives and psychology of internal structures in favour of theories of intrapsychic interpersonal relationships (object-relations theory).[16]

As these schools developed in the United Kingdom, their influence travelled across the Atlantic. First, Kohut, strongly influenced by Winnicott (albeit without explicit acknowledgement), evolved a psychoanalytic psychology of the self.[17] Shortly after, Kernberg arrived at an imaginative integration of ego-psychological and Kleinian ideas.[18] In the meantime, in the United Kingdom, the Kleinian movement rapidly progressed in their understanding of psychoanalytic clinical experience, moving beyond Klein's original work and integrating some of the key features of the Anna Freudian and the British object-relations traditions.[19] In the United States, disillusionment with the false certainty provided by ego-psychology became intense throughout the late 1970s and early 1980s and a radical change in psychoanalytic thinking took place with the emergence of the interpersonal relational perspective, which is in part rooted in the work of Harry Stack Sullivan.[20,21] The relational psychoanalysis of the 1980s and 1990s consolidated several lines of thought initiated by justified critiques of traditional analytic theory[22]; including feminism, the hermeneutic-constructivist critique of the analyst's authority, infancy research, and, closely related to this, the intersubjectivist-phenomenological philosophy of mind—as well as a general political movement to improve and democratize access to analytic ideas and training.[23]

There are many other new psychoanalytic theoretical approaches, bringing the field increasingly close to total fragmentation.[24] This is because the emergence of new approaches in no way signals the demise of any previous orientations, most of which continue to enjoy considerable popularity among specific groups of psychoanalysts.

Psychoanalytic therapy as treatment

The history of psychoanalysis as a therapeutic approach is rather different. Broadly speaking, it may be argued that psychoanalysis and other long-term psychodynamic therapies are predominantly verbal, interpretive, insight-oriented approaches which aim to modify or re-structure maladaptive relationship representations. It is implicitly assumed that genetic and early environmental factors give rise to partial, unintegrated, and generally troublesome relationship representations (e.g. a helpless 'infant' requiring total care from an adult, a self with exaggerated sense of power, and entitlement requiring constant confirmation from outside) that lie at the root of psychological disturbance. It is believed that the integration of these partial representations into more complex schemata, primarily but not exclusively through the use of insight, leads to improved internal and social adjustment.

Psychoanalysis is the most intensive form of these long-term therapies. The analysand attends treatment three or more times a week over a period of years. The use of the couch and the instruction to the analysand to free associate have been considered hallmarks. The distinction between psychoanalysis and other forms of psychotherapy is normally made in terms of the frequency of

sessions rather than in terms of the therapeutic stance of the analyst. It is difficult to avoid the conclusion that in the absence of plausible, theoretically based criteria for what is or is not psychoanalytic, against the background of an overwhelming diversity of theoretical frameworks, psychoanalysts have attempted to find common ground in readily identifiable treatment parameters. This problem arises as a consequence of an extremely loose relationship between psychoanalytic theory and clinical practice.[24] It is an indisputable fact that, whereas theory has evolved extremely rapidly in the last half of the twentieth century and continues to change, psychoanalytic practice has, until recently, changed surprisingly little and continues to provide the core of the psychoanalytic identity. On the other hand, the follow-along study by Sandell *et al.*[25] found that psychoanalysis and psychoanalytic psychotherapy were 'separate things'. When psychotherapy was performed using mainly psychoanalytic techniques, it was less effective than psychotherapy performed with modified and adjusted techniques (that is, not performed as an 'as-if analysis'). The findings from the Stockholm study suggest that psychoanalysis and psychoanalytic psychotherapy may be separate endeavours, although how exactly they differ is far from clear.

In this chapter we will not consider the theoretical richness of this field but instead will focus on the clinical constructs which run across the diverse intellectual approaches. The intersection of the two is perhaps clearest in one area which we shall consider in some detail—namely, the therapeutic action of long-term psychoanalytically oriented psychotherapeutic treatment.

Background

Historical development of the psychoanalytic approach to treatment

As is well known, Freud's discovery of the talking cure[26] was really that of an intelligent patient (Anna O) and her physician (Breuer). The patient reported that certain symptoms disappeared when she succeeded in linking up fragments of what she said and did in an altered state of consciousness (which we might now call dissociative) with forgotten impressions from her waking life. Breuer's remarkable contribution was that he had faith in the reality of the memories which emerged and did not dismiss the patient's associations as products of a deranged mind. The patient's response to treatment was probably less complete than Breuer and the young Freud had hoped[27] but the 'treatment' defined the basic elements of the 'cathartic' method-linking memory of trauma (the circumstances of her experience of her father's death) to her many symptoms.

At first Freud rigorously pursued the traumatogenic origins of neuroses. Later, when confronted by evidently incorrect statements, he modified his theory, assuming consistency between recollection and childhood psychic reality rather than physical reality.[28] The issue of accuracy of memories of childhood sexual trauma remains controversial, although its relevance to psychoanalytic technique is at best tangential.[29] Freud's technique, however, was dramatically modified by his discoveries. The intense emotional relationship between patient and physician, which had its roots in catharsis following hypnotic suggestion, had gradually subsided into what was principally an intellectual exercise to reconstruct the repressed causes of psychiatric disturbance from the fragments of material derived from the patient's associations. It was a highly mechanistic approach reminiscent of a complex crossword puzzle. In the light of therapeutic failures, however, Freud once more restored the emotional charge into the patient–physician relationship.[30] However, in place of hypnosis and suggestion, he used the patient's emotion, signs of transference of affect and affective resistance which were manifest in the analytic relationship. Instead of seeing the patient's intense emotional reaction to the therapist as an interference, Freud came to recognize the importance of transference as a representation of earlier relationship experiences which could make the reconstruction of those experiences in analysis highly meaningful to that individual.[31]

Freud's early clinical work evidently lacked some of the rigour which came to characterize classical psychoanalysis.[32] His occasional encouragement to his patients to join him on holiday might now be considered a boundary violation.[33] What is perhaps less well known is that Freud remained somewhat sceptical about the effectiveness of psychoanalysis as a method of treatment.[34] Indeed, autobiographies of some of his patients testify to his great flexibility as a clinician and use of non-psychoanalytic techniques, including behavioural methods.[35] Nor was Freud the only clinician to use psychoanalytic ideas flexibly. The Hungarian analyst Sandór Ferenczi should be credited with the discovery of the treatment of phobic disorders by relaxation and exposure[36] although many of his well-intentioned actions were criticized by contemporaries and more recently on arguable ethical grounds.[37]

The technique of psychoanalysis after Freud's death came to be codified. Those (such as Alexander and French and Freda Fromm-Reichmann) who attempted to revive or retain Freud's original clinical flexibility were subjected to powerful intellectual rebuttals.[38] In reality, psychoanalysts probably continued to vary in the extent to which they observed the ideals of therapeutic neutrality, abstinence, and a primarily interpretive stance, but these deviations could no longer be exposed to public scrutiny for fear of colleagues' forceful condemnation. Personal accounts of analyses with leading figures yield fascinating insights into variations in technique, principally in terms of the extent to which the analyst made use of a personal relationship.[39] There has been an ongoing dialectic throughout the history of psychodynamic approaches between those who emphasize interpretation and insight and those who stress the unique emotional relationship between patient and therapist as the primary vehicle of change. The controversy dates back to disputes concerning the work of Ferenczi and Rank[40] but re-emerged with the first papers of Balint and Winnicott in London opposing a Freudian and Kleinian tradition, and somewhat later in the United States with Kohut and more subtly Loewald opposing classical ego psychology.

In the last two decades, the pluralistic approach of modern psychoanalysis has brought out into the open many important dimensions along which psychoanalysts' techniques may vary. In particular, the recent trend to consider analyst and patient as equal partners engaged in a mutual exploration of meaning[41] directly challenged many of the classical constructs. The emphasis on the mutual influence of infant and caregiver shaped the emerging relational model of therapy as a two-person process in which there was little room for a detached analyst with pretensions of 'objectivity'. Drawing on the assumption that humans are predisposed towards two-person co-constructed systems that provide a context for psychic change, the quality of engagement

between therapist and patient became the core of therapeutic action. What changes the mind is not the insights gained but learning from the interactional experience of being with another person. Neither the analyst nor the patient can be considered as forging meaning; rather, meaning is co-constructed.

Technique—principal features

Neutrality and abstinence

Based in the classical framework of libidinal theory, Freud made an explicit injunction against the analyst giving in to the temptation of gratifying the patient's sexual desire.[42] Obviously, this is primarily an ethical issue. However, within the psychoanalytic context it also justifies the analyst's stance of resisting the patient's curiosity or using the therapeutic relationship in any way that consciously or unconsciously could be seen as motivated by the need to gratify their own hidden desires. Within this classical frame of reference, the patient must also agree to forgo significant life changes where these could be seen as relevant to current psychotherapeutic work. In practice, such abstinence on the part of the patient is rare. Yet long-term psychodynamic treatment may founder if the emotional experiences of the therapy are obscured by the upheavals of significant life events.

The primary function of abstinence is to ensure the neutrality of the therapist. The analyst assumes an attitude of open curiosity, empathy, and concern in relation to the patient. The therapist resists the temptation to direct the patient's associations and remains neutral irrespective of the subject matter of the patient's experiences or fantasies. While it is easy to take this issue too lightly, (and it is perhaps this aspect of the psychoanalyst's therapeutic stance which makes them most vulnerable to ridicule), it is probably genuinely critical for the therapist to retain emotional distance from the patient to a degree which enables the latter to bring fantasies and fears of which they feel uncertain. Nevertheless, neutrality at its worst denies the possibility of sensitivity; recent literature on the process and outcome of psychotherapy makes it clear that the therapist's genuine concern for the patient must become manifest if significant therapeutic change is to be achieved.[43] The quality of the alliance is one of the better predictors of outcome[44] and alliance is impacted by the patient's attachment style and quality of object-relations.[45]

Mechanisms of defence

The term 'psychic defences' may risk reification and anthropomorphism (precisely who is defending whom against what?) yet the existence of self-serving distortions of mental states relative to an external or internal reality is generally accepted, and frequently demonstrated experimentally.[46–48] Within classical psychoanalytical theory and its modern equivalent (ego psychology), intra-psychic conflict is seen as the core of mental functioning.[49] Here defences are seen as adaptations to reduce conflict. Within many object-relations theories, defences are seen as helpful to the individual to maintain an authentic or 'true' self-representation or a nuclear self.[17] Models of representations of relationships are of course often defensive. Traumatic experiences may give rise to omnipotent internal working models to address a feeling of helplessness. Within attachment theory, defences are construed as assisting in the maintenance of desirable relationships.[50] The Klein–Bion model makes limited use of the notion of defence mechanisms but uses the term in the context of more complex hypothetical structures called defensive organizations.[19] The term underscores the relative inflexibility of some defensive structures, which are thus best conceived of as personality types. For example, narcissistic personality disorder combines idealization and destructiveness; genuine love and truth are devalued. Such a personality type may have been protective to the individual at an earlier developmental stage, and has now acquired a stability or autonomy which must be rooted in the emotional gratification which such a self-limiting form of adaptation provides.[51]

Irrespective of the theoretical frame of reference, from a therapeutic viewpoint clinicians tend to differentiate between so-called primitive and mature defences based on the cognitive complexity entailed in their functioning.[52] In clinical work, primitive defences are often noted together in the same individual. For example, individuals loosely considered 'borderline' tend to idealize and then derogate the therapist. Thus they maintain their self-esteem by using splitting (clear separation of good from bad self-perception) and then projection. Projective identification[53] is an elaboration of the process of projection. An individual may ascribe an undesirable mental state to the other through projection but when the other can be unconsciously forced to accept the projection and experience its impact, the defence becomes far more powerful and stable. The analyst's experiencing of a fragment of the patient's self-state, has in recent years been considered an essential part of therapeutic understanding.[54]

Whether in fantasy or in actualized form, through projective identification the patient can experience a primitive mode of control over the therapist. Bion argued that when the self is experienced as being within another person (the therapist) the patient frequently attempts to exert total control over the recipient of the projection as part of an attempt to control split-off aspects of the self. Bion[55] also argued that not all such externalizations were of 'bad' parts of the self. Desirable aspects of the self may also be projected, and thus projective identification can be seen as a primitive mode of communication in infancy. There are other aspects of projective identification which we commonly encounter clinically. These include the acquisition of the object's attributes in fantasy, the protection of a valued aspect of the self from internal persecution through its evacuation into the object, and the avoidance or denial of separateness. It is thus a fundamental aspect of interpersonal relationship focused on unconscious fantasy and its appreciation is critical for the adequate practice of long-term psychotherapy.[56]

Classifications of defences have been frequently attempted[52,57–61] and often as a method for categorizing individuals or mental disorders.[4,5] An attachment theory-based classification rooted in the notion of habitual deactivation or hyperactivation of the attachment system ('attachment style') has achieved general acceptance.[62,63] Deactivating ('avoidant' or 'dismissing') strategies include suppression of ideas related to painful attachment experiences, repressing painful memories, minimizing stress and distress, segregated mental systems that result in the defensive exclusion of distressing material from the stream of consciousness.[64,65] Ingenious experimental studies have shown that individuals who habitually use avoidant defences are more efficient, when instructed, at suppressing conscious thoughts and associated feelings about a romantic partner leaving them for someone else[66] and are more likely to attribute their own unwanted traits to others

(projection) which serves to both increase self-other differentiation and enhance self-worth.[67] In a further, remarkable study the same group of researchers demonstrated that the above advantages of the suppression strategy of those using avoidant defence fall away in the laboratory situation if a cognitive load is placed on the participant which then leaves them literally defenceless so that they experience a heightened rebound of previously suppressed thought about painful separation.[68] The cognitive and socio-cognitive strategies associated with reducing anxiety or displeasure and enhancing safety, which both the attachment theory and psychoanalytic literatures tend to refer to as defences, are perhaps better thought of not as independent classes of mental activity or psychological entities but as a pervasive dynamic aspect of complex cognition interfacing with attachment relationships and emotional experience. Some mechanisms of defence are thought to be more characteristic of the less severe psychological disorders (e.g. depression, anxiety, obsessive–compulsive disorders, etc.). It is beyond the scope of this chapter to consider the various defence mechanisms in detail.

Modes of therapeutic action

The primary mode of the therapeutic action of psychoanalytic psychotherapy is generally considered to be insight.[69] Insight may be defined as the conscious recognition of the role of unconscious factors on current experience and behaviour. Unconscious factors encompass unconscious feelings, experiences, and fantasies. The psychodynamic model has been seen as a model of the mind that emphasizes repudiated wishes and ideas which have been warded off, defensively excluded from conscious experience. In our view this is a narrow and somewhat misleading way to define the therapeutic mechanism for approaches that are considered as psychodynamic. The psychodynamic approach is better seen as a stance taken to human subjectivity that is comprehensive, and aimed at understanding all aspects of the individual's relationship with her or his environment, external, and internal. Freud's great discovery ('where id was, there ego shall be', Freud[70] p. 80), often misinterpreted, points to the power of the conscious mind radically to alter its position with respect to aspects of its own functions, including the capacity to end its own existence through killing the body. Psychodynamic, in our view, refers to this extraordinary potential for dynamic self-alteration and self-correction—seemingly totally outside the reach of non-human species. Engaging with this potential to bring change through understanding, is the science and the art of the psychodynamic clinician.

Conscious insight is more than mere intellectual knowledge[71,72] or descriptive insights. Prototypically, psychodynamic therapy achieves demonstrated or ostensive insights which represent a more direct form of knowing, implying emotional contact with an event one has experienced previously. Working with what is non-conscious is at the heart of the dynamic approach to bringing about psychological change because of the force that awareness of unconscious expectations can bring to the interpretation of behaviour. Although specific formulations of the effect of insight depend on the theoretical framework in which explanations are couched, there is general agreement that insight has its therapeutic effect by in some way integrating mental structures.[72] Kleinian analysts[73] tend to see the healing of defensively created splits in the patient's representation of self and others as crucial. Split or part-objects may also be understood as isolated representations of intentional beings whose motivation is insufficiently well understood for these to be seen as coherent beings.[74] In this case insight could be seen as a development of the capacity to understand internal and external objects in mental state terms, thus lending them coherence and consistency.[75] The same phenomenon may be described as an increasing willingness on the part of the patient to see the interpersonal world from a third person's perspective.[76]

A simple demonstration to the patient of such an integrated picture of self or others is not thought to be sufficient.[31] The patient needs to 'work through' a newly arrived integration. Working through is a process of both unlearning and learning: actively discarding prior misconceptions and assimilating learning to work with new constructions. The technique of working through is not well described in the literature, yet it represents the critical advantage of long-term over short-term therapy.[77] Working through should be systematic and much of the advantage of long-term treatment may be lost if the therapist does not follow through insights in a relatively consistent and coherent manner.

In contrast to the emphasis on insight and working through are those clinicians who, as we have seen, emphasize the 'relationship aspect' of psychoanalytic therapy (Balint, Winnicott, Loewald, Mitchell, and many others). This aspect of psychoanalytic therapy was perhaps most eloquently described by Loewald when he wrote about the process of change as: 'set in motion, not simply by the technical skill of the analyst but by the fact that the analyst makes himself available for the development of a new 'object-relationship' between the patient and the analyst . . . '(Loewald, 1960, pp. 224–5).[78] Sandler and Dreher[79] have recently observed 'while insight is aimed for it is no longer regarded as an absolutely necessary requirement without which the analysis cannot proceed'. There is general agreement that the past polarization of interpretation and insight on the one hand, and bringing about change by presenting the patient with a new relationship on the other, was unhelpful. It seems that patients require both, and both may be required for either to be effective.[80]

Controversy remains even if all accept that neutrality is an impossible and undesirable fiction and that patient and therapist affect each other in myriad mutually influencing ways. Projective identification is seen as occurring in a bidirectional interpersonal field between analyst and patient—a model clearly adapted from Kleinian approaches to infant-caregiver interaction.[23] If we take this perspective seriously, we have to concede that all analytic interventions change the situations into which they are introduced, and their content and style always reflect the analyst's countertransference/response to the treatment situation.[81] Relational psychoanalysis advocates making the interactional influence of analyst upon patient explicit. As Levenson[82](p. 9) put it, the key therapeutic question is not 'what does this mean?' but rather 'what is going on around here?' The therapist will 'act' on the patient; this is not a therapeutic disaster but rather a potentially progressive and certainly inevitable part of the process.

It has been suggested that change in analysis will always be individualized according to the characteristics of the patient or the analyst.[83] For example, Blatt[84] suggested that patients who were 'introjective' (preoccupied with establishing and maintaining a viable self-concept rather than establishing intimacy) were more responsive to interpretation and insight. By contrast, anaclitic patients (more concerned with issues of relatedness than of self-development) were more likely to benefit from the quality of

the therapeutic relationship than from interpretation. Taking a second look at large-scale outcome investigations Blatt found strong evidence for the oft made but rarely demonstrated claim of patient personality—therapeutic technique fit.[85]

Indications and contraindications and selection procedures

Medical treatments normally have indications and contraindications. In psychodynamic treatment the term 'suitability' indicates a looser notion of the appropriateness of the approach.[86] Nevertheless, based primarily on clinical experience, some writers have arrived at specific criteria for long-term psychodynamic therapy.[87] Some authors have also suggested relatively systematic methods of assessment yielding both diagnostic and prognostic information.[88] The majority of psychodynamic clinicians, however, rely on clinical judgements based on interpersonal aspects of their first meeting with the patient.[71] The three areas of assessment are personal history, the content of the interview, and the style of the presentation.

A history of one good relationship has been traditionally regarded as a good indicator.[89] By contrast, a history of psychotic breakdown, severe obsessional states, somatization, and lack of frustration tolerance are generally considered contraindications. For example, a challenging set of re-analyses of the Treatment of Depression Collaborative Research Program found that the trait of perfectionism was associated with poor outcome, and could undermine the therapeutic alliance and the patient's satisfaction with social relations, limiting their improvement in the course of brief treatment for depression.[90]

Empirical literature, to the meagre extent that this is available, suggests that many of the presuppositions about suitability are unfounded. It was, for example, assumed that patients who manifested more serious mental illness, especially disturbances in reality testing, were unsuitable for psychoanalysis; however, a recent study showed that some patients with serious disturbances in reality testing were able to benefit from psychoanalysis when their analysts were able to tolerate and analyse this level of psychopathology.[91] What does seem to be consistent is that severity of symptoms, as well as functional levels in work and relationships, are correlated with the outcome of psychotherapy[92]—although no single patient variable is a strong predictor of outcome. This is why the effects of psychotherapy, good and bad, can sometimes be surprising.

Predicition based on the content of assessment interviews is hard. In general, the presence of some kind of 'mutuality' between therapist and patient is a positive indicator. Some clinicians offer 'trial interpretations' which summarize their initial impressions, and a positive thoughtful response to these is regarded a good indication. The capacity to respond emotionally within the assessment session is a further indicator.[93] Motivation for treatment is harder to ascertain. Most patients express enthusiasm for the treatment, which falls away once they are asked to confront unpleasant or unflattering parts of themselves.

More recently, psychodynamic therapists have given increasing consideration to the style of the patient's discourse during assessment rather than its content. Holmes,[94] for example, attempts to identify whether patients' narrative styles are avoidant (sparse and dismissing of interpersonal issues) or enmeshed and entangled (excessive current anger about past hurts and insults). The findings of one study indicate that, in a severely personality disordered population at least, the avoidant type of patient has a better prognosis in psychodynamic therapy.[95] A further relevant capacity is reflective function or mentalization, often reflected in narrative; this has been variously described as seeing oneself from the outside,[96] reflecting on one's inner world[87] or having fluidity of thought.[97]

Managing treatment

Starting treatment

(a) Establishing parameters

Most psychodynamic therapists, explicitly or implicitly, convey objectives and expectations to their patients. The details of this agreement normally include arrangements for a time and a place as well as the length and frequency of sessions. Usually a tentative idea is offered as to the likely duration of therapy: 'It is likely to take years rather than months.' Most therapists also describe the expected behaviour of the patient and the therapist: 'I would like you to be as open and honest with me as possible and say absolutely everything that comes into your mind. This is the fundamental rule.' In fact it is very likely, in view of the variety of such agreements that tend to be made, that its emotional context is more relevant than the specific items agreed upon. Such a 'contract' implies recognition by both patient and therapist that the process of therapy needs protecting and that it is important enough to require a sacrifice from both parties.

In the treatment of severe personality disorders, contracts may have an additional important function—that of protecting the therapy from incessant enactments, self-harming, parasuicidal gestures, and so on. In Kernberg's approach to the treatment of borderline patients, the patient formally undertakes not to seek the therapist's help outside of office hours, not to engage in acts of violence and to deal with self-destructive acts through normal medical channels.[98] Whilst such agreements are commonly made in long-term therapy, it is by no means clear that they are either essential or useful. For example, in an alternative form of psychodynamic therapy, Mentalization-Based Treatment (MBT), contracts are not recommended.[99]

(b) Formulation of patients' problems

An important part of initiating any psychosocial treatment is arriving at least at a preliminary formulation of the patient's problems. In the case of psychodynamic therapies this represents a special challenge because of the diversity of the possible theories to draw on. In principle, psychodynamic formulations would identify key unconscious conflicts, central maladaptive defences, unhelpful unconscious fantasies and expectations, deficits in personal development, and so on. The complexity of such formulations is such that agreements are hard to arrive at even when clinicians follow similar orientations. In the absence of a generally accepted format for formulating the patient's problems, a list of key parameters for the level of maturity of personality organization may be offered:

(a) the maturity of relationship representations (three or more persons versus just a self-other dimension)

(b) the maturity of psychic defences (primarily based on projective versus internalizing processes)

(c) the extent of whole as opposed to part object-relations (e.g. whether a person is represented as performing more than a single function for the patient)

(d) the general mutuality of the relationship patterns described; the quality of attachment to others.

It should be noted that psychodynamic formulations tend to change as treatment progresses. Indeed, Winnicott described psychoanalysis as 'an extended form of history taking'.[100] Within certain psychodynamic approaches formulation is communicated formally to patients (e.g. by letter in cognitive analytic therapy Ryle[101]).

The middle phase

(a) Supportive and directive interventions in psychodynamic therapy

Supportive techniques are used both explicitly and implicitly in psychodynamic treatment. They include offering explicit support and affirmation; offering reassurances concerning, for example, irrational anxieties about the therapeutic arrangements; expressing concern and sympathy to a patient who has suffered a recent loss; and general empathy for the patient's anxieties and struggles with the treatment.[102]

From a psychodynamic point of view, such supportive interventions are by no means straightforward. For example, Feldman[103] illustrated how patients may sometimes experience the therapist's submission to a demand for reassurance as a source of anxiety rather than comfort. They may be unconsciously aware that the therapist's true stance is not compatible with reassurance and therefore face anxieties about the therapist's weakness in allowing themselves to be manipulated. By contrast, Kohut's[17] emphasis on interpersonal empathy was probably a welcome antidote to the somewhat rigid interpretive stance of American ego psychologists, particularly for those whose history of psychosocial deprivation meant that they had experienced little by way of genuine warmth or concern in the past.

The most common use of supportive and directive techniques in psychodynamic psychotherapy are in the service of the therapy itself. Elaborative techniques (e.g. the simple question: 'Could you tell me more?') are undoubtedly directive in specifying a topic of interest, but at the same time may be crucial antecedents to interpretive work. Clarification stands in between supportive and interpretive interventions. It is a restatement in the therapist's words of the patient's communication. It may also be crucial in offering a verbal (symbolic) label for a confused set of internal experiences which the patient is poorly equipped to represent coherently. Confrontation is also in between a directive and an interpretive approach. At its gentlest, confrontation may involve the therapist simply identifying an inconsistency in the patient's communication and bringing this to the patient's attention. For example: 'You seem to express no sadness about this loss, yet in the past you claimed to have cared a great deal for him'.

(b) Regression

An important facet of psychoanalysis and long-term psychodynamic therapy is the activation and exploration of parts of the patient's personality which may be normally hidden behind an over-riding demand to adapt to the demands of every day life. Access to these aspects of personality is achieved through the process of regression. It has been suggested that rather than encouraging regression, the process is best conceived of as inhibiting 'an anti-regressive function' in much the same way that certain intimate interpersonal experiences, large group situations, and alcohol appear to bring out the more infantile aspects of our character.[104] Some psychoanalysts consider regression to be crucial to successful psychoanalytic treatment, but others consider the concept and its clinical application outmoded and counterproductive.[105] The extent to which a particular treatment involves significant regression appears to be a function of the patient's personality as well as the therapist's particular approach. Fear of regression is an important source of resistance to long-term psychotherapy, particularly amongst those with previous experience of psychotic episodes.[104]

(c) Resistance

Resistance is inevitably encountered in any long-term psychodynamic treatment. In fact, the presence of resistance is implied by the term dynamic, which suggests psychic forces both pulling against and pushing towards change. Like regression, resistance fluctuates in the middle stage of treatment. In borderline and narcissistic disorders, the patient's intense resistance signals the patient's desperation to protect extremely fragile self-esteem. In less severe cases, what appears to be at issue is preventing a painful integration of experience, such as the integration of love and hate directed towards the same object.[106]

In clinical practice resistance takes a variety of forms. In repression resistance, the patient may experience a temporary difficulty in gaining access to particular ideas and feelings; for example, failing to remember dreams. In transference resistance the patient may appear to wish to keep their relationship with their therapist at an extremely superficial level. In a negative therapeutic reaction the increase of symptomatology occurs alongside therapeutic progress. In Freud's formulation this may be attributed to unconscious guilt. It is quite likely that in at least some patients this form of resistance against psychotherapy is part of a pervasive so-called 'envious' predisposition to eradicate any aspect of their life that they experience as 'good' but beyond their immediate control.[107]

(d) The experience of the transference

Patients may experience a whole range of feelings about an analyst including love, admiration, excitement or anger, disappointment, and suspicion. The feelings appear to have little to do with the therapist's actual personality as different patients are likely to bring quite disparate feelings about the same analyst at the same time. While clearly not realistic, the actual nature of transference experience and its use in therapy is quite controversial.[108] Object-relations theorists consider the analyst a vehicle onto which an internal object (a person, an aspect of a person, the self, or an aspect of the self) is projected.[109] Clearly internal objects are representations which are heavily distorted by both fantasy and defensive processes.

For John Bowlby[64] transference feelings are based on expectations gathered through past relationship experience with an attachment figure. Patients resist understanding of the past relationship by insisting on repeating it. Bowlby's[110] suggestion that therapists function as secure bases implies that psychodynamic therapists are, in part, conducting attachment therapy as inevitably they serve as attachment figures for their patients. There is accumulating evidence for this claim[111–114] with a number of studies linking specific

transference schemas and attachment.[115–117] Many analysts do not accept such an isomorphism between past and present. Rather, they see it as something which gives coherence to the patient's experience of the analytic relationship—an aspect of narrative rather than a representation of the historical realities of the patient's experience.[118] In contrast, analysts who work in the Klein–Bion frame of reference see transference as providing an inevitably accurate picture of the patient's current internal world.[119] For example, a transference where the analyst is idealized may reflect psychotic anxieties in the patient linked to an intensification of the death instinct. The idealization serves to protect both the patient and the analyst from fantasized destruction which threatens to engulf them both. Marcia Cavell[120] demonstrated that these alternative models of transference have their philosophical roots in the debate between correspondence and coherence models of truth.

There is significant debate regarding from what point and how much psychoanalytic therapists should work 'in the transference'. Some analysts are inclined to see transference as pertinent to every aspect of the psychoanalytic situation. For example, Joseph[119] considers the therapeutic situation in toto as mirroring the internal state of the patient. Thus the therapeutic alliance or the 'real relationship'[121] are regarded as subsumed under the transference relationship. In this context it makes little sense to interpret anything other than the transference from the very beginning of the analysis. By contrast, Strachey[122] understood transference as an attempted externalization of the patient's superego. Unlike other people in the patient's life, the analyst does not accept this externalization, whether it is idealized, denigratory, or judgemental. The analyst conveys his or her understanding of the externalization by a so-called 'mutative interpretation'. While Strachey implied that only interpretation of the transference is therapeutic, his view clearly admits other aspects of the therapeutic relationship. Other therapists, particularly Freudian psychoanalysts, regard transference interpretations as an important but not uniquely therapeutic way of providing the patient with insight and consider the almost exclusive reliance on understanding the patient through their thoughts and feelings about their therapists as unhelpful and even dangerous.[123] The only systematic investigation of this technical controversy, where patients were randomly assigned to a transference and a non-transference-oriented psychological therapy, could not show a significant difference between the overall effectiveness of these two treatments, although there was a tendency for those with more dysfunctional object-relationship representations to do better in therapy which used transference interpretations.[124,125]

The nature of the transference appears to systematically relate to specific clinical groups and hence may have an aetiological significance. For example, specific transference patterns appear to characterize particular groups of narcissistic patients.[17] The 'mirroring' transference is one where patients crave the approbation and admiration of the therapist. This may be a consequence of the failure of the original self-objects (parents) in their mirroring function. If this transference is undermined by premature interpretations, an opportunity for restoring self-esteem is lost. The 'idealizing' transference also enables the patient to address a deficiency in self-esteem by secretly identifying with the object of admiration (the analyst). If the analyst destroys this idealized image, within Kohut's framework, this is equivalent to a direct attack on the patient's self-regard. Other analysts would suspect that behind such an exaggeratedly positive image lies the patient's true image of the analyst as frustrating or inadequate, an image which is simply placed out of harm's way by the idealization. An interesting empirical study of clinicians' experience of the transference with personality disordered patients was reported from Drew Westen's laboratory.[115] The study identified five transference dimensions: angry/entitled, anxious/preoccupied, avoidant/counterdependent, secure/engaged, and sexualized which were associated in predictable ways with Axis II pathology and confirmed that the way patients interact with their therapists can provide important data about their personality, attachment patterns, and interpersonal functioning.

Commonly, transference includes an erotic component, regardless of the age or even the gender of the analyst.[126] Admitting to such feelings may border on the unacceptable for some patients. Attachment theorists may suggest that sexual fantasies are used in the service of obtaining the attention of an unresponsive attachment figure.[127] Eroticized transference, relatively common in severely traumatized patients, represents an expression of a need for sexual gratification which, in the context of the therapy, is not considered by the patient as unrealistic.[71] Some view this phenomenon as an indication of an immature mode of representing internal reality, where only the physically observable outcome is believed to be real.[128]

(e) Experience of the countertransference

Countertransference is a somewhat controversial concept in psychoanalytic clinical work. The therapist during the course of an intensive long-term treatment is likely to have a range of feelings which are related to the patient's current experience but which may serve to either illuminate or obscure this. Some countertransference experiences may be instances of projective identification and thus can be appropriately attributed to the patient,[129] whereas others are likely to be the analyst's neurotic emotional reactions to the patient's behaviour or the material he or she brings. For Freud,[130] countertransference was always of this latter type, a neurotic reaction which was likely to obstruct psychoanalytic treatment. It was not until Paula Heimann[131] pointed out that the analyst's feelings and thoughts could contain important clues about the patient's unconscious mental state that countertransference started to be seriously considered as part of the analyst's therapeutic armamentarium. Those following an interpersonalist tradition saw the recognition of the complementarity of the therapeutic relationship as highly appropriate. From this point of view, the assumption of perfect neutrality on the part of the analyst who is a participant as well as an observer is both an anathema and an anachronism.[132] The psychotherapeutic process is more accurately viewed as a complex mixture of complementary interpersonal processes which establish themselves in 'custom designed' configurations in each treatment.[133]

The therapist's feelings may be either complementary to or concordant with those of the patient.[134] Concordant countertransferences are the product of primitive, empathic processes within the therapist who 'feels' for the patient, who may unconsciously react to experiences implied but not yet verbalized by the patient; for example, inexplicable overwhelming sadness. Complementary countertransferences tend to occur when the patient treats the analyst in a manner consistent with interpersonal interactions within a past relationship. Most commonly this occurs when the patient treats the therapist as he or she experienced being treated as a child. This is known as the 'reverse transference'.[135]

The mechanisms of countertransference are poorly understood. To assert that countertransference functions via projective identification merely brings one poorly understood phenomenon to account for a second even less well understood one. Sandler[136] suggested that an instantaneous process of automatic mirroring of one's partner in an act of communication accounted for concordant countertransference. The process, which he termed primary identification, was non-conscious and could be brought into awareness only upon reflection. Recent work on the mirror neurone system[137,138] suggests that the fundamental mechanism that allows us to understand the actions and emotions of others involves the activation of the mirror neurone system for actions and the activation of visceromotor centres for the understanding of affect. An alternative account suggests that a secondary mode of encoding is available within language whereby the use of a language of pretend gestures at the phonemic, syntactic, or even semantic level enables the communicator to address directly the unconscious of the recipient of the communication.[139] In other words, anything that can be said in gestures may be communicated unconsciously through language, through phonemic distortion, intonation, and other paralinguistic features and picked up impressionistically by the therapist.

When either concordant or complementary countertransferences mobilize defensive processes within the analyst, countertransference is in danger of becoming disruptive to therapeutic understanding. The analyst may react by unconsciously withdrawing from the therapeutic relationship. For example, in the case of a concordant countertransference where the patient's feelings of inadequacy create a similar feeling in the analyst, the analyst's vulnerability in this area may lead him or her to become defensively angry or excessively motivated to demonstrate his or her efficacy. There may be no simple way of regulating such reactions and the only reasonable strategy might be to carefully monitor one's style of relating, noting anything that is unusual. A number of analysts have pointed to the importance of reflectiveness in this context.

Some feelings in relation to the patient are not provoked either by the patient's projections or the neurotic feelings these give rise to in the therapist. It required someone of the stature of Donald Winnicott[140] to make the self-evident observation that the provocative behaviour of certain patients (particularly those in the borderline spectrum) can lead to a normal reaction of 'objective hate'. These reactions are merely indications of the therapist's humanity. Analytic understanding of these sometimes intense reactions to patients helps, but models of countertransference ill-fit such experiences. The objective study of countertransference has had to wait for a recent ingenious methodological development from Westen's laboratory.[141] The Countertransference Questionnaire yielded eight clinically and conceptually coherent factors that were independent of clinicians' theoretical orientation: (i) overwhelmed/disorganized, (ii) helpless/inadequate, (iii) positive, (iv) special/overinvolved, (v) sexualized, (vi) disengaged, (vii) parental/protective, and (viii) criticized/mistreated. Countertransference patterns were systematically related to patients' personality pathology across therapeutic approaches, suggesting that clinicians, regardless of therapeutic orientation, can make diagnostic and therapeutic use of their own responses to the patient.

(f) Interpretation

Interpretive interventions are at the core of psychoanalytic and psychodynamic treatment. However, the importance of interpretation is often exaggerated in relation to other aspects of the therapy. It is a sobering reminder that follow-up studies of long-term psychodynamic therapies invariably demonstrate that patients remember their analyst not for their interpretive interventions, rarely remembering individual interpretations, but rather for their 'emotional presence', regardless of the analyst's therapeutic perspective.[142]

Interpretations may be classified according to the aspect of a conflict they aim to address: the defence, the anxiety, or the underlying wish or feeling. Similarly, the content of the interpretation may be used in classifying interpretations: whether it relates to external reality, the transference relationship, or childhood relationships. In principle, in the earliest phases of treatment interpretations relating to current events are most common and, as the treatment progresses, transference issues and the patient's past may increasingly take over as foci of analytic work. Interpretations should start with the patient's anxiety, by identifying the defence used by the patient to protect himself from repudiated wishes and affects. In reality, these are guidelines that are rarely followed in practice. For example, very long-term treatments tend to end up being principally supportive explorations of the patient's current experience.[143] Furthermore, interpretations of the distant past tend to be least helpful to individuals with severe personality disorders.[144] Working in the so-called 'here and now' is more effective with those patients whose representation of the past is unreliable and distorted.[145]

Steiner[146] distinguished analyst-centred from patient-centred interpretations. The former refers to comments on the patient's reactions in terms of what the patient thinks may be going on in the analyst's mind, while the latter directly addresses the analyst's perception of the patient's non-conscious mental state. In either case the patient is directly learning about how minds interact in the context of social relationships. The distinction is important since when patient-centred interpretations are used exclusively the therapist may appear to be persecutory and not to be cognizant of the patient's genuine difficulties in being in an intimate relationship with another person. Others have argued, that at least in the case of severe personality disorder, interpretations, if they were to have therapeutic value, should focus on the patient's understanding of thoughts and feelings in themselves or in others at the level of what was conscious rather than unconscious, what patients could discover for themselves rather what they received as a communication from a 'mind expert'.[147] This implies that interpretation of the transference is about helping the patient represent their own and their therapist's mental states in the treatment room in all their complexity but with a stance conveying enquiry and playful curiosity about something that is not readily knowable (the mental state of the other is always opaque) with the aim of making thinking about thoughts and feelings safe again rather than communicating powerful insights.

The idealization of the transference has led some therapists to neglect interpretation of the patient's behaviour outside of the therapy. Most clinicians now agree that a balance needs to be struck between these two approaches. Treatment which is over-focused on the transference becomes a claustrophobic enclave.[148] In certain instances, the direct communication of the therapist's experience of frustration (objective hate in Winnicott's terms) may help to break a rigid repetitive pattern in the therapy.[149] Disclosing the therapist's experience is one of the cutting edges of the relational

approach to psychodynamic therapy.[150] In cases where the therapeutic alliance falters, perhaps following an empathic failure on the part of the therapist, it turns out that the recovery of the alliance may have particular therapeutic value both in showing the possibility of repair[151] but also as an opportunity to understand misunderstanding, an ideal opportunity for the recovery of mentalization.[152]

Ending treatment

The ending of psychoanalytic therapy is often idealized in clinical descriptions. As there is little agreement on the goals of psychoanalytic therapy,[79] it is hardly surprising that there is little general agreement about when ending is appropriate. Desirable final outcomes are mostly stated in terms of the process of treatment and are thus mostly specified in theoretical terms (e.g. increased awareness of impulses and fantasies, a reintegration of aspects of the self lost through projective identification, the capacity to engage in self-analysis, etc.). All these, even if observable in the course of treatment, are only loosely related to the aims the patient might have in concluding a lengthy treatment process.

The patient's own goals tend to be outcome rather than process goals and are more easily defined: the decline of symptoms, improved relationships, greater well-being, increased capacity for work, higher self-esteem, a capacity for assertiveness. As such changes are clearly achievable without psychodynamic treatment, many psychodynamic clinicians erroneously regard such criteria for ending as superficial. Independent evidence will be required to show that the achievement of process aims results in a more permanent or general achievement of outcome aims, in order to validate process aims as an appropriate criterion for ending.

Ending itself, of course, is a process. There is significant disagreement between authors, however, as to its nature; it has been labelled among other things as a mourning,[153] a detachment,[71] and a maturation.[154] It is inevitable that there is disappointment and disillusionment at the ending of long-term therapy as what is achieved is never quite the same as what has been hoped for.[155] Also, the patient loses the object who has been available as a receptacle for projections.[146] It is not surprising then, that symptoms sometimes return, even if only briefly, as part of the process of termination and the full benefit is not seen until some months after termination.[25] There is general agreement, however, that with these unconscious issues worked through the ending of therapy requires no special form of intervention on the part of the therapist.

Efficacy

It is often said that there are no studies on the effectiveness of psychoanalysis and long-term psychodynamic psychotherapy. In fact, this is not true. There are a number of comprehensive reviews[156–160] and they tend to come to similar conclusions. There is considerable evidence for the effectiveness of psychoanalytic approaches but definitive randomized controlled trials of its efficacy are still lacking.

The Boston Psychotherapy study[161] compared long-term psychoanalytic therapy (two or more times a week) with supportive therapy for clients with schizophrenia in a randomized controlled design. On the whole clients who received psychoanalytic therapy fared no better than those who received supportive treatment. In a partial-hospital RCT[162,163] the psychoanalytic arm of the treatment included therapy groups three times a week as well as individual therapy once or twice a week over an 18 month period.

The Stockholm Outcome of Psychotherapy and Psychoanalysis Project[164–166] followed 756 persons who received national insurance funded treatment for up to 3 years in psychoanalysis or psychoanalytic psychotherapy. The groups were matched on many clinical variables. Four or five times weekly analysis had similar outcomes at termination when compared with one to two sessions per week psychotherapy. During the follow-up period, psychotherapy patients did not change but those who had had psychoanalysis continued to improve, almost to a point where their scores were indistinguishable from those obtained from a non-clinical Swedish sample.

The German Psychoanalytic Association undertook a major follow-up study ($n = 401$) of psychoanalytic treatments undertaken in that country between 1990 and 1993.[159,167] Between 70 per cent and 80 per cent of the patients achieved (average 6.5 years after the end of treatment) good and stable psychic changes according to the evaluations of the patients, their analysts, independent psychoanalytic and non-psychoanalytic experts, and questionnaires commonly applied in psychotherapy research. The evaluation of mental health costs showed a cost reduction through fewer days of sick leave during the 7 years following the end of long-term psychoanalytic treatments. In the absence of pre-treatment measures it is impossible to estimate the size of the treatment effect.

The Research Committee of the International Psychoanalytic Association recently prepared a comprehensive review of North American and European outcome studies of psychoanalytic treatment.[157] Four case record studies, 13 naturalistic pre-post or quasi-experimental studies, nine follow-up studies, and nine experimental studies were identified. In addition, six process-outcome studies were also reviewed. The committee concluded that existing studies failed to demonstrate unequivocally the efficacy of psychoanalysis relative to either alternative treatment or active placebo. Studies showed a range of methodological and design problems including absence of intent to treat controls, heterogeneous patient groups, lack of random assignments, failure to use independently administered standardized measures of outcome, etc.

Another overview[168] suggested that psychoanalytic treatments may be necessary when other treatments proved to be ineffective. The authors concluded that psychoanalysis appears to be consistently helpful to patients with milder disorders and somewhat helpful to those with more severe disturbances. More controlled studies are necessary to confirm these impressions. A number of studies testing psychoanalysis with 'state of the art' methodology are ongoing and are likely to produce more compelling evidence over the next years. Despite the limitations of the completed studies, evidence across a significant number of pre-post investigations suggests that psychoanalysis appears to be consistently helpful to patients with milder (neurotic) disorders and somewhat less consistently so for other, more severe groups. Across a range of uncontrolled or poorly controlled cohort studies, mostly carried out in Europe, longer intensive treatments tended to have better outcomes than shorter, non-intensive treatments (demonstration of a dose-effect relationship). The impact of psychoanalysis was apparent beyond symptomatology, in measures of work functioning and reductions in health care costs. Studies report results which other psychotherapies have not been able to achieve; some studies show very long-term benefits from psychoanalytic treatment; the

results tend to be highly consistent across studies; some of the populations studied have been larger than most better controlled treatment trials. So whereas it is true to say that little that is definite can be stated about the outcome of psychoanalysis, a number of suggestive conclusions may be drawn and these are listed below.

Across a number of studies and measures psychoanalysis has been shown to benefit the majority of those who are offered this treatment[169] and can bring the functioning of a clinical group to the level of the normal population.[167] Completed treatments tend to be associated with greater benefits.[170] On the whole longer treatments have better outcomes[171] and intensive psychoanalytic treatment is generally more effective than psychoanalytic psychotherapy,[25] but its superiority sometimes only becomes apparent on long-term follow-up.[172] Psychoanalysis can lead to a reduction in health care related use and expenditure[173] and this is maintained for a number of years after therapy ends[174] but it does not invariably achieve this.[166] Psychoanalytic treatment can lead to a reduction in the use of psychotropic medication amongst inpatients.[175] Long-term psychoanalytic therapy can reduce symptomatology in severe personality disorders such as BPD[162,176,177]and these improvements are maintained.[163]

Training

Training in psychoanalytic psychotherapy and psychoanalysis has three components: a personal psychoanalytic psychotherapy, theoretical training, and supervised clinical practice. A variety of trainings are available, although in most countries there is only one training organization that is recognized by the International Psychoanalytic Association. Training is long, chiefly because of the length of supervised treatments. Training standards are carefully monitored by national and international bodies.

Conclusion

Psychoanalysis is hardly a practical treatment alternative for the twenty-first century. The principles derived from this treatment, however, have powerfully influenced other psychotherapeutic approaches, whether long-term or short-term therapy or psychiatric care more generally, particularly in the United States. At the time of its invention, it was the unique effective psychosocial treatment method for psychiatric disorder which offered a genuine alternative to the sometimes barbaric and generally ineffective treatment methods available. Not surprisingly, its proponents adopted an almost religious zeal in defending its value against alternative approaches. While understandable, such an attitude has no place in the sophisticated evidence base underpinning multi-agency service planning. Psychoanalytic clinicians face a challenge in identifying their niche in the complex mental health care delivery systems of the twenty-first century.

6.3.6 Group methods in adult psychiatry

John Schlapobersky and Malcolm Pines

Introduction

After a century of development, group therapy is today one of the most widely practised treatment methods in psychiatry with an extensive literature. There are three principles common to its wide range of applications. First, the therapist calls the 'community' into the consulting room where, together with the therapist, it becomes the therapeutic agent. Second, the therapist assembles a group of people who can contribute to a commonly held resource from which its members can each derive benefits. And third, the therapist does nothing for them in the context of the group, that they can do for themselves, and one another.

This chapter starts by providing a conceptual framework that differentiates methods, models, and applications for the practice of group therapy in adult psychiatry. After classification of the different methods and applications we discuss the main theoretical models; explore the dynamic life of therapy groups; consider some of the key clinical issues facing practitioners; their applications to a range of patient populations and settings; their evaluation and justification and their historical evolution this century. In the conclusion we consider the planning of group services and the training of their practitioners. This revision of the chapter has brought it up-to-date with the contemporary literature in a field that has seen a great deal of innovation since the original 2000 edition.

The developing evidence base for group psychotherapy is 'Guardedly optimistic. The literature has become stronger and deeper and is capable of supporting evidence-based treatment recommendations for some patient populations.' The evidence base for the effectiveness of group psychotherapy has been growing with the field. Some 700 studies, spanning the past three decades, have shown that the group format consistently produced positive effects with diverse disorders and treatment models.[1] These show that both individual and group psychotherapy will effect much the same set of results. For group therapy to be effective it has to utilize those therapeutic factors originally laid out by Foulkes[2] and later by Yalom[3]—the group has to be the primary focus of therapy; patients need to be well selected; and therapists need to be adequately trained. The chapter will address these questions of focus, selection, and training.

Although the two authors of this chapter are both group analysts, we have set out to provide a full account of the wide range of group work practice. The United Kingdom is our own working location which lends emphasis to the chapter but it is compiled with sources and references that address the international field and it gives attention to current literature in many countries including North and South America and Continental Europe.

Basic methods

In Fig. 6.3.6.1 we have used two simple factors—therapeutic goals and group leadership—to provide a simple classification of the many different methods.

Therapeutic goals

Groups will be more or less specific in their therapeutic goals. For example, those catering for a homogeneous population with a commonly defined problem whose solution provides the basis for entry to the group—such as overcoming drink or drug dependence—are classified here with specific goals. Groups that provide psychoanalytic psychotherapy, whether run according to Interpersonal, Tavistock, or Group-Analytic models, are classified here with non-specific goals. There is a wide range of variation between these extremes and within each of these main psychodynamic models.

Leadership

The more the leader directs the group, the more prominent he becomes as the group's 'model object'. The less the leader directs the group, the more scope there is for the emergence of unconscious dynamics and for attention to transference and counter-transference. In this case, therapy progresses through the development of relationships. The greater the leadership activity, the more likely it

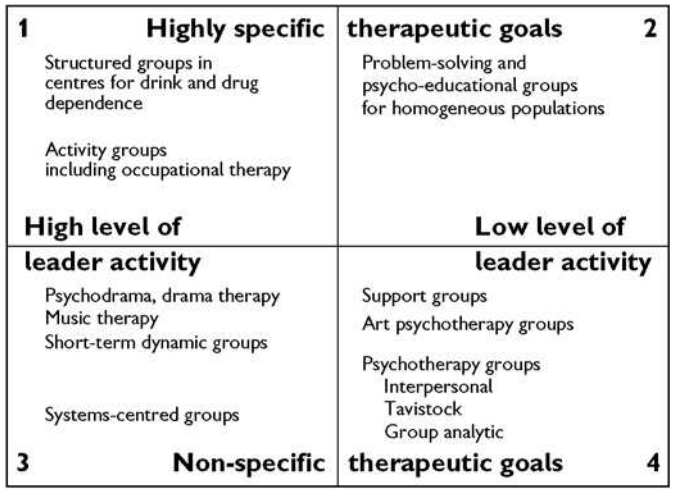

Fig. 6.3.6.1 A simple classification of group methods.

is that group members are being offered a technique or skill in the setting of a group. The lower this activity, the stronger will be the relational content of the therapy and the therapist's skills of fostering relationships will equip the group to work developmentally and in depth on both the obvious and hidden issues that its members bring. The three principal psychodynamic methods discussed in The principal model of psychodynamic group therapy below share a non-directive philosophy with subtle but significant differences between their models of practice.

Using these two basic indicators—specificity of goals and levels of leadership activity—the four quadrants in the diagram provide us with a simple way of 'placing' the different group therapies.

Goal-specific therapy with high level of leader activity: quadrant 1

In many drug and alcohol dependency regimes, participants are required to fulfil obligations tied to each stage of a structured programme. They move forward when stage-specific obligations are fulfilled. As the novice moves up, he/she becomes a trainer to the newcomers with the therapist(s) directing the process in active terms. Cognitive therapy given in a group setting uses the group as an assembly who learn from and discuss with the expert. Dependency on a shared and valued leader, and attention to group dynamics amplify the learning and some group cohesion develops, but this is not the primary focus of the therapy.

Goal-directed with lower level of leader activity: quadrant 2

Problem-solving or psycho-educational groups for homogeneous populations, such as those set up for eating disorders or offenders, which are run along analytic lines, can be placed in this category. Although there are clear and directed goals, the leader's level of activity is confined to a facilitating, linking, or enabling one, followed by analysis and interpretation. Group discussion and cohesion amplify the affective experience and enhance the learning.

Non-specific goals with high level of leader activity: quadrant 3

In **psychodrama groups**, leadership is explicitly vested in the psychodrama director. The needs and goals of group members are diffuse and often diverse and, in psychiatric practice, will have to do with relief from mental suffering. The psychodrama director can draw on many techniques. Affective arousal can be high so the power of sharing through discussion and the sympathy; and empathy of group members towards one another become powerful therapeutic tools. Strong conflict arousal and its subsequent resolution is similarly therapeutic.

Systems-centred therapy (as developed by Agazarian)[4] similarly provides a high level of leadership activity for groups that have non-specific goals. Short-term dynamic groups are frequently constituted with non-specific goals but are run over 10 or 20 sessions by leaders who maintain a high level of involvement and direction, often demarcated according to the different stages of the group's progress.

Non-specific goals with low level of leader activity: quadrant 4

The goals of group-analytic or psychoanalytic group therapy are most frequently diffuse and non-specific involving relief from symptoms and other forms of suffering; personal growth; and psychological change. There are three main schools considered in this chapter—the Interpersonal (Yalom), Tavistock (Bion or group-as-a-whole), and the Group-Analytic. They share non-specific goals and have low levels of leader activity but differ from one another in how the leadership role and function is understood and discharged. They share assumptions about the importance of unconscious individual and group dynamics and look to the group for its transformational potential. Their differences affect the way in which transference and counter-transference is understood and worked with. There is a comparative appraisal of these models below.

The application of basic methods

We now provide a more detailed overview of the current field and offer a brief set of training requirements for practitioners in each of the methods discussed.

The field can be divided into **five basic methods**—activity, supportive, problem-solving, psycho-educational, and psychodynamic. The first three methods are goal-specific as indicated by their descriptions, the fourth is less specific and the fifth is a non-directive analytic psychotherapy. In supportive and problem-solving groups, therapeutic leadership can be highly directed or not, depending on the approach. Activity and psycho-educational groups will inevitably have a high level of directed group leadership, whilst psychodynamic groups have a much lower level of directed group leadership. All five methods rely on the same basic procedures—the selection and grouping of a number of people seeking help who have regular meetings together with one or more well-trained therapist(s).

Activity groups

The most vulnerable and disturbed patients can be placed in therapy groups defined by an activity that provides a convening function such as exercise or cooking. They can then be used to create conditions for a wide range of secondary functions that foster affiliations, develop social skills, address unspoken anxieties, and express troubling emotions. Occupational therapists and nurses using art media or other socially syntonic activity like gardening or

hair-dressing have been developing a wide range of group services in both acute and rehabilitation psychiatry for many years.[5] The approach has been used in a wide range of other settings including medical rehabilitation, rehabilitation with refugees, social work and fostering, and adoption programmes. Groups that keep the original activity as their primary focus, working with art media for example, need to be differentiated from those which use such media to develop an analytic focus on psychological work. The arts psychotherapies belong to this latter group. They have non-specific therapeutic goals and might, as in the case of music therapy, have a high level of leadership activity or, in the case of art therapy, have a low level of leadership activity.

Whilst therapists do not engage in the uncovering and exploration of unconscious dynamics, they will need leadership abilities, capabilities in organizing group activities, and should have a basic understanding of psychopathology and group dynamics.

Supportive groups

These groups function as a form of social support providing containment, the improvement of social skills, and the enhancement of participants' capacities for social adaptation. They aim to reduce the deleterious effects of social isolation, bring people out of withdrawal into a social context, and provide opportunities for problem sharing. They cater to patient populations with long-standing personality disorders not open to uncovering exploration; those with chronic mental and physical illness,[6] physical handicap, mental retardation, and carers for those with any of these problems. They will often allow a certain amount of psycho-education with the group leader influencing members' attitudes as in the case, for example, of a group for young sexually active adults with learning disability who might receive guidance on contraception.

Whilst therapists do not engage in the uncovering and exploration of unconscious dynamics, they will need leadership abilities, capabilities in organizing group activities, and should have a basic understanding of psychopathology and group dynamics.

Problem-solving groups

Group therapy is provided for a set of referral criteria to resolve a defined and sometimes circumscribed problem. Alcoholics Anonymous, Alanon, Gamblers Anonymous, and groups for people with poor impulse control, eating disorders, or other habitual problems such as smoking, are a few of the examples. These groups can take on many of the features of long-term support groups, in that they offer ego-supportive and adaptive resources, providing an extended service for monitoring by the patient or by professionals, without necessarily committing members to the deeper and more radical analytic work entailed by a psychodynamic group. In many cases, the problem-solving focus provides a convening frame by which to engage a population who are soon drawn into psychodynamic work that sees them through profound changes. Many of the groups run by clinicians in primary hospital care—occupational therapists, nurses, doctors, and psychologists—take this form. The Group Work Programme at the Medical Foundation For Victims Of Torture in London is another example (see also section on trauma in specical population, below).

Where they cater for the more severely disturbed, staff will need to be well-trained in one of the core professions. They will need leadership abilities, capabilities in organizing group activities, should have a basic understanding of psychopathology, and be sufficiently well-trained to explore the dynamic group issues that lead from the problem back to the personality structure of their membership. If therapeutic goals involve major changes in personality and social functioning, this will involve the uncovering and exploration of unconscious dynamics.

Psycho-educational groups

The original groups for servicemen with war neurosis at Northfield took this form in which people were given the role of students of their disorders rather than 'sick' people. Patients become open to new information and are better able to unlearn maladaptive attitudes about the nature of their disorder. This more cognitive approach can be applied in homogeneous problem-solving groups. Information can be provided through lectures, discussions, and suitable reading material. There are different ways of lowering anxiety and uncovering maladaptive and inappropriate attitudes towards such problems as anxiety states, phobias and obsessions, and psychosomatic disorders. Many of the groups run for those with serious physical illness (see also section on the medically ill in special populations, below) take this form. And there is often a major psycho-educational component in support groups—for example, those with chronic mental illness who can be helped to understand and cope with delusions, hallucinations, and the stigma of illness.[7] (see also section on the mentally ill in special populations, below)

Staff need leadership abilities; capabilities in organizing group activities, a basic understanding of psychopathology, and need to be sufficiently well-trained in their chosen problem area to be able to relate its educational focus to thematic group issues. If therapeutic goals involve major changes in personality and social functioning, this will involve the uncovering and exploration of unconscious dynamics.

Psychodynamic groups

There are supportive, problem-solving, and psycho-educational components in all psychodynamic groups, but the description 'psychodynamic' is reserved for those in which the declared goal is lasting personal change through a non-directive, free-associative therapy. The range of different group contexts is so varied that—at first sight—they might appear to have little in common. But there will be common principles offering therapy to a group of people on an in-patient unit recovering from psychosis and meeting thrice weekly; those in a secure unit for violent offenders meeting once weekly; and those—including mental health trainees—attending a group in private practice once or twice weekly. These principles can be summarized in the table, Table 6.3.6.1 below.

Within these parameters therapy is part of the cultural domain of all shared, conversational experience in which people struggle with meaning—in congregational life, in the confessional, in theatre, narrative or poetry.[8,9]

Staff need to be trained to the level already described. They need good leadership ability, capabilities in organizing group activities, and a good understanding of psychopathology. Beyond these requirements, therapeutic goals will involve major changes in personality and social functioning involving the uncovering and exploration of unconscious dynamics. So staff will need access to a

Table 6.3.6.1 Organizing principles for group therapy

1	Members will have been chosen by the therapist.
2	They will have chosen to join and participate.
3	They will be expected to justify their place by reliable attendance and participation.
4	The work will be governed by a psychotherapeutic contract.
5	The contract will include definitions of confidentiality and other boundaries.
6	A therapeutic alliance with individual members will be established either prior to their joining the group or during the early stages of their attendance in the group.
7	Agreed parameters will include the duration and time-boundaries of the group as well as its membership and composition.
8	Groups can be homogeneous or heterogeneous.
9	Groups may have a fixed time limit or continue on a slow–open basis for many years.
10	Groups may have a stable and fixed, or a rotating membership with empty places taken by new members.

range of specialized training opportunities which should provide psychodynamic theory, clinical supervision and, ideally, some opportunity for the practitioners' own personal development.

The contemporary field and its history

The paradigm shift that led to a vision of the group as a whole began over a period of time and in a number of locations. Trigant Burrow coined the term group analysis in the USA in the 1920s.[10,11] Further development in the years after World War II period enabled workers to recognize the dynamics of groups and institutions and led to group and family therapy, milieu therapy, and therapeutic community concept and practice.

Second World War

In Britain and the US, during the Second World War, an appreciation of group psychology led to a wide range of innovations, the most important of which included:

- The use of group methods for selection and allocation of work responsibilities
- Studies of group morale
- The integration of psychiatric knowledge to the management of large groups through the role of the command psychiatrist
- The treatment of acute and prolonged battle stress and the rehabilitation of returned prisoners of war.

Clinicians used the opportunities created within army psychiatry to apply methods developed in the pre-war years.[12] Brigadier J.R. Rees, Director of the Tavistock Clinic in the 1930s, largely created this opportunity in the British Army. His Tavistock colleagues formed an 'invisible college' and were responsible for signal achievements in the advances in selection and treatment.[13]

Foremost amongst these were Northfield, the military hospital near Birmingham where S.H. Foulkes was a senior medical officer.[14] A refugee from Nazi Germany, Foulkes brought with him from the Frankfurt Institute the revised understanding of Freudian theory that was also to prove influential in the US. In the New School for Social Research, New York, and in the work of Neo-Freudians like Erich Fromm, Frieda Fromm-Reichman, and social theorists like Adorno, Marcuse, and Norbert Elias, psychoanalysis and Marxist theory were brought into a new, creative relationship.[15] In the United Kingdom Foulkes first developed his approach to group therapy in Exeter before the war and was able to apply it successfully on a large scale to the treatment of war neuroses at Northfield.

Post-war period

Group psychotherapy moved from inspirational and didactic models to psychodynamic and analytic ones in the post-war period.

(a) United Kingdom

The Group-Analytic Tradition: Foulkes gathered around him a small group of clinicians and others who developed his ideas and practises. Drawing on the ideas of Trigant Burrow, they called it group analysis and later established the Group-Analytic Society, and trained generations of clinicians. His first book written in the heat of the Northfield experience outlined the basics of his approach.[16] Other publications followed and, with Malcolm Pines, training courses were established which lead to the founding of the Institutes of Group Analysis and Family Therapy, the Association of Family Therapists, and Association of Therapeutic Communities. There are now training courses in group analysis in many centres in the United Kingdom and continental Europe. The Journal, *Group Analysis*, established by Foulkes, continues to be the major publication in European group psychotherapy. Group-analytic psychotherapy has undergone clinical evaluation by a number of clinicians.[17–19]

The 'Tavistock' Approach: The approach originates in the work of Bion, Ezriel, Sutherland, and their colleagues. It shares with group analysis an interest in the underlying pattern of object relations in groups but, under the influence of Bion—its major exponent—his 'basic assumption theory' is applied to the exclusion of almost everything else. (Bion's monograph was his only publication on groups and marked the end of his interest in the subject.[20]) The approach has been especially influential in staff training and consultancy which, given the slender theoretical foundations on which it rests, suggests a wide responsiveness in the field of basic assumption theory. The approach has undergone further development in the United States where it is often referred to as group-as-a-whole. When employed as a therapy, it can overlook the individuality of a group's members, disturbing some patients whose experience of the group situation can repeat early developmental traumas of neglect and misunderstanding by caretakers. Malan's study of effectiveness[21] raised serious questions about the model's efficacy in its clinical applications but its training applications continue to influence the field.

(b) United States

(i) Early pioneers

Jacob Moreno was the innovator of group psychodrama, a pioneer form of group psychotherapy.[22] He also introduced sociometry, a scientific method for the study of group affiliations and conflicts, widely accepted and used by social psychologists. **Slavson** was an educationalist of psychoanalytic persuasion who became the central figure in the early development of group psychotherapy. His clinical influence, particularly with groups for the parents of children in difficulty, and his focus on the dynamics of projection in groups has been of lasting importance.[23] His organizational efforts lead to the formation of the American Group Psychotherapy

Association. **Emanuel Schwartz** began to apply psychoanalytic ideas to group psychotherapy in the late 1930s and was later joined by **Alexander Wolf**.[24, 25] In their approach, people underwent an individual psychotherapy in the setting of a group, a kind of parallel process alongside their fellow patients, with attention focused on the transferential relationship between each individual and their therapist. The approach has been of lasting importance in creating a clinical framework for combining individual and group therapy. Foulkes' criticism at the time was that the approach overlooked any systematic use of group-specific process. In contrast to their 'psychotherapy in the group' he offered group analysis as a clinical alternative, describing it as 'psychotherapy by the group'.

(ii) Irving Yalom

Yalom's interpersonal approach is influenced by the interpersonal psychotherapy of Sullivan and Frank. His *Theory And Practice of Group Psychotherapy,* now in its fifth edition and written jointly with Leszcz, is the first systematic account of groups informed by research and remains one of the most influential books in the field.[3] Yalom's later text on inpatient group psychotherapy systematized group work in that setting.[26]

(iii) The contemporary field

There are many centres of excellence, a wide range of methods and models and an empirical base grounded in research. The most useful single text is by Rutan and Stone, now in its fourth edition.[27] Collections by Kaplan and Sadock[28] and by Alonso and Swiller[29] cover the field. Psychoanalytic models have a rich diversity of theory with contributions from object relations, self psychology, and social systems theory.[30] The Modern Group movement is amongst the most innovative, beginning with a classic text by Spotnitz[31] and developing through an active training programme, a journal, *The Modern Group,* and publications by Ormont[32] and others.

(iv) South America

There is a vigorous field of development throughout South America that draws on both the Tavistock and Group Analytic traditions but is informed by independent sources based largely on the work of Pichon-Riviere. Tubert-Oklander and Hernandez de Tubert have introduced this approach, referred to as Operative Groups, to the English-speaking world.[33]

(v) Continental Europe

Group methods have played an active part in the reconstruction of mental health services throughout Europe in the post-war period. Distinctive approaches are emerging. Those in Germany include psychosomatic practice[34] and the Gottingen model.[35] The journal of the Heidelberg Institute of Group Analysis gives access to a vigorous field. A major research study is in process, based in Germany, in which therapists throughout Europe are taking part and which aims to provide a detailed evaluation of group therapy, its patients, and its therapists.[36] Other distinctive developments include those in Italy[43] and original training models, for example, those in Greece[37] and Norway.[38]

Principal models of psychodynamic group therapy

The therapist

The therapist is responsible to the group— and to the institution in which it is set—for achieving and maintaining professional competence and should have a level of training appropriate to the task. A formal qualification in psychotherapy is the ideal training. This will have included theory, personal therapy for the therapist, and clinical supervision. Mental health professionals from all disciplines make an active contribution to a rich and diverse service with the training requirements of theory and supervision arranged at their workplace. The opportunity to run a group is provided in most psychiatric and psychology training programmes. Many centres and training institutions offer training in group methods and several are wholly committed to the training of group therapists who have their own professional associations in the UK and internationally. Private once- or twice-weekly analytic groups are now regarded by many mental health professionals as the therapy of choice for their personal development. Other requirements for a good therapist are listed in table 6.3.6.2.

(a) Making a beginning

The establishment of a group begins as a management task in the definition of its goals, recruitment of its members, protection of its setting, venue and timetable, and in the maintenance of its ongoing life. It evolves as a therapeutic task in which the therapist is responsible for maintaining a therapeutic attitude to the individual members and to the group as a whole. Powerful affects and attitudes will be directed towards her which she will monitor and transform into verbal and non-verbal therapeutic responses.

The therapeutic rationale will allow the therapist to be discriminating and consistent about interventions of various kinds during the life of the group and what follows below provides an orientation—based on the dynamic elements of structure, process and content—to the three main models used in the UK.

Structure, process, and content: the dynamic elements of a group

Regardless of the therapist's method, people usually start in groups with a form of serial monologue. Out of this arise the capacities to talk and listen that are often undeveloped or even non-existent at the outset of therapy but which are its core constituents. From talking and listening comes self-disclosure and out of this social exchange identification emerges, which in due course leads to dialogue and differentiation. So the conductor must give a place to monologue whilst, at the same time, cultivating dialogue—the exchange between members or sub-groups—and, ultimately,

Table 6.3.6.2 Requirements for therapeutic competence

Requirements for therapeutic competence include:
1 The ability to follow complex interactions and processes.
2 The ability to discriminate between appropriate activity and a containing form of silence.
3 A reflective attitude and the capacity to consider and reflect upon the processes concerning both the individual members and the group as a whole.
4 An eye for both the visible and invisible group and a curiosity about the unconscious or otherwise hidden aspects of a group's life. This will require the therapist's access to their own internal process and a capacity to make use of it.
5 A therapeutic rationale for action related to the group tasks and leadership requirements including the psychopathology of the individuals, their psychodynamics, and group dynamics.

promoting discourse, defined here as the free interaction of participants in the flexible and complex exchange that distinguishes the communication of a group.

Structure describes the more enduring aspects of any group's makeup, the 'architecture' of its interpersonal relations conceptualized first in terms of the setting and its boundaries and then conceptualized in the bond between each individual, the therapist(s), and the group as a whole. Process describes the fluid and dynamic fluctuations of emotion and experience, the business of relating and communicating, the changes of association and inter-member responses. The content of a group's exchange is in its visible and audible events, in the narrative line and dramatic content of peoples' encounters, the topics raised, their thematic development, and the extent to which they are explored or avoided.

As Fig. 6.3.6.2 illustrates, each of these three dynamic elements has a determining influence on each of the others. For example, a group in which there was a problem caused by the institution's failure to honour its commitment to reliable space for regular meetings, would have a serious structural problem. Intrusion, relocation, or a conflict over space might then emerge in the content of the members' associations as they talked about shared past experience. The therapist would need to decide whether to direct the process towards the connection between past and present anxieties, or reassurance that the therapist would—from now on—be able to protect their space.

(a) Overview of the Interpersonal, Tavistock, and Group-Analytic Models

In the Interpersonal school, intra-group interactions, including those between its members and the leader, are taken in their totality, but differentiating the leader as a different 'sort' of person from the others. In the Tavistock model, a two-body psychology is used to analyse the interchange between the leader and the group taken as a whole. The therapist's principal role is in the analysis and interpretation of defences against primitive anxieties (or basic assumptions). The Group-Analytic Model calls on elements of both foregoing models. Like the Tavistock model it considers the leader as structurally different to other group members but like the Interpersonal model, it encourages the leader to work in the group with individuals. A three-body psychology is used to understand the role of the leader who is referred to here as the conductor. Therapy proceeds through the dynamic interaction between each individual, the conductor, and the group as a whole.

(b) The model of interpersonal group therapy

The focus is on interpersonal learning as a primary mechanism of change. The group provides the antidote to maladaptive interpersonal beliefs and behaviours through feedback from others and encouragement to experiment with healthier behaviours first within the group and then outside. The joint examination of intra-group transference reactions allows members to replace processes that have a historical origin in the 'there and then', the dynamic past, with those more appropriate to the 'here and now', the dynamic present. The approach emphasizes the educational opportunities of working in the 'here and now' of the group. The therapist takes the responsibility for leading the group towards awareness of these interpersonal dynamics and their expressions. There is also greater therapist transparency than in other psychodynamic approaches with the therapist modelling desired behaviours, sharing the reactions to events in the group directly, and being open to feedback from other group members.

As the diagram indicates, interpersonal dynamics are kept at the forefront of members' attention by the therapist. This sets a pattern in which the content of members' discussions and the process of their interactions gives the group its agenda. The interpersonal approach places the therapist amongst other members of the group without giving him a distinctive structural identity and omits any formal demarcation for the boundaries of the group as a whole.

The model provided the early descriptive research on the phases of small groups, on the basis of which Yalom tabulated the **curative factors** in a group's life (see Table 6.3.6.3).

This construction has been very influential. Yalom's use of the term 'curative' poses many problems for those clinicians who see the goals of therapy involving personal growth and change. He did much to address this difficulty by singling out the last of his 'curative' factors—existential issues—for special treatment in a subsequent text.[49]

(c) The Tavistock model

Bion's ideas have an explanatory power and simplicity of application that continues to prove illuminating.[40] In a group at any

point in time, its culture and climate are governed by primitive, unconscious anxieties that impede its capacities for rational work in which the person or representation of the leader plays a crucial part. The anxieties, organized into one of three categories, referred to as **basic assumptions**, are dependency, fight or flight, and pairing. They affect the group as a whole in which only one basic assumption is believed to be operative at any point in time. Bion saw basic assumptions as interfering with the 'work group', the more rational, higher-level functioning of the group and its members. The therapist's key task lies in understanding and interpreting the operative basic assumption to the whole group. The meaning of individuals' experience is subsumed by this understanding of the whole. This therapist-centred approach sees transference only as directed towards the therapist who represents authority. In **dependency**, the group tries to elicit protection through passive or dependent behaviour. In **fight/flight** they will attack the therapist or some other issue; or retreat and withdraw. And in **pairing** they may create a group illusion that some magical form of rescue may arise from the dilemmas of group life through charged partnerships. Hopper has introduced a fourth basic assumption that he calls **massification/aggregation** in which the defensive structures of groups or societies in crisis is thought to entail either a rigid fusion of identities excluding individuality, or extensive withdrawal preventing mutuality.

The two-body psychology used here enforces a series of clinical constraints that reduce the complexity of group interaction to a bi-personal exchange between therapist and group taken as a whole. As Fig. 6.3.6.4 illustrates, intra-group dynamics are considered only in their entirety for what they reveal about the unconscious state of the group as a whole, and for what they indicate about the nature of the group's relationship with the therapist. Figure 6.3.6.4 illustrates how the therapist stands outside the group in a stance that is not only neutral and dispassionate but also opaque and withholding of self.

Ezriel, basing his work on Bion, developed his theory of **common group tension**.[41] He believed that the group would be caught up at any given time in a commonly shared conflict centred on the unconscious fear of catastrophe, what he called **the dreaded state**. People would avoid a state in the group—say one in which they talked about sad feelings—because of the unconscious fear that talking about sadness would lead to a dreaded state, in this case a depressive collapse. A group would be driven into unconscious, defensive organization—what he called **the required state**—to keep sadness at bay. For example, an extended period of manic humour, the required state, would help prevent **the avoided state**, sadness, and this would in turn protect against the dreaded state. Interpretations would allow members to become increasingly aware of the underlying catastrophic fears and reduce their need for defensive organization.

Horwitz calls Ezriel's approach 'deductive', in that it relates individual's contributions only to the common group tension. He realized that this deductive approach was clinically unproductive and developed, what he called an 'inductive' method which is group-centred.[42] Interventions are first addressed to individual members in the group. Only after working with patients individually does the therapist introduce a common theme that binds them together. Thus the therapist, as in the Group-Analytic model, works on a figure/ground basis in which individual contributions are valued and explored in their own right before they are contextualized in the life of the group as a whole.

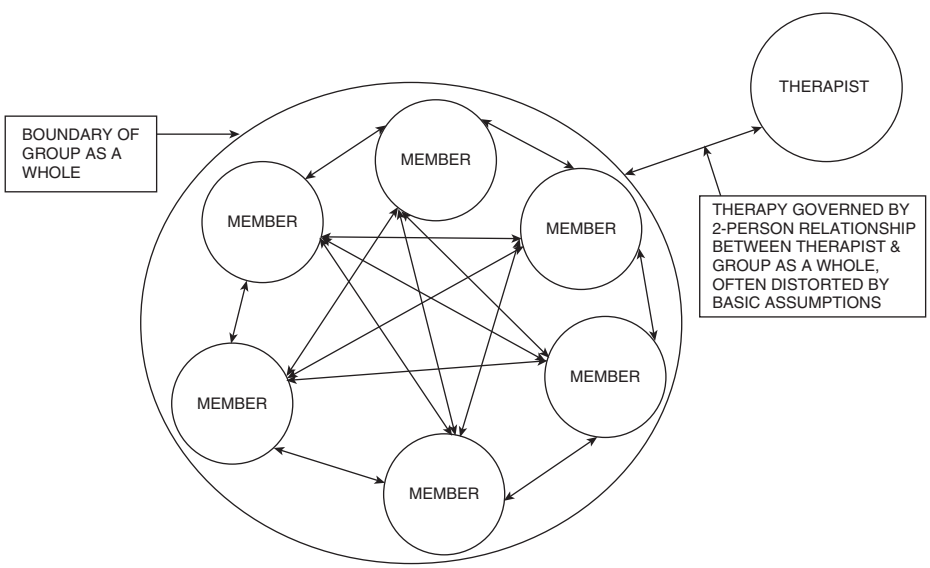

Fig. 6.3.6.4 The elements of a Tavistock group.

Another approach, **focal conflict theory**, as developed by Whitaker and Lieberman[43] is similar to Ezriel's in focussing the therapist on a conflict that becomes his point of emphasis, but it answers Horwitz's criticisms. On their account, underlying **disturbing motives** in group behaviour are acted against by unconscious, **restrictive solutions**. On their account the therapist—by focusing on such key conflicts—helps give members access to the unconscious anxieties and once these have been relieved they can construct more **enabling solutions** to the shared dilemmas of the group. The idea of focal conflicts, conceived of in these broader terms, has become an integral part of the Group-Analytic model.

(d) The Group-Analytic model

This approach integrates important aspects of the two preceding models but introduces a number of new elements. As Fig. 6.3.6.5 suggests, the therapist is encouraged to address the individual as well as the whole group and considers the more conscious and individual dynamics as well as the unconscious and potentially destructive whole-group dynamics. The approach is guided by an integrated set of concepts relating structure, process, and content to one another in which the group conductor works both as therapist and as group member to foster and cultivate the ordinary language of shared conversational experience. He will at times take up the position of the group's manager, and at other times he will speak personally as one of its members. Groups may begin with a relatively high level of leadership activity, referred to as **dynamic administration**, which is flexibly reduced with a decrescendo of responsibility as the group becomes the therapist and the leadership function is devolved upon its membership who becomes active co-therapists in each other's treatment[44]. Figure 6.3.6.6 indicates how, in this approach, at one key moment in the group its theme can focus on structural dynamics that link one member to both the therapist and to the group as a whole. The web of interconnecting dynamics between any one member and all the others, is summarized by 'the group as a whole', and this is called on to represent the inter-connecting latticework of relationships that includes all the members and the therapist.

(c) The Matrix

As Fig. 6.3.6.6 indicates, the conductor is inside and a part of the group, the structural elements of which provide a way of understanding the crucial links between each member, the conductor and the group as a whole. The triangle by which the group's psychological objects are linked to each other illustrates one of the 6 corresponding patterns of connection. When replicated for each of the 6 members, the diagram will produce a **matrix** of relational patterns, a complex relational field that will undergo change in terms of alliances, sub-groups, and polarizations. This concept of the matrix is crucial in group analytic theory. It allows us to accept that all events in a group will become part of an unconscious network that is intrapsychic, interpersonal, and transpersonal. The developing matrix creates the capacity to receive, contain, and eventually transform individuals' contributions, fostering integration at the individual level as it does so in the group as a whole.

Free-floating discussion: Free floating discussion is the group-analytic equivalent of free-association. The term originates in Foulkes' own writing and describes a set of key clinical concepts in therapeutic practice that distinguish the group-analytic approach. The language of the group is discussed in the dynamic life of groups, below.

Group-specific process: These processes, also mapped out originally by Foulkes, have been studied further by Pines[45] and by Agazarian and Peters.[46] The key concept of **resonance** describes the unconscious communication of emotion. The group provides its members with a wide field of meaning which is explored as they **mirror** one another's experience, find their emotions **amplified** by association with one another, and find **condensed**, sometimes highly aroused, cathartic experience, moments charged with significance.

Content analysis: Foulkes described four levels at which the content of the group's discussion can be analysed in the search for meaning.[47] In the Tavistock model this is the therapist's exclusive task, whereas here interpretation is only one amongst a number of others. The therapist's overall stance is to foster communication and educate the group's members about the dynamic links between the group's structure, the content of the discussion, and the form

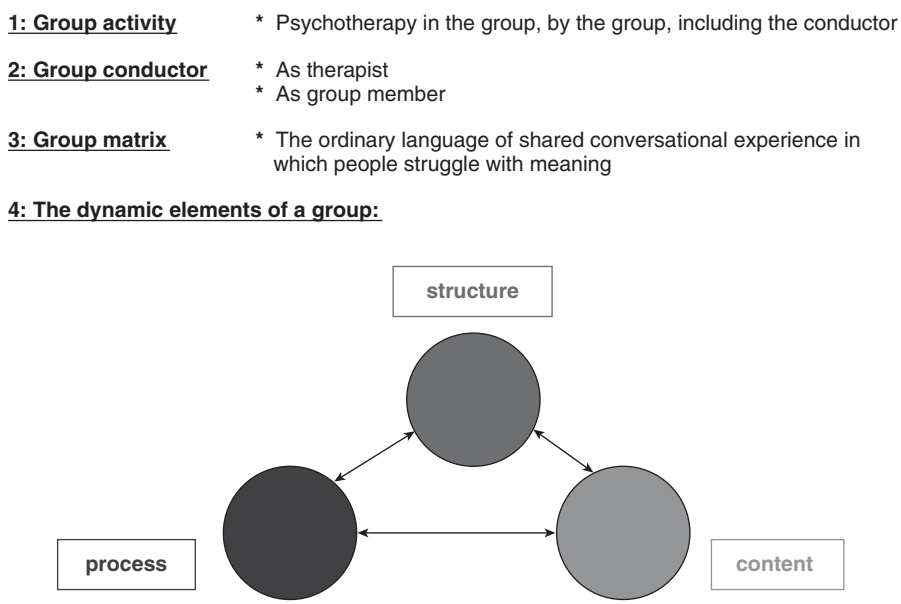

Fig. 6.3.6.5 Group Analytic psychotherapy.

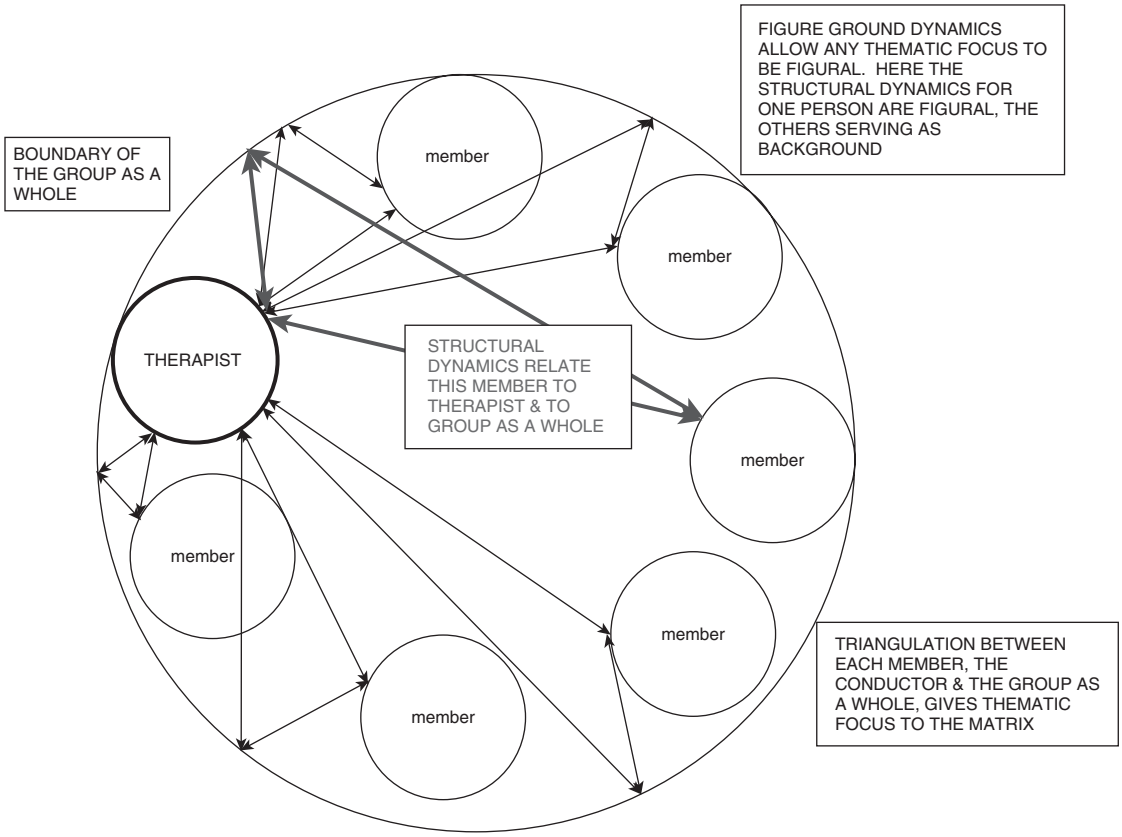

Fig. 6.3.6.6 The elements of a group-analytic theory.

in which it takes place. Figure 6.3.6.7 illustrates the conductor's therapeutic role in relation to each of these dynamic elements of the discussion.

(f) Recent developments in group-analytic psychotherapy

The role of dreams in group psychotherapy has been reconsidered.[48] Friedman described two of the unconscious functions they serve in group therapy—requests for containment and influence on relations with the dream audience.[49] Lipgar and Pines[50] work towards an integration of the ideas and methods of Bion and Foulkes with discussion from an international panel. Nitsun[51] considers sexuality in group psychotherapy: sexual identity, boundary transgression, erotic connection, dissociation of desire, the group as witness, erotic transference and counter-transference, and the effectiveness of psychotherapy.

(g) The conductor as therapist and group member

At times of coherence, when the members are close in the shared experience of a moment, or when there is an issue charged with meaning, the group-analytic approach comes into its own. The symbolic content of the discourse might evolve in the language content, the flux of interactions, or the attention given to an individual's problems. The conductor needs to be able to model this use of imaginative play—with images, associations, or exchanges—and then stand back to allow members to take the enquiry forward. Cox[52] shows how images can safely hold experience too painful or brittle to tolerate much analysis. People discover that images can touch the depths before they stir the surface, giving access to profoundly felt and deeply hidden concerns. When used and played with in this way, **the mutative use of metaphor** provides the whole group with a vehicle for change. Other aspects of the therapist's activity are summarized in Table 6.3.6.4.

The dynamic life of groups

In the sections that follow we draw on our own Group-Analytic model to examine a range of clinical considerations and make them as relevant as possible to the widest range of practitioners, regardless of their own models.

Group development theory

Many schemata have been proposed, usually derived from time-limited experiential and study groups but some of these can provide a useful orientation. Bennis and Shepard,[53] followed by Yalom, write about the initial stages of **orientation**, involving a search for structure and goals, dependence on the leader, and concern with boundaries. Their second stage is characterized by **conflict**, particularly over **norms**, authority, and control. Their third stage is achieved with a high level of group **coherence** that allows for inter- and intra-personal exploration. They acknowledge that the boundaries between phases are not clear and that a group never graduates permanently from any one phase.

In slow open groups, especially, this idea of discrete phases has its limits. The group-analytic approach provides a cyclic model in which focal issues such as affection, intimacy, personal history, and change, are understood and struggled with repeatedly. A group

III Archaic and primordial experience

understands in these terms struggles with **developmental tasks** rather than phases, in the course of which it is the individuals who enjoy growth, differentiation, and progressive change.

(a) Developmental stages and thematic focus

Figure 6.3.6.8 provides a map of these developmental tasks conceived of in logical rather than sequential terms. The way in which one person comes into the group will be different to the arrival of another. The terms on which one person joins will have a determining influence on each of the stages they pass through. For example, preoccupations about how someone came into the group—the terms of their engagement—might be resolved only when the person leaves perhaps one, three, or five years later, when they have to assess the outlook for their future as they look back over the years spent in therapy. So the diagram can be used as a thematic map for one person's journey through therapy, or as a way of appraising the stage reached by the group as a whole.

Early stages are dominated by the anxiety of being involved in a new situation and by questions about other group members. Preoccupations are likely about boundary issues, confidentiality and security. In the second stage, those familiar with psychotherapy—or otherwise accustomed to talking about themselves—will be at an advantage. There will be a range of tensions about group norms and disclosures, reasons for joining and discrepant levels of confidence about using the group. In the third stage, members will defend against intimacy with one another and struggle with questions of trust, attachment, and affiliations. In the

fourth stage, as members become increasingly able to trust the group with self-disclosure, observed changes might become manifest as self-exploration yields the beneficial experience of individuation and differentiation. In the concluding stage, people prepare for departure and find themselves comparing points of difference between changes achieved in the group and the state of their lives outside—generalising from the arena of therapy to that of real life. Has therapy made a lasting difference? Will it be maintained outside?

The language of the group

Foulkes suggested that 'symptoms, in themselves unsuitable for sharing, exert, for this very reason, an increasing pressure upon the individual to express them'.[54] The group equips the person to transform the mute and inchoate language of symptoms into a socially understandable form of discourse. Following publication of Schlapobersky's paper, The Language of the Group, there is increasing interest in characterizing group phases in terms of the language that predominates, using theory from discourse analysis and the Foulksian concept of free-floating discussion.[16]

It is possible to differentiate between three primary forms of speech that arise in the matrix of any group. At the most basic level **monologue**—speaking alone (with or without an audience)—is a form of individual self-expression. At the next level **dialogue**—a conversation between two people—is the form of communication that distinguishes a bipersonal exchange. And at the third level **discourse**—the speech pattern of three or more people—allows the free interaction of all its participants in a flexible and complex exchange that distinguishes the communication of a group. These patterns of speech are universal cultural forms arising in all communication and are present in the life of every group, although in no set order. Monologue can be understood as a soliloquy, dialogue as the resolution of opposites or the search for intimacy, and discourse as the work of a chorus. The use of free-floating discussion allows a pattern of exchange to move freely between these different speech forms, each of which constitutes a distinctive type of communication. It is through this movement—from monologue through dialogue to discourse and back again—that the group-analytic method comes into its own, creating an arena in which the dialectic between the psyche and the social world helps to refashion both.[13,14]

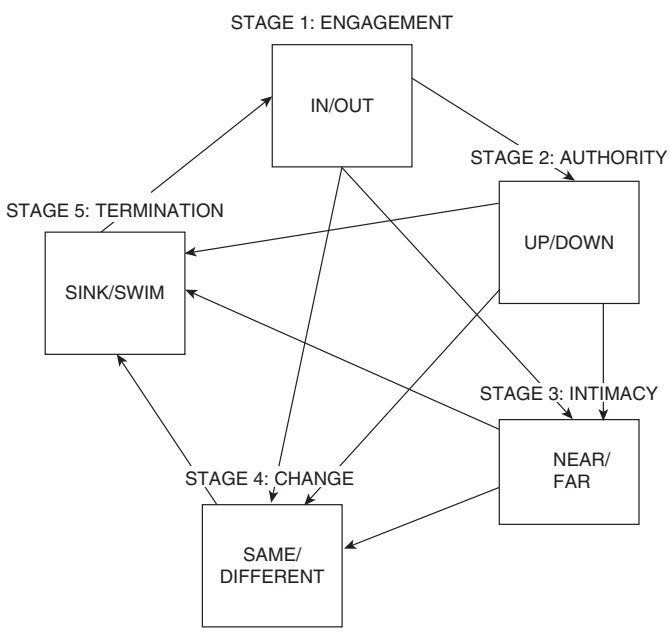

Fig. 6.3.6.8 Developmental stages and thematic focus.

Leadership

The group analyst works as both group member and therapist, beginning with dynamic administration, assuming an active role in a new group and allowing a **decrescendo** of his own role as the group gains authority. He is responsible for helping the group with the **location** of disturbance in its process and for providing a balance between analytic and integrative forces whilst manifest content is translated into language that describes the unconscious. Transference is prominent but the work is undertaken in the dynamic present. Foulkes' account in the following passage,[55] of the conductor at work in a group, stands in dramatic contrast to Freud's account of the psychoanalyst at work behind the couch:

> He treats the group as adults on an equal level to his own and exerts an important influence by his own example . . . representing and promoting reality, reason, tolerance, understanding, insight, catharsis, independence, frankness, and an open mind for new experiences. This happens by way of a living, corrective emotional experience.

Disturbed, narcissistic, or borderline patients bring to the group more primitive psychic structures and processes that put strain on the resources of other group members. Such patients can create turmoil in which the leader's task is to maintain the group at a more mature level of psychic organization. By responding to part-object relationships and processes on the level of whole-object relations, containing responses can be established. Progressively, these help to build for the disturbed patient a more benign world of inner object relationships and processes. More disturbed patients desperately seek attention in ways that are inappropriate and disruptive. This search for **attention** arises because the patient cannot establish a sense of **connection** between herself and the processes of the group. Mirroring and resonance can steadily come to replace these isolated and fragmentary responses allowing the patient to attain—for the first time—a coherent sense of self and a capacity to recognize the identity of others.

(a) The dynamics of change

As noted above, Yalom cited 11 'curative' factors responsible for change in groups. Foulkes believed there were four key group-specific factors: mirroring, exchange, social integration, and activation of the collective unconscious. Tschuschke and Dies[56] have identified five key factors that they could study empirically (Table 6.3.6.5).

(b) Binding forces: alliance, cohesion, and coherence

Group alliance has as its major focus the quality of the relationship that develops between each individual member and the therapist(s). These alliances grow as each individual develops a transference relationship to the therapist and can feel that their own particular individual dynamics are recognized. Group cohesion used to be compared to the concept of therapeutic alliance in individual psychotherapy but current research shows that alliance (defined as the affective bond that develops between each group member and the therapist) can be differentiated from group cohesion.

Group cohesion describes the bonds between group members, their attitudes, and their commitment to therapeutic work, in particular

Table 6.3.6.5 Five factors in the dynamics of change open to empirical evaluation[56]

1 Cohesiveness	Closely related to 2 & 3 as determining factors that influence outcome in 4 and 5
2 Self-disclosure	Closely related to 1 & 3 as determining factors that influence outcome in 4 and 5
3 Feedback	Closely related to 1 & 2 as determining factors that influence outcome in 4 and 5
4 Interpersonal learning output	Evidence of working through process seen in 4
5 Family re-enactment	Findings of change in these patterns provides evidence of enduring psychic change

their feelings of attraction and dependency. These processes are interdependent and in combination they provide optimal conditions for positive group process and outcome.[57]

Group coherence is a more evolved group state requiring but going beyond cohesion. It evolves as a semantic matrix, built on the earlier, relational matrix. When a group moves through support and understanding to be able to recognize and work through conflict, it can achieve a sense of containment.[58] At this stage the group becomes a more complex, self-evolving, and self-defining entity capable of reaching deeper levels of exploration, acceptance, and understanding.

(c) Corrective emotional experience

The concept was introduced by Alexander to describe the patient's recognition of discrepancies between present and past experience. Grotjahn, a colleague of his, applied this to the group, describing it as 'the corrective family experience'.

> There is a built-in correction of the transference phenomena through the peer relationship in groups. An analyst is trained to let the transference neurosis to grow to full bloom. Members of a group are neither trained nor willing to accept such projections . . . and will correct them. This is the basis of a corrective therapeutic family experience.[59]

Oedipal, sibling, and pre-oedipal constellations are activated in group therapy and can be worked through as the members play parts in each other's family scenarios.[60] The task of the therapist interprets transference and helps the group as a whole to develop coherent norms of understanding and responsiveness that equip its members to go beyond the private preoccupations that might have brought them into therapy. Garland calls this **taking the non-problem seriously**.[61]

(d) Resonance, mirroring, and other dynamic processes

Foulkes described the group as 'a hall of mirrors'. Each person, he thought, could see aspects of themselves reflected in the personality and behaviour of others and could often more easily recognize these aspects of the self than by direct introspection. We cannot know ourselves in the absence of reflective mirroring, the feedback and information we obtain from others according to our presence and behaviour in the group brings us to a greater awareness of who we are. Resonance in the group is the unconscious communication of emotion by which the other process dynamics—like mirroring, amplification and condensation—are effected.

Insight and outsight, regressive and progressive forces in groups

The dictum, 'where id was, ego shall be', coined originally by Freud to ground the psychoanalytic enterprise in an easily comprehensible principle, has been superseded for group workers by the idea of **ego training in action**, coined by Foulkes. It emphasizes two related issues. The first is that **insight**—the understanding of the self—is related to **outsight** defined as the understanding of the other(s). And the second is that people find growth and change as much in what they do for others—**progressive behaviour**—as in what others can do for them—**regressive behaviour**. So the group is designed to create an arena in which there is continuous flux between these different elements.

(e) Imitation, identification, internalization, and differentiation

(i) Imitation

From early in infancy, we observe and copy what others do. A therapeutic group is designed to create conditions in which imitative behaviour, or modelling, can be experienced, monitored, and understood. It brings the group members closer together and, as it develops into identification and internalization, it increases the cohesiveness of the group.

(ii) Identification

Peoples' predominant modes of relatedness to one another—such as compliance, avoidance, dominance, receptivity, exploitation, and need—become apparent in the group. The group exposes these patterns of relatedness to reveal how the internal objects with which members have identified can be externalized and encountered in the group through projection and introjection. Members compel each other to play and re-play the dramas of their interior lives and past injuries in the 'here and now' of group experience.

(iii) Internalization

Intimacy with others is developed through the exchange of understanding. As it is given and received, it allows for new forms of intimacy within the self. **Constructive** experience in the group is taken in and becomes part of the self. This can allow the recognition and reappraisal or **deconstruction** of repetitive patterns and fixed, maladaptive characteristics. And this can lead to the **reconstruction** of the self in the concluding phases.

(iv) Differentiation

Over time people become aware of significant differences in their reactions, emotions, and psychological structures. Examples are increased tolerance of affect, understanding and modification of self-inflicted pain, diminution of guilt and shame, retrieval of lost aspects of the self, increased openness with others, increased spontaneity and creativity, and, most critically, feelings of tolerance for or forgiveness of the self, for the constraints into which it has been driven by past injury and present defence.[62]

(f) Personal and group resistances

Some resistances are manifestations in the group of the characteristic defences of the members, evident in their interpersonal behaviour. Others are resistances of the group as a whole, shown in blockage of free-floating discussion, opposition to group interaction, sub-grouping, and opposition to the deepening and broadening of the group's exploration. A constructive function of resistances should be kept in mind when monitoring the pace at which both individuals and the group can progress without experiencing

overwhelming anxiety. Resistances can protect people from fears of loss of self and identity; and from fears of engulfment through excessive intimacy. Resistances then become opportunities for understanding fear of change, for the re-working early developmental patterns, and for discovering the freedom that can follow release from excessive internal control.

(g) The anti-group

Nitsun developed an understanding of the anti-group, bringing together the work of Bion and Foulkes.[63] He introduced the concept to help understand the negative experiences therapists face in periods of stagnation, hostile silence, severe conflict in or premature departure from the group, or negative feelings about the work of the group. These situations can arise when the group recapitulates early experiences of loss, deprivation, anger and envy or in an effort to avoid these emotions. Negative emotions can then be projected towards the group and the conductor who represent early care-givers. These feelings can be worked on when the therapist uses counter-transference to recognize and verbalize projected feelings. The idea of **negative elaboration** (see below) is a useful guide in this process.

Basic clinical issues

Dynamic administration

(a) Selection and composition

Group composition is the therapist's first and most enduring contribution to the group for its membership will determine the outcome of therapy. Preparing patients for treatment with several individual sessions or, if necessary, an extended programme of preparatory work will provide the therapist and patient with a basis for judgement about therapeutic prospects. Preparatory work has been found likely to enhance participation and reduce drop-out rates, although findings are not conclusive.[64]

The criteria for selection are exclusive rather than inclusive since most patients seeking psychotherapy can be accommodated in a group, provided a suitable one is available. The selection process should take into account both the patient needs and the composition of the group. A service should, ideally, provide a selection of groups into which people can be placed both according to their needs and characteristics, and those of the particular group. Selection criteria aim to optimize the 'fit' between the needs and resources of the individual and those of the group.

Table 6.3.6.6 lists inclusion criteria, while Table 6.3.6.7 gives a shortlist of excluding criteria. Lists of this kind should be used with caution. In general, at least four inclusive criteria should be found amongst those to be included in outpatient, dynamic psychotherapy groups with a mixed population. If there are four exclusion criteria, one should be very wary about including the person in a group. However, there are many exceptions.

The criteria in Tables 6.3.6.6 and 6.3.6.7 hold good for mixed groups and outpatient services generally. With homogeneous groups for special populations, the range of potential candidates is much wider, for example, Hearst describes a population of severely deprived mothers drawn entirely from those on the exclusion list.[65]

(b) Homogeneous and heterogeneous groups

Homogeneous groups: Are for people with similar symptomatic or diagnostic pictures, such as phobias, anxiety, or depression. Such groups offer more immediate support to members, are better attended, and provide faster symptomatic relief. However they may remain at a more superficial level with less interpersonal learning.[67]

Homogeneous groups are also used for those with similar personality structure or life-history, particularly those in socially extreme categories. For example, men with histories of sexual violence or women who have suffered rape or torture may be treated.

Heterogeneous groups: Melnick and Woods[67] suggest that group composition should be guided by an optimal balance between conditions ensuring group maintenance or homogeneity, and those maximizing interpersonal learning or heterogeneity. A group which shares one strong characteristic—a diagnosis such as an eating disorder, or a personal attribute like intelligence—can accommodate a diversity of presenting problems or social backgrounds. If, on the other hand, the members are similar in social background, diversity can be incorporated on another basis, such as diagnosis. Thygesen[68] found that diversity enabled group members to recognize and work with differences in mental and emotional attitudes, life histories, and developmental problems. Recognizing and working with difference develops emotional resources, promotes flexibility, and the tolerance of emotional tension. And it encourages the group to move from **cohesion**, in which security is based on identification, to **coherence** in which relationships are based on differentiation.

It is useful also to identify members likely to be isolated from the rest of the group by age, ethnicity, gender, personality, or problems or a history that noone else shares, for they are likely to find

Table 6.3.6.6 Inclusion criteria for psychodynamic groups (at least four of these criteria should be present, for someone to join a group)

1	Motivation to address personal issues, to resolve problems
2	Willingness to try and participate
3	Some experience of successful relationships in childhood or present
4	Some interest in exploring and understanding the self
5	Some capacity to talk, listen, and relate
7	Some interest in others
8	Some sense that being amongst others could be helpful
9	Some ability to sympathize or empathize with others' needs and problems
10	Some indication of future reliability in attendance

Table 6.3.6.7 Exclusion criteria for psychodynamic groups[66] (if four or more of these criteria are present, then questions should be raised about inclusion)

1	Those in acute crisis
2	Prior history of broken attendance in therapy
3	Major problems of self-disclosure
4	Major problems with reality testing, i.e. paranoid projections or psychosis
5	Pathological narcissism
6	Difficulties with intimacy generalized into personal distrust
7	Defences that rely excessively on denial and disassociation
8	Emotional unavailability
9	Tendency to be verbally subdued or withdrawn
10	Tendency to be hostile and aggressive, verbally or otherwise

the group experience threatening. We do not put a patient into a position of being isolated.

Managing the structure, setting, and time boundaries

(a) Optimal and sub-optimal size

The optimal number for small group psychotherapy, ranging from five to nine, is determined by practical considerations. A smaller number than this minimum is likely to have an active attendance of only two or three and will not necessarily generate the corporate energy to produce movement. A group larger than this will exceed the number that can be taken into one person's confidence in a face-to-face exchange.

Sub-optimal groups can provide valuable therapy under good conditions.[69] Low and irregular attendance is often associated with a problematic composition, particularly if there is a high proportion of members with character disorders and borderline features. Their inner sense of deprivation and loss can make the group seem unreliable and threatening which can be reinforced if the therapist is seen to be in difficulty. Therapists who can maintain an understanding attitude and positive commitment to the group's future will usually find the situation settles into a working nucleus of members that can then be built upon.

(b) Setting and time-boundaries

The therapist supplies, creates, and maintains the setting throughout the group's life. This requires attention to such matters as meeting times, punctual beginnings and endings, confidentiality, the predictable frequency of its meetings and breaks, and the general guarantee of a stable background.

Every aspect of the group's life, including absences, departures, late attendance, and extra-group communication in terms of letters, phone calls, and messages, referred to generically as **boundary events**, are open for discussion. Boundary events are interpreted for the meaning they might hold for the life of the group as a whole. This is a task initiated by but not confined to the therapist. Also, the setting itself—to which each member is seen to contribute—comes to acquire a capacity to **hold** the individual members and **contain** their anxieties and insecurities. The issue of containment is of great importance, as is the discovery—by people who may have no belief in themselves as responsible members—that they can take responsibility for themselves and expect responsibility from others. The group is thus responsible not only for the nurture, acceptance, and security of its members, but also for their containment, the setting of limits and the maintenance of consistent authority. The therapist will often have to lead the way in modelling both roles for the group's members.

Fostering therapeutic norms and a culture of enquiry

The therapist encourages the sharing of experience and helps to balance participation, recognition, and translation. The thrust of a group's life is towards greater shared involvement and the expression of emotions. The expression of feeling may arise in the recounting of members' life-situations and their reasons for therapy—**narrative emotion**—or it may arise in the interpersonal encounters engendered by the telling—in the **drama** of 'here and now'. Therapy becomes effective when the problems that brought the patient into treatment become recognizable in their interpersonal encounters. At this point the affect lodged in the narrative will interact with the drama of the group's current emotions, creating opportunities for corrective emotional experience. As the group progresses from **constructive** to **deconstructive**, and ultimately to **reconstructive**, experience, it will encompass gesture, behaviour, body-language, and other non-verbal communication, and actions that convey feelings when emotions have no words.

Guidelines for intervention

There are four modalities of time and place in any therapy group. The content of the exchange might be located in the past outside the group, the past inside the group, the present outside the group, and the present in the group.

Free-floating discussion will carry the focus of the exchange between these different modalities. The therapist's task is to follow the interaction, to use interventions sparingly and strategically, to cultivate a reflective curiosity for which Table 6.3.6.8 offers some pointers, and to work towards a progressive shift in the focus of attention, from no. 1, in Fig. 6.3.6.9 towards 4, via 2 and 3. A group governed by narrative in its free-floating discussion is likely to be dominated either by the the group's own past or by the past of its members outside the group or by their current lives outside. A group governed by members' intense experience of one another in the present, is likely to be governed by the drama of immediate encounter and understanding. The corrective recapitulation of early family life is likely to arise when the issues that predominate in no's 1, 2, and 3, are translated into issues that prevail in 4, where they can be addressed in the present which allows new resolutions to be forged.

Groups for special populations

Nine distinctive clinical populations or approaches merit special mention. Some pose distinctive problems for group workers and, as we indicate in the section on borderline patients, they sometimes need co-therapists working together in the group.

Table 6.3.6.8 Interventions in time and place

1	Address process rather than content
2	Help members recognize aspects of themselves in others and accept the viewpoints of others on themselves
3	Monitor the intensity of participation to allow an enabling pace so members can develop resources to deal with the intimacies of each others' lives
4	Establish a sense of enquiry about the fluctuations of mood and outlook, and a sense of curiosity about thematic movement between the different modalities of time and place
5	Help the group recognize role configurations taken up by individuals (therapist's assistant or rival, joker, complainer)
6	Hold in mind the gestalt of figure and ground. If someone stands out, what is the background against which they do so? If the ground changes the underlying pattern of the group, how might the figural person be affected?
7	Help the group recognize sequences and patterns
8	Help the group decode and find meaning in the constructive, deconstructive, and reconstructive elements of its exchange
9	Work towards the coherency of the group
10	Foster the integration and integrity of its members

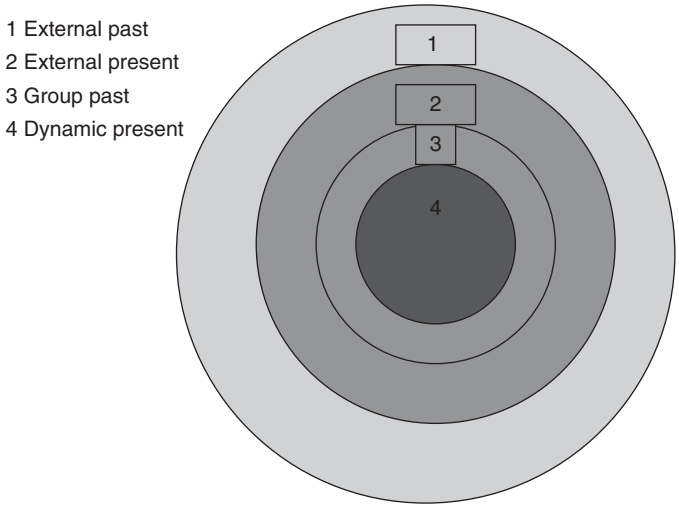

Fig. 6.3.6.9 Location of group discourse in time and place.

Intensive outpatient psychotherapy heterogeneous groups for mixed populations

Group analytic psychotherapy has come into its own as a treatment modality in out-patient settings in the context of clinical agencies in public and private Health Services. Table 6.3.6.9 gives a picture of patients' clinical needs in the private practice of John Schlapobersky over a twenty-year period. Some attempt has been made to indicate how these categories are mapped against those in ICD 10 and DSM IV.

The medically ill

Groups have been used successfully for people with diseases of the cardiovascular, endocrine, gastro-intestinal, pulmonary, neurological, and renal systems. Amongst the applications are groups for those with renal dialysis and organ transplantation; chronic conditions such as diabetes, irritable-bowel syndrome, and rheumatic disease; and life-threatening conditions such as metastatic cancers.

Groups usually have members with a single disorder, last for 20 sessions or fewer, and are psycho-educational in purpose. They emphasize compliance with treatment regimes and opportunities to share and explore the affective consequences of the conditions. The focus is on helping patients come to terms with the complaint; make changes in lifestyle, including diet, exercise, work, and recreation; deal with the inevitable anxieties about death, stigma, demoralisation, feared dependency, and loss of control; and resolve issues in relationships with loved ones and care staff. Clinicians write of how, despite their brevity, these groups provide a forum for sometimes profound exchange about major existential issues including pain, fear, and impending death.[70]

Evaluation indicates such groups are effective in improving quality of life and, to some extent, in prolonging its duration even with metastatic cancer.[71] Improved survival correlates significantly with enhanced, active coping. Spiegel reported a significant, near-doubling of survival effects in 86 women with metastatic breast cancer treated for one year with weekly, supportive-expressive group therapy.[72,73]

The chronic mentally ill

In North American literature there are consistent findings that schizophrenic patients do best in support groups that help them manage their symptoms and devise coping strategies for day-to-day problems.[74] Group discussion is used to help overcome problems of social isolation, develop social skills and coping resources, and learn about maladaptive interactions evident in the 'here and now' of the group. The leader creates a sense of safety and security with supportive feedback. Areas that people find helpful include the management of symptoms, expression of emotion, and relationships with others. Groups are less valued for acquiring insight or receiving guidance about the illness, medication, or economic problems. Interpretations that reveal or explore unconscious conflicts, particularly transferential issues between members or with the therapist, are more likely to be harmful than helpful.[75] Patients respond positively to an interactive, open, and safe group environment, with gradually increased cohesion, decreased avoidance, and decreased conflict.[10]

Recently, Resnik[76] has described the use of insight-orientated psychotherapy with delusional problems using psychoanalytic principles in long-term group psychotherapy for psychotics.

Borderline personality disorders

Working with these patients can pose difficult clinical problems based on their 'stable instability', including their inability to form a stable therapeutic alliance, mood oscillations, poor impulse control, limited reflective ability, painful states of psychic emptiness, followed by self destructive acting-out including self-destructive gestures and self-mutilation, violence; substance abuse, sexual acting out, and eating disorders. Some attempts at short-term group therapy combining cognitive behavioural approaches with the psychodynamic have shown promise. Longer therapies in out-patient groups have been encouraging but have not been evaluated. Good results are reported with in-patient applications at, for example, The Cassel and Henderson Hospitals, and in other forensic settings where day hospital group treatments are followed by outpatient group therapy in a carefully monitored programme.[77]

Homogeneous outpatient groups do not do well because the members use similar 'primitive' defences of splitting, projection and denial, and have not acquired a stable sense of identity. They are suspicious of close interpersonal contact and have little capacity to care for or be cared for by others. Such groups lack cohesion, are pervaded by a sense of pessimism, hostility, rivalry, and easily fragment. Self-destructiveness is turned onto the group and its therapists who may experience intense counter-transference feelings of frustration, despair, and anger.

These problems can be managed in the containing setting of closed or specialized institutions. However, it is generally better to place one or two borderline patients in an otherwise well-functioning group where other members will not always respond to borderline pathology at the same primitive level. They may—like the adult carers of children—respond with understanding, find ways of setting limits, and expect co-operation with the task at hand. After sometime, lengthy periods in which borderline patients maintain a frustrating presence on the margins of the group, or make themselves felt in aggravating terms at its very centre, they can acquire resources to take part in the group's work in more mature terms. This combination of borderline and neurotic members in a carefully composed group can benefit both parties. Borderline members will often have an unerring accuracy of perception about others, they can shake the group into more active interactions, and may not collude with others' neurotic defences.

Table 6.3.6.9 Categories of clinical need catered for by intensive, outpatient group therapy with mixed populations (many of those who join groups are found in more than one of these categories of need)

1. High dependency need including:	2. Problematic reactions to traumatic life events including:	3. Character problems including:	4. Serious relational problems including:	5. Selected people with borderline personality disorders including	6. Training of mental health professionals including:	7. Those seeking personal growth or understanding including:
a Recovery from serious or enduring mental and physical illness b Help with the resolution of moderate psychiatric symptoms c Resolving addiction and substance abuse	a Loss, injury, illness, disorder, infertility b Massive psychic and physical trauma c Adult sequelae of child sexual abuse	a Immaturity and developmental problems b Chaotic life situations c Problems of identity and meaning d Problems of gender, sexuality, and orientation e Occupational problems	a Intimacy avoidance b Recurrent broken relationships c Intractable conflicts	Those with insight who both need and can tolerate containment	Psychotherapists, psychiatrists, psychologists, social workers, clergy	People who would have previously sought this through individual psychoanalysis

(John Schlapobersky: Group-Analytic Practice & Southwood Practice: 1987–2007)

Category 1: Corresponds to Axis I in DSM IV and Groups F1–4 in ICD 10.

Category 2: Corresponds to Axes III, IV, & V in DSM IV and Group F5 in ICD 10.

Category 3: Corresponds to Axes IV and V in DSM IV and Group F8 in ICD 10.

Category 4: Corresponds to Axis V in DSM IV and Group F8 in ICD 10.

Category 5: Corresponds to Axis II in DSM IV and Group F6 in ICD 10.

The containing resources of the other members that set the norms and values of the group can slowly be internalized by the borderlines. As with many of these specialist areas, therapists working with these populations will need to acquaint themselves with the literature, have ongoing supervision and may—to begin with—work more fruitfully in co-therapy.

For a review of group psychotherapy for personality disorders see [78, 79].

Forensic groups

Group therapy has been used for forensic populations, previously thought untreatable. Pioneering work has been done in the UK in special hospitals,[80,81] in prisons such as Grendon,[82] and great strides have been made in outpatient services at the Portman Clinic in London.[83] Therapeutic community treatment for mentally disordered offenders in North America and Western Europe has been reviewed by Lees, Manning, and Rawlings.[84]

The aim of forensic group therapy is to help patients find words, rather than actions, to express impulses and compulsions. A major part of the group's work is to provide psychic space for perspective, negotiation, recognition, acceptance, and verbalization of hurt. Sharing the past and present can make it accessible as internalized, persecutory, and vengeful monologues are brought into dialogue.

In Britain, the Probation Service is the agency most actively involved in the groupwork with offenders.[85] A report for the NHS Centre for Reviews and Dissemination (CRD Report 17) reviews studies of therapeutic communities and small groups and indicates that these show the most promising results of any form of treatment for anti-social personality disorders.[86]

Trauma

Group work with trauma victims is a comparatively new field but one in which there is a vigorous range of applications. The most comprehensive overview is Van der Kolk's text.[87] There are groups for survivors of sexual abuse,[88] war trauma,[89] and torture and other forms of organized violence. Group work applications to traumatized children and adolescents is discussed in reference 90 and more generally in reference 91.

At the Medical Foundation for The Care of Victims of Torture in London, a group work programme caters for refugees and asylum-seekers. The groups provide psychotherapy for massive psychic and physical trauma, for problems of displacement and exile, and for trans-cultural problems.[92] The diversity of different kinds of groups, including a range of activity, problem-solving, and psychodynamic groups, ensures that people can be provided with an environment in which they can each realize their own potential for self-healing. The programme is grounded in commitment to human rights, to team-work that addresses counter-transference issues, and to principles of positive intervention to counter emotions of hopelessness, and despair.[93,94]

Couples groups

These groups cater for people in stable but troubled relationships in which there is some form of pernicious collusion. The approach can provide symptom relief and personality change in even severe difficulties with relationships that last but do not work. Family therapy is concerned with the systemic function served by symptoms. Psychoanalysis is concerned with the origins of the

symptoms in object relationships. Group analysis provides a bridge between these paradigms, helping therapists find a point of intervention between marital and object relationships.

In a group, the process moves between the psychology of the individuals and the dynamics of their marriages. This interplay between the pair and the person—the interactive and historical dynamics—is part of the group's free-floating discussion. The therapist uses this interplay, following the patterns of the group's progress and making interpretations. Work is at times transferential, other times, systemic techniques are used to address immediate issues.[95] Themes to which the group resonates are amplified and members are helped to condense from this discourse, the kind of personal knowledge that promotes growth and change. There is insufficient evaluation of the method's efficacy, but experience in hospital and private practice is very encouraging.[96]

The elderly

This is an area of relatively new therapeutic exploration. A range of groups has been found useful in helping the aged to face their problems, improve their functioning, and feel happier about themselves. The groups include those offering support, activity, psycho-education, problem-solving, and insight, and takes place in many settings. Common themes include the ubiquity of loss, the acceptance of death, and the value of humour in lightening mood.[97]

Brief therapy in groups

Spurred by economic and managerial pressures a distinctive modality has evolved. Sessions are held weekly and number between 6 and 30. Characteristics that differentiate brief from long-term therapy include: clearly defined therapeutic goals agreed at the outset, the early establishment of a therapeutic alliance, active and flexible therapeutic style, a focus on 'here and now' group process, the maintenance of time awareness, monitored in stage-specific terms, and the vigorous, directed exploration of thematic content.

Short-term groups may be homo- or heterogeneous. Homogenous groups have proved effective in helping patients deal with loss and grief, the consequences of trauma and abuse, and common problems coping with physical illness and disability. Heteregenous groups require more psychodynamic commonalities such as shared problems in inter-personal relationships, the ability to recognize and work on psychological issues, and the ability to cope with the speed and intensity of the process. Those who lack psychological sophistication or are not motivated for self-exploration, are not suited.

Research and evaluation

The general trends in literature show ample empirical confirmation that group treatments represent a powerful therapeutic intervention. A comprehensive overview of literature described positive outcomes with alcoholism, anxiety disorders, bereavement, bulimia, depression, schizophrenia, and sexual abuse.[98] There is also evidence of the adverse outcomes in group psychotherapy which can guide the clinicians training for the work.[99]

(a) Outcome research

A meta-analysis of 58 controlled studies of psychotherapy for the treatment of depression showed that in comparison to a waiting list control the average treated patient was better off than 80 per cent of the controls.[100] The efficacy of group and individual therapy was almost identical. Tyllitski[101] also reported no appreciable difference between individual and group therapy effectiveness, both doing better than the control condition. Budman et al. found significant improvement in time-limited individual and group therapies. It seems that most patients who are suitable for psychotherapy will benefit in either modality.

(b) Process research

(i) Preparation of patients for group therapy

In a review of 20 controlled or comparative studies, Piper and Perrault[102] found that preparation has a positive effect upon attendance but that it could not be shown to have a direct effect on outcome.

(ii) Therapist activity

Development of constructive group norms will depend on factors such as careful group composition and leadership style. Foulkes' idea that the conductor has, at first, a relatively high rate of activity which decreases as the group develops its own resources for psychological work has been supported by later research findings.[103]

(iii) Group process variables

Research on therapeutic factors (e.g. self-disclosure and feedback) and leadership technique indicate that members in well-established groups are engaged in many different types of psychological work. They are less group-centred and more likely to be confronting the personal distress and maladaptive interpersonal styles that brought them to treatment in the first place.[104]

(iv) Therapeutic factors

In a study of long-term in-patient groups, Tschuschke and Dies[105] investigated five therapeutic factors: cohesiveness, self-disclosure, feedback, interpersonal learning-output, and family re-enactment. All five therapeutic factors were associated with clinical improvement with group cohesiveness, an important ingredient. They suggested that **affective integration** into the group, that is the high and positive emotional relatedness to co-members, promotes the capacity to disclose and leads to more frequent and intense feedback from fellow patients. It appeared that feedback given earlier in the group had a stronger relationship to treatment outcome. This may suggest that **interpersonal feedback** needs time to be assimilated and worked through before it can be utilized effectively. There are significant differences between successful and unsuccessful patients in terms of level of group cohesion and amount of self-disclosure. Patients who disclose little and do not feel drawn to the group receive relatively little meaningful interpersonal feedback and become neglected. They concluded that **cohesiveness, self-disclosure**, and **feedback** and together promote **interpersonal learning** within the group.

These findings were confirmed by the author's later studies, the most recent of which was published in 2007[106] and by recent independent studies using different parameters; see, for example, references [107–109].

Conclusion: planning a service

For group psychotherapy to be effective the group has to be the primary focus of therapy; patients need to be well selected; and

therapists need to be adequately trained. Therapeutic competence is not a function of mastering the literature so much as it is the outcome of experience in the group situation itself. Courses introducing different group methods are now widely available throughout the UK, Continental Europe, and the USA. Group training is also provided in many general training programmes and, along with clinical supervision, is offered in many health and other service agencies.

Long-term **outpatient** group therapy of 100 sessions or more is effective and economic in producing lasting benefits for patients with a wide range of medical and psychiatric symptoms, interpersonal problems, traumatic life experiences, character and personality disorders. **In-patient** group therapy is an effective resource in the context of acute units working with crisis, and in secure units working with long-term problems. **Short-term** group therapy for selected conditions requires careful composition of the group and an active, flexible therapeutic approach.

We have not tried to cover the range of group services and approaches for children. Chapters by Schamess[110] and by Kymissis[111] cover group work with children and adolescents, respectively. Further reading is available in Evan's text[112] and Melzack.[113]

There are economic arguments for group therapy. In one study, the quality of improvement between individual and group therapy of psychiatric patients was not significantly different but the cost of the service was different. Cost savings were calculated as the reduction in medical consultations and hospital attendance, and lost workdays. For those treated with psychotherapy of any kind, the cost of treatment was 25 per cent per patient less than it was for those who did not receive psychotherapy. The cost of group psychotherapy per patient was about a third less than for individual psychotherapy.[114]

Further information

A. Bateman, D. Brown and J. Pedder's (2000) *Introduction To Psychotherapy* (Routledge) sets group therapy in the context of other psychotherapies. D. Stock Whittaker's (1995) introduction, *Using Groups To Help People* (Routledge) and M. Aveline and W. Dryden's (1988) *Group Psychotherapy In Britain Today* (Open University Press) give a general overview of UK practice in the past. There are three good texts that introduce the group-analytic approach. The most recent by H, Behr and L. Hearst (2005) is *Group Analysis: A Meeting of Minds* (John Wiley). W. Barnes, S. Ernst and K. Hyde have written a recent overview, (1999) *An introduction to groupwork: a group-analytic perspective* (Palgrave Macmillan). And an earlier text by D. Kennard (1993) *The Workbook of Group Analysis* (Routledge) provides a clinically grounded study of practitioners at work. The range of other books in the International Library of Group Analysis and the journals, *Group Analysis, Group, and The International Journal of Group Psychotherapy* give access to the many specialist applications discussed here.

6.3.7 Psychotherapy with couples

Michael Crowe

Introduction and background

There is an ongoing crisis in the institution of marriage, at least in Western cultures. There has for some time been a tendency to idealize marriage, and at the same time social forces are operating which tend to undermine it.(1) These influences have probably made a contribution to the increasing divorce rate, as well as the tendency for fewer couples to marry, and have probably also led to an increase in the number of couples seeking help with their relationships.

In the United Kingdom, for example, the number of marriages taking place each year has fallen for the first time in living memory, and the number of divorces is still steadily increasing, reaching 40 per cent of marriages in 1996.(2) There are also a large number of 'common-law' marriages, often with children, as well as more transient cohabiting or non-cohabiting sexual relationships, both heterosexual and homosexual. The stability of these relationships is, of course, not recorded in the marriage or divorce statistics, and the rate of breakup can only be guessed at; however, it is very probable from clinical experience that in these non-marital relationships there is a higher than 40 per cent incidence of breakup. In the wake of these changes, there are a large number of

single-parent families and 'reconstituted' or blended families, as reviewed by Robinson,[3] and there is a decreasing proportion of children who are being brought up in the traditional nuclear family with two biological parents.

In addition to these new factors affecting marriage in the early 21st century we should also be aware of the fact that many countries, especially those in the developed world, have a multicultural society, and that immigrant cultures have different attitudes to marriage and family life. For example, families from the Indian subcontinent often prefer to arrange marriages for their children, and in some cases insist that the couple live in the husband's parents' house. On the other hand, West African couples often leave their children in Africa to be looked after by family members for long periods of time, while the parents work or study in the West.

In the last few years, Gay marriage or Civil Partnership has been recognized in many western countries. Couples in Gay relationships have many of the same problems and satisfactions as heterosexual couples, and in addition, must live with fairly widespread negative attitudes and homophobia from neighbours, family and society generally. Their relationships have to be, if anything, stronger than heterosexual ones to survive these pressures, and may be more in need of therapy.

Couple therapy must be able to take account of these factors, and whilst much of what is contained in this chapter will relate to heterosexual married British couples living with their biological children, it should be understood that there are many other types of relationship which can be helped using a similar approach, with appropriate changes of emphasis. In a later section, there will be some additional discussion of the specific problems relating to couples from other cultures, and ways of managing these.

Couple counselling and couple therapy

The concept of couple counselling dates from the 1920s when in the United States the American Association for Marital Counselling was formed; in the United Kingdom the Marriage Guidance Council (now called Relate) was founded in 1938. Counselling mainly took the form of giving advice on practical issues, but in more recent years, Relate counselling has been orientated more towards psychodynamic approaches, and favours a longer-term involvement with the couple. Couple counselling continues in both countries, and the great majority of couples seeking help with their relationships are seen by couple counsellors, rather than any other types of therapist.

The distinction between couple counselling and couple therapy is not an easy one, because many of the interventions are similar. In a simplistic sense therapy attempts to make a more radical difference to the couple's functioning than counselling, which has the general aim of improving adjustment to the situation as it is. However, many forms of both couple therapy and couple counselling are based on a theoretical formulation which is derived from a related school of individual psychotherapy (for example, cognitive behavioural or psychodynamic). Thus, theoretical formulations in the resultant couple work are so different between therapies (e.g. psychodynamic as against behavioural) that a particular form of counselling may have more in common with a related form of couple therapy than that therapy itself has with another type of couple therapy.

Psychoanalytic/psychodynamic couple therapy

Couple therapy using a psychodynamic model began in the United Kingdom in 1948, when Dicks and his colleagues founded the Institute of Marital Studies. The theories and techniques involved have been ably reviewed by Daniell[4] and Clulow.[5] The central concept used is that the inner (unconscious) world of the two partners determines their interaction and their response to changing circumstances. It is as though each partner has an internal blueprint, both of themselves and each other, formed partly by observation but also partly by the influence of earlier intimate attachment experiences with parents, siblings, or friends. These influences may actually determine the choice of partner, and the nature of each partner's patterns of attachment (secure or insecure) will affect the ways in which they cope with the stresses of the new relationship. There may then be projections which lead one partner to attribute motives such as hostility or sadism to the other, whereas in fact this is a split-off and denied characteristic of the first partner. Other consequences of this unconscious process may include the system of shared fantasies and defences which builds up as the relationship continues.

In therapy, four premises are used, which inform a relatively long-term and open-ended series of sessions. The first is that a person's emotional health is related to his or her capacity to manage both internal conflict and external stress: it is important to be able to experience fear as well as trust, pain as well as pleasure, doubt as well as certainty, frustration as well as satisfaction. Secondly, significant relationships can be used to resurrect, but also change, inflexible patterns of behaviour established in the past. Thirdly, unconscious processes need to be taken into account when attempting to understand problems in relationships. Fourthly, change takes time because it requires a reordering of perceptions of self and others, perhaps with the help of transference interpretations by the therapist involving both partners.

Therapy in this mode may be carried out by one therapist seeing both partners, but is more often done by two therapists either seeing the couple together or in parallel individual sessions, using one partner with one therapist, with joint supervision of the two therapists. An intriguing aspect of this therapeutic format is that sometimes the two cotherapists find themselves interacting in unfamiliar ways, in sessions and between sessions, which are thought to represent the projection of fantasies and feelings by the couple on to the therapists; the therapists' understanding of these projections in their joint supervision may play a role in advancing the therapy itself. If these insights are used to inform the therapists' interaction with the couple, the individual partners may then be made aware of their own conflicts, fantasies, and projections, and thus be able to give up some of their repetitive patterns of behaviour and withdraw damaging projections.

The psychoanalytic approach has been an important source of theoretical ideas in couple therapy, especially the concepts of attachment and loss developed by Bowlby.[6] It has also the distinction of being the first theory to be adapted to this area of work. There are, however, some drawbacks to working in this way, as enumerated by Wile.[7] He sees the emphasis on negative impulses and emotions (e.g. dependence, narcissism, sadism, manipulation, and exploitation) as painting a rather unflattering and negative picture of the couple in therapy, and perhaps therefore reducing

their motivation to continue. A more serious problem with the approach is that the psychodynamic concepts, whether of defence mechanisms, projections, or shared fantasies, are treated as if they were as real as observed behaviour, whereas in fact they must remain assumptions based on hypothetical constructs, and are really only valuable in so far as the therapy based on them is effective.[1]

The question of efficacy is raised later in the chapter, but it must be stated here that the psychodynamic therapies for couple problems have only seldom been submitted to controlled trial, and then usually in a relatively short-term form. The therapy may be quite long term, and the improvements seen are usually not dramatic, so that in the last analysis the approach has to remain of uncertain value.

Behavioural couple therapy

The behavioural approach, in contrast, makes no assumptions about internal conflicts or underlying mechanisms in the individuals. The approach was initiated in 1969 by Stuart[8] and Liberman[9] as behavioural marital therapy. They worked from the principles of operant conditioning and made the assumption that couples who were having difficulties were either giving each other very low levels of positive reinforcement or were using punishment or negative reinforcement to coerce each other into behaving differently. The remedy that they proposed for this situation was to help the partners to learn how to persuade each other to conform to the desired pattern of behaviour by the use of prompting and positive reinforcement. Thus, complaints would be transformed into requests and requests into tasks agreed by both partners.

Behavioural marital therapy relies on the therapist's observation of the couple's behaviour in the session and on the problems they report from the previous week or equivalent timespan. There are two types of therapeutic activity in behavioural marital therapy. The first is reciprocity negotiation, in which the partners request changes in behaviour on each side and negotiate how this can be achieved through mutually agreed tasks. The second is communication training, in which the partners are encouraged to speak directly and unambiguously to each other about feelings, plans, or perceptions, and to feed back what they have heard and understood. In both these approaches, the deeper meanings behind a particular piece of behaviour are ignored, the emphasis being on change in the interaction both in the here and now and in the immediate future. The approach has been the subject of many controlled trials (see below), and is of proven efficacy.

Cognitive behavioural and rational–emotive couple therapy

Aaron Beck,[10] in his cognitive behavioural approach to couple therapy, identifies in the communication of disturbed couples many of the problems found in the thinking of depressed patients, and attempts to correct these. Thus, he tackles misunderstandings, generalizations, untested assumptions, and automatic negative thoughts by challenging assumptions, reducing unrealistic expectations, relaxing absolute rules, improving the clarity of the communication and focusing on the positive rather than the negative.

Similarly, Albert Ellis (reviewed by Dryden[11]) uses a rational-emotive approach to couple problems. Here, the main focus is on the use of words; terms such as 'intolerable' are replaced by (for example) 'difficult to accept', and the couple are encouraged to express desires rather than demands. There is an analysis of the repetitive cycles of cognitive and behavioural disturbance, in which each partner may attribute the other's behaviour to a negative motive and assume that nothing can be done about it. The general thrust of this therapy is similar to that of Beck, but with a more lively and less formalized approach in the session.

Systems therapy for couple problems

The systems approach to couple therapy derives partly from concepts developed by Minuchin[12] and Haley,[13] and partly from the work of Selvini Palazzoli *et al.*[14] All these pioneers worked predominantly with families rather than couples, but many of their ideas and techniques are relevant to the treatment of couples. Although the systems approach to therapy has broadened and deepened since the 1980s, many of the early concepts are still very useful.

A central concept in thinking about couple relationships is 'enmeshment', by which is meant an excessive involvement in what is essentially the private business of another person. It is quite common to find an enmeshed relationship between parents and their teenage children, in which both sides find it very hard to 'let go'. It can also be found in couple relationships where one partner wants to be closer than the other, and a conflict arises as to what is the best distance to maintain. Systems therapy aims to help them to find a compromise 'distance' which suits them both, and thereby to reinforce the necessary 'boundaries' which people need in maintaining their individuality within a relationship.

The concept of circular causality is also central to systems work. This enables the couple to get away from the idea that one person is necessarily to blame for a particular situation by considering the continuous cycle of cause and effect in which A's actions may be caused by B's actions and also B's may equally be caused by A's. Thus, systems therapists, when approaching a couple problem, do not focus on one partner's behaviour, but rather on the pattern of interaction obtaining in the relationship. They will then try to effect a change in which both partners contribute actively to the solution of the problem.

Systems therapists have many techniques at their disposal, including those which increase the couple's understanding of the system they are participating in. These include family genograms (a form of family tree construction which leads to discussion of transgenerational influences or 'systems over time'), family 'sculpting' (in which the members position themselves and each other wordlessly to represent their current relationships), and the discussion of 'family myths' and stories. More active techniques, designed to play a part in changing the family interaction, include creating conflict in the session, giving homework tasks, and the use of 'paradoxical injunctions' in which the therapist tells the family to continue with the current interaction because, even though it is problematic, it seems to be protecting them from worse consequences. These more active techniques will be dealt with in more detail in the main part of this chapter on behavioural–systems therapy.

Mixed or eclectic approaches

Most couple therapists use a mixture of techniques, and it seems that this is probably an inevitable consequence of the difficulties

involved in applying one therapeutic method rigorously in a clinical setting. A number of specific combinations have been advocated, and will be briefly mentioned here.

The first is the psychodynamic-behavioural approach of Segraves.[15] In this, the basic underlying cause of marital disturbance is assumed to be the partners' conflicting internal and unconscious projections, and their interactions. The therapy, however, is not only directed at helping them to understand these (as in psychodynamic therapy) but also to increase their negotiating and communicating skills (as in behavioural marital therapy).

The second is a more comprehensive mixture of theory and technique, known as the intersystem model, and advocated by Weeks.[16] This tries to take account of the individual, interactional, and intergenerational aspects of couple relationships, and combines them in what is probably closest to a systems model, but with more emphasis on the psyche of the individual. Interventions are on both a conjoint and individual basis, and the techniques of decentring (see below) and paradoxical injunctions are often used.

The third eclectic approach is that of Spinks and Birchler.[17] This is called behavioural–systems marital therapy, and makes use of behavioural marital therapy as the main form of intervention, moving into the systems mode when 'resistance' emerges. There are many similarities between this form of treatment and the one described in the main part of this chapter, but our 'behavioural–systems approach' is more integrated as between the two components of the method.

The fourth eclectic approach which should be mentioned is that of Berg-Cross.[18] She uses rational-emotive, sociocognitive, systemic, psychodynamic, humanistic, and theological concepts to understand and modify couple relationships. Like that of Weeks, her approach gives the therapist a very wide canvas to work on, but may lose some of the focus by being very general and all-embracing.

The behavioural–systems approach to couple therapy

Behavioural–systems couple therapy is the approach that will be described in detail in the present chapter, and although it is only one of several approaches to couple problems, it has the advantage of spanning two of them, and issues such as indications for therapy and assessment are shared with both the pure behavioural and systemic approaches. It is the method developed at the Maudsley Hospital Couple Therapy Clinic in the 1980s. It has been expounded at greater length by Crowe and Ridley,[1] and like some of the other eclectic models mentioned above it combines two different approaches, behavioural marital therapy and systems family therapy. The behavioural dimension, similarly to that described by Stuart (8) and Jacobson and Margolin,[19] consists of the relatively straightforward methods of reciprocity negotiation and communication training. The systems dimension is more complicated, and involves systems thinking, structural moves during the session, tasks and timetables for the couple between sessions, and the use of paradox. The method was developed in a predominantly psychiatric setting, and has been found to be particularly suitable for those couples where one or both partners has psychiatric problems in addition to their relationship difficulties. It is also useful as an adjunct to psychosexual therapy where a sexual dysfunction or a sexual motivation problem seems to be connected with relationship issues.

The method should be thought of as a series of menus from which the practitioner can choose techniques rather than as a set course of therapy beginning at one point and ending at another. Thus, the various components of behavioural–systems couple therapy can be incorporated at any time in the therapy session, although in practice, negotiation, communication training, and structural moves are usually employed in the earlier part of the session, while tasks, timetables, and paradox are usually reserved for the 'message' at the end, and are linked to homework assignments to be carried out between sessions.

The different techniques of behavioural–systems couple therapy can be thought of as belonging to a kind of hierarchy. The so-called 'hierarchy of alternative levels of intervention (ALI)'[1] links each type of intervention with a particular set of clinical problems and makes recommendations as to the type of intervention that is appropriate. The ALI hierarchy is shown in diagrammatic form in Fig. 6.3.7.1. As may be seen, where the couple appear to have greater rigidity in their behaviour, where they show more symptoms, and where they show more reluctance to accept the relationship as the focus of work, the therapist needs to move to the systems end of the hierarchy, and use more ingenuity in the development of interventions. If, however, the couple accept the interactional focus and show willingness to recognize the part that the relationship is playing in maintaining the problems, the therapist may be quite comfortable and effective working behaviourally. By and large, the preference is to work behaviourally, since this implies collaborating with the couple and accepting their stated goals, whereas the systems approach puts the therapist into a more managing role, deciding what is best for the couple and suggesting tasks that may not be what they would expect. It should be emphasized that the therapist may at any stage move up or down the hierarchy, according to the couple's response: an increase in flexibility shown by the couple could be the trigger for the therapist to begin working in a more behavioural way, whereas an increase in rigidity or a failure to respond to behavioural work could be met by a more systemic approach.

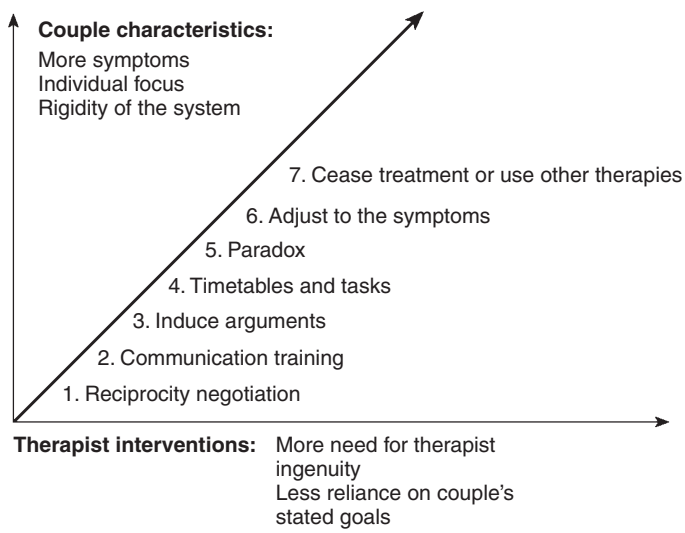

Fig. 6.3.7.1 The alternative levels of intervention hierarchy.

Indications and contraindications

If there is a relationship problem identified by either the couple or their advisers, even if there are also individual psychiatric or behavioural problems, and if the couple are willing to attend together, then in most cases they are suitable for behavioural–systems couple therapy. The breadth of the therapeutic approach, the fact that the behavioural techniques are of proven efficacy (see below), and the fact that the systemic interventions are suitable for those with more psychiatric symptoms or similar problem behaviours, all give the therapy a wide range of positive indications.

(a) The nature of the problem

Clearly those with relationship problems such as arguments and tensions are highly suitable for couple therapy. Another related indication is those relationships in which one partner (who might be attending a counsellor or psychiatrist alone) spends much time complaining about the absent partner's behaviour. A third indication is where the health of one partner suffers following the other partner's individual therapy.

Many problems with sexual function would be suitable for couple therapy, including those couples where there is a disparity in sexual desire, or those where one partner has a specific phobia for sex. In some such cases there is also a need for individual therapy, especially where one partner is the survivor of earlier childhood sexual abuse.

Many people with depression or anxiety, especially those where there is also poor self-esteem, may be suitable for couple therapy. There are often aspects of the illness that are exacerbated by problems in the relationship. Indeed, in a study by Leff *et al.* in 2000[20] it was shown that couple therapy was an effective and acceptable form of treatment for couples in whom one partner was depressed.

Where jealousy is present the problem usually affects the non-jealous partner to a greater or lesser extent, and here it would almost always be useful to have at least a few conjoint sessions with the couple, as suggested by De Silva.[21]

Some problems are perhaps less amenable to couple work, and among these are, for example, phobias which seem unconnected with home life in any way, and post-traumatic stress reactions where the event happened away from the partner. Some alcoholic and drug-addicted patients have so much of their existence involved with the addiction that they are not available emotionally to do couple work, and the work would at that stage be wasted on them. Similarly, those with an acute psychosis would, at the time they are acutely ill, be unavailable to this kind of therapy, and should not be offered it. However, in both cases, when the acute crisis is over and the addiction or psychosis is under control, it would be very appropriate to offer them some kind of couple therapy, even if this had limited aims and expectations. Some of the most useful psychological interventions in schizophrenia, after the acute illness has resolved, involve the nearest relative, as shown by McFarlane.[22]

(b) Degree of connection with the relationship

Some problems in individuals have been in existence long before they entered the present relationship. If this is the case, the therapist should consider whether it is best to embark on couple therapy or whether individual therapy would be better. However, even when there seems no causal connection with the relationship, the effect of the problem on the partner may be such as to warrant at least one or two couple sessions.[23]

(c) Availability and willingness for joint therapy

If the partner of a patient is unavailable or unwilling to attend for therapy, it may be appropriate to let the situation be, and not offer treatment. In some immigrant couples, for example those from the Indian subcontinent, there are cultural reasons given for a wife not attending therapy, and we usually have to respect these. However, in both situations it is sometimes right to put some pressure on the absent partner to attend, because the reasons for non-attendance may be relevant to the couple problems we are trying to treat.

(d) Is the relationship continuing?

If the person who is asking for therapy is going through a divorce or equivalent breakup of a relationship, it may not be appropriate or possible to treat both partners. However, in some cases there is good work to be done in arranging a more satisfactory breakup, in terms of domicile and care of any children. This 'mediation' work is increasingly being done, and many of the processes are similar to those of couple therapy.

Assessment and selection

This is not an easy process, because there is a dearth of research on the types of couple problem presenting for treatment and on the outcome of treatment itself. However, on the basis of the referral letter (usually from a GP or psychiatrist) the therapist will usually arrange a preliminary session with the couple. The only reason not to see the couple in the first instance is that they are not willing to attend as a couple, or the problem is seen clearly as an individual one (see above).

Another, more subtle, form of selection occurs during the first therapy session, when the couple are in contact with the process of therapy. In this session, the therapist considers the ability of the partners to empathize with each other, their pattern of communication, their stage in the 'family life cycle' (see below) with its associated stresses, and their flexibility in response to simple therapeutic interventions. He or she will attempt to use reciprocity negotiation or other straightforward techniques of therapy, partly as a treatment trial, and partly to see whether the couple is ready for this kind of intervention. If not, the therapist can move to a more systemic approach, or decide after a few visits that there is no future at this point in further therapy of this kind, and that something else (e.g. individual therapy) is needed (Fig. 6.3.7.1).

The process of therapy: beginning and continuing

Behavioural–systems couple therapy is essentially a short-term therapy involving perhaps 5 to 10 sessions of 60 minutes each, over a period of 3 to 6 months. Although the therapy was developed in a room with a one-way screen and live supervision, it is quite possible to use behavioural–systems couple therapy in any conventional consulting room without a team or live supervision. If the one-way screen is used, the therapist and the team (which may include students as well as experienced colleagues) begin by reading the referral letter and the biographical questionnaires which the couple will have completed, and discuss the case with a view to formulating the problem from an interactional point of view. This may involve, for example, thinking about the couple's stage in the 'family life cycle' (e.g. birth of the first child or the 'empty nest'),

any recent event such as a bereavement or a new relationship, or the diagnosis of a serious illness. Hypotheses about the possible causation of the recent problems are not necessarily thought of as 'true' explanations, but have the function of informing the therapist's thinking and suggesting what level of the ALI hierarchy to choose at the initial meeting and what strategy to employ in the session.

There are several important issues to address in the first session, which functions both as a kind of assessment and as the beginning of the therapeutic work. It is necessary:

- to remain in control;
- to develop rapport with both partners, without favouring either;
- to maintain the momentum of the session and the interactional focus;
- to maximize the opportunities for the couple to experience a change in the nature of their interaction.

A particularly useful move at some stage in the first session, and one which we almost always use, is to ask the partners to talk directly to each other rather than the therapist; this is the so-called 'decentring' technique originated by Minuchin.[12] Keeping this configuration for as much as possible of the session enables the therapist to observe the couple's typical pattern of interaction, to intervene as a 'theatrical producer' rather than a diplomatic negotiator, to avoid as far as possible taking sides, and to encourage the kind of negotiation which hopefully the couple will be able to carry on at home without the presence of a third party. It is not necessary to remain decentred for the whole session, but if it does not happen at all in the first session, an opportunity for effective work will have been lost.

It may be difficult to remain decentred in the face of pressures from one or both partners to talk to the therapist directly. One way to participate while still remaining decentred is to request the partners to ask each other questions to which the therapist would like to know the answer. For example, one might say: 'Could you ask your partner what she thinks about your coolness on this matter?' or 'Perhaps your partner disagrees with you; could you check with him?'. In this way the couple can continue to talk to each other in the decentred position without undue 'triangling in' of the therapist.

One situation which causes particular problems for the behavioural–systems therapist is where one partner persists with monologues, either about his or her own symptoms and problems or about the partner's unreasonable behaviour. This is a perfectly acceptable way to present a problem in one-to-one therapy, but in couple therapy it slows down the interaction and prevents the therapist focusing on the relationship. One way to overcome this is by decentring, but in some couples this is too difficult, and another possibility is to ask the non-verbal partner to comment on the spokesperson's problems. This can provoke a minor crisis in the couple, and lead to the spokesperson realizing that the problems are not all one-sided. It is a technique related to circular questioning, and is used fairly extensively in family therapy see Chapter 6.3.8

Another obstacle to progress is the situation in which the partners have intractable arguments, perhaps about other family members. If such battles continue to dominate the sessions the therapist may have to devise a method for putting them 'on ice for the time being' and concentrating instead on negotiating everyday problems to do with the house or the children.

Momentum may also be slowed by the therapist's own style of working. Students of the behavioural systems approach may need to 'unlearn' some of their otherwise good therapeutic habits such as being a good and empathetic listener. They may be able to achieve this by decentring or by asking circular questions in order to refocus on the interaction and increase momentum.

On the other hand, it is still important for the therapist to be able to feel and show empathy to the two individuals in therapy. The difficulty may be that to show empathy to one partner may be interpreted by the other as side-taking. A possible remedy lies in a particular skill, which, however, is not easy to acquire, of saying something to show that one has understood one partner without antagonizing the other. One way to develop this skill is for the therapist not to become emotionally involved in the issues, but to concentrate on the process of interaction, thinking all the time in terms of balance and communication rather than worrying about the rights and wrongs of what is being discussed. This must be done while still showing respect to both the partners, taking their problems seriously, and at the same time conveying hope that they can be solved.

It is also very helpful for the partners themselves to be in touch with each other emotionally and take each other seriously. Some individuals are very good at communicating, but only at an intellectual level, and cannot express empathy with each other. Their interaction is like that of fellow committee members, and they tend to suppress any expression of feelings such as sadness or anger which are 'not on the agenda'. In other couples, there is an imbalance, with one partner expressing feelings openly and the other being exclusively logical and self-controlled. In both situations it is necessary to help them to communicate both intellectually and emotionally, encouraging the self-controlled individual to be more open and the person who is emotionally open to try to be more restrained at times.

Ending the session

Every session must have an ending, and the purpose in the behavioural–systems approach is to send the couple away with something to work at in the weeks before the next session. About two-thirds of the way through a supervized session the therapist will usually go behind the one-way screen, turning off the camera and closing the shutters (although when working alone this luxury is not available and the therapist must work independently to end the session on a positive note). The team and the therapist then spend about 15 minutes in discussion, planning the 'message' to be given to the couple at the end. Part of this discussion will centre round the team's thinking about the significance of the problems from a systems point of view, but part will also be concerned with how the therapist can help the couple to change their interaction.

The introduction to the message will give the date of the next appointment, and usually also contains some positive and sympathetic comments for both partners. It is important as far as possible to keep them both 'on side' at this stage, so that it would be unwise to say something which could be seen by either partner as favouring the other one. A good example of an introductory comment would be: 'The team and I are aware of the great difficulties you are experiencing, but we think you have what is basically a good relationship, and you are both working hard to improve things'.

The message itself will vary according to the level of the hierarchy at which the therapy is being pitched. If it is mainly a session of reciprocity negotiation the main theme may be simply to reiterate the negotiated plans for both partners which have emerged from the earlier discussion. If, however, the therapist is working more systemically, the message may contain a task, a timetable, or a paradoxical injunction which is designed to alter both the behaviour of the couple and the way they conceptualize their relationship. In some cases, it is appropriate to use a 'split-team' message , in which one part of the team is said to favour a more behavioural task while the other part believes that that will be impossible to achieve and therefore prefers to 'prescribe the symptom'.

The final part of the message is again likely to reiterate the positive sentiments of the introduction. There are good therapeutic reasons for this, in that people tend to remember the positive things that they hear about themselves, and may then link these to the more specific tasks or injunctions that are given with them. In many cases we also send a written copy of the message to the couple, so that they can think it over between sessions and not forget what has been discussed.

Where therapists are working alone, they will be unable to have the 15 minute break in the session, but it is always useful to spend a little time thinking about the message to be given at the end of the session, and to think what other team members might have said or suggested for a final message.

Specific techniques in behavioural–systems couple therapy

(a) Reciprocity negotiation

Within the alternative levels of intervention hierarchy, reciprocity negotiation is at the lowest level, relating closely to the goals that the couple themselves has set, and depending on a fairly co-operative attitude on both sides. The partners state their complaints in everyday terms, and the task of the therapist is then to help them to achieve a compromise by each doing what the other partner wants in a reciprocal way.

Reciprocity negotiation is partly based on operant conditioning and partly on the social exchange theory of Thibault and Kelley.[24] The assumption is that satisfaction in marriage and other intimate relationships is based on a relatively equal and high level of input by each partner of positive (i.e. rewarding) behaviour and a relatively low input of negative or unacceptable behaviour. Problematic marriages have a low level of these mutually rewarding behaviours on both sides, or may have a gross imbalance in the input from the two different partners. Instead of exchanging positive behaviour, the partners may use coercive methods to try and force the other to stop doing those things of which they disapprove.

The remedy proposed by behavioural marital therapy is that each partner should state their **complaints**, but that these complaints should then be translated into **wishes** for an alternative way of behaving which is more acceptable, and, as a second stage, into **tasks**. It is very useful to concentrate on practical, domestic issues for these tasks, as these are easily grasped, frequently repeated, and more likely to be remembered than more abstract tasks. In principle the tasks for each partner should be linked and reciprocal, but if this is not possible a 'bank account' approach can be used in which each partner builds up a fund of good behaviour and they work out at the end of a period of time whether it has been mutually acceptable. In moving from complaints to tasks one also moves from past to future, and this is one of the most characteristic features of reciprocity negotiation. The therapist is thus more interested in what will happen next week than in what happened last week or last year.

The way that reciprocity negotiation is used in behavioural–systems couple therapy is a little different from its use in behavioural marital therapy. We will usually have the couple in a decentred position while negotiating, and feel that this helps the process both to be effective, and to translate more successfully to their home setting. We also use it quite briefly at different stages of therapy, rather than as the mainstay of therapy throughout.

The tasks developed for each partner in reciprocity negotiation should be:

1 specific,

2 positive,

3 repeatable,

4 practicable, and

5 acceptable to both partners.

They should also be concerned with everyday activities, rather than once-only events such as arranging an overseas holiday. Sometimes sexual problems can be brought in to the negotiation.

Reciprocity negotiation is a well-tried and effective method of couple therapy in those who accept that they have marital problems. It is also an advantage that the therapist here works in a way which is straightforward and takes an adult-to-adult approach. But it is also, in our setting, a way of assessing whether the couple are ready for this sort of intervention; if not, they can be offered a more systemic input until they are more ready to negotiate.

(b) Communication training

The second strategy in the alternative levels of intervention hierarchy is training in communication. This too is part of the behavioural marital therapy spectrum, but not so exclusively, because work on communication is part of most types of couple therapy. The characteristic feature of the form of communication training used in our setting, however, is that it aims for efficient and clear communication, with positive and constructive requests rather than complaints. Other forms of communication training[25] emphasize other skills such as empathy, reflective listening, and supportive comments. In the present form of communication training these are also issues to be considered, but the main emphasis is on issues such as reducing misunderstandings, ensuring that both partners have an equal say, and helping them both to speak from the 'I' position.

Problems encountered in couple therapy amenable to communication training include:

- lack of empathy
- inability to express emotion
- failing to listen
- monologues with no break for feedback
- one partner the spokesperson and the other silent
- mind-reading (i.e. A knowing better than B what is in B's mind)

- sting in the tail (a positive comment followed by a criticism)
- wandering off the topic
- continual criticism.

In carrying out communication training, the therapist first decentres him- or herself, and asks the couple to converse about a relevant topic. When a problem of communication arises the therapist acts as a 'director' and asks them to discuss the topic in another way. If the problem observed is one of lack of empathy, this may include asking one partner to attend to the emotional state of the other, and perhaps to feed back his or her understanding. If it is of inability to express emotion, the therapist may try to intensify the interaction, pointing out the way in which they are holding back their emotions, and encouraging more expressiveness.

The next three problems are connected: failing to listen, talking in monologues, and the 'spokesperson' problem. Remedies can be decentring, encouraging each partner to speak for him- or herself, stopping the talkative partner (perhaps by asking them to listen to what the other partner has to say), and cutting any monologues short by asking for feedback from the other partner. In dealing with mind-reading one may have to be quite diplomatic, because the process is rather similar to psychotherapeutic interpretation, and some partners may feel that this is a legitimate way of giving insight; however, it should be tactfully blocked, usually by asking the partner whose mind is being 'read' to say whether that is what he or she really thinks.

The 'sting in the tail' is dealt with usually by simply pointing it out, but in some cases it can be neutralized by asking the speaker to restate the idea the opposite way round with the 'sting' first. An example of this is given by a man who said 'I realize you were hurt by what I did, but I had no intention to harm you (i.e. you are being oversensitive)'. He was asked to rephrase it as 'I had no intention to harm you, but I realize that you must have been hurt', and his wife found this much more acceptable, because she could respond to the more positive part of the comment.

The problems of wandering off the topic and continuous criticism are often rather intractable. One way, however, of keeping them to task is to bring them back frequently to the problem first presented, and ask whether they can concentrate on solving it. In the case of mutual criticism, one way of coping is to slow down the interaction so that each partner speaks only after the therapist has intervened to reframe what has just been said.

As with reciprocity negotiation, communication training is used not as a self-contained therapy in itself, but rather as part of a menu of techniques to be chosen according to the problem presented or observed at the time.

(c) Structural moves in session

The main interventions under this heading are raising arguments (or heated discussions) in the session, reversed role play, and 'sculpting'.

There are many couples in which there is a reluctance to enter any sort of conflict. They avoid differences of opinion, and pretend that there is agreement on almost every issue. The more dominant partner, usually more at ease verbally, effortlessly takes the spokesperson role. The other partner is either silent much of the time or spends much effort placating the other in order to reduce conflict.

One strategy with such couples is to ask them to argue (or, to put it more acceptably, to have a **heated discussion**) about a fairly trivial topic. An example of this might be whether the toilet seat should be left up or down after it has been used. It must be a genuine difference of opinion, and not simply one manufactured for the purpose, but it is important that it should be of a trivial nature, as otherwise the couple may feel inhibited about discussing it.

They are then asked to discuss the issue with the therapist observing, and the therapist particularly encourages the more submissive partner to participate with enthusiasm. It may be necessary to ask him or her to speak louder, or to ask the other partner to listen more carefully to what the quiet partner has said, but the therapist should not take sides as such. What is being dealt with is not the issue itself, but the process of arguing. The outcome does not matter, except that the submissive partner should not be allowed to 'get away with' their usual tactic of giving in for the sake of peace. The couple may 'agree to differ' or the submissive partner may have a better than usual hearing, and even win the argument.

This intervention is particularly useful for those couples where there is a degree of depression in the quieter partner, or where the quieter partner is very reluctant to be involved sexually, and is blaming him- or herself.

Another intervention in session which can have an impact on the interaction is the '**reversed role play**'. Here the couple is asked to discuss a particular issue, but they are asked to act as if they were the other partner, even perhaps changing chairs for the purpose. The exercise is useful for some couples who have difficulty understanding each other's point of view, and may promote better mutual understanding.

A third intervention in session is the use of '**sculpting**', in which the partners position themselves and each other wordlessly in a kind of tableau to express some aspects of the relationship. For example, a wife who feels herself excluded from her husband's life may place him looking away from her, while her husband might place the two arm-in-arm and facing the same way. Neither position would represent the objective truth, but each would gain some understanding of the views of the other. The different views could also be the subject for discussion in session or during 'homework'. As with reversed role play, sculpting, with the accompanying 'experiential' insight, can be useful in those couples where there is little understanding of the other's point of view.

(d) Timetables and tasks

These are perhaps the most frequently used of our interventions. They are always given as part of the 'homework' at the end of the session, and may be of a behavioural nature or more systemic. Systems tasks are usually used for behaviour which is thought of as being out of control. Thus, they may be used in a couple where there is a jealous partner: this partner would be asked to raise his or her doubts about the other's fidelity, but only at a specified time each day and for a limited period (e.g. half an hour). If the topic comes up at any other time, they are asked to postpone any discussion till the appointed time. This can be frustrating for the jealous partner, although he or she will perhaps be reassured that the other will give the topic his or her full attention at the set time: but for the other partner it can come as a great relief that the issue of jealousy is at last under some sort of control, even in this simple form.

A timetabled task may be used in other situations, for example, when one partner has a series of complaints which the other is rejecting. The couple can again be asked to discuss the issue only

at certain times and for a limited duration. The advantage of a timetable under these circumstances is that the therapist does not have to adjudicate as to who is right or wrong in the content of the argument, but simply deals with the process of arguing by asking the couple to raise their legitimate complaints at home at an appropriate but limited time.

Another frequently used timetable is the 'talk' timetable, in which a couple who do not communicate very often are asked to set a time each day or evening when they can get together for a discussion about the day's events. In cases where there are difficulties with empathy, it may be useful in addition to ask each partner at the daily talk session to repeat back what the other one has said to reassure the other that they have understood what is meant.

One situation which responds particularly well to timetabling is where the male partner is very keen on sex and the female (while not having a sexual dysfunction as such) is much less enthusiastic. Here the partners are encouraged to reach a compromise on the agreed frequency at which sexual relations might occur, and then they agree on a suitable timetable. The day of the week has to be fixed in advance, since if this is not done the usual arguments will ensue as to whether sex should take place that night, and they are also asked to make the chosen night something special, with perhaps a dinner and the telephone disconnected. If, however, the enthusiastic partner suggests sex on another night, the other can simply remind him that it has been arranged and that they should stick to the arrangement. This remedy may seem somewhat crude, and it is often simply a temporary measure. However, it can be said to have virtually saved some relationships, because it takes the heat out of the sexual conflict which could otherwise lead to divorce, and its use can open up the discussions in subsequent sessions to include non-sexual topics which would otherwise be pushed out by the sexual issue.

It should be mentioned here that many relationship problems have a sexual and a general dimension. When the sexual difficulty is motivational rather than dysfunctional, it is often most productive to deal with it in couple relationship therapy either alone or in combination with psychosexual therapy. In such a case it is quite appropriate to suggest techniques such as the Masters and Johnson 'sensate focusing'[26] in addition to the couple therapy approaches already mentioned.

(e) Paradoxical interventions

Paradox is a relatively infrequently used option in couple therapy (Fig. 6.3.7.1), and is brought in when other methods are ineffective or where the couple relationship seems so rigid that no other intervention can be used. The rationale for paradox depends on a systemic hypothesis which states that the homeostatic forces in the system may be so strong that no straightforward intervention will alter it. All systems tend towards a resistance to change, but in some the resistance is maintained by powerful forces which themselves seem to be informed by extreme anxiety.[14] In these couples or families the only intervention likely to succeed in changing the system is one which prohibits change, but for unacceptable reasons. Although the above explanation is somewhat unsatisfactory, paradox remains in practice a technique which can unlock an otherwise stuck relationship and get the couple back on course for continued therapy.

Paradox is always applied with care and in a sympathetic manner. A common form is to 'prescribe the symptom', that is to advise the couple that it is best 'for the time being' to persist with both the behaviour complained of and the reciprocal behaviour in the other partner. The reason given for this conclusion is a plausible, but challenging and perhaps unacceptable, explanation based on systemic understanding of the relationship.

In using paradox the therapist should think in four stages. First, there should be a positive connotation of the 'symptom' and the reciprocal behaviour. Secondly, there should be a rehearsal of why they are at present helpful for the couple. Thirdly, a statement should be made of the hypothesized feared consequences if the behaviours were to stop. Fourthly, the symptom and the reciprocal behaviour should be prescribed. A case example may make this process a little clearer.

Case Study: A couple who presented with depression in the wife (Edna) and a rather overprotective attitude on the husband, George's, side were in therapy for some weeks without much progress. Following a session in which the therapist asked many questions of both of them about the circumstances and consequences of the depressive episodes, the paradox was presented as follows. 'This depression seems in some ways to be quite good for you as a couple, because it enables Edna to help George by giving him a role in life as her protector. If the depression were to disappear it might be difficult for you both to continue your peaceful relationship, because the differences between your views and ideals would become very clear and you might argue all the time. So for the time being it is better for Edna to remain depressed and for George to be her spokesman and protector'.

This intervention led to quite an outburst from the wife, who up to that time had always been very quiet, and she began to talk of some of the differences of opinion that they had actually had. The husband looked rather disconcerted, and questioned the therapist's reasoning. In the next two sessions the couple reversed their imbalance to some extent, the wife became more assertive than the husband, and her depression became less severe.

The paradox can thus be a powerful mechanism for change, but it must be used with some caution, since an instruction given paradoxically may be taken literally. So it would be inappropriate to include in a paradox any instructions to break the law, to harm oneself or others, or to act irresponsibly. If given as recommended, however, the paradox can unlock a 'stuck' system and put the couple on the road to change and improvement.

In a team setting it is probably best to use a **'split team'** message rather than a paradox as such. This presents the paradox as above, but in the form of an alternative, for example in the form of a disagreement between the therapist and the supervising team. 'I feel that you can carry on with the tasks that I have been giving you, but my team think I am being naïve, and that you really need the depressive symptoms and the overprotection to keep your marriage from falling apart'. The effect is similar, but the impact is softened somewhat by this technique.

Couple therapy with couples from other cultures

As mentioned above, most western countries are now multicultural, and a significant minority of those seeking therapy, especially in urban centres, are from immigrant backgrounds. Probably the most frequently seen in Britain are those of South Asian origin, but Eastern European, African and African- Caribbean

couples are also seen quite often. In the USA there are many people of Latin American and Oriental backgrounds, and here again these will be more commonly encountered in urban settings. The author's experience is mainly with South Asians, and the examples will be mainly from this group.

Cultural factors in counselling have been highlighted by d'Ardenne and Mahtani,[27] and include the need for awareness in the counsellor that he or she also comes from a specific culture which may be just as difficult for the client to comprehend as the client's is to the counsellor. They emphasize the need for humility in the face of difference, and the responsibility of the counsellor to check with the clients before making assumptions about their lifestyles and beliefs. Their advice on the use of interpreters is that unofficial interpreters, including members of the clients' own families, should be discouraged because they are inclined to act as therapists themselves, may translate inaccurately, may ignore cultural differences and may even exploit the clients. It is better to use official interpreters, though this may become expensive to the treatment unit, and the interpreters themselves may translate inaccurately in accord with what they think the therapist wants to hear. Ideally a unit would have multilingual counsellors, but this is not always practicable. In practice, it is often possible with a modicum of understanding of the language for a couple relationship therapist to carry out therapy in English without an interpreter, but with a little bit of necessary translation by the partner whose English is better.

Little has been written specifically on cultural factors in relationship therapy, but Ahmed and Bhugra[28] have reviewed the role of culture in sexual dysfunctions, and their observations are also relevant to couple therapy. They emphasize the need to adapt the techniques of 'western' sex therapy to accommodate the cultural backgrounds of the patients, in particular the gender roles in the culture, and they highlight the risks of ignoring these in therapy.

Couple therapists need to be flexible in regard to the aims of therapy in these couples, which may be rather different from the typical white British couple, and there may also be limits to the kind of therapeutic change possible. For example, a couple from South Asia may be orientated towards a male dominated marital pattern, and both partners may be reluctant to accept the kind of equal relationship that typical couple therapy would expect. In other cases, the more traditional male partner may be concerned to retain the traditional dominance, while the (more westernized) woman may be demanding equality. Similar problems may arise in couples who come from different cultures, and there are clearly more interracial relationships developing as the cultures become more integrated.

Religious considerations may bring difficulties to therapy. Strict Muslim couples may be reluctant to attend therapy together, particularly with a male therapist, because of the difficulty of the wife talking to a male stranger. Masters and Johnson[26] found that one of the most reliable prognostic factors in their therapy was the negative effect of any strong religious belief on the outcome. It has also been observed that in a sexual dysfunction clinic Asian couples were more likely than white couples to default from therapy, a finding put down to their pursuit of organic explanations for the problems and educational and language barriers.[29]

Similarly African-Caribbean couples will have different aims and limitations from white British couples. The father in these families may traditionally be more of an absentee, and leave the upbringing of the children to his partner, who becomes the main authority figure in the family. Again, the therapist must remain aware of possible differences from his/her own culture, and remember that the key consideration is the wishes and wellbeing of the couple rather than any imposed set of rules derived from theory. In particular it is usually impossible to persuade the man to take a more active role in child care, even when the woman wants this, and their relationship will usually remain 'semi-detached'.

One particular 'problem constellation' which the author has seen many times is that of an Englishman married to a North American woman. This should theoretically present no problems, as the language and cultures of both are similar. However, they are divided by the tendency for the British man to be reserved and sometimes resentful and the American woman to be outspoken and critical. Such difficulties have also been found with couples from other disparate backgrounds, such as North American and Latin American partners, and Southern European and British couples. These differences in outlook can lead to repetitive quarrels, in which neither partner can understand where the other is coming from, and often there is also a lack of sexual contact between them. In therapy it is usually necessary to explain each partner to the other, using positive terms and helping them to appreciate the cultural differences without condemning the partner. Then they can usually cooperate with reciprocity negotiation and communication training.

Although the examples given are mainly of South Asian and Western couples, the principles for dealing with cross-cultural relationships of all sorts are basically similar. The therapist needs to respect the differences between their culture and his/her own, trying not to impose solutions which are alien to the couple's own culture. In those cases where they each come from a different background, the general approach is to try to build bridges between them, and use the techniques of behavioural systems therapy to solve their difficulties.

Efficacy of couple therapy

The efficacy of couple therapy is not an easy topic to discuss. Problems arise as to how one should assess efficacy, and while most authors would agree that a measurable improvement in marital adjustment is a valid measure of improvement, some authors dismiss that as being too subjective or too superficial. On the other hand, to use an objective criterion such as divorce as an outcome variable might be seen as being too strict on the therapy, since divorce happens for many reasons, and it might not actually be a bad outcome in some relationships.

A review of efficacy in couple therapy has been carried out by Baucom *et al.*[30] They did a very thorough search of the literature, and made some far-reaching and challenging observations. They comment that the untreated improvement rate is very low in couple problems, and that many of the non-behavioural approaches are of unproven efficacy. They conclude however that behavioural marital therapy (comparing mean effect size over a series of 17 independent controlled outcome studies) is an efficacious and specific intervention for marital distress. The improvement is likely to last for up to a year after treatment but there is less certainty over longer follow-up periods. The addition of cognitive restructuring to behavioural couple therapy did not add anything to the efficacy, but the numbers were rather small.

Snyder and Wills[31] evaluated the outcomes of behavioural versus insight-orientated marital therapy, and found that there was equal improvement in the two conditions, with both being superior to waiting list controls. There was, however, a difference at follow-up, with more of those who had had behavioural therapy divorcing than those who had had insight-orientated therapy.

In a controlled study of behavioural versus interpretative couple therapy, Crowe[32] found that both approaches were effective, but that the behavioural approach produced results more quickly. The follow-up at 18 months showed both methods to be of lasting efficacy, with no differences between them at that point.

Another treatment approach, emotion-focused therapy,[33] has produced good results with couples in therapy. As with behavioural couple therapy the couples improved significantly more than those on a waiting list, but this therapy seems less effective in couples with higher levels of distress.

In one of the relatively few studies on the efficacy of systems-orientated couple therapy. Emmelkamp *et al.*[34] evaluated the effects of behavioural versus systems couple therapy, and concluded that the two approaches had very similar results, but both did better than waiting-list controls.

The London Depression Study[20] (see above) found that systemic couple therapy produced good improvement not only in terms of the couple satisfaction but also on the depression in the depressed partner. The therapy was also associated with a lower drop-out rate than the antidepressant condition, and was thus more acceptable to the patients and their partners.

Thus, the two components of behavioural–systems couple therapy have both been validated by outcome research, although at a much higher level for the behavioural than the systemic. It would be desirable to carry out research on the combined therapy, but this has not yet been done, and the best that can be said is that it is a combination of two probably effective treatment approaches, and therefore likely to be effective.

Training

Training for work with couples using a behavioural–systems approach has been thoroughly reviewed by Crowe and Ridley.[1] It requires an ability in the therapist to understand and use different approaches, and an ability to adapt ones activity to the needs of the couple. Before beginning to work as a couple therapist the trainee should have a basic understanding of the dynamics of couple and family interaction, the phases of human development, the impact on the individual of life events, sexual function and interaction and the impact of physical illness on couple and family relationships. These can be dealt with in the traditional seminar format, in which the trainee can also learn about theoretical and technical aspects of the approach to couple therapy itself. It is also important in selecting candidates for training to ensure that they have some experience of counselling individuals or of being in a therapeutic role, for example as a nurse or doctor.

In addition to the seminars there are also more active training sessions in which the trainee is given the technical skills to carry out therapy. The latter take three main forms: role play, observation, and supervized practice. In role play the trainees are encouraged to use either an existing couple or a fictional one and role play a couple therapy session. Ideally they should each, in different exercises, have the opportunity to play the husband, wife, therapist, and observer in therapy.[35] This helps both in the development of technical skills and in learning to be empathetic to clients through having experienced the client role. In role play the trainee can practise any of the techniques required in therapy, but it is perhaps especially useful in the area of communication training, in which the therapist needs to be alert to the problems shown by the partners and able to apply the appropriate technique smoothly and effectively.

In observation and supervision other aspects of the therapy can be taught, especially the more systemic methods such as arguments, reversed role play, and the framing of messages. The trainees move quite quickly from live observation of therapy in the clinic to being firstly a co-therapist and then the sole therapist in the session, supported and supervised by the trainer and the observation team on the other side of the screen. It is in this activity that trainees begin to display their skills or deficits as therapists, and the trainer must be able to assess progress at this stage and take remedial action if a trainee does not seem to be working as well as expected.

Conclusions

The field of couple therapy is a wide and varied one, and there are almost as many different approaches to treatment as in individual psychotherapy. The relatively brief therapeutic method presented here, behavioural systems couple therapy, is an eclectic one, taking techniques from two approaches of proven efficacy and combining them into a flexible and versatile therapy capable of being used in a wide variety of presenting problems. These include simple relationship problems, psychosexual problems, and such psychiatric conditions as anxiety, depression, and morbid jealousy. It is relatively easy to teach, and although it has not yet been subjected to controlled trials it can be assumed to be no less effective than its component therapies which are both effective. It has recently also been recommended in a package for self-help[36] with homework exercises and theoretical explanations to be used without the intervention of a therapist. There are few contraindications for the therapy, and it can be used both as a therapy in its own right or as an adjunctive therapy in, for example, the treatment of depression, psychosis or sexual dysfunctions. It can thus be a useful addition to the various methods available for the reduction of distress, whether in couples or individuals.

6.3.8 Family therapy in the adult psychiatric setting

Sidney Bloch and Edwin Harari

The term 'family therapy' covers a range of approaches. At one extreme, it is a method which seeks to help an individual patient. At the other extreme, the focus is on the relationships between people; according to this view psychopathology reflects recurring, problematic interactive patterns among family members. Midway between the two positions is one that views the family as acting potentially either as a resource or a liability for an identified patient. In this chapter, we cover the spectrum but confine ourselves to the adult psychiatric setting.

A historical and theoretical context

The family has long been recognized as a core aspect of social organization. The folklore of all cultures emphasize the family's role to mould the character of its members. In the past 150 years academic disciplines, such as anthropology and sociology, have studied the various forms of family structure found in different cultures, and at different times. Since the 1960s, psychiatry has also developed a clinical and research interest in the family beyond that of genetics.

Scattered through Freud's writings are interesting comments about marital and family relationships and their possible roles in

both individual normal and abnormal development.[1] His description of unconscious processes like introjection, projection, and identification illuminate how individual experiences may be transmitted across generations. In 1921, J.C. Flugel published the first comprehensive psychoanalytic account of family relationships.[2] Influenced by Anna Freud, Melanie Klein, and Donald Winnicott, the child guidance movement in Britain, mainly consisting of social workers, devised a model of one therapist working with the disturbed child and another with the mother. The two clinicians then collaborated in order to appreciate how the mother's anxieties distorted her perception and handling of her child, leading to developmental difficulties.

Proliferation of theoretical schools

Psychoanalytic and related approaches

Things took a different turn in the United States where Nathan Ackerman[3] began in the 1950s to treat families with a disturbed child, using psychodynamic principles. An interest in working with two or more generations arose concurrently with 'transgenerational'-oriented family analysts using object–relations concepts. Thus, Murray Bowen[4] noted that the capacity of psychotic children to differentiate from their families, while still retaining a sense of age-appropriate belonging, was impaired by the effects of unresolved losses and other trauma in parental and grandparental generations. He also devised the genogram, a schematic depiction of family structure, with a notation for notable events; this remains a standard part of family assessment (see below).

Boszormenyi-Nagy and Spark[5] similarly addressed the transgenerational theme, describing how relationships were organized around a ledger of entitlements and obligations, which conferred on each family member a sense of justice or injustice about their situation. This, in turn, reflected childhood experiences of neglect or sacrifices made on another relative's behalf for which redress was sought in adult life.

Systems-oriented (see later)

Bowen[4] also introduced the principles of 'systems theory' into family therapy. A system is defined as a set of interrelated elements that function as a unity within a particular environment and where the whole is larger than the sum of the parts. 'General systems theory', propounded in the 1940s by a German biologist,[6] contains among its key concepts the place of hierarchy and the emergence of new features in the system as it transforms itself, necessarily, from one level of organization to another. A family is an example of a partially open system that interacts with both its biological and socio-cultural environments and changes over time to accommodate developments such as the advent of a first child or the death of a grandparent.

Working with delinquent youth, Salvador Minuchin recognized the relevance of systems thinking. The youngsters often came from poor, emotionally deprived families, headed by a demoralized single parent (usually the mother) who alternated between excessive discipline and helpless delegation of responsibilities to a child or to her own critical mother. Since these families were beyond the reach of conventional 'talking' therapies, Minuchin applied action-oriented techniques which enabled him to 'join' the family and to re-establish an adaptive hierarchy and effective boundaries between subsystems (marital, parent–child, siblings).

Later, treating 'psychosomatic families' where the problem was a child or adolescent suffering from anorexia nervosa, unstable diabetes or asthma, Minuchin and his colleagues noted that these families, while intact and articulate, were often enmeshed. Members avoided challenging the apparent sense of family unity. Typically, marital conflict was detoured through the symptomatic child, resulting in maladaptive coalitions between parent and child (sometimes between grandparent and child) and the involvement of third parties (e.g. helping agencies) in family life; loss of hierarchy and boundaries ensued. Because words were used to avoid change in these well-educated families, non-verbal strategies were devised to face unspoken fears of conflict and change.[7]

Jay Haley's 'strategic therapy'[8] combined features of Minuchin's model with ideas of Milton Erickson whose techniques had skilfully exploited the notion that a covert message lurks behind explicit communication, which defines the power relationship between family members. Related theoretical developments took place in Palo Alto, California in the 1950s, where a group of clinicians, together with the anthropologist Gregory Bateson,[9] observed that implicit in communication were tacit, non-verbal 'meta-communications' which defined the ties between participants. A contradictory quality between these two levels of communication—in which messages carried persuasive, moral, or coercive force for the recipient—formed part of what they called a 'double-bind'; this form of entrapment was proposed, albeit erroneously, as a possible basis for the formal thought disorder found in schizophrenia.[10,11]

(a) Systems-oriented models: further developments

All the above system-oriented views assume that family functioning can be objectively studied. However, therapists are not value-free and may actively orchestrate changes in accordance with their preferred theoretical model; neglected in these circumstances are therapists' biases and their influence.

This tendency probably reflected the determination of family therapists to distance themselves from psychoanalytical theory; but it also led them to neglect the family's past history and changes through the lifecycle, including the relevance of traumatic events.

In response to this criticism there was a shift away from a problem-focused approach, which had typified most communication-based views of psychopathology. The so-called Milan school[12] (see course of therapy below), whose founders were psychoanalysts, launched profound conceptual changes in how to approach the family, particularly in interviewing them. Another innovation was the participation of observers behind a one-way screen whose task was to offer hypotheses about the family-plus-therapist system to the protagonists.

A Norwegian group[13] took the idea one step further by developing the 'reflecting team dialogue'. Here, following a session, the family could observe the therapeutic team discussing their problems and possible causes, and what factors might have prompted them to seek certain remedies—especially those they had persevered with despite the clear lack of effectiveness.

(b) Post-modern developments

Family therapists also began to ask whether families might be hampered from trying out new ways to solve their difficulties because of the ways they themselves had interpreted their past experiences or unwittingly absorbed the explanatory narratives of external 'experts' or society at large.

This led to a shift from considering the family as a system defined by its organizational structure to a linguistic-based one. According to this view the narrative a family relates about themselves is a means to integrate in specific ways their past experience and its significance. Other 'stories' are excluded from consideration. For instance, when a family with an ill member talk to health professionals, the conversations inevitably revolve around problems (a problem-saturated description). The family ignore times when problems were absent or minimal, or when they were confined to manageable proportions. A different story might be told if they were to examine the factors that could have led, or still lead, to better outcomes than those currently deemed pathological.

Several narrative-based approaches apply these concepts.[14–16] Philosophically, they align themselves with post-modernism, a movement which challenges the idea that there is a fundamental truth or grand theory known only by the expert.

(c) Criticism of systems approaches

Many criticisms have been levelled at systems-based approaches, these include:

- disregard of the subjective experiences of family members
- neglect of the family's history
- inattention to unconscious motives in interpersonal behaviour
- not addressing the issue of unequal power in a family, particularly violence against women and child abuse, and
- ignoring various forms of injustice based on societal attitudes regarding gender, ethnicity, and class.

This critique has led to integrating systems-oriented and psychoanalytic concepts, particularly those derived from object–relations theory.[17–20] Specific disorders such as schizophrenia[21] and anorexia nervosa[22] have been targeted. Another noteworthy variant of integration is Byng-Hall's[23] synthesis of attachment theory, systems-thinking, and a narrative approach.

Another criticism of systems-oriented approaches is minimizing the impact of material reality, such as physical handicap, or biological factors, in the causation of mental illness, as well as sociopolitical phenomena like unemployment, racism, and poverty. These are obviously not merely the result of social constructions or linguistic games and the distress they may inflict on people are potentially considerable.

The 'psycho-educational' approach and 'family crisis intervention' have arisen in the context of the burden that severe mental illness, particularly schizophrenia, places on the family and the potential for members to influence dramatically the course of the condition. This has led to a series of family interventions:

- educating the family about the nature, cause, course, and treatment of schizophrenia
- providing the family with opportunities to discuss their difficulties in caring for the patient, and to devise pertinent strategies
- clarifying the role of conflict, not only about the illness but also about other relational issues
- regularly evaluating the impact of the illness on the family, both individually and collectively
- helping to resolve other conflicts possibly aggravated by the demands of caring for a enduringly ill person.

This type of work may be done with a single family or with several families meeting together, known as Multiple-Family Group Treatment (MFGT). The latter has emerged as a powerful adjunct to conventional individual-based treatment of schizophrenia, bipolar disorder, major depression, obsessive-compulsive disorder, somatization disorder, and an array of chronic medical conditions. Good results have been achieved in reducing the relapse rate, duration, and frequency of hospitalization and in boosting compliance with medication.[24] Family crisis intervention, initially devised for families with a schizophrenic relative but since applied to other clinical states, operates on the premise that deterioration or a request by the family to hospitalize a member may reflect change in a previously stable pattern of family functioning. Convening an emergency meeting with the patient, spouse, and other key family members may help to avoid admission. Social and institutional forces outside the family often contribute to a crisis, and may precipitate a psychotic episode in a vulnerable member. The 'open dialogue' model of family crisis interviewing, developed in Finland, fosters discussion about such forces, using concepts and techniques derived from, *inter alia*, the Milan school, narrative approaches, and psychodynamic thinking; this integrated perspective has much potential.[25]

Indications

A measure of controversy has dogged the issue of what constitutes the indications for family therapy. Pioneering practitioners claimed, somewhat overzealously, that their methods were suited to most conditions. A more balanced view since the mid-1990s encompasses a consensus that considering the systemic context is advantageous in assessing and treating any psychiatric problem. However, it does not follow that family therapy is the treatment of choice (or even indicated).

Family therapy, it should be stressed, does not constitute a unitary approach, with one principal purpose. The diversity of theoretical models we have alluded to above, with their corresponding techniques, should make this obvious. Regrettably, attempts to link indications to specific models have contributed little to the field.

It has also become clear that DSM or ICD diagnoses do not serve well as a basis for determining indications for family interventions. DSM has a minuscule section, the V diagnoses, covering 'relational problems'; these are limited in scope and not elaborated upon.[26] We are only informed that the problem in relating can involve a couple, a parent, and child, siblings, or 'not otherwise specified'. ICD neglects this relational area entirely.

In mapping out indications, we need to avoid blurring family assessment and family therapy. A patient's family may be recruited in order to gain more knowledge about diagnosis and treatment. This does not necessarily lead to family therapy. Indeed, it may point to marital therapy or to long-term supportive therapy. Thus, we need to distinguish carefully between an assessment family interview and family therapy *per se*.

A typology of family psychopathology, which might allow us to differentiate one pattern of dysfunction from another and so map out corresponding interventions, remains elusive. Empirical evidence is inconclusive and clinical consensus lacking. An inherent difficulty is in selecting dimensions of family functioning central to creating a typology.[27] Communication, cohesiveness, adaptability,

boundaries between family members and subgroups, and level of conflict are a few of the contenders offered (see our own classification below).

There are no clear correlates between conventional diagnoses and family type. Efforts to establish links, such as an anorexia nervosa family[28] or a psychosomatic family[29] have not been fruitful. Similarly, investigations into the family and schizophrenia have yielded no durable results.[4,10] Clinicians and researchers have reluctantly accepted that models of effective family-based treatment for mental illness may not necessarily follow an understanding of the apparent causes of a condition in terms of observed disturbances in family relating. This complex matter is helpfully reviewed by Eisler regarding studies of the treatment of anorexia nervosa, but has implications for the entire field.[30]

What follows is our attempt to distil clinical and theoretical contributions.[31] Given the considerable overlap in clinical practice, categories are not mutually exclusive; and a family may require family therapy based on more than one indication. We should stress that family dysfunction is obvious in certain clinical situations and covert in others, often being concealed by a specific member's clinical presentation. Six categories emerge:

1 The problem manifests in explicit family terms and the therapist readily notes the family's dysfunction. For example, a marital conflict dominates, with repercussions for the children; or tension between parents and an adolescent child dislocates family life with everyone ensnared in conflict. In these situations the family is the target of intervention by dint of its clear dysfunctional pattern, and family therapy undoubtedly is the treatment of choice.

2 The family has experienced a disruptive life event which has led to its dysfunction. These events are either predictable or accidental and include, for instance, suicidal death, financial embarrassment, diagnosis of a serious physical illness, and the unexpected departure of a child from home. Any family stability that prevailed previously has been disturbed; the ensuing disequilibrium becomes associated with family dysfunction and/or the development of symptoms in one or more members. Family efforts to rectify the situation may inadvertently aggravate it.

3 Continuing, demanding circumstances in a family are of such a magnitude as to lead to ineffective adjustment. The family's resources may be stretched to the hilt; external sources of support may be scanty or unavailable. Typical situations are chronic physical illness, persistent or recurrent psychiatric illness, and the presence of a frail elderly member.

4 An identified patient may have become symptomatic in the context of a dysfunctional family; symptoms are in fact an expression of that dysfunction. Depression in a mother, an eating problem in a daughter, alcohol misuse in a father, through family assessment, are adjudged to reflect underlying family difficulties.

5 A family member is diagnosed with a conventional condition such as schizophrenia, agoraphobia, obsessive-compulsive disorder, or depression; the complications are the adverse reverberations within the family stemming from that diagnosis. For example, the son with schizophrenia taxes his parents in ways that exceed their 'problem-solving' capacity; an agoraphobic woman insists on the constant company of her husband in activities of daily living; a recurrently depressed mother comes to rely on the support of her eldest daughter. In these circumstances, members begin to respond maladaptively to the diagnosed relative, which paves the way for a deterioration of her condition, manifest as an enduring or relapsing course.

6 Thoroughly disorganized families, buffeted by many problems, are viewed as the principal target of help. This is apposite, even though, for instance, one member abuses drugs, another is prone to violence, and a third manifests antisocial behaviour. Regarding the family as the core dysfunctional unit is the rationale rather than a focus on each member's individual problems.

To reiterate, family therapy may not be the only treatment indicated. Thus, in helping a disturbed family struggling to deal with a schizophrenic member, supportive therapy and medication for the patient are usually as pertinent as any family treatment. Similarly, an indication for family therapy does not negate the possible use of another psychological approach for one or more family members. For instance, an adolescent striving to separate and individuate may benefit from individual therapy following family treatment (or in parallel with it), while his parents may require a separate programme to focus on their sexual relationship.

Contraindications

These are self-evident and therefore mentioned only briefly.

1 The family is unavailable because of geographical dispersal or death.

2 Shared motivation for change is lacking. One or more members may wish to participate, but their chances of benefiting from a family approach are likely to be less than if committing themselves to individual therapy. We need to distinguish here between poor motivation and ambivalence; in the latter, the assessor teases out factors that underlie it and may encourage the family to engage.

3 The level of family disturbance is so severe or long-standing, or both, that a family approach seems futile, according to the best possible clinical judgement. For example, a family that has fought bitterly and incessantly for years is unlikely to engage in the constructive purpose of exploring their patterns of functioning.

4 Family equilibrium is so precarious that the inevitable turbulence[32] arising from family therapy is likely to lead to decompensation of one or more members; for example, a sexually abused adult may do better in individual therapy than by confronting the abusing relative.

5 The patient is too incapacitated to withstand the demands of family therapy. Someone in the midst of a psychotic episode or buffeted by severe melancholia is too affected by the illness to engage in family work.

6 An identified patient acknowledges family factors in the evolution of his problem, but seeks the privacy of individual therapy to explore it, at least initially. For example, a university student struggling to achieve a coherent sense of identity may benefit more from her individual pursuit of self-understanding. Such an approach does not negate an attempt to understand the contribution of family factors to the problem.

Assessment

Family assessment, an extension of individual psychiatric assessment, adds a broader context to the formulation. The range and pace of the enquiry depends on the specifics of the case. Its phases are history from the patient, a provisional formulation concerning the relevance of the family, an interview with one or more members, and a revised formulation. In some cases, it is clear from the outset that the problem resides in the family group, thus rendering the phases below superfluous.

History from the patient

The most effective way to obtain a family history is by constructing a family tree. Apart from showing the structure, it allows relevant information about noteworthy life events and a range of family features to be added. Scrutiny of the tree also provides a source of issues warranting exploration and, eventually, the potential for formulating hypotheses.

Personal details such as age, date of birth and death, occupation, education, and illness are recorded for each member, as well as critical family events (for example, migration, crucial relationship changes, notable losses, and achievements), and the quality of relationships. For an excellent discussion of the family tree—its construction, interpretation, and clinical uses—see McGoldrick and Gerson.[33] (See Fig 6.3.8.1 for genogram conventions.)

Useful principles are to work from the presenting clinical problem to the broader context, from the current situation to its historical origins and evolution, from 'facts' to inferences, and from non-threatening to more sensitive themes.

Questions are best preceded by a statement such as: 'In order to understand your problems better I need to know something of your background and your current situation'. This can be enriched by questions that allude to interactive patterns: 'Who knows about the problem? How does each of them see it? Has anyone else in the family faced similar problems? Who have you found most helpful and least helpful so far? What do they think needs to be done'. Attitudes of family members can be thus explored and light shed on the clinical picture.

The presenting problem and changes in the family

Questions to understand the current context include: 'What has been happening recently in the family? Have there been any changes (e.g. births, deaths, illness, losses). Has your relationship with family members changed? Have relationships in the family altered?'

The wider family context

A broader enquiry flows logically in terms of other family members to be considered, and in the time span of the family's history. Other significant figures, which may include caregivers and professionals, should not be forgotten.

Apart from information about the extended family's structure, questions about their response to major events can be posed: for example, 'How did the family react when your grandmother died? Who took it the hardest? How did migration affect your parents?'

Relationships are explored at all levels, covering those between the patient and other members and between these other members. Conflicted ties are particularly illuminating. Understanding who takes what 'roles' is also useful: 'Who tends to take care of others? Who needs most care? Who tends to be the most sensitive to what is going on in the family?' Asking direct questions about members is informative, but a better strategy is to seek the patient's views about their beliefs and feelings and to look for differences between members: 'What worries your mother most about your problem? What worries your father most?' Several lines of enquiry may reveal differences.

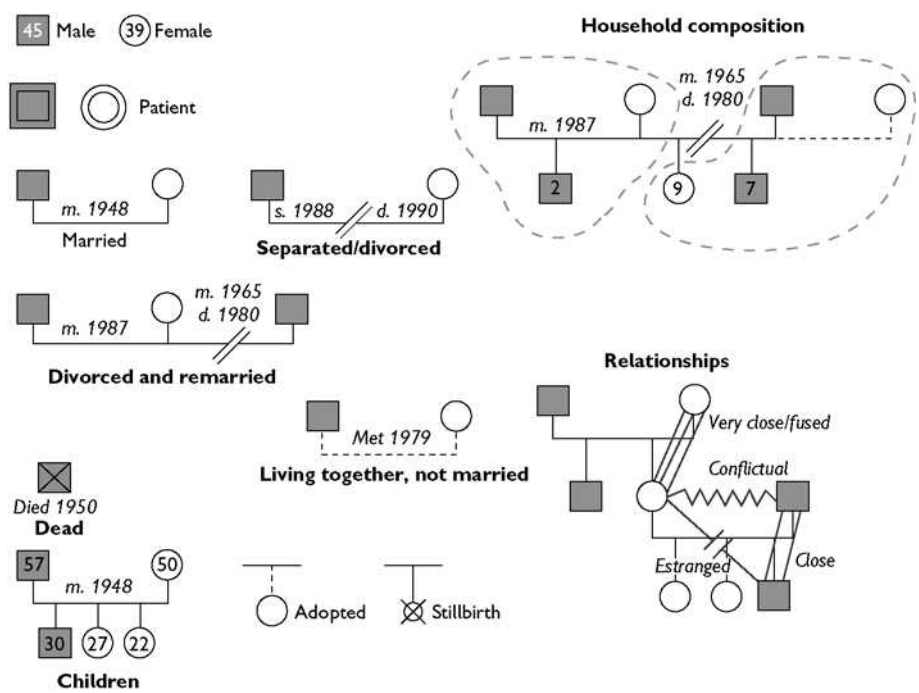

Fig. 6.3.8.1 Genogram conventions.

- Pursuing sequential interactions: 'What does your father do when you say your depressions are dreadful? How does your mother respond when your father advises you to pull up your socks? How do you react when she contradicts him?
- 'Ranking' responses: 'Everyone is worried that you may harm yourself.Who worries most? Who is most likely to do something when you talk about suicide?'
- Looking for relational changes since the problem: 'Does your husband spend more or less time with you since your difficulties began? Has he become closer or more distant from your daughter?'
- Hypothetical questions dealing with imagined situations: 'How do you think your relationship with your wife will change if you don't improve? Who would be most likely to notice that you were getting better?'

Triadic questions help to gain information about relationships which go beyond pairs; for example: 'How do you see your relationship with your mother? How does your father see that relationship? How would your mother react to what you have told me if she were here today?'

Making a provisional formulation

Two questions arise from the above interview—how does the family typically function and are there any family features relevant to the patient's problems?

(a) How does the family typically function?

A schema to organize ideas about family functioning builds from simple to complex observations: structure, changes, relationships, interaction, and the way in which the family works as a whole.

- The family tree will reveal the many family structures possible—single-parented, divorced, remarried, siblings with large age gaps, adoptees. Unusual configurations invite conjecture about inherent difficulties.
- Data will be obtained about notable family changes and events; the timing of predictable transitions is pertinent. Have external events coincided with these transitions (times at which the family may be more vulnerable)? How has the family met such changes?
- Relationships refer to how members interact with one another. What is the degree of closeness and emotional quality (e.g. warm, tense, rivalrous, hostile)? Major conflicts may be noted, as may be overly intense relationships.
- Particular interactive patterns may become apparent which go beyond pairs. Triadic relationships are more revealing about how a family functions overall. A third person is often integral to defining the relationship between another pair. A conflict, for instance, may be re-routed through the third person, preventing direct resolution. A child may act in coalition with one parent against the other or with a grandparent against a parent.
- At a higher level of abstraction, the clinician notes how the family works as a whole. Particular patterns (possibly a series of triads) may emerge that may have recurred across generations. For example, mothers and eldest sons have fused relationships, with fathers excluded, while daughters and mothers-in-law are in conflict.

Idiosyncratic shared beliefs may be discerned, explaining much of the way the family does things. 'Rules' governing members' behaviour towards one another or to the outside world may flow from these beliefs. For example, a family may hold that 'You can only trust your own family; the outside world is always dangerous'; they may therefore avoid conflict at any cost, and prohibit seeking external support.

Evidence of family difficulties may be found at each of these five levels. If they are, the question arises whether these do or do not relate to the patient's problems.

(b) Are family factors involved in the patient's problems?

Links between family functioning and the patient's problems take various forms, but the following categories cover most situations:

- the family as reactive
- the family as a resource, and
- the family in problem maintenance

Often, more than one will apply.

The family as reactive

The patient's illness, or its exacerbation, may have occurred at a time of family upheaval. While the precipitant for the upheaval may have been inherent in the illness itself, an escalating combination of the two may pertain. The illness may have occurred in the face of family stress; it pressurizes the family all the more, and this in turn exacerbates the illness.

The family as a resource

The family may be well placed to assist in treatment. This may be as straightforward as supervising medication, ensuring clinic attendance, and detecting early signs of relapse, or providing a home environment that promotes and maintains recovery. The family may also call on friends and agencies, professional or voluntary, to offer support.

The family in problem maintenance

Interactions revolving around the patient's illness may act to maintain it.

1 First, the illness becomes a way of 'solving' a family problem, the best that can be achieved. For example, anorexia nervosa in a teenager due to attend a distant university may lead to her abandoning this plan since she feels unable to care for herself. Were she to leave, parental conflict would become more exposed and her mother, with whom the patient is in coalition against her father, would find herself unsupported. The illness therefore keeps the patient at home and enmeshed in the parental relationship, and also provides a focus for shared concerns and an ostensible sense of unity.

2 Maintenance of the illness does not solve a family problem but may have done so in the past. An interactive pattern persists even though it lacks utility. In the previous example, the father's mother died 9 months later. His wife subsequently expressed feelings of closeness which he had not experienced for years; their relationship gradually improved. Both parents, however, continued to treat their daughter as incapable of achieving

autonomy, reinforcing her own uncertainty about coping independently if she were to recover.

3 Persistence of illness reflects a perception by the family of themselves and their problems, to which they are bound by the persuasive power of the narrative they have shaped for themselves. This often stems from the health care professional's explanatory schema.

Interview with key informants

The clinician will by now have made an initial assessment of the patient's problems and of the family context. The next step is an interview with one or more informants, usually family members, to corroborate the story, to fill in gaps, to determine influences impinging on the patient, and to recruit others to help. A family meeting is most effective to accomplish these goals.

Implementing the session may prove difficult since the patient may oppose it for all sorts of reasons: symptoms have been kept secret, he regards it as unfair to burden others, he is ashamed of seeing a psychiatrist, he is fearful the family will be blamed, he is suspicious of them, and so forth. These concerns need ventilating, particularly if the family context is pivotal and it is likely that treatment will be enhanced by their involvement. The patient will agree in most cases. Where the safety of the patient or others is threatened, refusal may be overridden on ethical grounds. Otherwise, refusal must be respected. A family session can be suggested again after a more trusting relationship has been established.

Who should be seen depends on the purpose of the interview; generally, all those living in the household are likely to be affected by the patient's illness. The more family factors pertain, the more desirable the attendance by all. The patient's views are sought since he will provide insight into the members he deems crucial to his 'story'.

The family interview

Much information will have been garnered by the time the family is seen. The clinician should consider any biases that may have infiltrated her thinking about the family, and how best to avoid being drawn into alliances. A non-judgemental stance is paramount.

Introductions are made in the initial phase. Names and preferred modes of address are clarified. The clinician then explains the meeting's purpose, details of which may well influence future participation. She invites everyone to share views about the nature and effects of problems they face.

The clinician has an idea about how the patient's problems relate to family function, and can test it out by asking probing questions and observing interactions. This is kept to herself since it is unhelpful for a hypothesis to be offered prematurely. Instead, details about everyday events are sought and inferences drawn later. For example, rather than focusing on 'closeness', questions can be asked about time spent together, whether intimate experiences are shared, who helps with family tasks, and so on.

Triadic relationships can be scrutinized both through questioning (what does A do when B says this to C?) and observation (what does A do when B and C reveal tensions?). The scope for such 'circular' questioning (a method ushered in by the Milan school) is enhanced if several members participate. A third person may be asked to comment on what two others convey to each other when a particular event occurs. This strategy of not posing questions to which the family may have stereotypical responses challenges them to think about their relationships in a fresh way.

Information is elicited that elaborates the family tree. Observations may be made concerning family structure and functioning; for example, who makes decisions, who controls others and in what areas, the quality of specific dyadic relationships, conflict, alliances, how clearly people communicate and how they solve problems. The discussion then extends to all spheres of family life: beliefs, traditions, rules, and values.

Throughout the interview the clinician affirms the experiences of all family members. Concerns are attended to and the members' strengths and efforts acknowledged.

The interview concludes with a summary of what has emerged. The clinician may wish to continue the assessment or recommend family therapy. If the latter, an explanation of its aim and rationale is then given.

Arrangements are made for a follow-up session, purportedly the launch of family therapy *per se*, but in essence a continuation of 'work' in progress.

Revised formulation

Since new information becomes available at each point, the initial formulation is revised as necessary.

Five observational levels —of structure, transitions, relationships, patterns of interaction, and global functioning—are re-examined in terms of the family as reactive, resourceful, or problem-maintaining. We now turn to the course of family therapy.

The course of therapy

With a family approach agreed upon, therapy begins. However, when a family is referred as a group on the premise that the problem is inherently a family one, it is made explicit that the initial stage incorporates assessment.

Given the plethora of 'schools' of family therapy it would be laborious to chart the course of treatment based on each. We shall focus on the Milan approach,[12] but stress that it has undergone refinements. Our account highlights core features but first we comment briefly on the different roles the therapist may assume.

Role of the family therapist

Beels and Ferber,[34] early observers of possible roles for family therapists, divide them into 'conductors' and 'reactors'; this differentiation remains useful since it transcends schools. Virginia Satir[35] is a good illustration of the conductor given that she espoused the notion of family therapist as a teacher who shares her expertise in how to communicate well by setting goals and the direction of treatment. She guided the family to adopt a new form of language to resolve communication problems, which she saw as the root of their troubles. Additionally, the therapist instils confidence, promotes hope for change, and makes them feel comfortable. Conductor-type therapists are explicit authorities, who intervene actively.

The therapist as reactor resonates with, and responds to, what the family exhibits to her. Psychoanalytically oriented and 'pure' systems therapists are representative since they typically share observations about patterns of relating that emerge. We will illustrate this in our account of the Milan school.[12]

The Milan approach

With assessment complete, the therapist (sometimes a pair) meets the family for about an hour. With her preparatory knowledge, she develops a hypothesis about the nature of the family's dysfunction. She has the opportunity on observing patterns *in vivo* to confirm her notions. Patterns usually emerge from the start, making the therapist's job correspondingly easier. Apart from hypothesis-testing, another key task is to engage the family so they will be motivated to reattend. We could interpolate a dictum here: a primary aim of the first session is to facilitate a second session. A vital element in encouraging engagement is for the therapist to promote a sense of curiosity in family members so that they raise questions about themselves and the family as a group.[36]

The chief strategy is circular questioning.[37] Its main purpose is to address the family's issues indirectly; this avoids applying pressure on members and possibly inviting their resistance. For example, the therapist questions an adolescent about how his parents get on with each other, a mother about how her husband relates to the eldest son, a grandmother about which grandchild is closest to the parents, and so forth. This generates illuminating data about individual members and about the family as a group. In this phase, it helps to clarify the hypothesis and to engage participants. It also affords the therapist a greater facility to remain neutral. Because the system and not a patient is the target of change, the therapist is wary of showing any bias.

Various options are then available. If the therapist works as part of a team, her colleagues have busily observed the proceedings through a one-way screen. The family's consent for this will of course have been obtained. During a break, the team—observers and therapist(s)—pool impressions.[38] This is always enlightening since team members note something that others have missed. A consensus evolves, conclusions are drawn and converted into 'messages'. The therapist returns to the family to convey them. The actual messages and their oracular quality comprise a potent intervention, but not necessarily more cogent than circular questions made during the working session. We should mention here that the narrative school has brought with it a de-emphasis on the 'message' on the grounds that 'truth' is a shared construction.

One to three messages are usually given, with maximal clarity. These have a range of purposes including promotion of intersessional 'work'. Homework may be assigned and another session planned (unless termination was set for this point). Meetings commonly occur 3 to 4 weeks apart, and for good reason. During this time, the family, armed with new ideas, tackle them in their day-to-day lives. It is not critical how they go about it but that they do so. As Cecchin has posited,[36] the family's interest in their functioning should have been so aroused that they will be motivated to continue looking at themselves between sessions.

The varied nature of the message makes them classifiable.[39] Messages are supportive, hypothesis-related, or prescriptive. First, the message has a reassuring and encouraging quality and is not related to the hypothesis. A *complimentary message* might be that 'The team were impressed by how open you all were in the session', and a *reassuring message* that 'This is tantamount to a new start for the family and uncertainties are likely'.

Hypothesis-related messages refer to the hypothesis worked out by the team, and may assume diverse forms. It may be stated directly; for example, 'Susan has assumed the role of therapist for her parents and sister to save the family from breaking up'. There may be reference to change such as, 'The team sees John taking responsibility; John and his father's improved relationship has enabled this to occur'. The family may be offered choices related to the hypothesis; for instance, 'The family could risk openness or remain self-preoccupied'. *Paradoxical messages* are a means to communicate a hypothesis which invites the family to revisit a feature of their functioning so that the family's difficulties are positively promoted and explicitly encouraged; for example, 'The team sense that your problem is working for the good of your marriage; sticking with your illness can save the marriage'. More creatively, the paradox may be split, in that the family are told about a divergence of opinion in the team[40]; for instance, some members believe it is too risky for them to communicate openly, others suggest the family can begin to do so. Through a *prescriptive message* the family is given a task. This may or may not be related to the hypothesis. For example, the family is urged to meet on their own before the next session to explore what inhibits a member from relating closely to the others.

Whatever the form of message, the therapist de-emphasizes the pathological status of the patient and applies what the Milan school calls *positive connotation*. This brilliant innovation rests on the premise that all behaviour is purposeful, and that the purpose can be construed positively. An adolescent's 'open grieving' is reframed as sparing the family the anguish of grief. This quality of message calls for creative thinking and flies in the face of the customary view of symptoms as evidence of psychopathology. Again, curiosity enters the picture as the family hears a positive communication concerning an issue they hitherto regarded as abnormal.

The process described continues in succeeding meetings, with attention also paid to family life between sessions. Duration of therapy depends on how entrenched the family dysfunction is rather than on the status of the patient's problems. Thus, systemic change is aimed for, with the family invited to consider a substitute mode of functioning that is feasible and safe. In practice, the number of sessions ranges from 1 to 12. If progress has not been made by about the seventh session, it is likely that alternate ways of helping family and/or patient are needed.

Ending therapy

Termination issues are less profound than in individual or group therapy. The reason is obvious. The family has come as a living unit and will continue as such. Even when the therapist is a pure conductor, the family's intrinsic resources are highlighted so that they can be drawn on after the therapist's departure. Determining the end-point is not usually problematic. There is a shared sense that the work has been accomplished.

A hypothesis (or set of hypotheses) has been introduced, tested, and confirmed. The family system has been examined so that impediments are recognized and understood and better modes of functioning devised and implemented. The family is not required to leave functioning optimally. Instead, termination occurs when there is agreement that the family feels confident to try out newly discovered options.

As alluded to earlier, this may be determined alongside a judgement that the identified patient (or another family member) requires another form of therapy in their own right. An adolescent who has felt unable to separate and individuate is a good example. While family work has explored the system that hindered his

'graduation', the sense prevails that he could benefit further from individual or group therapy. In another example, the parents may conclude, with the therapist's support that they have an agenda which is not pertinent to their children and is therefore best undertaken in couple therapy.

Problems encountered in therapy

Where assessment has been carried out diligently and motivation for change sustained, treatment proceeds smoothly. A crisis may still buffet the group but, rather than being derailed, the family regard it as a challenge with which to grapple.

Family treatment does not always succeed. Indeed, deterioration may occur, albeit in a small percentage of cases. What common difficulties are encountered? The non-engaging family is problematic in that while evidence points to the need for family intervention, members cannot participate in the task, usually because they resist letting go of 'the devil they know'. In another variation, engagement of some members may fail. This is particularly so in the case of fathers who, in the wake of their denial, tend to see the target of therapy as the identified patient rather than the family as a group. This belief may apply to any member.

Missed appointments may punctuate therapy, often linked to turbulent experiences between sessions or apprehension about what a forthcoming session may engender. Like any psychotherapy, drop-out is possible. On occasion, this is appropriate in that the indication for family therapy was misconstrued. In other circumstances, drop-out is tantamount to failure and may stem from such factors as therapist ineptitude, unearthing of family conflict which they cannot tolerate, and inappropriate selection of a family based on faulty assessment.

Given that the family continues as a living group during treatment, they are exposed to all manners of vicissitudes, and these may disrupt the therapeutic work. For example, an overdose by the patient, abrupt marital separation, or admission to a psychiatric hospital may take its toll and undermine treatment.

In discussing termination, we commented on outcome. Not all families will benefit. The family's dysfunction may be so intractable that it proves impervious to change, hypotheses may be 'off the mark', the family may lack sufficient psychological-mindedness, members may retreat in the face of change because of insecurity, and so forth.

Occasionally, dependency becomes a problem as the family discards any vestige of autonomy and only feels secure in the authoritative hands of the therapist. The latter may inadvertently foster such dependency by assuming undue authority, so precluding any sense of a growing partnership. The family's inherent resources are then not permitted expression.

Finally, part of the family may harbour a secret that threatens the principle of open communication. The therapist may be inveigled into a subgroup, although knowing that secrets are not conducive to the therapeutic process. For example, a wife calling the therapist to say she has been having an affair but cannot divulge this to her husband or children lest she hurt them imposes a burden on the therapist and the process (see Bloch *et al.*[27] for an overview of confidentiality in family therapy).

Sound clinical judgement is required in all these situations. Since no ready-made prescriptions are available, the therapist must be aware that difficulties may occur even in a highly motivated, well-selected family. The general principle, however, is to prevent their evolution if at all possible or to recognize them early and 'nip them in the bud'.

Research in family therapy

Selective reviews of the vast research literature in family therapy have been provided by Carr.[41,42] Larner[43] has examined political and conceptual issues raised by family therapists' attempts to conform to the criteria of evidence-based practice while Stratton and his colleagues[44] have looked at the impact of such research on clinicians. An argument for the continuing relevance of single-case studies has been mounted by Datillio[45] and the possibilities of conducting qualitative research in a systems model by Burck.[46]

The long-standing debate between the role of 'common basic factors' versus 'model-specific factors', which has bedevilled research in individual therapy, also pertains to family therapy. Simon[47] has proposed a testable hypothesis, rich in its implications, that the most effective model is one whose concepts and values most closely resemble the world view of the therapist. He offers this as a conceptual bridge between the two approaches to therapeutic research, although he curiously says nothing about the family's world view.

Modifying the psychoeducational model of family-based treatment to incorporate clinically relevant socio-cultural factors has been proposed for the treatment of adolescents and young adults suffering from schizophrenia[48] and depression.[49]

In appraising the contemporary state of family therapy research in adult clinical psychiatry, we may be cautiously optimistic. Immense strides have been made in developing theoretical concepts. As can be seen in the first section of the chapter, we have a rich array of therapeutic approaches.[50] On the other hand, the growth occurred at a dizzy pace, with the inevitable consequence of overload. How can we make sense of so many offerings? Is integration needed to forestall fragmentation? Have we reached the point to pause and reflect? Are we in a position to evaluate the effectiveness of diverse approaches, and for various types of clinical problems?

Observers of the research[51,52] have pointed to a complicating factor in contemplating future work, namely the therapist assembling a natural group, of varying composition, in which the principal goal is to improve its functioning. We face the conundrum of what constitutes optimal outcome and how it is best measured. We can best illustrate this by citing Asen and his colleagues.[53] In their trial of family therapy they had agreed to apply multidimensional measures to assess outcome—at individual, dyadic, and family system levels. At follow-up they noticed changes at the first two levels, but not in the family as a whole. The latter involved ratings of such aspects as communication, boundaries, adaptability, and competence. The researchers were candid in sharing their doubts about how to deal with the divergent findings. Several interpretations were offered: for example, no change was achieved in family functioning, the instrument of family functioning was non-reactive to treatment since it was a trait measure, and an inappropriate model of therapy was applied in the first place. The group concluded that the 'assumptive worlds' of therapists and researchers were under scrutiny rather than the families themselves.

A group in Oxford[54] encountered similar difficulties in their study of consecutive families treated in an adult family therapy clinic. Whereas two-thirds of the identified patients were judged improved at termination, only half the families were rated as

functioning at a better level. Again, the investigators were left with questions of how to determine what had actually been achieved.

A methodologically simpler method is to focus only on the identified patient. The work of Hafner *et al.*[55] exemplifies this choice—a case-controlled evaluation of family therapy in an inpatient setting with subsequent hospital admission data as the chief outcome criterion. Satisfactory as this study is in design, the omission of a family-system outcome measure leaves us ignorant about the level of family functioning following the intervention.

With these tricky matters in mind, what does research need to sort out? The diffuse question of whether family therapy works is of little utility, and is reminiscent of the sterile debate that typified individual psychotherapy outcome research for decades.[56] While subsequent meta-analyses demonstrated that psychological interventions overall exerted useful effects across a range of conditions, the field was still open to the criticism that efficacy of a specific approach for a particular clinical state remained unanswered. Family therapy should not repeat the same mistake; instead of posing the futile question of whether family therapy is effective in adult psychiatry, we should ascertain whether a specific family therapeutic approach, whose character is well identified and measurable, is useful for both the identified patient, with a specific clinical presentation, and his family's functioning, again well defined.

We have good examples of such research. Many intervention studies of families with a schizophrenic member have carefully described the principles of treatment, its rationale, process aspects, and outcome measures in the patient and (in some cases) the family.[57–60]

As mentioned earlier, multiple family group therapy (MFGT) is emerging as the preferred psychosocial intervention for adolescents and young adults with schizophrenia. A comparison with the 'open dialogue' model we mentioned earlier has not been conducted, and may not be feasible, since the latter is part of a comprehensive treatment paradigm.[61] A Danish study[62] which combined MFGT with assertive community-based treatment of young people with schizophrenia reported improvement not only of psychotic features (both positive and negative), but also a decline in use of alcohol and illicit drugs. Given the major problem of co-morbidity, this is a welcome development.

MFGT has also been directed to helping the caregivers of patients with schizophrenia. In a randomized controlled trial, Hazel *et al.*[63] found that those in the treatment programme for over a 2-year period experienced greater relief from distress compared to controls, but they were not able to determine the mechanism for this effect.

Work in the area of affective disorders and family therapy has been innovative, with MFGT, again, gaining popularity.[64] As in schizophrenia, the family treatment aims to reduce members' hostility and criticism expressed toward the depressed patient.

An excellently designed and executed study on anorexia and bulimia nervosa illustrates how outcome research can contribute to the clinical sphere.[65] In a well-controlled study, patients were randomized to either family therapy or 'routine individual supportive therapy', following their discharge from a weight-restoration programme. The family intervention focused on providing the members with information about the eating disorder and the effects of starvation. Parental anxiety was acknowledged and efforts made to help them take control of their daughter's diet. In parallel with improved physical status, therapy turned progressively to typical adolescent issues of autonomy and how these might be achieved. Overall, a structural approach was applied, with systemic and strategic methods added as necessary. Applying these principles to groups of families with adolescents with anorexia nervosa appears to be useful.[66]

While the above studies concerning particular diagnoses, and involving an identified patient, is necessary for progress,[67] this does not preclude outcome studies where the family system is the main target of change. We illustrate this with a particular form of family grief therapy.[68] The model was derived from earlier empirical research on the outcome of family grieving in an oncology setting. A 13-month follow-up yielded five family clusters, two of which were distinctly dysfunctional, two functional, and an intermediate group vulnerable to maladaptive grieving. Three dimensions of family relational functioning were critical: cohesiveness, conflict, and expressiveness. The researchers then developed a treatment model highlighting the goals of promoting cohesiveness, expressiveness, and optimal management of conflict. A screening instrument was found which could readily identify dysfunctional families. A randomized controlled trial was then carried out which showed certain family types benefiting but others remaining unchanged, and a small group even being made worse.[69]

This necessarily schematic account of research on family therapy in adult psychiatry points to action needed in future. We can best summarize what investigators should strive for as: 'Specificity is of the essence'.

Training

From charismatic figures devising innovative methods of family therapy, the field has developed into a worldwide enterprise, with dozens of books, scores of training courses, several journals, and a busy programme of national and international conferences and workshops on offer.[70] Formal training may be given as follows[71]:

1 University-based programmes that regard family therapy as a distinct professional pursuit, with a corresponding corpus of knowledge, and offer degree courses at various academic levels.

2 Free-standing institutes that also see family therapy as a distinct discipline and provide training, generally part-time and of briefer duration than university-based programmes.

3 Within university-affiliated hospitals and clinics that arrange professional training in psychiatry, psychiatric nursing, psychology, social work, and occupational therapy. Although there is a tremendous diversity in the above programmes, most include:

- Supervision of clinical work with the experienced practitioner (and perhaps other students) observing the trainee and family from behind a one-way screen. Some clinicians however consider the one-way screen as dehumanizing. They advocate instead a model of co-therapy between trainee and supervisor, often with other students sitting in the same room as the family.
- Video recording the trainee's work, which she then reviews with the supervisor and fellow students, is widely used. Tapes conducted by eminent therapists are also popular.

Whether training requires familiarity with concepts and techniques of diverse schools or whether it is preferable to develop expertise in only one school remains an open question. The free-standing institutes tend to be run by practitioners of a particular school so

that, after a mostly cursory overview of the field, training concentrates on a specific model. Wendel and his colleagues[72] have proposed a model of training for multidisciplinary mental health settings which places most emphasis on integrating empirically derived knowledge; flexibility is a crucial feature for facilitating its optimal application.

Conclusion

Family therapy has the potential to play a major role in the adult psychiatric setting. As we have commented above, research reveals several promising developments. Clinicians should seriously consider applying this mode of treatment; they will be much rewarded in doing so.

6.3.9 Therapeutic communities

David Kennard and Rex Haigh

Introduction

Two of the best-known pioneers of therapeutic communities, Tom Main and Maxwell Jones, defined them as follows:

> An attempt to use a hospital not as an organization run by doctors in the interests of their own greater technical efficiency, but as a community with the immediate aim of full participation of all its members in its daily life and the eventual aim of the resocialization of the neurotic individual for life in ordinary society.[1]

> What distinguishes a therapeutic community from other comparable treatment centres is the way in which the institution's total resources, staff, patients, and their relatives, are self-consciously pooled in furthering treatment. That implies, above all, a change in the usual status of patients.[2]

Today therapeutic communities can be defined by a number of common features, but a word of warning. For reasons of historical coincidence, the term is used in the fields of mental health and addictions to refer to two somewhat different treatment models. In the addiction field they are also known as hierarchical, drug-free or concept-based therapeutic communities, or simply addiction therapeutic communities,[3] in contrast to the more democratized programmes in mental health. The two models have similar goals but their methods differ, although there are signs of increasing rapprochement between them. This chapter deals mainly with therapeutic communities in mental health, but reference will also be made to addiction therapeutic communities and those in long-term care settings. It is worth noting that those admitted to a therapeutic community for treatment are usually referred to as residents, clients, or members, rather than as patients.

Defining beliefs

Certain beliefs about human relationships and the nature of therapy are central to therapeutic communities.

1 Staff are not completely 'well' and residents are not completely 'sick'. There is a basic equality as human beings between staff and residents, who share many of the same psychological processes and experiences.

2 Whatever the symptoms or behaviour problems, the individual's difficulties are primarily in his or her relationships with other people.

3 Therapy is essentially a learning process, both in the sense of learning new skills—how to relate to others or deal more appropriately with distress—and learning to understand oneself and others.

Defining principles

A study of one of the best-known therapeutic communities, Henderson Hospital,[4] identified four principles or 'themes' that have come to be widely associated with therapeutic community treatment.

Four principles of therapeutic community treatment

- **Democratization** Every member of the community should share equally in the exercise of power in decision-making about community affairs.
- **Permissiveness** All members should tolerate from one another a wide degree of behaviour that might be distressing or seem deviant by ordinary standards.
- **Communalism** There should be tight-knit intimate sets of relationships, with sharing of amenities (dining room etc.), use of first names, and free communication.
- **Reality confrontation** Residents should be continuously presented with interpretations of their behaviour as it is seen by others in order to counteract their tendency to distort, deny, or withdraw from their difficulties in getting on with others.

Defining aspects of current practice

The generalizability of these principles to newer therapeutic communities is now being questioned and others are developing theoretical frameworks for different therapeutic communities.[5] In 2002, a quality network including most British therapeutic communities started, the 'Community of Communities', with the explicit aim of defining good practice and improving it. In 2006 the first version of 'Core Standards' was published.[6] This comprised 16 standards which were derived from consensus and consultation exercises to determine what practitioners and service users thought reflected the underlying values of therapeutic communities.

Box 6.3.9.1 illustrates a sample of eight of the standards. Note that 'all community members' should be taken to include both resident or client members, and staff.

Background

Evolution of different types of therapeutic community

Communities providing sanctuary for mentally ill people have been known as far back as the fourteenth century at Geel in Belgium. In 1796 the Retreat was opened by the Quakers in York, England, where personal relationships and social expectations in a family-like atmosphere enabled previously dangerous and unpredictable individuals to control and modify their behaviour.[7] This model, known as 'moral treatment', strongly influenced the creation of asylums in Britain and the United States in the first half of the nineteenth century. In the early twentieth century, pioneers in therapeutic education, inspired by a Christian belief in the therapeutic power of love and by Freud's new method of psychoanalysis (see Chapter 3.1), created residential schools for maladjusted children that demonstrated most of the practices and attitudes outlined above.[8] The modern equivalent of communities such as Geel can be found in the intentional communities run by third sector (voluntary) organizations such as l'Arche and the Camphill communities for people with learning disabilities. (The term 'intentional community' avoids language that implies clinical responsibility or a focus on therapy or change, and has been defined as 'a relatively small group of people who have created a whole way of life for the attainment of a certain set of goals'.) A number of therapeutic communities for children and young people now exist as voluntary organizations in the educational sector, as progressive schools, and as long-term treatment units for very disturbed children.

The history of mental health therapeutic communities for adults began during the Second World War, when the psychoanalyst Wilfred Bion was put in charge of the training wing at Northfield Military Hospital in Birmingham, England. His brief attempt in 1943 to establish a therapeutic community failed, but was soon followed by others who were more successful: Tom Main, S. H. Foulkes, and Harold Bridger at Northfield, and Maxwell Jones at Mill Hill Hospital, London. In dealing with psychiatric casualties among soldiers they developed a radical new approach, which was first described in a series of papers in 1946. One of these coined the term 'therapeutic community'.[1] Main and Jones continued to develop different versions of this new method after the war, Main as director of the Cassel Hospital and Jones at Belmont Hospital Industrial Neurosis Unit, which was renamed the Henderson

Box 6.3.9.1 Core standards for therapeutic communities

1 The whole community meets regularly

2 All community members work alongside each other on day-to-day tasks

3 All community members share meals together

4 All community members can discuss any aspects of life within the community

5 All community members create an emotionally safe environment for the work of the community

6 All community members participate in the process of a new client member joining the community

7 There is an understanding and tolerance of disturbed behaviour and emotional expression

8 Positive risk taking is seen as an essential part of the process of change

Hospital in 1958. The Cassel Hospital continues as an inpatient psychotherapy hospital, and Henderson Hospital replicated itself in 2000 to serve national needs for 'severe personality disorder' provision by founding Main House in Birmingham and Webb House in Crewe.

The creation of the National Health Service in 1948 provided the stimulus to address the major problems of institutionalization revealed in a number of studies of large mental hospitals in the United Kingdom and United States.[9,10] In the 1950s and 1960s social psychiatry was in the ascendancy and a number of these hospitals developed what Clark called the 'therapeutic community approach".[11] In the 1970s and 1980s concepts of collective responsibility fell from favour and individualism prevailed, with a decline in the fortunes of therapeutic communities. The 1990s and 2000s have seen a revival of interest in therapeutic communities within more specific mental health contexts, including prisons, personality disorder services, and for the management of people with enduring mental illness in the community. The problem of degraded and poorly functioning inpatient units is now being addressed by attention to establishing and maintaining 'therapeutic environments' in acute settings, in a direct parallel to the 'therapeutic community approach' 40 years earlier.[12,13]

Alongside these developments two other types of therapeutic community have emerged. In 1958 a self-help organization in the United States called Synanon became the prototype for concept-based therapeutic communities for ex-addicts. Phoenix House and Daytop were two major programmes that grew from this, and today therapeutic communities modelled on them can be found in more than 50 countries worldwide.[3] A development that grew out of the antipsychiatry movement in the 1960s is known at Soteria. These are small low-stress family-like environments where psychosis is responded to with intensive therapeutic support rather than medication. These communities are mainly found in Europe.[14]

Scientific background

Therapeutic communities have drawn on the concepts of psychoanalysis, group analysis (see Chapter 6.3.6), humanistic and integrative psychotherapies, and on sociological studies of mental hospitals which identified phenomena such as the total institution[10] and patterns of behaviour associated with psychiatric treatment in institutions.[15] They are also underpinned by studies of the impact of unconscious processes in organizations,[16,17] and by anthropological studies such as that of Rapoport[4] which found a typical pattern of oscillation in the therapeutic community.

A developmental model based on the 'required emotional experiences' of attachment, containment, communication, inclusion, and agency has been proposed by Haigh.[18] This identifies ways in which a range of psychological theories and approaches are relevant to therapeutic community practice, and illustrates how they are replicated in the structures and culture of a therapeutic community. It also proposes that disturbance of 'primary emotional development' (which all humans undergo early in life) can to some extent be made good by a satisfactory experience of 'secondary emotional development' in a therapeutic community.

Technique—how change is brought about

Since the therapeutic community *is* the treatment, managing treatment involves attention to two parallel processes: the progress of each resident through the community, and the effective functioning of the therapeutic community as a whole. Responsibility for managing these two processes ultimately belongs to the staff, though it is shared with the residents when the community is functioning well.

Most if not all the treatment in a therapeutic community takes place in groups and in the everyday life of the community, although some also use individual psychotherapy. The essence of the therapeutic community technique has been encapsulated in two phrases.

1 A *living–learning* situation: this refers to the fact that everything that happens between members of a therapeutic community in the course of living together, and in particular when a crisis occurs, is used as a learning opportunity.[19]

2 *Culture of enquiry*: this refers to the creation not just of certain structures but of a basic culture among the staff of 'honest enquiry into difficulty'. There is a conscious effort to identify and challenge dogmatic assertions or accepted wisdoms.[20]

The basic mechanism of change is not difficult to explain. The therapeutic community provides a wide range of lifelike situations in which the difficulties a member has experienced in their relationships with others outside are re-experienced, with regular opportunities in small group and community meetings to examine and learn from these difficulties. If the therapeutic community is to work as a therapeutic method, all its constituent parts described in this chapter must be in good-working order. This requires a process by which new members adopt the values of the community, emphasizing openness, responsibility, and active participation, and in turn pass these on when the next new members arrive. To operate this mechanism requires both staff and residents to fulfil a number of roles (Box 6.3.9.2).

Staff training

The need for specialized training for leading or working as a staff member in a therapeutic community has been a matter of some debate.[21] There is an argument that the emphasis on egalitarianism and democratization means that this form of treatment is best delivered by people without special training who can just 'be themselves'. Unqualified social therapists often form a key part of the staff complement. However, the other argument is now increasingly accepted, that while being oneself is an important part of the staff role (see above), therapeutic community work requires a high level of skill and knowledge in a number of areas, together with a well-developed capacity for open honest discussion and reflection.

Training courses exist in the United Kingdom, Finland, Norway, the Netherlands, and Greece, but there is no set standard or curriculum. Some relevant theoretical training is obtainable as part of group therapy and systemic therapy courses, and the case has also been made for a placement in a therapeutic community to be part of professional training in psychiatry and psychotherapy. The benefits include learning at first hand about the treatment of personality disorders, experience of group-based treatment, and working as a member of a multi-disciplinary team, thus gaining first-hand experience of institutional dynamics and the way individuals react to their wider social networks. One of the most popular short courses in the United Kingdom and the Netherlands

Box 6.3.9.2 Staff and client/resident roles in a therapeutic community

Role	Role activity of client/resident members	Role activity of staff members
Participation and involvement in the daily life of the community('Living–learning')	To explain how the community works to those referred, to visitors, and new members	To spend informal time with client/residents (those who appear aloof may be challenged about this)
	To take responsibility for various tasks which contribute to the running of the community	To work alongside clients/residents in day-to-day tasks
	To contribute to various 'extras' such as being involved in teaching and research	To monitor other staff members' emotional involvement and consider in supervision
	To notice and include those who isolate themselves	
Contributing to and managing therapeutic processes ('Culture of enquiry')	To use identification to challenge or support peers	To use therapeutic interventions in groups of various modalities (e.g. group analytic, psychodrama, art therapy, CBT)
	To be open to the challenge and support of one's peers	To encourage client/resident members to take a therapeutic role, in some cases delegating responsibility for out-of- hours support to them
	To support those in crisis, often including out-of-hours	
	To maintain community structures such as rules and timekeeping	
Responsibility for decision-making and 'Democratization'	To make decisions about day-to-day and domestic matters, including rotas and elections	To decide the level of decision-making which would be optimal for the therapeutic benefit of the client group, according to their capabilities and needs
	To participate in decisions about therapeutic matters (e.g. deciding consequences of breaking rules)	To monitor the functioning of the therapeutic environment and titrate the level of staff input and leadership required
	To be involved in planning local events and service developments (e.g. open days, starting new groups)	To ensure good communication with managers, commissioners, referrers, clinical colleagues, and other relevant organizations
	Senior and ex-members can offer invaluable support in maintaining effective external relations (e.g. with organizational executives)	

is a brief residential simulated therapeutic community.[22] Here, 20 to 30 health professionals live together for a few days in the roles of residents with a 'staff' group working with them. This provides a valuable opportunity to experience at first hand the workings and impact of this form of treatment.

Indications and contraindications

Universal indications for therapeutic community treatment are difficult to give. Modified therapeutic communities have been developed for people with different types and levels of psychiatric disorder, and even the same therapeutic community may fluctuate in its capacity to absorb difficult members. An individual's suitability will need to be judged in relation to a particular therapeutic community at a particular time. Having made this caveat, the general indications and contraindications will usually apply (Box 6.3.9.3).

Pathways and process: phases in the therapeutic journey

There are usually four distinct but overlapping phases in a member's journey to and through a therapeutic community:

Engagement phase: Referral, preparation, and selection procedures are an integral part of therapeutic community practice, involving both the prospective member and existing residents as active participants in the process, which start with referral or self-referral. Many prospective members of therapeutic communities are wary or fearful of the forthcoming therapy, and need support and encouragement to persist. This is often effectively delivered by current or ex-members, arranged in partnership with voluntary agencies, or with internet support groups. During this time, any regular support from mental health teams or other agencies should continue.

Assessment and preparation phase: When a decision to proceed towards formal treatment has been made, several arrangements may need to be made. These include formal assessment processes, practical planning, and agreeing a treatment contract. This work is frequently arranged through the use of an 'assessment and preparation group', which is also designed to be a time-limited foretaste of what the treatment phase entails. The assessment process can be undertaken in this group itself, in smaller groups, or with individual appointments. The practical planning involves matters such as arranging childcare, securing stable accommodation, and agreeing plans for medication and risk management. It also includes an

Box 6.3.9.3 Indications and contraindications for therapeutic community treatment

Indications	Indications for specialized TC	Contraindications
Diagnosis of:		
◆ Personality disorder	First episode psychosis	Physically dependent addictions
◆ Self-harm	Serious and enduring mental illness	Current mania
◆ Adjustment disorders	Less than 18 years old	Depression with severe retardation
◆ Recurrent depressive disorders	Learning disabilities	Dementia
◆ Bipolar disorder	Perpetrators of sexual abuse	Dangerously low weight
◆ Intractable anxiety disorders		Antisocial PD with history of intimidation and deception
◆ Eating disorder		No capacity for social involvement
◆ Addictions		Inability to see problems in terms of relationships
		Unwillingness to engage in informal, intimate, and open style of relating with professionals
Age:		
No age limits: young children to elderly members can show benefit		Belief that only experts can help

explicit treatment contract, which may be a verbal agreement about understanding the community rules, or a formal written and signed agreement.

Treatment phase: This usually begins with a formal 'case conference' or 'selection panel' including current community members with a decision made by voting. Subsequent therapy programmes vary considerably: from 1 day per week to whole-time residential; from predominantly sociotherapy to a range of psychoanalytic, cognitive behavioural, humanistic and interpersonal and systemic groups; from a few weeks duration to several years, either time-limited or open-ended; and from group size of less than 6 to more than 50. Some communities include individual therapy, but others consider this inimical to the group dynamic process. A modal or typical programme would be for between 3 and 5 days per week, with all interventions in groups comprising a mixture of community meetings, small therapy groups, shared lunch, and informal time together. A typical community would have between 12 and 24 members divided into three small groups, who would stay for 12 to 18 months. Suitable arrangements would be in place for crisis meetings to be called at short notice, as would a system for members to support each other out-of-hours.

During the first few weeks of treatment the new member will be feeling his or her way, forming attachments to one or two others, but still wary of the groups. After the first month or two he or she will begin participating more actively in the groups, taking part in the full life of the community with certain role responsibilities, helping and supporting other members. This will probably include experience of situations similar to those triggering referral, such as having to deal with authority, fear of failure, feeling rejected or abandoned, situations evoking rivalry and competition, or many others. As before, these may trigger destructive or violent impulses towards the self or another person, or the experience of other symptoms of distress. Through the group meetings the member is confronted with the effects of their behaviour on fellow members and the meaning of the behaviour or symptoms is explored, making full use of the insights and understanding of fellow members. Through this repeated process the member gradually comes to experience himself and others differently. As one member wrote: *Bit by bit, almost grudgingly, the fact dawned on me that I wasn't surrounded by forty sticks of furniture but by Jim, Gary, Jane . . .* [23]

Re-entry phase: Until recently, many therapeutic communities had a 'cliff-edge' ending, where one day members are able to have the community's full emotional and practical support, and the next are not allowed to contact any other members. Although this has some theoretical justification in terms of 'coming to term with endings', and has strong advocates amongst ex-members of therapeutic communities, it is now generally considered better practice to support members over the leaving process, and then into re-establishing mainstream social networks. This can be done with a specific 'leavers group', that members join while in the full treatment phase and continue afterwards, for either a fixed or indefinite period. These groups normally include a practical focus, and are social and supportive rather than exploratory and therapeutic. For those who are ready and able, they can have objectives of securing employment or education for members. In the case of prison-based therapeutic communities for ex-addicts the provision of drug-free housing and vocational training have been found to improve success rates.[24]

As well as planned endings there are various other types of ending. Some members may leave prematurely, unable to cope with therapy; some may be 'voted out' by the community for a serious or repeated transgression of community rules. Such endings do not necessarily indicate a treatment failure, although the longer members remain the more likely they are to benefit.

Research evidence

The effectiveness of therapeutic communities has been investigated in relation to different clinical problems, which are discussed separately.

Personality disorders

Until recently there has been little systematic evidence of the efficacy of therapeutic communities for treating personality disorders, and disagreement over whether those who did benefit were really suffering from psychopathic or personality disorder. While efficacy in this area is still questioned (see Chapter 4.12.7), the picture has recently become clearer with the publication of the first systematic

review of therapeutic community treatment for people with personality disorders.[25] The authors carried out a full search of therapeutic community publications and grey literature, collecting over 8000 references from 38 countries. These were reduced to 29 research studies that met the criteria of randomized controlled trial design (eight studies) or comparative or controlled studies that reported raw data and used conservative outcome criteria (e.g. reconviction rates rather than psychological improvement). A meta-analysis found that 19 studies showed a positive effect within the 95 per cent level of confidence while the remaining 10 straddled the neutral score. The overall summary log odds ratio was −0.567, with a 95 per cent confidence interval, −0.524 to −0.614. The authors concluded that there is strong evidence for the effectiveness of therapeutic communities. A more recent systematic review assessed evidence for interventions for people with PD in general and for dangerous and severe personality disordered offenders and made clear recommendations about the most promising treatment interventions for PD in use or currently in development. The reviewers covered therapeutic community programmes; cognitive, behavioural, cognitive behavioural, and psychodynamic psychotherapies; pharmacological and physical treatments. They concluded that 'the TC model currently has the most promising evidence base in this poor field'.[26]

Offending behaviour

Therapeutic communities have been established in prisons to deal with disruptive, violent inmates, and also with the underlying problems of antisocial personality disorder. Results at Barlinnie Special Unit in Scotland demonstrated substantial reductions in violent incidents within prison. Reconviction studies carried out at Grendon, a prison run entirely on therapeutic community lines, found that prisoners had lower rates of reconviction, fewer custodial sentences, and fewer reconvictions for violent offences than prisoners on the Grendon waiting list who never went there. Those who stayed at Grendon longer than 18 months showed the greatest reductions in reconviction rates. Re-offending rates have also been found to be lower in the former Federal Republic of Germany for prisoners in Social Therapeutic Institutions than those receiving standard prison sentences.[27] In 2004, the 'Democratic Therapeutic Community Core Model' was accredited as a treatment programme for use in prisons in England and Wales. Such programmes must show evidence of their capacity to impact on dynamic risk factors known to be associated with re-offending. Risk factors that therapeutic communities have been found to have a positive influence on include negative attitudes towards authority, identification with antisocial role models, and acceptance of responsibility for offending behaviour.

Drug dependence

Therapeutic communities for drug dependence use the hierarchical or concept-based model. These form one part of the range of treatments for drug abuse, which includes other residential models such as Christian communities and the Minnesota model, as well as methadone maintenance programmes and psychotherapy. Therapeutic communities for drug dependence, often modified to suit different local cultures, can now be found in many European and international countries as well as in the United States where they originated. Although the model began, and continues, as a residential peer-support programme in the community, it has adapted well to secure environments, and concept-based therapeutic communities for drug dependence have been established in American prisons since the mid-1980s, accompanied by a growing number of aftercare programmes providing employment and drug-free accommodation. Several national studies have evaluated the outcome of these programmes. Randomized controlled trials show that no-treatment groups have a higher level of recidivism than those who complete treatment in a prison therapeutic community, and that recidivism is further reduced by participation in a community aftercare therapeutic community.[24] Since 1995 a number of these therapeutic communities have also been established in English prisons. The general conclusion, for both secure and non-secure therapeutic communities, is that residents who stay in programmes for longer periods have lower rates of drug use and criminal behaviour and higher rates of employment than those who stay for shorter times. However, there are no direct comparisons between therapeutic communities and other treatment models, and it is likely that therapeutic communities are successful for those who are well motivated. Although this may be only a relatively small proportion of all drug abusers, studies, and admission policies, suggest those who enter these high intervention therapeutic communities tend to be severely addicted and damaged, often dually diagnosed with personality disorder, and less likely to respond to low intervention treatments.[28]

First episode psychosis

A small number of therapeutic communities have been developed in the United Kingdom, United States, Switzerland, and Germany on the principle that first episodes of psychosis can be effectively treated in low-stress family-like settings providing round the clock personal support, with no or minimal use of neuroleptics. This has become known as the Soteria model. Two Soteria houses, in California and Berne, have been subjected to randomized or matched control trials comparing them with usual hospital treatment. One study found that completing subjects with schizophrenia exhibited a large effect size benefit with Soteria treatment, especially in the areas of psychopathology, work, and social functioning. Length of stay in Soteria Berne was initially longer but this was subsequently reduced to less than the admission ward. In both studies the 2-year outcomes were at least as good in the Soteria group and less antipsychotics were prescribed for the Soteria group.[14] A 20-year study of an acute psychiatric ward in Finland found that people with acute psychotic episodes and borderline conditions seemed to benefit from the therapeutic community model with a high level of support, negotiation, order, and organization.

Severe and enduring mental illness

The therapeutic community approach[11] has been widely used in large mental hospitals to counter the effects of institutionalization and to mobilize the residual capacity of those suffering from chronic mental illness for social relationships, purposeful employment, and personal responsibility. The method was as much about improving the sense of purpose and morale of the staff and the general quality of life in the institutions as it was about clinical improvement, and its success was demonstrated in the way some large old mental hospitals were turned into centres of excellence.

With the re-provision of services for people with enduring mental illness in the community, therapeutic community principles have been found to be an effective way of structuring staffed hostels and homes. In one version of this, the 'ward in a house', the model is close to the original practice of the York Retreat, an antecedent of therapeutic communities (see above).[29] The challenges presented by the severely mentally ill chemical user have also been addressed using a modified therapeutic community with some evidence of success. Three main modifications required to the TC structure were increased flexibility, decreased intensity, and greater individualization.[30]

Children and adolescents

Therapeutic communities for children and adolescents were first developed in the field of therapeutic education almost a century ago, and now exist for a variety of needs: learning disability, delinquency, and emotional disturbance. Little systematic evaluation has been carried out. A survey of 186 children in nine therapeutic communities for emotionally disturbed children found evidence of increased stability and hopeful outcomes for those who stayed. A 20-year follow-up of 28 children in one community reported evidence of long-term improvement.[31]

Wright and Richardson, reviewing the current state of research for therapeutic communities for children and young people, conclude that, 'when rigorous quality controls are introduced there are as yet too few studies to draw any aggregated conclusions. Perhaps the clearest qualified statement would be that there is low-level evidence that some residential therapeutic placements produce changes in the mental and social functioning of some young people who have been unable to cope with family life'.[32]

Learning disabilities

Long-term residential communities for adults with learning disabilities exist in the charitable sector in many countries around the world. These are value based rather than evidence based. There is some evidence that many families express a strong preference for village-style communities such as the Camphill for their mentally handicapped relatives.[33]

6.4

Treatment by other professions

Contents

6.4.1 Rehabilitation techniques

W. Rössler

The goal of psychiatric rehabilitation is to help disabled individuals to establish the emotional, social, and intellectual skills needed **to live, learn, and work in the community** with the least amount of professional support.(1)

Rehabilitation practice has changed the perception of mental illness. Enabling disabled people to live a normal life in the community causes a shift away from a focus on an illness model towards **a model of functional disability**. As such, other outcome measures aside from clinical conditions become relevant. Social role functioning including social relationship, work, and leisure as well as quality of life and family burden are of major interest for the people affected living in the community.(25)

The relevance of psychosocial and environmental problems is reflected in the DSM-IV and ICD-10. Axis IV of DSM-IV and codes Z55–Z65 and Z73 of ICD-10 are assigned for reporting psychosocial and environmental problems that may affect the diagnosis, treatment, and prognosis of mental disorders.

The International Classification of Functioning, Disability and Health

Long-term consequences of major mental disorders might be described using different dimensions. A useful tool was provided by the International Classification of Impairment, Disability and Handicaps (ICIDH), first published by the World Health Organization in 1980. The ICIDH has been recently revised. The revised '**International Classification of Functioning, Disability and Health'** (ICF) includes a change from negative descriptions of impairments, disabilities and handicaps to neutral descriptions of body structure and function, activities and participation. A further change has been the inclusion of a section on environmental factors as part of the classification. This is in recognition of the importance of the role of environmental factors in either facilitating functioning or creating barriers for people with disabilities. Environmental factors interact with a given health condition to create a disability or restore functioning, depending on whether the environmental factor is a facilitator or a barrier.

ICF is a useful tool to comprehend chronically mentally ill in all their dimensions including impairments at the structural or functional level of the body, at the person level concerning activity limitations and at the societal level with respect to restrictions of participation. Each level encompasses a theoretical foundation on which a respective rehabilitative intervention can be formulated.

Target population

During the course of psychiatric reforms the predominant objective of psychiatric rehabilitation was to resettle patients from large custodial institutions to community settings. Today all patients suffering from severe mental illness require rehabilitation. The core group is drawn from patients with the following:

- persistent psychopathology
- marked instability characterized by frequent relapse
- social maladaptation.(28)

There are other definitions currently used to characterize the chronically mentally ill. But they all share some common elements, that is a diagnosis of mental illness, prolonged duration, and **role incapacity**.

Although the majority of the chronically mentally ill have the diagnosis of schizophrenic disorders, other patient groups with psychotic and non-psychotic disorders are targeted by psychiatric rehabilitation. Up to 50 per cent of people with severe mental illness carry **dual diagnoses** especially in combination with substance abuse.

The role of the psychiatrist in rehabilitation

Psychiatric rehabilitation is by its very nature, **multidisciplinary;** because of the many different competencies required. Monitoring medication is a key task of the psychiatrist.

Pharmacotherapy in psychiatric rehabilitation needs some special consideration. Symptom control does not necessarily have the highest priority as some side effects of pharmacological treatment can weaken a person's ability to perform his social roles, and impair vocational rehabilitation. Many patients living in the community **want to take responsibility for their medication** themselves. This also includes the varying of medication without consultation within certain limits.

The starting point for an adequate understanding of rehabilitation is that it is concerned with the individual person in the context of his or her specific environment. Psychiatric rehabilitation is regularly **carried out under real life conditions**. Thus, rehabilitation practitioners have to take into consideration the realistic life circumstances that the affected persons are likely to encounter in their day-to-day living.

A necessary second step is helping disabled persons to **identify their personal goals**. Motivational interviews provide a sophisticated approach to identify the individuals' personal costs and benefits associated with the needs listed.[8] This makes it also necessary to assess the individuals' readiness for change.[15] Functional assessment and individual goal setting are prerequisites of a differentiated rehabilitation intervention plan and should be repeated in different stages of the rehabilitation process.

The rehabilitative planning process **focuses on the patient's strengths**. Irrespective of the degree of psychopathology of a given patient, the rehabilitation practitioner must **work with the 'well part of the ego'** as 'there is always an intact portion of the ego to which treatment and rehabilitation efforts can be directed' (Lamb 1984[2]). This leads to a closely related concept: the aim of restoring hope to people who suffered major setbacks in self-esteem because of their illness. As Bachrach[2] states 'it is the kind of hope that comes with learning to accept the fact of one's illness and one's limitations and, proceeding from there'.

Psychiatric rehabilitation **concentrates on peoples' rights as a respected partner** and **endorses their involvement and self-determination** concerning all aspects of the treatment and rehabilitation process. These rehabilitation values are also incorporated in the **concept of recovery.**[9] Within the concept of recovery, the **therapeutic alliance** plays a crucial role in engaging the patient in his or her own care planning. It is essential that the patient can rely on his or her therapist's understanding and trust as most of the chronically mentally ill and disabled persons lose close, intimate, and stable relationships in the course of the disease. Recent research has suggested that social support is associated with recovery from chronic diseases, greater life satisfaction, and enhanced ability to cope with life stressors.[24] Therefore, psychiatric rehabilitation is also an exercise in network building.

Current approaches

Psychiatric rehabilitation aims at **changing the natural course** of the disease. Yet, there is no consensus among rehabilitation researchers on what rehabilitation actually does accomplish. Some understand rehabilitation as an approach to help disabled people to compensate for impairments and to function optimally with the deficiencies they have. Other researchers assume that rehabilitation helps the patient to recover from the disorder itself, while the contributing factors to the healing process are not clear.

The overall philosophy of psychiatric rehabilitation comprises two intervention strategies. The first strategy is individual-centered and aims at **developing the patient's skill** to interact with a stressful environment. The second strategy is ecological and is directed towards **developing environmental** resources to reduce potential stressors. Most disabled people need a combination of both approaches.

As a general rule people with psychiatric disabilities tend to have the **same life aspirations** as people without disabilities in their society or culture. They want to be respected as autonomous individuals and lead a life as normal as possible. As such they mostly desire (1) their own housing, (2) an adequate education and a meaningful work career, (3) satisfying social and intimate relationships, and (4) participation in community life with full rights.

Housing

The objective of psychiatric reforms since the mid-50s of the 20th century has been to resettle chronically mentally ill persons from large custodial institutions to community settings. Providing sheltered housing in the community for the long-term patients of the old asylums was one of the first steps in the process of deinstitutionalization. Most long-stay patients can successfully **leave psychiatric hospitals and live in community settings**.

Ideally, a **residential continuum** (RC) with different housing options should be provided. RC ranges from round-the-clock staffed sheltered homes to more independent and less staffed sheltered apartments, which eventually allow individuals moving to independent housing in the community. Critics of RC contended that (1) up to date RC is rarely available in communities, (2) that RC does not meet the varying and fluctuating needs of persons with serious mental illnesses, and (3) that RC does not account for individuals' preferences and choices. **Supported housing**, i.e. independent housing coupled with the provision of support services emerged in the 1980s as an alternative to RC. Supported housing offers flexible and individualized services depending on the individual's demands. In the meantime, rehabilitation research could demonstrate that supported housing is a realistic goal for the majority of people with psychiatric disabilities.[23] Once in supported housing, the majority stay in housing and are less likely to become hospitalized. Other outcomes do not yield consistent results.

Work

The beneficial effects of work on mental health have been known for centuries.[11] Therefore, **vocational rehabilitation** has been

a core element of psychiatric rehabilitation since its beginning. Vocational rehabilitation is based on the assumption that work not only improves activity, social contacts, etc., but may also promote gains in related areas such as self-esteem and quality of life, as work and employment are a step away from dependency and a step closer to integration into society. **Enhanced self-esteem** in turn improves adherence to rehabilitation of individuals with impaired insight.

Vocational rehabilitation originated in psychiatric institutions where the lack of activity and stimulation led to apathy and withdrawal of their inpatients. Long before the introduction of medication, occupational and work therapy contributed to sustainable improvements in long-stay inpatients. Today occupational and work therapy are not any longer hospital-based but represent the starting point for a wide variety of rehabilitative techniques teaching vocational skills.

Vocational rehabilitation programs in the community provide a series of **graded steps to promote job entry or re-entry**. For less disabled persons, brief and focused techniques are used to teach how they can find a job, fill out applications, and conduct employment interviews. In transitional employment, a temporary work environment is provided to teach vocational skills, which should enable the affected person to move on to competitive employment. But all too often, the gap between transitional and competitive employment is so wide that the mentally disabled individuals remain in a temporary work environment. Sheltered workshops providing pre-vocational training also quite often prove a dead end for the disabled persons.

One consequence of the difficulties in integrating mentally disabled individuals into the common labour market has been the steady growth of cooperatives, which operate commercially with disabled and non-disabled staff working together on equal terms and sharing in management. The mental health professionals work in the background providing support and expertise.

Today, the most promising vocational rehabilitation model is **supported employment** (SE). In SE, disabled persons are placed in competitive employment according to their choices as soon as possible, and receive all support needed to maintain their position.[4] The support provided is continued indefinitely. Participation in SE programs is followed by an increase in the ability to find and keep employment.[7] Links were also found between job tenure and non-vocational outcomes, such as improved self-esteem, social integration, relationships, and control of substance abuse.[4,29] It was also demonstrated that those who had found long-term employment through SE had improved cognition, quality of life, and better symptom control.[17]

Although findings regarding SE are encouraging, some critical issues remain to be answered. Many individuals in SE obtain unskilled part-time jobs. Since most studies only evaluated short (12–18 months) follow-up periods, the long-term impact remains unclear. Currently, we do not know which individuals benefit from supported SE and which do not.[20] After all, we have to realise that the integration into the labour market does by no means only depend on the ability of the persons affected to fulfill a work role and on the provision of sophisticated vocational training and support techniques but also on the **willingness of society to integrate** its most disabled members.

Building relationships

In recent years, social skills training packaged in the form of modules with different topics has become very popular and has been widely promulgated. The modules focus on medication management, symptom management, substance abuse management, basic conversational skills, interpersonal problem solving, friendship and intimacy, recreation and leisure, workplace fundamentals, community (re-)entry, and family involvement. Each module is composed of skill areas. The skills areas are taught in exercises with demonstration videos, role-play and problem solving exercises, and *in-vivo* and homework assignments.[14]

The results of several control studies suggest that disabled individuals **can be taught a wide range of social skills**. Social and community functioning improve when the trained skills are relevant for the patient's daily life, and the environment perceives and reinforces the changed behaviour. Unlike medication effects, benefits from skills training occur more slowly. Furthermore, long-term training has to be provided for positive effects.[3] Overall, social skills training have been shown to be effective in the acquisition and maintenance of skills and their transfer to community life.[13]

Keeping relationships

As a consequence of deinstitutionalization the **burden of care** has increasingly fallen on the relatives of the mentally ill. Informal caregiving significantly contributes to health care and rehabilitation.[31] Fifty to ninety per cent of disabled persons live with their relatives following acute psychiatric treatment. This is a task many families do not choose voluntarily. Caregiving imposes a significant burden on families. Those providing informal care face considerable adverse health effects, including higher levels of stress and depression, and lower levels of subjective well being, physical health and self-efficacy. Additionally, not all families are equally capable of giving full support to their disabled member and are not willing to replace an insufficient health care system. Caregivers regularly experience higher levels of burden when they have poor coping resources and reduced social support. But **families also represent support systems**, which provide natural settings for context-dependent learning important for recovery of functioning. As such, there has been a growing interest in helping affected families since the beginning of care reforms.

One area of interest deals with the expectations of relatives concerning the provision of care. Relatives quite **often feel ignored**, not taken seriously, and also feel insufficiently informed by health professionals. They also may feel that their contribution to care is not appreciated or that they will be blamed for any patient problems. It certainly is no surprise that there is a lot of frustration and resentment among relatives considering the physical, financial and emotional family burden.

Family intervention programs have produced promising results. Family intervention is effective in lowering relapse rate, and also in improving outcome e.g., psychosocial functioning. Possibly, family intervention can reduce family burden. Furthermore, the treatment gains are fairly stable.[21] But we also have to appreciate, that it is not clear what the effective components of the different models are. Additionally, family interventions differ in frequency and length of treatment. There are also no criteria for the minimum amount of treatment necessary.

Finally, we have to be aware that most family interventions were developed in the context of western societies during deinstitutionalization. Family caregiving might be quite different in a **different cultural context**. This refers to other cultures in total as well as to minority groups in western societies.[31]

Participation in community life with full rights

Practitioners often are confronted with the **deleterious effects of stigma and discrimination** in the lives of people with serious mental illnesses. Numerous studies have examined stigmatizing attitudes toward people with mental illness.[12] In recent years, the scientific interest in the perspective of the labelled individual has increased too. There is extensive empirical evidence of the negative consequences of labelling and perceived stigmatization. These include demoralization, low quality of life, unemployment, and reduced social networks.[10,19] Once assigned the label 'mental illness' and having become aware of the related negative stereotypes, the affected individuals expect to be rejected, devaluated or discriminated against. This vicious cycle decreases the chance of recovery and normal life.

On the other hand, well-integrated people with mental illness exhibit better outcomes regarding psychopathology and quality of life. The importance of social integration is underlined even more when considering the subjective availability of support: perceived social support predicts outcome in terms of recovery from acute episodes of mental illness, community integration, and quality of life.[27,30]

On the basis of comprehensive research in this area during the last decade, several strategies have been developed to fight the stigma and discrimination suffered by those who have mental illnesses.[30] Different research centres developed interventions directed to specific target groups relevant for de-stigmatization, e.g., students[18] or police officers.[22] Persons in contact with mentally ill individuals quite often have a more positive attitude. Contact with the mentally ill persons also reduces social distance,[12] which is a strong argument in favour of community psychiatry. Other initiatives have targeted stigma by means of more comprehensive programs. The World Psychiatric Association launched one of the internationally best-known programs in 1996 (www.openthedoors.com). All these initiatives make clear that efforts in re-integrating persons with serious mental illness into community life must be accompanied by measures on the societal level.

The core elements of modern psychiatric rehabilitation are summarized in Box 6.4.1.1

Developing environmental resources

Effective psychiatric rehabilitation requires **individualized and specialized treatment**, which has to be embedded in a comprehensive and coordinated system of rehabilitative services. But even when a variety of services are available, they are poorly linked in many cases, and costly duplication may occur.

While developing community support systems it became obvious that there is a **need to coordinate and integrate the services** provided as each involved professional concentrates on different aspects of the same patient. Therefore, as a key coordinating and integrating mechanism, the concept of **case management** (CM) originated. CM focuses on all aspects of the physical and social environment. The core elements of CM are the assessment of patients' needs, the development of comprehensive service plans for the patients, and arrangement of service delivery.[26]

Over the past two decades, a variety of different models of CM have been developed which exceed the original idea that CM mainly intends to link the patient to needed services and to coordinate those services. Today most clinical case managers also provide direct services in the patient's natural environment. This model is called **Intensive Case Management** (ICM). ICM on its part is difficult to distinguish from **Assertive Community Treatment** (ACT).

Stein and Test have developed the basic compounds of ACT in the 1970's.[33] The original program was designed as a community based alternative to hospital treatment for persons with severe mental illnesses. A comprehensive range of treatment, rehabilitation, and support services in the community is provided through a multidisciplinary team. ACT is characterized by an assertive outreach approach i.e., interventions are mainly provided in the natural environment of the disabled individuals.[32]

Research on CM and ACT yielded 'mixed' results.[6] While the traditional office-based CM approach obviously is less successful, the ACT model was found to be more beneficial when compared with standard care.[16] ACT can reduce time in hospital,[20] but has moderate or only little effects on improving symptomatology and social functioning. The differing features of the respective services might explain the international variation. Six regularly occurring features of successful services were identified: smaller case loads, regularly visits at home, a high percentage of contacts at home, responsibility for health and social care, multidisciplinary teams, and a psychiatrist integrated in the team.[5]

Box 6.4.1.1 Core elements of psychiatric rehabilitation

- multidisciplinary
- carried out under real life conditions
- identify patient's personal goals
- focus on the patient's strengths
- work with the 'well part of the ego,
- concentrate on people's rights as a respected partner
- endorse their involvement and self-determination
- build a therapeutic alliance

6.4.2 Psychiatric nursing techniques

Kevin Gournay

Background

Psychiatric nursing as an entity has really only evolved since the Second World War. Psychiatric nurses (now often referred to as mental health nurses in the United Kingdom and Australasia) can now be found in most countries of the developed world, although in the developing world, psychiatric nursing is still not defined as a specific discipline. In many countries, psychiatric hospitals are still staffed by untrained 'Attendants' who may have some supervision from general trained nurses. Nevertheless, a number of initiatives, notably those of the Geneva Initiative in Psychiatry[(1)] in Eastern Europe and the former Soviet Union and the World Health Organization in African countries, have provided specific training in psychiatric nursing techniques.

The development of psychiatric nursing across the world needs to be seen in the context of changing and evolving patterns of mental health care. De-institutionalization, with the attendant setting up of community mental health teams, has prompted a range of innovations in psychiatric nursing and the psychiatric nurse of today, who in the United States and Europe is likely to be a university graduate, is a very different person to that of the nurse working in the post-Second World War asylums of 40 years ago.

In this chapter, we examine the development of psychiatric nursing in some detail and particularly emphasize the role of psychiatric nurses working in the community. Community psychiatric nursing first developed in the United Kingdom nearly 50 years ago and this model has been followed in countries such as Australia and New Zealand. However, this community role has not developed to any great extent in the United States, where the main presence of psychiatric nursing remains in hospital-based care. Furthermore, in the United Kingdom and Australasia, the development of community initiatives has seen the role of the psychiatric nurse blurring with that of other mental health professionals. Chapters such as this cannot really do justice to the whole range of techniques used by psychiatric nurses; neither can it examine in any detail the differences between psychiatric nursing practices across the world. However, a description of psychiatric nursing in six important areas will provide the reader with an appreciation of the range and diversity of psychiatric nursing skills:

- Inpatient care
- Psychosocial interventions in the community
- Prescribing and medication management

- Cognitive behaviour therapy
- Primary care
- Psychiatric nursing in the developing world.

Psychiatric nursing in inpatient settings

In the past three decades the population in psychiatric hospitals across the developed world has fallen dramatically in England from 160 000 to 30 000 beds over a period of 25 years and the duration of inpatient care in the United Kingdom in 2007 is approximately 36 days. However, today's inpatients are a population with much greater levels of illness than was previously the case; they tend to be more treatment-resistant, have complex problems, and display high levels of substance abuse and violence.[2] As a corollary of this, a greater proportion of patients are now detained under mental health legislation. Inpatient facilities consist of acute psychiatric units, local secure units, and high secure psychiatric hospitals for those patients who pose high levels of danger to themselves and others. In the United Kingdom, four high secure hospitals contain approximately 1600 patients. It should also be noted that, due to the large numbers of people with psychiatric problems in prisons, there are now several hundred psychiatric nurses employed in prison settings to carry out a range of assessment and treatment procedures. In addition, the NHS also has a number of 'in reach' schemes, which include sending NHS staff into prisons on a sessional basis.

Given that community care in the western World is now the norm, inpatient care is now seen as a short-term measure with the dual purposes of stabilizing the patient's condition and keeping the patient safe. Psychiatric nurses have a role to play in the overall assessment of the patient and, given that the nurse is—literally—with the patient 24 h a day, the observation of the patient's mental state and behaviour is of considerable importance. Unfortunately, this is an area where, outside the United States, a number of problems exist and suicide rates by inpatients are unacceptably high.[3] In the United States, inpatient wards tend to be much more secure than wards in countries such as the United Kingdom and Australia and, therefore, the incidence of inpatient suicide is much lower. The *UK National Confidential Inquiry into suicides and homicides*[3] demonstrates that nearly 200 suicides by inpatients occur every year, with hanging on the ward itself being still prevalent at unacceptably high levels. Recently the National Institute for Health and Clinical Excellence (NICE)[4] has published guidelines, which include the observation of patients at risk. This guidance sets out very careful protocols for the observation of patients at risk and includes recommendations regarding the prevention of absconding. In the United Kingdom and Australia, open-door policies still operate in acute psychiatric units and it is being increasingly recognized that balancing the rights of the patients against safety is a difficult issue. Nurses also have a major role to play in providing patients and their families with information about condition and treatment. We also know that there are interventions that can be applied by nurses, which would lead to improved outcomes. For example, Drury *et al.*[5] showed that a cognitive behavioural therapy package improved longer-term outcomes. Similarly, Kemp *et al.*[6] showed that motivational interviewing and psychoeducation methods produced clear, clinical, and economic benefits in patients who have compliance problems with medication.

With regard to the containment of violent behaviour, which is now so common in inpatient settings, nurses in the United Kingdom have been assisted by very comprehensive evidence-based guidance from the National Institute for Health and Clinical Excellence (NICE),[4] which sets out clear guidance on the use of de-escalation techniques and control and restraint, as well as providing a comprehensive algorithm for the use of rapid tranquillization. In respect of rapid tranquillization, nurses are now provided with the necessary skills to observe and monitor patients following rapid tranquillization, including the use of pulse oximetry and blood pressure. Whilst nurses in Australasia use the same methods of managing violent behaviour as nurses in the United Kingdom, psychiatric nurses in most European countries and in the United States use various forms of mechanical restraint and a very wide range of devices, including belts, straps, nets, and jackets. Whilst it needs to be recognized that there are a range of social and cultural influences that determine how violence in mentally ill people is managed, it is important to note that the evidence base for all forms of violence management, including rapid tranquillization, is very poor and a Cochrane review found that there is no evidence base for the use of seclusion and restraint.[7]

Psychosocial interventions in the community

In order to appreciate the current practice of psychiatric nurses working in the community, it is important to say something about the historical context. Until the early 1980s, community psychiatric nurses (CPNs) in the United Kingdom were generally based in large, Victorian psychiatric hospitals and worked mostly within a consultant psychiatrist team responsible for the follow-up of patients after discharge from hospital. Their main responsibilities were the administration of medication and the provision of general, supportive care, mostly to people with schizophrenia, the elderly with functional and organic illnesses, and to people with other serious and enduring mental illnesses. Initial research on the effectiveness of community psychiatric nurses produced very positive results. In a randomized trial conducted by Paykel *et al.*[8] CPNs were compared with psychiatric registrars in the provision of aftercare for patients who had suffered an acute episode requiring hospitalization. In general terms, this study showed that there was an equivalent outcome on clinical, social, and economic measures. Some 20 years ago, CPNs in the United Kingdom began to diversify their practice and separated themselves from consultant psychiatrists, attaching themselves to primary care settings and taking referrals directly from GPs. By 1990, a national survey showed that 40 per cent of CPNs worked in primary care.[9] The vast majority of this work involved treating people with depression, anxiety, and adjustment disorder, using counselling-based approaches. Whilst this work by CPNs became very popular with GPs and mental health professionals in general, research into the effectiveness of their work demonstrated that they were largely ineffective. Gournay and Brooking[10] carried out a randomized controlled trial involving 11 CPNs, working in six primary care settings in North London. In this study, 177 patients were randomized to either routine continuing care from their GP or to CPN intervention. The majority of patients had adjustment disorders and various states of general depression and anxiety. Patients, in both the CPN and

continuing GP care groups, showed significant improvement on a range of measures, clinical status, and social functioning but, at post-treatment and follow-up, there was no difference in outcomes demonstrated. Patients allocated to CPNs showed high levels of dropout (50 per cent) and patient satisfaction rating did not correlate with outcome measures. An economic analysis[11] showed that, per unit of health gain, CPN intervention was very expensive compared with interventions for people with schizophrenia. The Paykel and Gournay and Brooking studies still represent the only research evidence regarding the efficacy of CPNs working with common mental disorders.

During the early 1990s a National Review of Psychiatric Nursing in the United Kingdom led to CPNs refocusing their efforts on the seriously mentally ill and this trend has been followed in Australasia. In the last decade there has been a wide range of psychiatric nursing developments in respect of psychosocial interventions. The initial impetus for this development came from the Thorn Programme, this initiative taking its name from the Sir Jules Thorn Trust, a charitable foundation that provided the funds to inaugurate the first 3 years of the training programme for nurses, commencing in 1992. The initiative was originally led by Dr Jim Birley who, with a group of colleagues from other professions, became impressed by the work of nurses working in cancer care. Birley's initial aim was to train a substantial number of nurses specifically dedicated to the care of people with schizophrenia and their relatives. Indeed, Birley, who was one of the pioneers of Social Psychiatry in the United Kingdom, noted that the families of people with schizophrenia were often in great need of intervention. Previous work in Manchester[12] had confirmed that nurses could be trained in family intervention skills which in turn led to positive outcomes for the patient and family. This training in family work formed the basis of what has now become a more general initiative to train nurses in various evidence-based psychosocial interventions for schizophrenia. The Thorn Initiative has now become the national model of training in psychosocial interventions in the United Kingdom and similar programmes to Thorn have been set-up in Australasia and some European countries. The psychosocial interventions used by nurses are as follows:

- Assertive community treatment
- Family interventions for schizophrenia
- Cognitive behavioural techniques for managing hallucinations and delusions
- Approaches with dual diagnosis
- Medication management.

In addition to psychosocial interventions, training programmes for psychiatric nurses working in the community, now also include approaches to improve the physical health of people with serious mental health problems and nurses are now taking a more active lead in ensuring that this very vulnerable population obtains appropriate medical services including physical screening and health promotion activities. At the time of writing, there are also, in several parts of the United Kingdom, specific training programmes for nurses aimed at helping patients with chronic mental illness to deal with obesity, lack of exercise, and smoking.

On a cautionary note, there are now several studies[13] which demonstrate that more intensive case management may not be effective, the possible reason being that one needs to provide nurses with suitable levels of training in community approaches. In the UK700 study[13] mentioned above the nurses involved only received a few hours training in case management approaches, whist nurses undertaking basic psychosocial interventions training such as a Thorn diploma will receive 250 h of classroom instruction in addition to supervised practice. Whilst there have been considerable numbers of nurses trained in the above-mentioned evidence-based psychosocial interventions, unfortunately there are still many nurses working in the community without such training. Whilst their general psychiatric nursing skills will be reasonably sound, their impact on patient care will be somewhat limited.

In the early part of the twenty-first century, psychiatric nurses working in the United Kingdom, Europe, and Australasia are increasingly working in specialist community teams, for example, assertive outreach services, early intervention teams and crisis intervention, and home treatment teams. Whilst these approaches are commonly used across the United States, such teams are likely to be staffed by case managers who have backgrounds in social work and social care and psychiatric nurses are unlikely to be employed in large numbers. In the United States, psychiatric nurses are often specifically employed to run medication clinics, probably for reasons of cost, whilst in the United Kingdom, approximately 50 per cent of community mental health teams carrying out a very wide range of psychosocial functions are likely to be CPNs.

Prescribing and medication management

The work of Kemp *et al.*[6] who showed that motivational interviewing and psychoeducation methods produced good outcomes for patients who were non-compliant with their medication, led to the development of medication management training for nurses in the United Kingdom. Gray *et al.*[14] using a cluster randomized controlled trial, where 60 CPNs were randomly assigned to medication management training or carrying on with their usual treatment as usual, demonstrated that the nurses who had received medication management training produced very clear benefits in patients with schizophrenia. The study demonstrated a significantly greater reduction in patients' overall psychopathology for the trained group, compared with treatment as usual. At the end of the 6-month study period, the improvement in positive and negative symptoms for the trained nurses over the control was statistically and clinically significant. This training is now used by, literally, thousands of nurses in the United Kingdom, Australasia, and some non-English speaking countries in Europe. Whilst this training, which comprised a number of components, including improving the pharmacological knowledge of the nurses, the use of side effect monitoring and motivational interviewing for non-compliant patients, a European multi-centre trial, which tested adherence therapy as a treatment package over and above routine clinical care and delivered mostly by psychologists and psychiatrists, showed that the treatment package was no more effective than health education in improving quality of care.[15] Both studies raised a number of questions concerning the very complex issue of treatment compliance with medication and the specific difficulties associated with measurement of compliance itself and of patient insight.

Arguably, the most important recent development in psychiatric nursing has been the advent of nurse prescribing. This began more than a decade ago in the United States, where nurses have

prescriptive authority in virtually all states. The situation in the United States is, however, complex with a considerable variation in the level of prescriptive authority across the United States from complete independence to being able to prescribe under a physician protocol. In turn, the educational requirement for nurse prescribers also varies considerably. However, most states have fairly comprehensive regulations concerning not only course content, but also hours of instruction and supervision. The Website of the American Psychiatric Nurses,[16] provided at the end of this chapter, provides very detailed state-by-state information. In 2006, United Kingdom legislation was passed that means nurses may prescribe almost independently,[17] although—as in the United States—there is a variation across the country in terms of training and practice. Across nursing more generally, the law in the United Kingdom means that provided it is within their area of specialist work, nurses may independently prescribe any drug (including controlled substances such as opiates). By contrast to the different legislative frameworks that exist in the United States, the legislative framework for the United Kingdom is unitary. However, interpretation of that framework in the United Kingdom seems to vary between NHS services. There are now similar nurse prescribing initiatives in Australasia, where because of the nature of rural and remote populations, the development of nurse prescribing seems very logical.

At present, there are no randomized controlled trial data to compare nurse prescribing with more conventional doctor prescribing, neither is there any substantial data on patient efficacy. The advantages of nurse prescribing have been clearly set out in a *Maudsley discussion paper* by Gournay and Gray[18] and these include the delegation of routine prescribing tasks to nurses, so that psychiatrists may concentrate their prescribing efforts on difficult-to-manage patients who may be treatment-resistant and/or non-compliant and those patients who have substantial physical health co-morbidity. Another advantage might be that CPNs, who are case managers, may be able to spend more time than their psychiatrist colleagues in the detailed evaluation of effectiveness and side effect monitoring and management.

Cognitive behaviour therapy

For more than 35 years, nurses in the United Kingdom have been trained to provide psychological treatment to patients with various mental health problems. These developments began in 1972, when Isaac Marks, a psychiatrist working at the Maudsley hospital, began a 3-year experiment to determine whether nurses could be trained to deliver behavioural interventions for neurotic disorder. Isaac Marks was one of the first to recognize that the workforce of psychologists would be insufficient to deliver evidence-based treatment. Subsequently, Marks[19] published data which demonstrated both the clinical and economic effectiveness of nurses working with neurotic disorders in primary care. Over the years, training programmes for nurses have developed and now nurses are trained in a variety of university and clinical settings alongside their psychology colleagues in the practice of evidence-based psychological treatments, i.e. cognitive behaviour therapy for a very wide range of disorders. Whilst the original efforts to train nurses were centred on techniques for the treatment of phobias and obsessive–compulsive disorder, nurses are now trained more comprehensively in cognitive behavioural methods, which encompass treatment techniques used in the treatment of depression, schizophrenia, and personality disorders. In recent years there has been a small, but significant, growth in the United Kingdom of psychiatric nurses employed as psychological therapists. However, this trend has not been replicated in Australasia or Europe, where legislative frameworks prevent nurses from obtaining full accreditation as psychological therapists. In the United States, the situation is variable. Nevertheless, the American Psychiatric Nurses' Association membership comprises a significant number of nurses who have full accreditation as therapists in their respective states. Such nurses are now often prepared at a post-doctoral level and their expertise is arguably equivalent to that of their clinical psychologist colleagues.

Primary care

Following the refocus of CPNs efforts on people with schizophrenia and other serious and enduring illnesses, there have recently been a number of United Kingdom policy developments that will lead to more psychiatric nurses being employed in primary care settings. This trend follows the recognition that many people with common mental health problems do not receive evidence-based treatment or, if they do, they are subject to long periods on waiting lists. Psychiatric nurses are now being trained to provide brief evidence-based interventions in primary care and also to provide important assessment and screening functions, so as to ensure that patients who need the services of the community mental health teams are suitably referred and those who can be managed at primary care level are provided with appropriate treatments. Nurses are now also increasingly involved in the delivery of computerized cognitive behaviour therapy, which, as a recent NICE review demonstrated,[20] is effective in the treatment of a wide range of mental health problems. This method of treatment is particularly important given the scarcity of skilled therapist resources. Psychiatric nurses are therefore increasingly involved in the running of 'Computer clinics', which now use a very wide variety of treatment packages for a whole range of disorders. Whist most of these packages come at a cost, there are now free to access programmes on the Internet. These include 'Moodgym',[21] a programme for the self-help treatment of depression, which is based on a cognitive behavioural approach and developed in Australia at the Australian National University in Canberra. Moodgym has been evaluated and its use is supported by positive randomized trial data.[22]

Psychiatric nursing in the developing world

As noted above, there have been a number of training initiatives in the former communist countries of Eastern Europe and the former Soviet Union.[1] Nevertheless, the numbers of trained psychiatric nurses across this region still remains fairly small. It is also clear that the skills of psychiatric nurses, in these countries, are compromised by the relatively poor general standards of mental health care.

With the exception of South Africa, psychiatric nursing is very poorly developed in the African continent. However, the World Health Organization has a number of projects that aim to integrate mental health into primary care provision. For example, the Ministry of Health in Kenya, the Kenyan Psychiatric Association, and the Kenyan Nursing Council are working with the UK Department for International Development on a 5-year programme

that began in 2005, which has the ambitious aim of training 3000 primary care workers with some skills in very basic mental health care.

In Asia, psychiatric nursing is becoming increasingly recognized and there are now substantial training initiatives in the Indian subcontinent and China. Nevertheless, the numbers of psychiatric nurses who are needed in those vast countries are very great and, at present, the best way of describing the psychiatric nursing presence would be to say that it is sparse and patchy, with most nurses working in the large cities. An additional problem is that, where reasonable standards of education and training exist (and this applies particularly to India and China) there is a considerable loss to immigration to the developed world—to countries such as the United Kingdom and the United States, where the recruitment and retention of psychiatric nurses is an ongoing problem, and is financially very attractive.

There is obviously enormous potential for the development of psychiatric nursing across the developing world and, although current initiatives have focused on providing nurses with basic skills, there is obviously enormous potential for the provision of evidence-based psychosocial interventions and, given the tremendous shortage of psychiatrists in many countries, nurse prescribing (providing that the nurses have received adequate education and training) could obviously potentially provide widespread benefits for a substantial proportion of the literally millions of people whose illnesses are currently untreated.

Conclusion

Psychiatric nursing is a relatively new profession, which has evolved over the past 50 years, from a branch of general nursing, where the main role focused on the custodial care of people with chronic serious and enduring mental illnesses—such as schizophrenia—to the present day situation, where nurses are, in the developing world at least, more likely to be university graduates who may be employed in a number of very diverse roles. The setting for these roles could be in inpatient settings, where custodial care is challenging, to say the least, to the community with roles involving psychosocial interventions within primary health care teams, to inpatient and community settings where nurses are increasingly autonomous prescribers of medication or psychological therapists. It is pleasing to note that the education and training of psychiatric nurses is gradually becoming more evidence based and policy makers are apparently much more aware of the need to provide focused skill sets on populations of need.

6.4.3 Social work approaches to mental health work: international trends

Shulamit Ramon

The historical development of mental health social work

Social work was formally established in most European countries and North America at the end of the nineteenth century, before it took off gradually in other countries. It usually developed out of charitable work, which focused on financial support for poor families. The second main strand in social work was represented by the Settlement Movement, which concentrated on improving the communal life of poor people by living with them, using community work methods to support and empower.

The major impetus to developing mental health social work at the beginning of the twentieth century was related to the work of leading psychiatrists and psychologists with shell-shocked (PTSD) soldiers during the First World War.[1] This approach lead to the establishment of the psychodynamically oriented Tavistock Clinic in London, where the first British psychiatric social worker was appointed in 1920.[2] Stuart[3] argues that American mental health social work in the pre-1920 period concentrated more on care in the community in its social, rather than its administrative or psychological meaning, than after 1920, when it shifted further to the psychological dimension.

Social workers in both the children and the adults outpatient services provided comprehensive psychosocial history of the child/adult and their family, enabled parents, teachers, and partners of adult clients to understand the underlying psychological reasons for the index client's mental ill health, and guided them as to how they could actively support that family members.[2] It was only in the 1950s that qualified psychiatric social workers began to work in hospitals.

Since the 1970s all English-speaking countries have also opted for deinstitutionalization as their core mental health policy, leading to the closure of many of their psychiatric hospitals, replacing them by community-based services and by small psychiatric wards in general hospitals.[4,5] With the notable exception of Italy,[6,7] most continental European countries have opted for bed reduction coupled with less extensive community services.

The trend towards deinstitutionalization is formally adhered to also in Latin America, but thus far is only practised in some small-scale projects.[8,9] This applies also to Asia. MHSWs (mental health social workers) there focus mainly on sorting out benefits, though some are based in rehabilitation focused facilities where they work on connecting users to educational and employment opportunities.[10]

This fundamental change has led to the relocation of MHSWs away from institutions into community services,[5] to a renewed interest in rehabilitation, and more recently also in the newly defined recovery.[11]

The paralleled development of private, for-profit mental health services especially—but not exclusively—in the United States, has led to a further shift in the location of MHSWs and their work focus. Most United States MHSWs are to be found today working as psychotherapists in private practice or in managed care residential units.[12] In the latter they work with users who have long-term mental illness to a per capita budget.

Although the not-for-profit sector has grown considerably with the focus on care in the community, MHSWs work there only in certain countries in which the public sector has either been reduced or never played the major part it does in the United Kingdom (e.g. the Netherlands, Hong Kong).

Underpinning values

Social work, including its mental health branch, is ethically governed by a set of values, which are expected to be universal and adhered to in everyday practice,[13] even though its implementation may prove at times to be problematic in terms of balancing care and control.

The values are derived from the liberal collectivist, humanistic, tradition of the twentieth century in which social work has developed.

The core values are social justice, respect for people who social workers meet at their most vulnerable state, readiness to help in a way which will enable the client to retain dignity, self-determination, and enhance their problem-solving abilities. Social workers are expected to take an active stance against any type of discrimination. Furthermore, social workers are committed to pursing a psychosocial approach in any type of their practice, and believe that most clients have the potential to grow and positively change.

Several elements stand out as central to MHSW:

1 The right to fail—this comes as part of the right to self-determination, in that social workers are aware that risk needs to be taken at times to enable people to grow and develop, or as a basic human right of making a mistake. When social workers take this right seriously, they are able to have a genuine discussion with clients as to the pros and cons of risk-taking, of learning from success as much as of learning from failure.[14,15]

2 The wish to take an active stance against discrimination applies to working well with clients who come from ethnic minorities, from sexual orientation minorities, and to combating stigma against mental illness in one's practice.

3 The adherence to a psychosocial approach entails ensuring that both the psychological and the social aspects of users' lives are attended to, an issue of importance in mental health where often biological aspects are attended to, but the psychosocial ones are not getting the same priority.[16]

Conceptual developments

Psychodynamic approaches

As outlined above, mental health social work originated within the psychodynamic fold, though social workers did not practice psychoanalysis as a work method.

Social workers have tended to select from the range of psychodynamic perspectives those theories, which were more focused on the ego, rather than on the id or the unconscious. The impact of ego psychology was/is in evidence in terms of understanding how people come to develop and maintain mental distress and mental

illness, the importance of family dynamics, and of attachment to significant others.[17, 18, 19, 20]

American social workers developed the crisis approach in its application to all areas of social work.[21] Based on Erickson's notion of the normal crisis every person goes through when moving from one stage of life to another, major life events may lead initially to adverse reactions. However, with professional support people can reorganize their reactions more constructively, reduce the duration of these reactions, be more ready for change at the point of crisis, and learn how to improve their coping strategies and emotional responses. The problem-solving approach also originated from the United States, developed by Perlman.[22] Although the psychodynamic understanding of relationships is in evidence in her work, she focused on the process of social work with individuals and families (casework) and the client–worker relationships, beginning with the presenting problem.

The identification of child abuse, especially child sexual abuse, and its implications for the mental health of children and adults in the 1970s and the 1980s led to refocusing on the psychodynamic approach among social workers in this area[23] at a time in which all other approaches have paid less attention to the impact of such abuse on mental health.

Learning theory applications in social work

Behavioural social work

Behavioural social work developed in the United States in the 1950s, and is a leading approach in relation to people with milder forms of mental illness and problems of living.[24] Its application within social work does not differ in any significant way from its application within psychiatry or psychology. In this sense it is not a social work approach. A number of influential texts appeared in the United Kingdom which demonstrated the research evidence pertaining to the effectiveness of the approach in a number of social work areas.[25]

Task-centred social work

This orientation takes further the crisis perspective and the lessons from learning theories and behaviour modification.

Reid and Epstein[26, 27], as well as Marsh and Doel,[28] proposed that people work better on their problems if focused on specific targets and if the problem-solving effort leads to success, however small. Research evidence demonstrated the usefulness of this approach to different aspects of social work, such as direct work with children and their parents, as well as with people suffering from mild mental distress symptoms.

The social dimension in mental health social work

Social workers and theorists interested in the social dimension began usually from the assumption that inequality in opportunities and in civic participation due to poverty may increase the rate of mental illness among poor people. This assumption follows Merton's classical matrix of the reactions to the gap between social goals and means, in which mental illness is a reaction of people who accept socially desirable goals, but withdraw from obtaining them after being frustrated in doing so, whilst at the same time not adopting antisocial means (as in criminal behaviour) or developing an alternative model of society (social rebels).

This strand of thinking was reinforced in the 1960s and 1970s by the application of Marxist thinking and the combined impact of the deviancy and anti-psychiatry orientations.[29] Discrimination on the basis of age, ethnicity, gender, or sexual orientation was added in the 1980s to the likely social factors which foster inequality.

Social workers accepted the logic presented by sociologists such as Goffman and Scheff[30, 31, 32] that the stigma attached to mental illness is largely irreversible, as it is accepted both by others and by the individual concerned who in turn internalizes his or her poor social status.

Interestingly, although accepting the enormity of the labelling process, social workers did not count themselves among the labellers.

The appeal of the anti-psychiatry approach for social workers related to acknowledging the price of labelling for the individual concerned, and the considerable shortcomings of a system focused on the psychiatric hospital and medication in which psychological and social factors were largely ignored.

Today the social perspective implies a greater focus on social inclusion, supporting users and carers-led initiatives, ensuring financial support side-by-side with the critique of the medicalized approach to mental health and illness, of modernity and post-modernity.[16]

A more recent strand of this approach is outlined in the critical social work, which applies a post-modern perspective to the analysis of where social work is, as well as the issues and dilemmas related to mental health social work. Bainbridge[33] highlights the need to focus on the social dimension and sociological understanding of mental ill health in social work, as well as on issues of power and empowerment.

(a) The social role valourization (SRV) and the strength approach

This approach was initially developed by psychologists in the field of learning difficulties.[34–37]

SRV accepts the deviancy approach up to the point at which the impact of labelling and segregation is said to be irreversible. Conversely, SRV is focused on reversing the devaluation of the disabled person and the group, while accepting that a disability exists. The devalued existence can be reversed by the combined impact of the following:

- enabling those who have been segregated to live in the community by providing them with the opportunities to do so and the support they require for this purpose
- enhancing the competencies of the disabled person
- changing their public image, in part by their positive presence in ordinary settings in the community
- upgrading the state of the physical settings in which a disabled group is treated, lives, and works
- changing the derogatory language used in both professional and lay circles in describing people with disabilities.

Its protagonists are critical of professional attitudes, knowledge, and skills, including those of social workers (see Wolfensberger).[35] Yet as a group social workers have within their repertoire more of the attitudes, knowledge, and skills required by this approach than any other mental health profession. Furthermore, SRV offers an

interesting and comprehensive combination of psychological and social dimensions; for an application to how it can work with the Nearest Relative in mental health.[38]

In the United States and Canada, but much less so in the United Kingdom, SRV came into prominence within social work through the **strengths** model of social work.[39] The model is unique in concentrating on the strengths the person and his or her environment possess, and how these could be harnessed to solve the specific problem and lead to an improvement in the person's quality of life. Coming together with a focus on following people's ambitions (as long as these are within socially acceptable norms), this orientation has led to useful and positive outcomes in care management.[40] A further development of the strengths model is the growing interest in focusing on enhancing resilience in mental health social work.[41]

Interestingly, the approach has been adopted by other mental health professionals in the field of employment without acknowledging the debt to social work.

Legally anchored MHSW

The social mandate of social work is anchored within legal and policy frameworks; this applies to MHSW too.

Securing benefits

In all countries social workers are gatekeepers to and advocates for securing benefits either in cash (e.g. disability allowance, Direct Payment agreement) or in kind (e.g. housing, clothing). They often have to make the claim in addition to the client, verify the claim as against eligibility criteria, secure supporting documents from other professionals, at times negotiate with other agencies (e.g. social security, health, education), and in a number of countries they are indeed located in social security services (e.g. Portugal, Israel).

While this work is considered to be routine, its importance in the life of poor people cannot be underestimated. The evidence highlights that most people with enduring mental illness are poor,[42] and that remaining poor is a strong counter-indication to becoming mentally healthy. Furthermore, the evidence related to Direct Payment in mental health,[43] which enables users to take the driving seat as to how they spend their budget in agreement with the local authority and mental health trust, illustrates the social inclusion and recovery value of such a scheme which clearly comes out of the strengths model.

Knowledge of the available resources and eligibility is needed for this type of work, as well as the ability to inform users and enable them to participate as deserving partners.

In a large number of countries this is the main social work task in mental health (e.g. Brazil, Greece, Italy, Ireland, Portugal, and Poland).

The approved social worker

This role illustrates an enhanced legal position for MHSWs; its fullest form is practised in the United Kingdom.

The approved social worker was developed in Britain to provide a complementary measure to the psychiatric perspective within the 1982 amendments to the 1959 Mental Health Act.

Social workers were seen as suitable professional figures who would represent the psychosocial angle in parallel to the psychiatric view in the following instances:

- assessing people when an application has been made for a compulsory admission to a psychiatric unit
- the follow-up to such an admission
- mental health review tribunals (established within the 1959 Mental Health Act)
- work with the Nearest Relative[38]
- coordinate the multi-disciplinary assessment, which needs to be carried out by a psychiatrist and a GP in addition to the social worker. This assessment has to be carried out within a specified limited period of time.

Each of these tasks calls for somewhat different knowledge and skills, as well as emphasis and use of a range of more generic skills.[44] In each task social workers are asked not to replicate the psychiatric assessment but to compliment it. For example, they have to look for the least restrictive alternative to the hospitalization before they can recommend a hospital admission, rather than diagnose mental illness. Social workers have an autonomous position as they can disagree with the views of the other professions. The role requires exercising more social control than care, a contested issue within social work.

Training to become an approved social worker requires 60 days of academic input and supervised practice initially, followed by 5 days refresher training annually. Individual social workers can take it up after 2 years of post-qualification work experience. This compares with 2 days training for general practitioners and 1 day for psychiatrists.

Most of the activities undertaken by MHSWs with adults since 1983 are related to meeting the requirements of this role. Existing evidence[45] highlights that in most cases ASWs are working to a good standard. The role also offered MHSW a higher status and pay, but came with the price tag of giving up most of their previous activities, such as family work, group and community work, and work with users who have minor mental illness. However, the proposed new English Mental Health Act[46] includes the introduction of AMHPs (Approved Mental Health Practitioners) who can come from any mental health discipline, but likely to be nursing because of the numerical dominance of nurses in the English mental health service. ASWs are unhappy at being dethroned of their unique legal role, arguing that nurses do not have the same background training for psychosocial understanding and intervention.

Workforce research into ASWs[47] has highlighted a recent steady decrease in the number of ASWs, a high number of workers approaching retirement age and low morale, factors likely to have played a part in the government's wish to introduce other professions to this role. There are currently 4500 ASWs, a minority in the total workforce of social workers in England which stands at 46 000.

While current ASWs and MHSWs will be able to be part of the AMHP workforce, this change may also enable them to reclaim some of their previous roles and activities.

Care management

In all English-speaking countries and a number of European countries (e.g. the Netherlands, Slovenia), MHSWs are also often engaged in one form or another of care management, which follow the specific laws and regulations of each country (e.g. the Care in the Community 1990 Act in England).

Care management (not be confused with managed care) is a form of coordinating the assessment, planning, and interventions with people who require long-term care, including in mental health. It is aimed at preventing fragmentation and duplication of professional input and services, as well as ensuring that services follow the user's needs, and not vice versa as was—and still is—the case all too often. While in the United Kingdom, psychiatrists are formally the nominated care manager since 1995, and CPNs are the professionals in more frequent contact with the users, in other countries such as Australia, New Zealand, and Canada, social workers are often the nominated care coordinator.

Care management can be practised in a variety of ways, ranging from a purely administrative orientation, through clinical care management, to one anchored within the strengths and recovery orientations.[40, 48, 49] The choice is often dictated by the managers of a local authority or a mental health trust.

Community treatment orders (CTOs)

CTOs constitute a third legally defined area in which MHSWs are engaged. They originated in the United States, and exist in a variety of formats in Canada, Australia, and the United Kingdom.[50–52] They represent a response to the escalation of concerns about risk avoidance in the field of mental health, closely related to the growing fears of risk raised by modernity and post-modernity,[54, 55] and reinforced more recently by fears of terrorism as a particularly threatening type of risk. It is indicative that this preoccupation is not shared between North and South Europe; it is much more prominent in the North.

Following a legal process, CTOs enable the nominated mental health professional to require a service user to adhere to specific restrictions, such as to live in a certain facility or to present themselves for interventions at specific locations. This measure has been introduced to ensure that users with long-term mental illness who lead a disorganized life (e.g. often do not comply with medication, live rough, misuse substances, mishandle money, misagreed appointments, and get into trouble with the law) will have a safety net, which structures their lives. There is some evidence of the effectiveness of CTOs,[48, 49] but it seems restricted to specific subgroups within the broader category of people with severe and enduring mental illness.

Social workers are often the nominated professionals responsible for the agreed plan and enforcement of the CTO. This puts them in a somewhat conflictual position regarding the desired focus on care in social work, as it is tilted more towards the control element.[56]

Non-legally anchored MHSW

The constraints on this type of work come not only from the primacy of legally sanctioned work, but also from working within welfare bureaucracies, for a private employer interested primarily in profit, or for an impoverished not-for-profit service.

Despite these constraints, we have examples of good and innovative MHSW practice in most countries, which include:

- Successful attachment to primary care was established as early as 1965 in London, with the social workers, their clients, and the general practitioners expressing satisfaction with this way of working. Nevertheless, this form was largely abandoned owing to the focus on statutory responsibilities.
- Social workers pioneered collective user involvement approach during the early 1980s[57] some years before it became fashionable in wider circles.
- Applying self-directed group and community work approach to working with mothers of abused children, empowering them to take control over their lives.[58]
- Initiating de-institutionalization in social care institutions in Slovenia.[59]
- Creating family support teams[60] where most staff members are social workers providing brief assessment and consultation to families of children with minor mental distress, and are often successful in preventing the need for referral to more expensive services.
- Establishing the Building Bridges project in which parents with mental health difficulties and their children are supported together as well as separately.[61]
- Creating The Faith Links project, a multi-faith project within an inpatient service in which users, volunteers, and social workers plan joint activities which follow users' spiritual wishes.[62]
- Supported education and employment schemes in mental health initiated by social workers.[63]

Conclusion

Mental health social work is a broad, rather than a rigorous, church. Since the 1980s social workers have gained in professional status by the introduction of the roles of the approved social worker (or licensed to carry out civil commitment in the American context), care co-ordinators, managers of managed care facilities, or psychotherapists. These gains have come at a price outlined in the text above.

Often the cost of closer collaboration within the multi-disciplinary framework has led to the risk of giving up the attempt to hold on to, and further develop, an alternative and complimentary perspective from that of psychiatrists, nurses, or psychologists, as well as raising doubts as to the uniqueness of MHSW.

The increased narrowness of the role is not simply the byproduct of the legal framework. It is also due to increased specialization within mental health on the one hand, and the effects of neo-liberal policies globally on public sector funding on the other hand.

The move to privately contracted work, either in managed care or in psychotherapy so apparent in the United States, is yet another outcome of neo-liberal policies which fragments MHSW. As a trend we are likely to see growing beyond the United States, the increased concentration of mental health social workers within the private sector does not bode well for a profession whose value base focuses on the need to protect the more vulnerable and stigmatized populations, and to provide the dual perspectives of psychosocial input.

Mainly due to governmental pressure related to fear of risk and its potential political fallout, the focus on working exclusively with people experiencing long-term severe mental illness has contributed to the increasing narrowness of the role of social workers in most First World countries. The paralleled withdrawal of social work involvement with people who have milder forms of mental distress within public sector and not-for-profit services, and its

increased availability only to those who can afford it, is a reflection of this situation.

The core qualities of belief, optimism, and caring of MHSWs identified in a cross-national research[64] coupled with the ability of MHSW to innovate as highlighted in this chapter, illustrate the optimistic scenario for positive change within this branch of social work. However, unless theory building and research aspects are given the importance they deserve within MHSW globally, including an inevitable critical dimension of the existing system, mental health social work is likely to be no more than a reflection of the developments in other professions. This will not only mean curtailing its autonomous potential, but also the impoverishment of the multi-disciplinary framework as a whole of a crucial dimension necessary for its comprehensive work, as exemplified in some recent work on the social aspects of MHSW.[16]

In addition, mental health social work will have to develop a much stronger policy making function, if it is to provide a more responsive, effective, and comprehensive service to users, relatives, and the communities in which these people live.

6.4.4 Art therapy

Diane Waller

The fundamental principles of art therapy/art psychotherapy

Definitions

Descriptions of art therapy from two of the oldest and largest professional associations, the British Association of Art Therapists and the American Art Therapy Association refer to: the use of art materials for self-expression and reflection in the presence of a trained art therapist. Art therapy uses the flexible, creative problem-solving potential of art-making to improve and enhance the physical, mental, and emotional well-being of individuals of all ages. The relationship between the therapist, client, and their artwork is of central importance. Art therapy can be used on a one-to-one and group basis.

Art therapy (or art psychotherapy, both titles are protected by law) in the United Kingdom is firmly rooted in psychodynamic and humanistic concepts and practices appropriate to public sector settings, and adapted to the social and mental health of the client. It is a broad-based discipline, involving substantial knowledge of the visual arts, individual and group psychotherapy, social and communication sciences, and the impact of culture on health.[1]

Main premises

- That visual image-making is an important aspect of the human learning process;
- That art made in the presence of an art therapist may enable a person to get in touch with feelings that cannot easily be expressed in words;
- That the creative process helps people to resolve conflicts and problems;
- That art can act as a 'container' for powerful emotions and be a means of communication between client(s) and therapist;
- That the image can serve to illuminate the transference in the case of a psychodynamic approach.

Engagement in image-making is of central importance although clients do not need any prior experience of or skill in art, as the aim is not to produce a 'good' piece of art that can be exhibited. The images made in art therapy may embody thoughts and feelings, be a bridge between the 'inner world' and outer reality, be a mediator between unconscious and conscious, hold and symbolize past, present, and future aspects of a client's life. Ambivalence and conflict can be stated and contained within an image. In art therapy the client tries to give form to what seem to be inexpressible or unspeakable feelings, which they can then share with the art therapist.

The focus of the transference (bringing feelings from the past into the present), can be onto the art object rather than to the therapist directly, adding a 'third dimension' to the therapeutic process.[2–4]

An important aim, as with all psychotherapy, is to bring about change. Positive change may occur when a client can direct their strong feelings into making art and when the therapist helps the client to tell their story through the art. How, when, and if change occurs obviously depends on their capacity to engage with this process and needs much time and patience while the client builds confidence. For verbally inarticulate clients, or those who use words defensively, engagement with the art materials gives the opportunity to understand self and environment, communicate emotions to the therapist, receive feedback, and encouragement.

The historical development of art therapy in the United Kingdom, United States, and Europe

There are parallels in the development of art therapy in the United Kingdom and United States, early history being shared with that of group analytic psychotherapy as a phenomenon of the Second World War rehabilitation movement.[5–7] In the 1940s and 1950s art therapists were simply artists working in hospitals who emphasized the healing role of art. In 1963, the British Association of Art Therapists was formed from this small group of artists and art educators, who set themselves the task of defining and extending the activity, preparing standards for training in the higher education sector, informing the public and other professionals of the potential of art therapy, and working towards a career and salary structure in the National Health Service (NHS). The first *postgraduate trainings* began in the late 1960s. The positive response of the NHS and other organizations to art therapy's beneficial impact led to a petition being made for statutory regulation under the old Council for Professions Supplementary to Medicine in 1991, approved in 1997, after which art therapists, along with music and dramatherapists had their own federal Board at the Council. They were transferred to the Health Professions Council in 2001. Training in the United Kingdom is now at Master's level, in four universities in England, one in Scotland, one in Northern Ireland, and usually follows a degree in art and design. Study of psychotherapeutic principles, visual art, and practical placement are important elements in the training. Elsewhere in Europe the picture is very different with some countries sharing the UK standards, others having no training or a great variety of trainings in both the public and private sector. The United States, Australia, and New Zealand have the same requirements of a Master's level qualification in order to practice. (See website references for more information.)

The development of art therapy with specific client groups

One of art therapy's main advantages as a treatment is its flexibility. It can be used with many different client groups and some of these are discussed as follows:

Children

Many founder art therapists in the United Kingdom and United States were art teachers and were influenced by the 'child-centred' approach to art education that developed in the 1930s. American pioneer Kramer considered that it was art activity itself that had inherent healing properties; and that within a secure relationship with the therapist, a child could sublimate their destructive and aggressive feelings by producing an object, which would symbolize those feelings, prevent them being acted out and lead to more insight and control. This often led to change in behaviour.[8]

Others pioneers from the United States gave examples of how group work could enable angry and shameful feelings to be shared among the group members as well as the therapist, to the relief of the child as well as his peers.[9] Many art therapists specializing in work with children attest to the importance of play and to the role of art materials in allowing regression in the form of mess-making. This seems to be particularly beneficial for children who have suffered sexual abuse[10–12] due to the loosening of control that happens when a child becomes deeply immersed in the physical process of painting and is able to lower defences as a result. Materials may be smeared, spilled, and wasted and it is important that the therapist maintains control of the boundaries and is able to tolerate a high level of anxiety as the child attacks the therapeutic space.[13]

Art therapy is helpful for children suffering from chronic constipation, faecal overflow soiling, and also 'antisocial behaviour' and Aldridge[14] pointed out the relationship she observed between food, painting, and faeces while working with neglected and abused children in the context of a social services Unit and how mess-making was important in their creative development. Ambridge[15] discussed how images may be used to reflect mother–child relationships with children who have been sexually abused and are often so traumatized that they cannot speak about their experiences.

The physical involvement in the art materials in enabling regression and essentially in receiving containment and acceptance from the therapist is very important to all the children mentioned above.

Dubowski[16,17] used a Developmental Art Therapy approach in research with children with learning difficulties, aiming to help the child to achieve his or her maximum potential. Understanding creativity and mark-making in early childhood is as important in this model as understanding psychodynamics. Studies made by Kellog[18] of over 100 000 children's scribbles inform our understanding of the developmental process leading to production of meaningful marks. Visual problem-solving through picture-making is developed between the age of about 18 months (when hand-eye co-ordination has developed to the extent that they can grasp an implement and direct it to a picture surface while attending to the activity) and 4 years, by which time most have developed the capacity to make recognizable pictures endowed with symbolic meaning.[19] This model draws on insights from art educationists, most recently Matthews.[20,21] Art therapists have also contributed to the emotional and educational development of children with Autism.[22,23]

Art therapists also occasionally work with families and this is an emerging area of interest.

People with learning difficulties

Stott and Males[24] were among the first British art therapists to write about their work in a large hospital with people who had

lived in institutions most of their lives. They suggested that art therapy offered a means of communication and of self-expression through which difficulties of life in an institution, such as loss of identity, could be eased. Their goals were: to find the art medium of most use to each resident, bearing in mind any physical handicaps; to set-up the art therapy sessions at regular times and in the same place; record and report the results of sessions; to enable maximum communication to take place. For some long-term residents, the art therapy studio became an 'oasis' in the desert of the hospital and they gained an identity as 'artist'.

Their work was continued by a generation of art therapists concerned about the effects of institutionalization on long-stay residents. Drawing on Gardner's work concerning the categories of personal and spatial intelligence[25] Rees set-up a qualitative research project using a detailed observational schedule with a group of women with severe learning difficulties in a single-sex locked ward, conducted over 3 years to investigate clients' use of physical space and its potential symbolic significance. Rees found that by relating to physical and spatial aspects of their environment, some clients discovered an effective way of maintaining some level of psychological and emotional integration. They were helped to manage their often overwhelming feelings and to develop a stronger identity in their, albeit, very restricted environment.[26] Strand used a group interactive art therapy model with a group of learning disabled clients whom she observed to be suffering from loss and despair as a result of their emotional needs being neglected.[27]

Now that people with learning difficulties mainly live in the community, art therapists are now able to assist clients in developing resources to manage their day-to-day activities, and to improve their quality of living—particularly social interaction—through engagement in creative activity, often in groups. Insights from earlier work on institutionalization and exclusion now inform art therapy with older residents in care homes.

Offenders

Liebmann used art therapy within probation services to address 'offending behaviour' directly[28] summarizing the benefits to offenders as follows: as a means of non-verbal communication, important for the high percentage of offenders who have poor verbal skills, conversely with those who use words defensively; to release angry and aggressive as well as shameful and embarrassed feelings and provide an acceptable way of looking at and dealing with difficult emotions; client and therapist together could look back at the images over a series of sessions, see patterns and note developments; active participation is required, helping to mobilize those who may not be voluntary clients and bring about favourable behavioural changes that outlast the session itself. Liebmann devised strategies to help offenders gain insight into their behaviour, for example, the comic strip where the client is asked to draw an important life event within frames, the sequences of which can then be discussed and alternative options suggested.[29] This approach combines some elements of cognitive behavioural therapy with a psychodynamic approach, providing a structure, which is empathetic but on the other hand does not collude with offending behaviour, nor accept it as inevitable.

Teasdale produced a set of Guidelines while working in the prison service. These focus on inmates and on the prison environment, reinforce many of the points above, such as using art therapy to support prisoners in coping with their imprisonment, address feelings of separation, isolation, loss, low self-esteem. Specific advice is offered for conducting art therapy within a prison context.[30]

People with psychotic illness

From the 1940s art therapists have worked with long-stay clients in psychiatric hospitals modifying the effects of institutionalization through detailed attention to communication when even the most psychotic patients could communicate through images and have this acknowledged. Now that people with psychosis increasingly live in the community and cope with the challenges of everyday life the focus is on issues of independence, isolation, building relationships, managing the illness, and its impact on self and family.[31]

Work with acutely psychotic clients, on the other hand, takes place on wards, is normally brief and aimed at helping the client to interact positively with others usually in 'open' studio groups with a rapidly changing population, or for those in a serious acute state, on a one-to-one basis. Drawing on process-oriented psychology McClelland[32] has devised a new model using art therapy to work directly on the acute state itself, requiring an active and assertive therapist style and meeting the client in their own 'language' however bizarre this may seem.

Older people

With older people's mental health and well-being coming under increased government scrutiny, this is an area where art therapy has much potential to be beneficial. Art therapists in this field have noted that attention to loss, fear of illness and dying, feelings of helplessness and dependency is necessary in alleviating depression. Recent art therapy research with older people with dementia showed some improvements in mental acuity, calmness, sociability, and physical competence following 40 weekly sessions of group work, compared to no change in the control.[33]

As with other client groups, engaging in creative activity can also provide an outlet for frustrations to do with ageing, as well as possibly leading to a challenging and rewarding hobby.

Physical illness

Art therapy is used with people suffering from cancer, including terminal cancer[34,35] as well as with other long-term and progressive illnesses or conditions such as multiple sclerosis, ME, kidney disease, effects of stroke, Parkinson's disease, and in palliative care to manage anxiety and fear about death and dying. The aims are to assist clients in coping with the emotional impact of their illness, enabling expression of feeling, relieving depression and stress, and improving their quality of living.

Other areas where promising work is going on: with eating disorders, drug and alcohol addiction, and with refugees and asylum seekers, many of whom have been the victims of war, of torture and are suffering extreme stress; also with the moderately to severely depressed and those who have work and relationship difficulties.

Contextual issues

In the United Kingdom, over 50 per cent of art therapists work within the NHS where they may form part of the psychological therapies or occupational therapy department, or be autonomous. Others practise in Social Services, Education, Home Office,

non-Statutory services, and a fairly small percentage work privately or are self-employed.

All are capable of assessing the suitability of the client for art therapy. Exclusion criteria are minimal. Initial interviews usually explain that the client does not have to be 'good at art' and that art therapy is not a 'painting class' but that it may arouse strong and sometimes difficult feelings. All therapists are trained to work with individuals and groups, to function as members of multi-disciplinary teams, to manage health and safety issues concerning preparation and maintenance of the art therapy space, liaising regularly with medical, nursing, teaching, or other appropriate staff in the interests of the client. Ethical standards are laid down by the Health Professions Council as for the other arts therapists (drama and music and also dance) with whom there is regular contact.

Research

There is a substantial body of qualitative research in art therapy, however much of this would not meet the criteria for evidence-based practice required by today's public sector. Currently there is very little about art therapy within National Institute of Clinical Excellence guidelines, which have tended to emphasize quantitative studies. This is unfortunate as it gives the impression of a profession without a strong evidence base, which is not so as the flourishing Art Therapy Practice Research Network and a growing body of literature demonstrates.[36,37]

A few books and papers emerging from control group studies feature evaluations of art therapy groups with older people with moderate to severe dementia[38] and with schizophrenia. In 2006, the UK Health Technology Assessment supported a consortium headed by Crawford, Killaspy, and Waller (University of London) for a multi-centre random control group study of art therapy and schizophrenia. The Master's level training in art therapy requires a substantial dissertation, and a significant percentage of art therapists continue to doctorate research designed to use and test the hypotheses emerging from over 60 years of detailed casework.

6.5

Indigenous, folk healing practices

Wen-Shing Tseng

What are indigenous, folk healing practices?

Indigenous, folk healing practices are nonorthodox therapeutic practices based on indigenous cultural traditions, operating outside of official (modern) healthcare systems.[1] These practices are often validated by experience, but are not founded on scientific principles. Indigenous healing practices are observed in 'primitive' or 'pre-industrialized' societies as well as in modern or developed societies. All healing practices or psychotherapies are more or less culturally influenced, including modern and orthodox psychotherapies, but indigenous healing practices are described as 'culturally embedded' because they are often intensely embedded in the cultural systems in which they were invented and in which they are practised. They are, therefore, usually very difficult to transplant to entirely different cultural settings, where they do not have the same meaning or legitimacy.[2]

While indigenous healing practices function in general as healing methods for problems, they are not usually considered by either the healer or the clients to be psychological therapy for the clients' emotional or psychological problems. Rather, they are recognized as religious ceremonies or healing exercises related to supernatural or natural powers. However, from a mental health point of view, the indigenous healing practices often provide psychotherapeutic effects for the clients, and can be considered as folk psychotherapy.

Anthropologists have studied folk healing practices as a part of cultural behaviour. Recently, cultural psychiatrists have become interested in examining indigenous healing practices from clinical perspectives to explore the similarities and differences that exist between folk healing practices and modern psychotherapy, and to disclose the therapeutic mechanisms that are operating in and being utilized by indigenous healing practices. Many people in developed societies utilize folk healing practices as adjunctive to their primary (modern) therapy or as their main way to get help. Therefore, it is relevant for the modern psychiatrists to know what they are and the possible therapeutic mechanism they offer, or the possible negative effects they may receive by utilizing such indigenous healing practices.

Various practices are covered by the loosely defined terms, indigenous or folk healing. Religious healing practices and ceremonies are closely related to a specific religion. Shamanism involves a spirit medium. Divination, or various kinds of fortune-telling, including astrology or physiognomy, may be used by people to solve their psychological problems or to seek answers for life problems, and, therefore, can be viewed as folk counselling practices as well. Furthermore, the practice of meditation, a self-training exercise used to obtain tranquility, growth of mind, and prevention of emotional problems, can be considered a folk healing practice if one defines psychotherapy very broadly, as not only treating a suffering person but also providing a means for preventing problems and improving the quality of a person's mental life.[3]

No matter what terms are used, indigenous healing practices share some common features. They are invented and utilized by local people for the purpose of solving problems or treating suffering—therefore, they are called indigenous in contrast to universal. They are distinctly different from the modern (Western or orthodox) professional medical approaches—thus, they are called folk practices. Most of them are supernaturally oriented and remote from any scientific orientation. Such indigenous practices are usually rooted in traditional beliefs and folk interpretations of problems, and, thus, are closely related to cultural beliefs.

Subdivision of various healing practices

Based on their core nature and their basic therapeutic orientation, healing practices observed in different societies can be subdivided into different categories namely, supernatural orientation (such as spirit mediumship, religious healing ceremony, and divination); nature orientation (such as fortune-telling, astrology, and meditation); medical-physiological orientation (such as mesmerism, acupuncture, and herb medicine); and socio-psychological orientation (such as Zen training, Alcoholics Anonymous, est, and most modern psychotherapy).[4,5] It is recognized that such subdivisions are arbitrary, and often overlap. Yet these subcategories will help us to understand various healing practices that exist on a spectrum which includes the supernatural, natural, physiological, and psychological.

Spirit mediumship (trance-based healing system)

Spirit mediumship broadly refers to a situation in which the healer or the client, or both, experiences alternate states of consciousness in the form of dissociation or a possessed state at the time of the healing ritual. From a psychotherapeutic point of view, it is

important to distinguish which person is in an alternative state of consciousness, as the mechanism of therapy differs depending on whether it is the healer or the client who is dissociating.

(a) Shamanism

It is speculated that the geographic heartland of shamanism is Central and North Eurasia, with widespread diffusion to Southeast Asia and the Americas.[3] Through a religious ceremony, a shaman can work himself into a trance state in which he is possessed by a god. The rhythmic singing, dancing, or praying (quiet meditation) seems to assist the self-induction of the trance state. Among native healers in North and South America, a psychedelic substance (such as may be found in cactus) is frequently used to induce an altered state of consciousness and a special psychic experience for the healing performance. Whether the altered state of consciousness is substance- or self-induced, the healer is considered to be possessed by a supernatural power. The client can then consult the supernatural through the shaman for instructions on dealing with his or her problems.

The causes of problems are usually interpreted according to the folk concepts held by the culture—involving such things as loss of the soul, sorcery, spirit intrusion, or violation of taboos. Disharmony with nature may also be interpreted as the cause of problems. Coping methods are usually magical in nature, such as: prayer, the use of charms, or the performance of a ritual ceremony for extraction or exorcism. Utilizing supernatural powers, acting as an authority figure, making suggestions, and providing hope are some of the main mechanisms for healing provided by the shaman. The goal of the healing practice is to resolve the problems that a client is encountering.

(b) Zar ceremonies

The term *zar* refers to a ceremony as well as a class of spirits. *Zar* ritual is observed primarily in Muslim societies in the Mideast, including Ethiopia, Egypt, Iraq, Kuwait, Sudan, and Somaliland. *Zar* ritual is different from shamanism in that, in addition to the healer, the client also experiences the dissociated or possessed state.

The *zar* ceremony is primarily a female activity. All of those attending the ceremony wear new or clean clothing to please the spirits. The main patient usually wears a white gown, as much gold jewelry as possible, and is heavily perfumed. The ceremony master begins the ceremony with a song and drumming. When a spirit associated with some person in the audience is called, that person begins to shake in her seat, dancing, and trembling until she falls, exhausted, to the floor. Before the spirit consents to leave, it usually demands special favours, such as jewellery, new clothing, or expensive foods. It is the duty of the relatives and friends to gather around the prostrate woman and pacify the spirit. The whole tone of the ceremony is one of propitiation and persuasion, rather than coercion. The ceremony ends with an animal sacrifice and a feast.

The *zar* ceremony is primarily an adult female activity reflecting social conditions of sex-separation, low female status, restriction of women from religious participation, an unbalanced sex ratio, marital insecurity, and relative isolation. The *zar* ceremony provides women an ideal situation for relief of persistent and regular anxieties and tensions arising from their life conditions. The goods demanded during the ceremony are all things that their husbands should provide. This fulfills a woman's wish for attention and care. Emotional catharsis, fulfillment of unsatisfied desire, and compensation for the suppressed female role are some of the therapeutic mechanisms working in this kind of therapeutic ritual. Restoring balance in real life is the implicit goal of this culture-embedded healing practice.[6]

Religious healing ceremonies

A distinction needs to be made between religion and a religious healing ceremony. Religion refers to a system of belief in a divine or superhuman power or spiritual practice. As a part of a religion, some people may perform special ceremonies for the purpose of healing certain problems or disorders. There are various kinds of religious healing ceremonies observed in different societies that are considered by mental health workers to serve a therapeutic function for their participants.

(a) Sprit dancing ceremony

As observed among Salish-speaking Indians of the Pacific Coast of North America, healing ceremonies utilize psychological mechanisms and processes similar to those in brainwashing. The initiate has to go through three major therapeutic approaches: depatterning through shock treatment (such as physical restraint, blindfolding, hitting, kinetic stimulation, or intensive acoustic stimulation, followed by lying still, being forbidden to talk, and starvation); physical training (such as daily running, jumping into ice-cold waters, or frequent rounds of dancing); and, finally, indoctrination.[7]

(b) Sacrificial ritual

An example is found in Yoruba, Africa. A person's problems were identified by palm nuts tossed by the diviner. It was usually interpreted that the person or a member of his family had offended the family *orisa* (the lineage deity) or some other spirit. Then, the sacrifice of a certain animal was prescribed for resolution. In the sacrifice, the supplicant passed his bad luck or illness to the animal, and the animal was killed in the supplicant's stead. The healing power of the ritual lies in its reassurance and generation of conviction. The ritual demonstrates that proper curative steps are being taken.[8]

(c) The religious ceremony of mourning

This is practised among members of the Spiritual Baptist Church in the West Indies. In a desire for spiritual strength and other benefits, church members volunteer to participate in the practice. After ceremonial washing and anointing, the mourners are isolated in a small chamber at the back of the church, where they remain for a period of 7 days. During that time, each individual prays, fasts, and experiences dreams and visions. The mourners claim they obtained beneficial psychological relief on their moods; attainment of the ability to foresee and avoid danger; improvement in their decision-making abilities; cures for physical illnesses; and heightened facility to communicate with God.[9]

(d) Snake-handling cult

An extremely different form of religious ritual was a snake-handling cult in the southern United States. As part of cult activities, members, in trance states, handled poisonous snakes as a sign of being blessed by God. Occasionally, some of the members died when they were bitten by the snakes. Although forbidden by the government to perform such cult rituals, these activities still exists. The gratification of emotional excitement was interpreted

as one of the effects sought by cult members—even at the risk of their lives.[10]

(e) Christian religious healing

It is important to know that religious healing ceremonies are not only observed in primitive societies or among uncivilized populations, but are quite common in many industrialized societies, as well. In Christian religious healing, there is a broad spectrum of beliefs and activities, ranging from Christian Science to the fundamentalism of healers such as Oral Roberts to the Roman Catholic rite of anointing of the sick. The participating client is provided with the hope for supernatural resources against disease, thus increasing his or her security and sense of well-being.[11]

Thus, in various forms of religious healing ceremonies, the therapeutic operation is carried out through the ritual of prayer, testimony, sacrifice, reliving experience, or even spirit possession. Assurance, suggestions, and generation of conviction are some of the healing mechanisms utilized in the practices. The aims of therapy are to heal the problems and give a certain perspective to the client's life.

Divination

Divination refers to the act or practice of trying to foretell the future or the unknown by occult means. It relies on mysterious, magic, or religious methods. Since the interpretation of divine instruction is usually provided by the diviner himself, or an interpreter, the interaction between the diviner/interpreter and the client becomes an important variable.

There is a range of methods of divination. Some methods are very simple, while others are more complicated. For example, in Nigeria, Africa, the divination practised by the Nsukka Ibo (called *Afa*) is carried out by casting four strings containing half-shells of the seeds of the bush mango;[12] and by the people in Yoruba (known as *Ifa*) by tossing palm nuts.[8] In the divination practised in some parts of Africa, the diviner simply offers a certain sign himself. For example, divination may occur while his hand is shaking, with the belief that he is guided by a supernatural power to give instructions.

In ancient China, turtle shells or the bones of big animals were burned during divination ceremonies and divine instruction was interpreted through the cracks made from the heat. An elaborate divination system called *chien* has been developed in China, and a modified version is used in Japan. To obtain answers to questions about their lives, some Chinese or Japanese will visit temples for divination. After a sincere prayer to the god of the temple, the person will ask for divine instruction, which is provided through a fortune stick that the person selects. Corresponding to the number on the stick, there is a fortune paper with an answer written on it. This practice is called *chien* drawing in Chinese,[13] or *kujibiki* in Japanese.

No matter what method of divination is practised , the basic therapeutic operation is performed to provide a clear-cut answer for the problems presented. Thus, it is helpful psychologically for a client to find a definite way to address his problems. Naming effects are among the healing mechanisms operating in divination. It is assumed that human life is under the influence of supernatural regulation. It is the basic goal of the person seeking help to find the proper way to comply with the universe through divine instruction.

(a) Fortune-telling

The system of reference shifts from the supernatural to the natural in the practice of fortune-telling. Based on the concepts of microcosm and macrocosm, fortune-telling is oriented to the basic belief that human life and behaviour are parts of the universe. The nature of the problems is usually explained in terms of an imbalance of vital forces or disharmony with the natural principles that rule the universe. The objective of the practice is to help the client find out how to live compatibly with nature and adjust to the environment more harmoniously.

Based on the sources of information used, fortune-telling can be divided into several groups. In astrology, there is a basic belief that a person's life is correlated to and influenced by the movement of the stars, thus, their movement becomes the essential source of information for predicting one's life course. For the Chinese, an ancient record of universal change, the Oracle of Change (*Yi-Jing*), is used for fortune-telling. A person's date and time of birth, and the number of strokes in the Chinese character for his or her name, is the information needed to calculate an individual's fortune.

Physiognomy is based on the assumption that there is a close correlation between the mind and the body and that one's character, life, and fortune can be read by examining one's physical features. It is assumed that a person is born with a certain predisposition, which is shown in his physical appearance and will lead him to manifest certain behaviour patterns. A physiognomist tries to help a client understand his own character and behaviour patterns, learning how to make good use of his talents and, at the same time, make up for his shortcomings.

Although the basic assumption underlying fortune-telling is that every person has a predetermined course of life, such fate is not absolutely unchangeable—it may be subject to modification. Thus, it is not a completely passive acceptance of fate, but allows room for adjustment. Finding a way to adjust your own fortune is the purpose of fortune-telling.

Even though the basic orientation shifts from a supernatural to a natural one, and the sources of practice rely on the rules of nature, the therapeutic operation, like divination, is still characterized by offering folk-natured interpretation and providing concrete guidance for a client in making choices. Based on the concepts of microcosm and macrocosm, complying with the fundamental rules of nature is the basic goal of the practice.

Common therapeutic factors

Reviewing various forms of folk therapy, it has been pointed out that the core of the effectiveness of different methods of religious and magical healing seems to lie in their ability to arouse hope by capitalizing on the patient's dependency on others.[14] Comparing the healing practices carried out by witch doctors and psychiatrists, it has been pointed out that they share a common root. Both kinds of therapists are able to decrease the client's anxiety by identifying what is wrong with him—that is, to name the cause of the problems, providing the effect of the Rumpelstiltskin principle; the therapist presents certain personal qualities that are admired by the culture and contribute to the therapy; the client's expectations of therapy, and the emotional arousal that is usually enhanced by the therapeutic setting, the therapist's belief in himself, and his reputation; the emerging sense of learning and mastery that the

client obtains through therapy; and finally, the techniques of therapy that enhance the basic components of psychotherapy. It is clear that folk healing practices and modern psychotherapy share a number of nonspecific therapeutic mechanisms.[15] It has been indicated that traditional healing practices have several advantages over cosmopolitan modern medicine, namely: cultural congeniality, maximal use of the personality of the healer, a holistic approach, accessibility and availability (particularly for developing areas), effective use of affect and altered states of consciousness, collective therapy management, and cost-effectiveness.[1] It is important to recognize that both folk healing and modern therapy utilize symbols and metaphors for interpretation and suggestions.[16] In contrast to modern psychotherapists, some folk healers make use of symbolic interpretations and suggestions to enhance the effects of healing.

Attitudes towards indigenous healing practices

Different points of view exist among scholars, clinicians, and public health workers regarding whether or not to encourage or discourage indigenous folk healing practices in various societies. Some people (particularly modern clinicians) see folk healing as merely superstitious and primitive, insisting that such out-of-date practices should be discouraged or prohibited. Others (such as cultural anthropologists and cultural psychiatrists) consider these folk practices to be interesting subjects for academic study—examining the therapeutic elements that are utilized in these primitive healing practices, and why such supernaturally oriented therapeutic exercises are still popular among some groups. Still other people (such as some community health workers) believe that, due to the shortage of professional personnel available in the community, the existence of folk therapies should be supported. The position was taken that any folk healing practice that is proven (or at least considered) to be helpful to the client and useful to the community deserves the support and encouragement of clinicians as well as administrators.

Final comments: clinical implications

The comparative study of indigenous healing practices and modern psychotherapy has revealed the existence of certain universal elements of the healing process that operate as important factors for therapy, whether the therapy is carried out in a primitive or modern form. The universal and nonspecific healing factors identified are: the cultivation of hope, the activation of surrounding support, and the enhancement of culturally sanctioned coping. The study of indigenous healing practices has also pointed out the existence of supernatural dimensions of healing power, which are less intentionally utilized in modern therapy.

Despite the general usefulness of folk therapies, the ill effects of some have not been widely studied and reported. Yet, clinical observation has disclosed that some folk therapists cause harm to the clients who seek their services. Under the guise of treatment, tricking a client out of his money by deceit or fraud, or sexual involvement with a client, are examples of disreputable behaviour that are occasionally reported. Harming a client by prescribing dangerous substances, and physically injuring or even killing a client by accident during the performance of an exorcism, are other examples of serious complications that have occurred.

No matter what position is taken, there is one simple fact that deserves attention, namely, that there exists a wide range of professional quality among so-called folk healers, and different motivations for practice. Some are benign healers motivated by a desire to serve, while others are not. Some are well-trained in their particular professions and know how to practice within its limitations, while others are not—and are liable for malpractice. The major problem is that, from a public health point of view, in most societies, there still are no formal guidelines for regulating folk therapy, as there are for modern therapy. Folk therapy, whether it is shamanistic practice or faith healing, should be subject to periodic surveys and reevaluation by the public health administration, as is modern clinical work, so that its benefits to clients can be protected and any potential malpractice can be prevented. If any folk therapist refuses to be examined and regulated, he or she should be discouraged or prevented from practicing.

7.1

Public policy and mental health

Matt Muijen and Andrew McCulloch

Introduction

Public policy, and specifically national public policy, is one of the key factors that affects the practice of psychiatry, the shape of mental health services, and the environment within which mental health services work. The specific content of public policy varies greatly across the world and often even across neighbouring countries. It is therefore impossible within the space of this chapter to undertake systematic international comparisons. This chapter gives an overview of:

(a) what policy is and why it might be important;

(b) types of policy and policy development internationally;

(c) international structures and organizations that are relevant to the scope and content of policy, especially in the field of human rights which is often the starting point for policy;

(d) the breadth of policy activity that is relevant to mental health—stretching beyond the health ministry and health policy—and the partnerships that are necessary to tackle the mental health of individuals and populations.

What is public policy?

Koontz and Weihrich[1] define policy or policies as 'General statements or understandings which guide thinking on decision making.' This definition implies that:

1 policy may be stated in writing (statute, guidance, or statement) or may be unwritten and disseminated through management or political chains of command only;

2 policies may exist at various organizational levels albeit here we are mainly concerned with national policies;

3 policy is only one factor in any final management or clinical decision. Other factors will often be more important, and clinical behaviour is notoriously resistant to policy influence except where certain behaviour is directly prohibited.[2]

Therefore, the policy needs to be understood as just one of the factors which determine the nature and state of mental health services and mental health promotion or public mental health within a society.

In many developed countries, the management of the public sector has seen major changes over the last two decades, shifting from a hierarchical and bureaucratic administration to a model of 'managerialism'.[3] In the old model policy making and administration was separated, and governments were responsible for the provision of services often via related public sector agencies. The new model, inspired by business,[4] is characterized by governments introducing competition and market principles and involving the private sector in providing services, setting measurable objectives, and introducing performance management with the aim of delivering higher efficiency. This has affected professionals such as psychiatrists by shifting accountability for good medical practice as judged by peers to reporting on outputs to managers as specified by contracts and practice guidelines. Nevertheless, in most cases strong professional accountability remains, creating a dual accountability that may be appropriate but is always challenging and sometimes conflicting.

Mental health public policy

Public policy in mental health is driven by a range of influences and interests which policy makers will attempt to balance. Positive drivers, that is factors that encourage the development of progressive mental health policies, include:

- epidemiological evidence of the prevalence and the contribution of mental disorders to the burden of disease;
- evidence for effective and efficient interventions;
- public interest as expressed by politicians and the media;
- campaigns by NGOs and professional groups;
- human rights considerations;
- pressure from patient and family organizations;
- growing public expenditure.[5]

The strong interface between mental health issues and human rights explains the importance of human rights conventions and declarations in the shaping of policies and legislation, especially in countries where mental health policy and practice are less developed historically. Negative drivers, that is, factors that limit the commitment of policy makers, include budget limitations,

competition from other priority areas, discrimination, and the perception that mental health is not a fruitful area for investment.

The function of mental health policy

Mental health policy may serve a variety of functions ranging from the purely political and presentational through to delivering on a moral or social imperative. Often policy is mixed in function, enabling politicians to make a statement on an important human rights or social issue whilst also achieving real improvements for people with mental illness and delivering on economic targets. Mental health policy will also affect delivery of other aspects of policy in relation to crime, housing, education, and health. Thus, a coherent set of social policies cannot be developed without addressing mental health in some way. Mental health has been called a 'wicked' social policy issue (see Bogdanor for a discussion of such issues)[6] because it is hard to define, to address, and to deliver on tangibles, but unless we do, many of our social aspirations will not be fully realizable. Finally, the stated mission or desired outcome of policy may vary—for example some countries may have goals in terms of reduced prevalence of an outcome such as suicide, others may wish to achieve de-institutionalization.[7]

Broader public policy and mental health

Whilst policy on mental health services *per se* is likely to be the concern of the health ministry, the impact of other public policy on both mentally ill people, and the practical application of psychiatry may be even bigger. People with severe or persistent common mental health problems often face social exclusion and face difficulties with issues including housing/shelter, employment, education, and welfare or welfare benefits. All mental health professionals in all countries of the world will be aware of how much these issues can affect the lives of people with mental illness and indeed clinical outcomes. Box 7.1.1 summarizes some of the main relevant policy areas which will impact on mental health services.

It should be clear from only brief examination of this table that achieving a totally coherent mental health policy presents huge challenges:

- The views of different parties and the priorities of many different government departments must be reconciled;
- Policy must integrate horizontally—for example, across health, education, and local government, and vertically from small organizations up to government;
- The non-measurable side of what is offered is very important to the stakeholders—services must be responsive, caring, joined up and visible to users, carers, and the general public—yet these features of services are hard to influence from central government;
- The needs and demands are so large and diverse it is difficult to construct and resource a coherent system for delivery even in the richest countries;
- Achieving equity and balancing resource allocation across groups of people suffering from a range of mental disorders with different prevalence and causing a different burden to self, families, and communities. Different groups of disorders require different investment producing different potential benefits yet such decisions must often be made on the basis of ambiguous information whilst subject to conflicting pressures from advocacy groups, communities, media, colleagues, government ministries, and parliament.

Box 7.1.1 Policy links for mental health across government

Government department or ministry (generic description may not accord with structures in all countries)	Mental health relevant policy responsibility (Examples)
Department of health/health and social services	Primary mental health care Human resources for health and social care services Finance for health and social care Specialist mental health care policy Public mental health or mental health promotion
Department of employment/ social welfare	Welfare benefits for people with mental health problems Employment rights and protection Occupational health
Department of education	Education on mental health issues as part of wider curricula in schools and higher education Healthy schools Higher education for relevant vocational qualifications
Department of criminal justice/internal security	Diversion of mentally ill offenders from the criminal justice system Public security
Department of housing/ communities and local government/regions	Housing for mentally ill people Community development Urban policy
Department for constitutional affairs/human rights	Protection of those who lack capacity
Treasury or finance ministry	Financing of the above at a macro level Strategic value for money

(The authors after Jenkins *et al.* (2002))

Comparative policy

It can be argued that mental health policies in most countries fall within four broad groupings:

1 Provision for the basic protection of human rights of people with mental illness or those lacking mental capacity;

2 As one together with a simple health care policy to provide for the health care needs of people with serious mental illnesses;

3 The above but with a more comprehensive health and social care policy which addresses primary and specialist care needs for various groups of disorders;

4 A comprehensive cross-sectoral mental health policy that addresses care, public mental health, and broader issues such as housing.

No country in the world has a fully comprehensive policy although developed countries such as New Zealand, Australia, several

European countries, and states of Canada and the United States have advanced policies. This reflects the nature and resources of these societies, and does not necessarily result in differences in prevalence or outcomes.[8]

Human right conventions and legislation

Human rights have historically been a fundamental driver for the development of mental health policy in most countries of the world. The current Human Rights conventions derive from the United Nations, and are binding once they are ratified by member states following adoption by the United Nations General Assembly. The Universal Declaration of Human Rights was adopted in 1948. This was followed in 1966 by the International Covenant on Political and Civil Rights (ICCPR) and the International Covenant on Economic, Social and Cultural Rights (ICESCR), in combination known as the International Bill of Rights. None of the conventions directly addresses issues related to mental health care, although the right to the highest attainable standard of physical and mental health is included in Article 12 of the ICESCR. In non-binding general comments, the committee on Economic, Social and Cultural Rights specified that right to health covers availability, accessibility with a strong emphasis on equality and non-discrimination, and acceptability including cultural sensitivity and quality. The obligation of signatories to provide information on detentions and measures taken to prevent abuse for people admitted to mental hospitals is important.[9]

In 1991, the United Nations General Assembly adopted 'the principles for the protection of persons with mental illness and the improvement of mental healthcare', better known as the MI principles, which remains a key reference document for national mental health legislation. The document outlines 25 principles, stressing the importance of non-discriminatory practice within the health care system. The rights to which patients with mental health problems are entitled, according to the MI principles, include the right to live and work as far as possible in the community, and the right to the best available treatment and care in the least restrictive settings in conditions suited to the cultural background of the patient. The principles also set out expectations for confidentiality, the protection of autonomy, and the conditions for involuntary detention. In combination the principles offer a good foundation for modern mental health policies and legislation. Although the document is not legally binding, it is clearly stated that member states are expected to implement these principles fully.

An essential principle, confirmed by the World Conference on Human Rights in 1993, is that all human rights are universal, equally applying to people with disabilities and mental disorders. This is a strong driver for national governments to deliver anti-discrimination legislation, guidance, and practice.

International agencies

There are several relevant regional agencies that represent countries, including political organizations such as the European Union, the Council of Europe and the European Court of Human Rights, the African Commission on Human and People's Rights, and the Inter-American Court of Human Rights. All have produced conventions and declarations pertinent to people with mental health problems, some legally binding.[10]

The World Health Organization (WHO), the specialist health agency of the United Nations, is mandated by its constitution to support member states in all health areas, including mental health. Its core functions include to:

- propose conventions, agreements and regulations, and make recommendations with respect to international health matters;
- assist governments, upon request, in strengthening health services;
- promote improved standards of teaching and training in the health, medical, and related professions;
- study and report on, in cooperation with other specialized agencies where necessary, administrative and social techniques affecting public health and medical care from preventive and curative points of view, including hospital services and social welfare.

In 2001, WHO dedicated the World Health Report to mental health. The report entitled 'New Understanding, New Hope' urges member states 'to seek solutions for mental health that are already available and affordable'.[11] The report formulates a set of 10 recommendations for member states to address the challenges faced in various areas of mental health. By adopting the report (World Health Assembly Resolution WHA 55.10), governments have committed themselves to implement its recommendations to strengthen primary care and develop accessible and affordable community-based mental health services.

At WHO regional level there have been several declarations and action plans that elaborated the principles of the World Health Report 2001, and reinforced the commitment by governments to delivery. Examples include the Caracas Declaration for the Americas, anticipating the World Health Report, and the European Declaration for Mental Health signed in Helsinki 2005.

Why public mental health policy?

Although the governments of most countries accept a role for public policy in the regulation, commissioning, funding, resourcing, and provision of mental health care, particularly for persons with severe and enduring mental health problems, a case still should be made why mental health care cannot be left to a combination of the private market and civil society to deliver without central intervention. As we have argued, when national systems are compared, considerable variation emerges, even within developed countries. In some, the role of government is limited to regulation of independent health insurance groups that purchase from independent providers, and the public funding of a safety net for expensive acute care or long-term conditions. In other countries all parts of the health system are state owned and tax funded.

The World Bank produced a report on this question,[12] scrutinizing the arguments for public financing of mental disorders as compared to other conditions that compete for public money. In their opinion, disease burden, cost-effectiveness of interventions, and externalities are not sufficient arguments since these are not unique to mental health. However, the potential of catastrophic cost, the risk of insurance market failure, and the place of involuntary treatment and consequent issues of human rights are all disproportionately present in mental health care and plead in favour of a public role. One could add to this that stigma and

discrimination may negatively affect the availability and access to mental health services if left to market forces together with the argument advanced above that comprehensive social policies cannot logically leave out mental health.

Economic impact of disease burden

An important argument for the view that mental health should be central to health care and public policy in general is the burden of disease evidence, addressed elsewhere in this book (cross ref). The realization that mental disorders contribute so much to the overall burden of disease puts mental health care at least on an equal footing with other groups of disorders that have long been recognized as posing a major public health challenge such as infectious disease, cancer, and heart disease. Even more startling is the very high proportion of years lived with disability attributable to mental health problems and the days lost to employment due to mental health conditions. The majority of mental health problems contributing to disability are anxiety and depression and the burden of substance misuse and organic disorders in developed countries is also very high, and rising.

From a public policy perspective, this means that the consequences of mental health problems are no longer only an issue of health care, but are central to macro-economic national interests, particularly at times of skills shortages. This has become connected with the interest in the mental well-being of the population, based on the observation that level and growth in Gross National Product (GNP) is only very marginally associated with status of mental well-being of the population, and in some cases even inversely correlated.[13] This has resulted in the conclusion by economists that government's macro-economic policies should not simply be driven by the aim to maximize the Gross National Product and the income of its citizens. Rather, the 'happiness' of the population should become the prime driver of policy making.[14] Governments have consequently seen a need to stimulate the employment of people with mental disorders, both as part of the social inclusion agenda and to reverse the very high and increasing cost of mental disability. This could be considered as a somewhat symptomatic approach ignoring the more systemic problem of job stress and insecurity in very competitive market economies. However, there is also no doubt that loss of employment is a disastrous event for individuals and families in its own right, whether considered from an emotional, social, or financial perspective. The strong association of unemployment with divorce, mental illness, suicide, all factors associated with social exclusion[15] in their own right, supports the case for increasing employment rates, if not exclusively so. A challenge mental health services are facing is to identify the most appropriate and effective response to such broader societal needs as many of the levers for change lie outside the health care sector.

The scope of mental health public policy development

The scope of mental health policy making has broadened, as reflected in the content of international declarations. During the second half of the twentieth century mental health policy and expenditure was focused on people with severe and enduring conditions cared for in institutional settings. Increasingly the focus is broadening to incorporate mental health promotion and prevention and treatment of common mental disorders, including a key role for primary care. The reasons for this include:

- an increased demand for the treatment of stress and depression;
- the development of community-based services, lowering the threshold to access for, and acceptability of care;
- the growing evidence base for a range of interventions such as cognitive behavioural therapy (CBT);
- increased media interest in common mental disorders and their treatment;
- the reduction of stigma of common mental disorders;
- growing affluence in many countries making privately purchased therapies more affordable;
- an awareness that mental health problems are associated with many social determinants of health, including inequality, and macro-economic conditions;
- the co-morbidity between mental health problems and many physical diseases including diabetes and CHD, affecting mortality, and recovery rates;
- an awareness of the cost of mental illness to society, and the evidence of cost-effective promotion and prevention activities.

All these have major consequences for public policy. The complex interface between public mental health activities and mental illness services demands a multi-agency approach, crossing the responsibilities of government departments and local services and requires 'joined up government'. This requires clear policies with explicit objectives and targets, specifying responsibilities for delivery and funding. It requires the active ownership of mental health issues beyond the health care sector and its advocacy by leading practitioners across a range of sectors and disciplines.

Policy implementation

The growing range and complexity of mental health-related activities requires explicit strategies outlining the vision and values of reform, the planned service organization, capital and human resource implications, financing, quality monitoring, and human rights protection. The number of countries in the world with such detailed mental health policies as defined above is still low but growing. There are also many examples of good strategies, whether at national, state, regional, or local level, that have produced impressive change, and guidance for the drafting of policy and legislation is available.[16]

The common factors in countries with a successful track record of change include:

- full commitment by government;
- national consultation exercises, gaining the views and support of key stakeholders;
- clear and consistent communication of objectives;
- realistic and sustained resource allocation;
- workforce strategies including education and training.

However, there are also examples of countries that have drafted comprehensive strategies that have not been implemented.

Failure of implementation will create cynicism that may obviate future attempts. Main factors that lead to failure include:

1 Poor connection between the strategy and reality, and lack of focus. In some instances strategies are written by foreign experts ignorant of local circumstances. Other examples are of strategies that are based on ideology and are overambitious, repeating the content of declarations without taking into account local needs and resources.

2 Lack of financial commitment or poor grasp of the financial costs of a new model of care, causing rejection by the finance ministry or inability to deliver locally.

3 Neglect of the human resource implications. New models tend to require more staff with new skills, and implementation can create high levels of anxiety that need to be confronted.

4 Lack of consultation with professional groups, users, carers, and communities, who therefore reject or resist the strategy.

5 Insufficient joint planning either across government or with partner organizations that will carry responsibilities for the funding and delivery of essential components such as social care, housing, and employment. Incentives will need to be created for various groups such as professionals and the private sector to support the strategy. Added to this is the need to align incentives across different areas, and to prevent the development of perverse incentives, leading to conflicts of interest.[17]

6 Lack of a long-term perspective. It is often possible to develop local model services, but generalization to national and sustainable programmes requires different approaches.

7 Lack of all party political support. It is unlikely reform will be initiated and embedded within the lifetime of a single parliament/administration or under the governance of the same minister of health. Unless political support is strong across the political spectrum, the risk of reversal due to weak commitment or even hostility to previously agreed plans is high.

Human resources

Any strategy must include plans for sufficient staff with the right attitudes, skills, and competencies. The growing demand for mental health care has increased the need for staff. Many countries around the world are looking for ways to remedy staff shortages, particularly of doctors and nurses. Three approaches can be distinguished:

- increase of national recruitment;
- creation of different roles and responsibilities for staff;
- international recruitment.

Although the increase of training places is on the face of it an obvious approach, it does not solve the problem immediately since the lag time between the creation, for example, of a medical training place and the production of a psychiatrist will be at the least 10 years. The availability of training places assumes that places will be filled with able candidates, which is also not always the case. In some poorer countries students reject the option to become mental health workers due to stigma, poor working conditions, and poor pay.

An important alternative strategy is to take a more comprehensive competency-based approach, and analyse the roles and responsibilities of staff groups that are available and could be equally effective, sometimes even at lower cost. A potential example of this is nurse prescribing.[18] A step further is the creation of new workforce roles, compatible with the direction of reform. Community-based services may require a multi-disciplinary team involving a larger proportion of social workers and psychologists instead of only doctors and nurses. One could also consider new types of community workers focusing on prevention or early intervention, or support workers for patients with severe and enduring disorders. A primary care-based approach may suggest the development of mental health expertise for primary care workers. In practice, however, such models tend to create additional demands for staff and change roles of existing staff, rather than reducing the need for the specialists who remain in short supply.[19]

A short cut to solving staff shortages is international recruitment, setting up a three-way dilemma between ethical recruiting practice, the interest of both receiving and sending countries, and the benefit of individuals. In some trade zones the free migration of employees, including health care staff, is a basic right. It is also hard to argue that health care staff living in poverty and insecurity should be deprived of the opportunity to improve their lives by working in rich and secure countries. Developed countries argue that it is their responsibility to ensure access to health care for their population, although some consideration for the consequences of the country of origin should be shown. Ethical recruitment guidelines have been developed, distinguishing between active recruitment, that is deliberately setting out to attract staff, and passive recruitment, offering open opportunities, for example, by advertising in an international journal. The presence of a bilateral memorandum of agreement is also a indication of good practice.[20] It has to be recognized that international recruitment is not a phenomenon limited to western host countries. It is a global process, with a stream of staff following the trail of higher salaries.

Funding

If it is accepted that the public sector is responsible for the funding of mental health care, the total amount and by implication the proportion of the health budget to be allocated to mental health has to be determined, whether at a national, regional, or local level. In theory this could be calculated on the basis of a population needs assessment, matching the level of need with the cost of interventions. Many countries have performed epidemiological surveys with a sufficient degree of precision to allow an estimate of the prevalence of diagnostic groups.[21] It is more challenging to take account of the cost of treatment. Attempts to determine the costs of specific interventions are possible in research settings. However, in psychiatry, the cost variation even within homogeneous diagnostic groups attributable to factors such as severity, age, co-morbidity, ethnicity, geography, and social context, as well as supply factors such as the range of treatments and delivery options, make any prediction imprecise, as demonstrated by the challenge of developing Diagnosis Related Groups (DRGs) for mental health care.[22]

The variation of spending on mental health across countries is striking. About 20 per cent of countries in the world dedicate less than 1 per cent of the total health budget on mental health, and a

few more than 10 per cent as reported in the WHO Atlas project (2005),[23] with a strong positive correlation between the mental health budget and GDP. Thus, the poorest countries have a very low public spending on mental health, although this ignores the importance of out of pocket payments in many of these countries, sometimes with catastrophic impact on families.

Variations over time of the proportion of health budget allocated to mental health tend to be minor. This suggests that proportion of budget allocated to mental health can be attributed to static factors such as historical spending, often based on running costs of hospitals, adjusted by political priorities and influenced by factors such as advocacy and level of stigma. We do not know of any example of a national formula of rational health budget allocation at treasury/finance ministry level, although a number of countries use a psychiatric needs index to inform sub-national spending decisions.

Equitable resource allocation

A decision on basis of equity needs to balance the burden of disease for patients, families, and the community (see Chapter 7.5), intensity of human suffering, and the cost-effectiveness of treatment relative to other health conditions. In developed countries budgets can be expected to cover basic needs and simple evidence-based practices across all disease groups. It would be hard to accept in Western Europe or North America that patients have no access to treatments for conditions such as tuberculosis or schizophrenia. Some rationing in a variety of implicit or explicit forms is usually in place for expensive new technologies or costly treatments for common and mild conditions. Whilst mental health has few hi-tech interventions, interventions like CBT would be highly expensive if applied to more than defined subgroups of patients.

In poor countries with very low mental health budgets, many lives will depend on the decision how best to invest the scarce resources in order to gain the greatest cost-effectiveness as measured by DALYs averted. Cost-effectiveness studies have found that episodic treatment with older antidepressant drugs is the most cost-effective treatment in poor countries, whereas the treatment of schizophrenia is relatively more expensive.[24] Even more challenging is to decide on the merit of allocation across disease groups, for example, tuberculosis versus mental health.[25] However, one has to take into account that figures are based on averages, and ignore the very great personal and community benefits that some individual interventions can offer. In mental health, it also has to be considered that interventions are not only about treatment of diseases, but also involve in many instances action against major human rights abuses and the consequences of neglect, such as patients with schizophrenia locked up for years or children ignored in institutions. It is hard to put monetary values on such decisions, and this yet again places mental health activities beyond a narrow health treatment perspective, but shows it as one component of broad public policy making. The challenge is to keep mental health high on the agenda of all public policy makers, rather than it being allowed to slip down every government department's list of priorities.

7.2

Service needs of individuals and populations

Mike Slade, Michele Tansella, and Graham Thornicroft

Introduction

The importance of needs assessment has been one of the most consistent themes to emerge from the evolution of community mental health services. However, the concept of 'need' is used in different, and sometimes contradictory, ways. The aim of this chapter is to

- define needs assessment
- consider different approaches to assessing needs, both at the individual and at the population levels
- discuss how needs assessments can be applied in real-world settings in planning and delivering clinical care.

Defining needs

At its simplest, a need involves a lack of something. But of what? In operational terms the concept of need is usually applied to a difficulty (in this case in relation to a person with mental illness) for which a possibly effective intervention exists. By implication an experienced difficulty for which there is no known effective intervention is therefore not defined as a need.[1] The clearest categorization of such needs was identified by Brewin, who grouped definitions of need within mental health care into three categories: lack of health, lack of access to services or institutions, and lack of action by mental health workers.[2] Approaches to need within each of these three categories will be reviewed.

(a) Needs for improved health

The psychologist Maslow established probably the best-known hierarchy of need, when he formulated a theory of human motivation.[3] In his model, fundamental physiological needs (such as the need for food) underpin the higher needs of safety, love, self-esteem, and self-actualization. He proposed that people are motivated by the requirement to meet these needs, and that higher level needs could only be met once the lower and more fundamental needs were met. The clinical relevance of this theory is that it implies a hierarchy of clinical priorities—interventions to meet basic physiological need (e.g. to ensure adequate food supply) should take priority over interventions to foster, for example, self-esteem.

In practice health-related needs are often considered in a widely defined way. In England, for example, the requirement to base the provision of services on level of need was first made explicit in the National Health Service and Community Care Act,[4] which defined need as *the requirements of individuals to enable them to achieve, maintain, or restore an acceptable level of social independence or quality of life*. This requirement was retained when national standards for mental health services were set.[5] This involves **needs-led** care planning—basing care for an individual patient on an assessment of their health and social needs. The needs-led approach offers many benefits:

1 The overall level of need gives guidance about which part of the mental health system should treat the patient, for example that people with less disabling mental disorders should be seen in primary care settings.[6]

2 Needs assessment can improve the comprehensiveness of case formulations and care plans by incorporating a broad range of health determinants, such as poor housing or lack of social support.

3 Explicit identification of need can support clinician–patient discussions about care priorities, which is associated with improved treatment satisfaction[7,8] and compliance.[9,10]

4 Identification of needs helps to identify the contribution of services outside the psychiatric sector.

5 Needs-led care can facilitate more individualized treatment planning than diagnosis-driven approaches, by more closely matching the help offered to patient's needs and by explicitly identifying problems which require the involvement of both health and other agencies.

Needs-led care planning focussing on health can be differentiated from the assessment of care needs. Assessing care needs involves identifying whether the patient will benefit from a predefined menu of interventions, and by definition will not identify all unmet needs for individual patients. Assessment of need at the patient level should therefore be a separate process from decisions about what care or treatment to provide. There are, however, other reasons to assess needs for services, which we now review.

(b) Needs for services

The second category of need is a requirement for a particular type of service. At the population level, it is possible to use epidemiological methods to develop prevalence for different disorders, which can be translated into estimates of the need for services. A recent epidemiological survey in the United States, for example, found very considerable unmet need of the population level nationwide.[11] This study identified that between 1990–92 and 2001–03 the overall annual period prevalence of mental illnesses remained constant at between 29.4 and 30.5 per cent. Among these cases, however, there was an increase in the proportion who received any treatment at all, rising from 20.3 to 32.9 per cent between the two time periods. The inverse is however very revealing, namely that the most recent data show that 67 per cent of people with mental disorders in the United States receive no treatment. The situation is worse in other countries. A recent comparative international study of depression found that 0 per cent of patients in St Petersburg received evidence-based treatment in primary care, and only 3 per cent were referred on to specialist mental health care.[12] The inability of patients to afford out-of-pocket costs was the primary barrier to care for 75 per cent of the depressed Russian patients studied.

International comparisons of population-level needs have been conducted in recent years. The ESEMed Study, for example, carried out cross-sectional surveys in Belgium, France, Germany, Italy, the Netherlands, and Spain among 8796 representative members of the general population. Individuals with a 12-month mental disorder that was disabling or that had led to use of services in the previous 12 months were considered in need of care. The study found that about 6 per cent of the sample was defined as being in need of mental health care. Nearly half (48 per cent) of these people reported no formal health care use, so that 3.1 per cent of the adult population had an unmet need for mental health care. In contrast, only 8 per cent of the people with diabetes had reported no use of services for their physical condition.[13]

(c) Needs for action

In health care, the concept of need has been taken to mean the ability to benefit in some way from health care, and thus distinguished from demand (what the person asks for) and supply (services given).[14] For example, the MRC Needs for Care Assessment Schedule is premised on the assumption that need is 'a normative concept which is to be defined by experts'.[15]

Using this approach, an Australian study compared current and optimal treatment for 10 high-burden mental disorders in Australia.[16] This found that current levels of treatment at current coverage avert 13 per cent of the overall burden attributable to these disorders. Providing optimal treatment at current coverage would avert 20 per cent of the burden, and optimal treatment at optimal coverage would avert 28 per cent. The development of a more robust treatment evidence base makes this innovative approach to informing public policy more possible, and the approach can be recommended for evidence-based policy initiatives.

Patient and staff perceptions of need

There has been a long-standing recognition that differences in perceptions of need can exist, in particular between staff and patient. In the 1990s the emphasis was put on acknowledging these differences, but then prioritizing the staff perspective. For example, UK policy stated that *all users … should be encouraged to participate to the limit of their capacity. …Where it is impossible to reconcile different perceptions, these differences should be acknowledged and recorded*.[17] Several societal and scientific developments challenge this prioritization of staff over patient perspectives.

First, general societal changes towards consumerism and an emphasis on rights have produced more assertive mental health service users. Easier access by patients to internet-based information reduces the knowledge disparity. Reduced societal trust in the authoritative expert has eroded the position power of mental health staff. The emphasis put on choice and empowerment raise patient expectations of being more than passive recipients of care.[18,19]

Second, the prioritization of staff perspectives has been actively challenged by an increasingly vociferous and organized user movement. This opposition has found its voice in the 'recovery' movement, which emphasizes the meaning and values of the patient, and the need for services to foster self-management rather than dependency. There has been widespread international policy support for recovery-focussed services[20] although there can be tensions between what professionals construe as their duty of care and being led by the patient perspective on need, which can create ethical dilemmas. Care planning which emphasizes agreement between staff and patients may have additional advantages. A recent study in Verona showed staff–patient agreement on needs was significantly associated with better treatment outcomes both rated by the patient and by staff (psychopathology, social disability, global functioning, subjective quality of life, and satisfaction with care).[21] Similarly, there is emerging evidence that crisis plans (advanced statements) which are jointly agreed between staff and patient can be cost-effective in reducing compulsory admission to hospital.[22,23] Such emerging findings indicate that needs assessment and care planning, which are based on negotiation and jointly agreed analyses of problems and interventions, are likely to become increasingly important in future.

Finally, emerging empirical evidence strongly supports the positioning of the patient perspective at the heart of needs assessment and care planning. Evidence from several studies consistently shows differences between staff and patient perspectives on need,[24,25] so the two perspectives are not interchangeable. Empirical research suggests two reasons for basing care on the patient rather than staff assessment of need. First the patient rating is more stable than the staff rating.[26] Second, longitudinal studies indicate a causal relationship between patient-rated (but not staff-rated) unmet need and quality of life.[27–29] If the goal of mental health services is to improve quality of life, then best available evidence indicates that the patient's perspective on their unmet needs should drive care planning.

Assessing needs

In this section we identify specific approaches to assessing needs.

(a) Individual-level needs assessment measures

Several standardized approaches to the assessment of patient-level need have been developed, primarily in the United Kingdom. These have shown a transition along a continuum, from an initial focus on assessment of need as an objective state to be defined by experts following careful assessment, towards those which emphasize the subjective nature of needs assessment.

The earliest standardized needs assessment measure was the **Medical Research Council Needs for Care Assessment (NFCAS)**.[30]

The NFCAS assesses the need for further action by health care professionals, and links identification of a need with a predefined list of actions. This raises two problems. First, the emphasis on identifying available interventions which would be at least partly effective is problematic, given the complexities of deciding that a treatment has not worked. Second, updating the list of actions has proved problematic. However, as Bebbington notes, 'the inevitable value judgements inherent in the procedure have the virtue of being public and consequently accessible to argument'.[31] An important variation of the NFCAS is the **Cardinal Needs Schedule (CNS)**,[32] which also considers patient willingness to accept help and level of carer concern. Training is needed for using both the NFCAS and the CNS, and they are primarily used for research purposes.

At the other end of this continuum are needs assessment measures which emphasize individual difference and the subjective nature of need. The **AVON Mental Health Measure** was developed by service users, and assesses physical, social, behaviour, access, and mental health domains.[33] It can take up to 20 min for completion by the patient and 5 min by the staff, and its development has emphasized external validity over other psychometric properties. The **Carers and Users Experience of Services (CUES)** was developed by service users and staff, and assesses 16 domains: the place you live, money situation, the help you get, the way you spend time, your relationships, social life, information/advice, access to services, choice of mental health services, relationship with mental health workers, consultation and contact, advocacy, stigma, any treatment, access to physical health services, and relationship with physical health workers.[34] Completion can take up to 30 min. Neither AVON nor CUES have become widely used in mental health services.

The **Camberwell Assessment of Need (CAN)**[35] spans both ends of the continuum. It assesses 22 domains of health and social need, and a key development is that it records staff and patient views separately, without giving primacy to either perspective. Research (CAN-R), clinical (CAN-C), and brief versions (CANSAS) of the CAN have been developed for adults of working age with severe mental health problems,[36] and it has been translated in 22 languages. Variants have been developed for people with learning disabilities and mental health problems (CANDID),[37] mentally disordered offenders (CANFOR),[38] older adults (CANE),[39] and mothers with mental health problems (CAN-M).[40] An updated web resource for the CAN is available at www.iop.kcl.ac.uk/prism/can.

The CAN has become the most widely used needs assessment measure internationally,[41] and is the standardized needs assessment measure which is most relevant to routine clinical practice. The short version, CANSAS, can be recommended for routine use in community services. Two specific approaches have been empirically shown to produce patient-level benefit. First, the patient-rated two-way communication (2-COM) measure is an amended version of the CAN which gives the patient the opportunity to identify unmet needs and also prioritize those which they wish to discuss with their clinician.[42] Asking patients to complete 2-COM before an outpatient appointment and then using that information in the appointment was associated with greater patient satisfaction and more likelihood of treatment change.[7] Second, a structured approach to collating and feeding back staff and patient ratings for CANSAS and other assessments led to a reduction in psychiatric admissions, probably because of earlier intervention during relapse,[43] and improvements in patient-rated unmet need and quality of life for higher premorbid IQ patients.[44] Routine use of CANSAS brings patient-level benefits, and empirical evidence indicates the clinical focus should be on assessment and interventions for patient-rated, rather than staff-rated, unmet needs.

(b) Population-level needs assessment measure

Measures to assess population-based needs can be classified by the data and by the analytic approaches they use. Three types of data are commonly used. The most readily accessible documents the use of current mental health services. While this can be criticized as reflecting only current service provision, its ready availability and nationwide coverage means that is extensively used.

Simple population-based samples are very inefficient in estimating the prevalence of relatively rare conditions such as schizophrenia. Studies thus tend to use two-stage procedures, with a relatively brief initial screening process applied to a large number of people followed in-depth interviews for a selected few. 'Booster' samples, perhaps including all the known psychiatric patients for the areas surveyed, may be sought through mental health services.[45] Population surveys depend on the identification of randomly sampled individuals. Some types of mental health problems, notably substance misuse, are commonly associated with socially marginal lifestyles, making it likely that sufferers will be systematically underrepresented by traditional population sampling approaches. More sophisticated sampling approaches, such as capture–recapture methods, have been used for these situations.[46]

The third type of data relates to the views of local people. Local needs assessment studies entail a structured approach to eliciting the views of service users, their carers, interested voluntary sector organizations, and all statutory agencies with responsibilities in the area. Smith[47] has described how this type of study can be integrated into the overall planning process.

Government initiatives in England have tried to base the allocation of money between areas on the morbidity as well as the size of their populations. This has led to studies modelling this variation. The first widely used index[48] was developed on the basis of consensus between GPs about patient characteristics associated with high use of primary care services. While developed for wider purposes, this was shown to relate reasonably closely to variations in psychiatric admission. Later indices have been established by statistical modelling exercises seeking to quantify the relationship between social variables measured in censuses and either service use,[49] or population-based epidemiological findings. The variation between places in the prevalence of the less severe types of mental illness commonly dealt with in primary care is less than that for problems usually managed by specialist mental health services, which again is much less than that observed for forensic services. Thus models developed for one level of care should not be used to estimate patterns of need for other levels.

In practice, no single approach to assessing the needs of a population will suffice. Needs assessment at this level requires the integration of many perspectives. The Kings Fund review of London's mental health Services[50] illustrates how a detailed perspective can be assembled from many fragments of evidence, each of which would be inadequate in isolation. Recent examples of population-level needs assessment from the United States, Canada, and

New Zealand also reveal that epidemiological studies may not produce data that corresponds directly to needs, and that some sub-populations, for example particular ethnic groups, may be less well represented in such approaches, unless considerable methodological care is taken.[51–53]

If a mental health practitioner is asked to join a committee to plan services, for example, for a local catchment area, what approach is helpful to identify and use population-level needs? Table 7.2.1 indicates a series of steps to find the best available information on population prevalence rates.[54]

As Table 7.2.1 shows, we consider that the best possible information would be local epidemiological data on the occurrence of mental disorders, using a standard system of classification, alongside a measure of the needs for treatment among the prevalent cases identified.[55] Since these assessments are expensive and time-consuming, most sites will not have access to such recent local data. If the data in step (1) are not available then we suggest that country/regional epidemiological data (2) are used instead, and are then weighed for local socio-demographic characteristics. But if such larger scale prevalence data are not available, then a third option is to use international rates from 'comparison' countries or regions, again weighted for local socio-demographic characteristics (3). The results in this case will be less accurate because they are based on the additional assumption that the data can be transferred between countries. A newer set of techniques that offer considerable promise are rapid appraisal/rapid assessment techniques. These are methods to undertake brief assessments of population needs which are focussed upon key focussed questions, for example on how primary care services should be augmented to treat people with depression, and example of these approaches have been used to positive effect in South Africa.[56–58]

In some cases, none of the data described in steps 1–3 will be available, and then the next option (4) is to use a number of experts, some of whom may be from the local area, to produce a consensus statement on the local rates and characteristics of people with mental illness. Such a data synthesis can be based on the best available views, taking into account local factors (e.g. levels of non-health service provision, family support, traditions, degree of affluence, or migration). This pragmatic approach will yield data which are accurate enough to use for local service planning purposes.

Table 7.2.1 Ways to measure or estimate local population mental health prevalence

(1) Actual local epidemiological data on psychiatric morbidity and disability for the particular area by age, sex, ethnicity, social status, and degree of urbanicity
(if not available) ↓
(2) Country/regional epidemiological data weighed for local socio-demographic characteristics
(if not available) ↓
(3) International data from 'comparable' countries or regions, adjusted for local socio-demographic characteristics
(If 1, 2, 3 not sufficient) ↓
(4) Best estimates and expert synthesis and interpretation based on other sources of local information and opinions (e.g. extent of non-health service provision, family support, local traditions, or migration)

This raises the important topics of coverage and focussing. *Coverage* means the proportion of people who receive treatment who could benefit from it.[59] *Focussing* refers to how far those people who actually receive treatment in fact need it: do they have any form of mental illness?[60] Even in the most well-resourced countries one can find both low coverage and poor focussing.[61,62] From the public health perspective, therefore, the key issue is the appropriate use of resources, whatever the level of resources actually available, namely to increase both coverage and focus.

(c) The relationship between individual and population-level needs

We have argued in this chapter that the provision of care for individual patients should be based on assessment of their health and social needs. Can these individual assessments be aggregated to inform service? For population-level service planning, the key question is what types of interventions to provide, and with what capacity. Therefore data from individual needs assessments cannot simply be aggregated to inform service development decisions. While it is theoretically feasible to undertake routine standardized needs assessments on all patients within a service, this approach alone has three drawbacks. Firstly, despite the developing evidence reviewed earlier about the benefits of routine use of standardized outcome assessments, this remains the exception rather than the norm.[63,64] Secondly, there is not yet a sufficiently developed information infrastructure to support the national collection, management, and analysis of such data, despite this being a priority identified two decades ago.[65] Thirdly, even if individual needs assessments were nationally aggregated, the diversity of views (patient, staff, carer, taxpayer) would make a shared interpretation of the data problematic.

Conclusion

In this chapter we have emphasized that it is of central importance when planning mental health service for populations, to do so on the basis of (i) the occurrence of mental disorders in that particular population, (ii) the impairments caused by these disorders that require interventions, (iii) the nature and level of needs among these people, (iv) identifying from among these needs those which are unmet, and then (v) prioritizing new service development on the basis of these unmet needs, including a range of social supports and services (such as housing or employment opportunities, outside the mental health system), the requirements for enhanced physical/general health care, as well as improvements in the provision of specific mental health services. For all of these sectors there is an increasingly clear call from service user/consumer groups for involvement in these priority-setting planning exercises.[18,19]

At the level of individuals with mental illness, there is a similar trend to increasingly involve service users/consumers in assessing needs, with emerging evidence that this produces a more comprehensive basis for care planning. Indeed in the last decade there has been an important conceptual shift away from the view that professionals defined 'needs' while consumers stated 'demands', to a better appreciation of the many advantages to be gained from identifying, as far as possible, unmet needs in a joint and consensual way as a basis for action.

Cultural differences care pathways, service use, and outcome

Jim van Os and Kwame McKenzie

This chapter discusses the influence of culture on the route an individual takes to access treatment for psychological distress and the treatment received. Culture is difficult to measure. All categories of cultural variables have different meanings and measure different things. Research into them leads to different hypotheses. Given this reality, there is no need to join the cul-de-sac argument of whether one or the other is the most important. In the discussion below, the roles of ethnicity and of socio-economic, political, community, national, and other factors that help to define the culture of an individual or a group are acknowledged. Associations with pathways to care, service use, and outcome will be presented.

Care pathways

Cultural variation in pathways through care

At the beginning of the pathway to care, the individual displays cognitive, physical, or behavioural changes. They or their family, friends, or wider community interpret these as in need of some remedy. The individual's personal resources and then informal resources of family and friends are often triggered to help deal with the problem. These may lead to resolution but if they do not they may lead to presentation through an ever more distant and 'professional' array of caregivers, help agencies, and formal medical services. Most help for psychological problems is not given by mental health services. Interventions and their perceived success or failure move an individual along a pathway.

Pathways through care have differing directions and durations. These depend on where the pathway starts, the presenting symptoms, and psychosocial and cultural factors in the individual, their community, and the services used. Pathways are not random, they are structured and set by a dialogue between the individual, the community, and the code of the statutory services and the law set within that country.[1]

At each level the aim of care is to help the individual move down to less professional interventions until they are either back in the community or at the lowest intensity of care that meets their needs. Traditionally, care pathways have considered routes to getting treatment but with de-institutionalization, social inclusion and the recovery model, pathways out of care need to be considered more widely.

International comparisons

Cultural variation in pathways to care for a mental health problem is readily, though crudely, demonstrated through international comparisons. For example, in an international study of the pathways to care of 1554 patients newly referred to the mental health services in 11 centres in different countries, the majority of patients (63–80 per cent) were referred by their general practitioner in United Kingdom, Spain, Portugal, Czechoslovakia, Cuba, Mexico, and Aden Democratic Republic of Yemen. Only between 0–15 per cent of patients in these centres had referred themselves, with the exception of Mexico (24 per cent). In Kenya, only 7 per cent were referred by general practitioners but 72 per cent were referred by a hospital doctor. In Pakistan and India, a quarter of patients were referred by general practitioners, a quarter by hospital doctors, a third were self-referred, and 11–17 per cent were referred by religious healers. In Indonesia, both primary care and native healer referrals constituted each around a third of all referrals. The differences between these 11 centres largely reflected the people's choice of first port of call for a psychiatric problem.[2]

International differences in pathways are also reflected in primary health care studies. In a 14 country World Health Organization (WHO) investigation, the proportion of attendees with anxiety and depression as defined by the Composite International Diagnostic Interview (CIDI) varied five-fold across centers. Asian sites reported the lowest rates and European and South American sites the highest. The differences in prevalence may reflect a combination of demographic differences between attendees, true differences in population prevalence, the differential availability of other culture-specific pathways to care for the psychologically distressed, and differential sensitivity of the CIDI in picking up psychiatric disorder in different cultures.[3]

Geographically less dispersed countries also demonstrate significant differences in care pathways. In a recent study of 6 Eastern European countries, the percentage of new patients with schizophrenia who first sought care from psychiatric services ranged

from 69 per cent in Bucharest (Romania) to 47 per cent in Zagreb (Croatia). Thirteen percent of patients first sought care from general practitioners in Strumica, Macedonia but 47 per cent in Zagreb. The police were the first port of call in 8 per cent of cases in Bucharest but for none in Zagreb.[4]

This study used the 'encounter form' developed for the WHO which can be used to map and quantify pathways to care (Fig. 7.3.1).

Marked differences in pathways to care also exist within countries and groups. The increase in the use of involuntary admission of African-Caribbeans in the UK and African-Americans in the US is well documented. The reasons for this are unclear but some argue that it reflects service configuration.[5] More recently, increased involuntary admission rates have been reported in the Maori population of Auckland, New Zealand.[6]

Geographic and ecological factors may also contribute to variation in pathways to care within a country. In a Canadian province, involuntary admissions were shown to be related to the size of a community and its proximity to the hospital. Thus, involuntary admission rates were increased if a community was close to the hospital. Rates were also higher in both densely populated inner city areas as well as in cities of less than 500 people. The higher rates of involuntary admission in small towns may be related to a decreased likelihood of being tolerated or remaining anonymous.[7] Despite a similar mental health act, involuntary admissions in Greenland were found to be twice as high as they were in Denmark or the Faroe Islands. The excess risk was associated with the higher homicide rate, lower psychiatric bed availability, lower access to psychiatric care, small settlements, and increased alcohol consumption and violence in Greenland.[8]

Factors associated with cultural variation in pathways

How interpersonal or cultural factors are translated into differences in pathways has rarely been assessed. However, a number of factors have been identified that contribute to cross-national and cross-ethnic differences.

The family may play an important role. An American study reported that Chinese patients were kept for extended periods of time within their families at the beginning of pathways, while Anglo-Saxons and Central Europeans were referred by their relatives or themselves to a range of mental health and social agencies. Native Americans tended to be referred by people other than relatives or themselves.[9] In another study, both Asians and African-Americans showed more extended family involvement, and the involvement of key family members tended to be persistent and intensive in Asians. Ethnicity was also associated with the length of delay, Asians showing the longest delay and white people, the shortest.[10]

The history of and the way that institutions promote themselves can affect the attitude minority patients have to them and so their likelihood of using them. For example, the view of American hospital services by ethnic minority patients has been tarnished by the American Medical Association's support for segregated wards until the 1960s.[11]

The experience of illness is a culturally shaped phenomenon. The monitoring of change, the understanding of symptoms, the language used to present symptoms, and the fears that accompany symptoms are all suffused with cultural interpretations.[12] Cultural differences in displaying distress are most obviously seen in culture-bound syndromes but are present in the content of delusions and somatic presentation of distress. Somatic symptoms are located in multiple systems of meaning that serve diverse psychological and social functions. In one study, the experience of neurotic patients in India was labeled depressive by clinicians using DSM-IIIR, whereas the patients emphasized their somatic experience.[13] Such discrepancies between professional theory and patients' experience may have an impact on the recognition and treatment of psychiatric disorder. For example, ethnic difference between the doctor and the patient or linguistic/communication problems had previously been offered as reasons for British general practitioners missing depression in South Asian women. However, South Asian doctors are also more likely to miss

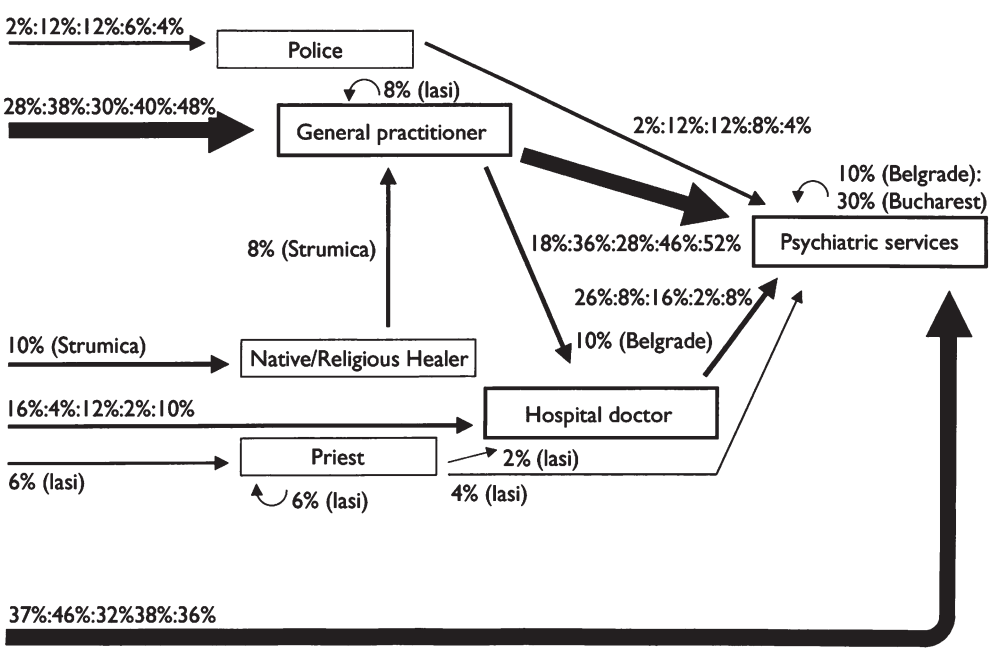

Fig. 7.3.1 Pathways to psychiatric care in Belgrade, Bucharest, Iasi, Strumica and Zagreb. Percentage of those taking each step for each centre respectively, for carers involved in more than 5 per cent of pathways. Steps occurring in only one or two centres are indicated as a single figure followed by the centre name in brackets. (Curved arrows above carer boxes indicate recursive pathways, where patients have gone from one to another of the same type of carer). Reproduced from Gater, R., Jordanova, V., Maric, N. *et al.* (2003). Pathways to psychiatric care in Eastern Europe. *British Journal of Psychiatry*, **186**, 529–35, copyright 2003, The Royal College of Psychiatrists.

depression in South Asian women.[14] Thus, rather than 'ethnic match', the culture of medicine may be the important determinant of recognition of depression in this group and its treatment. Longer delays in first contact with a mental health professional,[10] reduce likelihood of successful drug treatment,[15] and poorer outcomes[16] have been reported in groups of Asian patients. The mismatch between patient experience and culture of medicine appears ubiquitous. In Turkey, psychiatric patients with somatic presentations were shown to have longer delays because they went to see hospital doctors first before being referred to a psychiatrist.[17] A study in Nigeria found that a large proportion of depressed patients initially received another diagnosis because of somatic presentation.[18] However, emphasis on somatic experience on the part of the patient does not preclude the patient's recognition of psychological factors, and addressing culturally shaped experience of illness can help clinicians determine underlying aetiology and understand patients with challenging somatic symptoms.[19]

Beliefs about why the problem has arisen, shape the pathway into care. How important this is depends on how different a culture's models of illness and treatment are from that of the service providers. For example, in a study of help-seeking behaviour of families of patients with schizophrenia in India, most of those who believed in supernatural causation consulted indigenous healers first and those who identified schizophrenia as a medical problem consulted practitioners of modern medicine.[20] Similarly, a study in Ghana found that a perceived supernatural cause of mental health problems was associated with a marked reduction in the likelihood of consulting a mental hospital facility.[21] Surveys among Chinese Americans and Mexican Americans show that[22,23] the association between help-seeking, service and acculturation is mediated, amongst others, by beliefs and explanatory models of psychiatric symptoms. Patient satisfaction is highest if the explanatory model of the patient is matched with that of the service provider.[24] Mental health-care professionals are also prone to differences in explanatory models. For example, a comparison between mental health-care professionals in Saudi Arabia and the UK revealed that the staff in the UK believed in a greater range of possible causes and diagnoses for auditory hallucinations than staff in Saudi Arabia. Differences in belief were associated with different expectations regarding efficacy of possible treatments.[25]

Pathways to care are shaped by public opinion and stigma. Such factors can also contribute to the resources that a society will give, and where and by whom treatment is given. A population survey in Germany showed that the lay public generally held psychotherapy in high esteem and the vast majority of respondents rejected pharmacotherapy for psychological problems. Psychoanalysis was the most popular approach in the western part of Germany but in eastern Germany the preference was for group therapy.[26]

Similarly, because psychiatric practice remains to a large degree opinion-based within Europe, differences exist between national samples of psychiatrists with regard to the diagnosis, aetiology, treatment, and outcome of psychiatric disorders such as schizophrenia. Cultural divergence is especially evident with regard to differential emphasis on psychodynamic and biological approaches,[27] and the level of availability of psychotherapy within the health service in European countries appears to be associated with the dominant therapeutic culture of psychiatrists.[28]

The quality of mental health legislation, and, perhaps more importantly, the degree to which correct implementation is enforced have an effect on care pathways. Increased stigma of psychotic illness and fear of public safety have led to compulsory treatment in the community becoming law in the UK. This could change pathways to and through care.[29] In the Netherlands, a weak and impractical act has been criticized for denying patients with severe mental illness the treatment they need. In Spain, to date no specific mental health act exists. In countries like the United Kingdom and France, involuntary admission is in practice, a largely clinical decision, and therefore more easily to put into effect compared with, for example, The Netherlands and most of Germany where the decision is ultimately made by the judiciary. In the United Kingdom and France, the police may bypass medical referral and take people behaving strangely in a public place directly to a psychiatric hospital. This has been shown to be an important pathway for certain ethnic minority groups, such as African-Caribbeans in the United Kingdom.[30]

Filters on the pathway to care and service use

Filter permeability and service use

The majority of people in psychological distress never present to formal health services. If formal help is sought, the likelihood of receiving such help is influenced by the permeability of a number of filters (see Chapter 7.8). For example, once the decision to seek formal help is taken, actual receipt of help depends on the ability of the professional at the first port of call (usually primary care services) to recognize the presence of mental disorder. The permeability of subsequent filters determines the rate with which patients move from primary care service to specialist mental health outpatient services, and from specialist outpatient to hospital-based psychiatric services and back down the hierarchy.

(a) Cross-ethnic differences

There are important cross-ethnic and cross-national differences in the permeability of filters along the pathway to care. Recognition of symptoms by mental health professionals is an important factor. Recognition of distress is dependent on the way symptoms are elicited. For instance, the recognition by primary care doctors of psychiatric disorder in African-Caribbeans and South Asians in the United Kingdom has been shown to be poor.[31] There are a number of reasons for this including differences between the symptoms expected by doctors and those presented.[12] Despite the fact that they visit their general practitioner more often, women of South Asian origin with depression are less likely to be diagnosed and treated than white British women. Detection of depression depends on the doctor's skill but also whether the patient tells the general practitioner about her worries. Those who believed that a doctor was the right person to deal with depression were found to be more likely to disclose information and more likely to be diagnosed and treated.[12] South Asian women are less likely than white British women to think that a doctor was the right person to deal with depression.[32] A one-year follow-up of the sample of the Epidemiologic Catchment Area Program revealed that African-Americans, Hispanics, and other minorities were much less likely to have consulted with a professional in the specialized mental health care sector than white people. The odds of consultation in African-Americans was less than one-quarter of that in white people even after adjustment for confounders.[33] Similarly,

African-American children and adolescents may also remain under-treated although they may have higher levels of symptomatology.[34] Differences between American ethnic groups are also apparent in populations with identical insurance coverage.[35] Hence, these findings[36] suggest low permeability of filters on the pathway to mental health care. Reasons for this may include that African-Americans are less inclined to seek professional help because of increased tolerance to depressive symptoms, but also because of fear of hospital admission.[37] In comparison to all other ethnic groups, African-Americans make more use of emergency rooms for routine psychiatric care.[38]

Despite the low permeability of the filters on the pathway to care there is an over-representation of African-Caribbeans and African-Americans at the level of hospital-based psychiatric services. Possible mechanisms for this include failure of community services to engage mentally ill African-Caribbean men[39] and bypass of the usual filters by, for example, compulsory admission to hospital with or without police involvement.[40] It has been shown that police involvement and compulsory admission to hospital is strongly associated with the absence of general practitioner involvement.[41] Levels of perceived violence and rates of involuntary admission may be due to stereotyped attitudes of the police and mental health professionals or may be in part due to a higher rate of presentation of psychosis that is superimposed on intact premorbid personalities. It has been suggested that reactive forms of psychotic illness in African-Caribbeans are wrongly labelled as schizophrenia.[42] Higher functioning, less withdrawn patients may be perceived as constituting a higher risk by police and mental health professionals. Another factor is that, despite low rates of recognition by general practitioners, African-Caribbeans are most likely to be referred on to a specialist, followed by white people and then people from south Asia even when socioeconomic class and diagnosis are taken into account.[31]

(b) Cross-national differences

Cross-national differences in filter permeability and service use are difficult to examine. Service organization plays an important role. For example, compared with south Manchester, in the United Kingdom, closer integration between community and inpatient psychiatric services in south Verona, Italy, resulted in a greater permeability of the filter between inpatient and community care, as evidenced by higher hospital admission rates and shorter lengths of stay. Conversely, greater permeability of the general practitioner referral filter in south Manchester resulted in more referrals, and therefore higher treated incidence and prevalence rates of psychiatric disorder.[43] Similarly, compared with the more institution-based system in Groningen, in The Netherlands, the south Verona community-based system provided for a higher degree of continuity of care across services for patients with schizophrenia.[44]

Because of convergence in methodology, fascinating material on cross-national differences in the dynamic balance between psychological distress, need for care, and actual treatment received is now available from large prevalence surveys of representative samples in different countries. Comparative data are available on three large population studies in three countries. In the United States and Ontario (Canada), samples representative of all non-institutionalized individuals aged 18 to 54 years were examined using the Composite International Diagnostic Interview (CIDI) in 1990 and samples of people aged 18 to 64 years in The Netherlands were examined in 1996 (Nemesis Study).[45–47]

The three studies show that help-seeking rates among individuals with a diagnosable disorder vary widely. The contact rate with any type of formal or informal service was lowest in the United States (33.9 per cent) and not far from twice as high in The Netherlands (56.7 per cent) (Table 7.3.1). Among individuals with a diagnosable disorder, ambulatory service use in the general medical sector was much higher in Ontario and The Netherlands than in the United States, especially among those with more severe comorbid

Table 7.3.1 Prevalence of CIDI disorder and service use in three countries

		Service use			
	12-month prevalence	General medical[a]	Ambulatory mental health[b]	Any service	Perceived need for care in non-users of professional services
National Comorbidity Survey					
No disorder[c]	54.0	2.6	2.6	7.6	
One disorder	1S.7	5.6	8.3	18.8	8.4
Two disorders	12.0	10.2	18.6	33.9	
Ontario					
No disorder'	65.6	1.5	1.2	3.3	
One disorder	127	9.7	6.3	17.8	5.4
Two disorders	5.9	24.3	23.5	39.4	
Nemesis					
No disorder[c]	58.8	3.8	1.8	6.1	
One disorder	15.3	15.5	7.8	22.5	3.8
Two disorders	8.1	42.8	30.3	56.7	

[a] Non-psychiatrist physician in any setting or allied health professional in a general medical setting.

[b] Psychiatrist or psychologist in any setting or allied health professional (e.g. nurse, social worker) in a psychiatric or addiction treatment setting.

[c] No lifetime history of any disorder at all.

Weighted data from Kessler *et al.*[45] and Bijl *et al.*[47]

disorders. Individuals in the United States with more severe disorders were less likely to use services in the health-care sector as a whole, but if treatment from self-help and other sources is included, the difference between Ontario and Nemesis on the one hand, and the United States on the other, is attenuated. This suggests that low permeability of the primary care access and primary care referral filters in the United States may lead to increased use of non-professional services to fill the gap.

Table 7.3.1 shows that the higher the contact rates with professional services of individuals with a CIDI diagnosis, the lower the number of individuals who were not using professional services but felt they were in need of such help (level of unmet need) (Table 7.3.1). Such differences in the population level of unmet need are important from the point of view of public health. For example, if 90 per cent in a population of 200 million are non-users of professional services for mental health problems, then the difference between 8.4 per cent (United States) and 3.8 per cent (The Netherlands) in perceived need is a difference of 9.2 million individuals.

The substantial differences in mental health care provided by the general practitioner are likely to have an equally substantive impact on the likelihood of receiving appropriate management. Thus, the proportion of patients with major depression (as defined in DSM-IIIR) in the previous 12 months who received appropriate medication management, defined as a combination of antidepressant medication use and four or more visits to any health-care provider within the previous 12 months, was much higher in Ontario (14.9 per cent) than in the United States (7.3 per cent). This difference was especially marked for the lowest income groups in the two countries. Individuals in the lowest income groups in the United States were found to be 7.5 times less likely to make contact with either general or specialty health-care providers than their peers in Ontario. For the highest income groups, however, contact rates differed only by a factor 2.1.[48] These data suggest that economic barriers play an important role in determining the permeability of the filters on the pathway to care. In a United Kingdom national survey, 16 per cent of patients with a depressive episode in the past week according to the Revised Clinical Interview Schedule were current users of antidepressant medication.[49]

Because the majority of the population does not have a mental disorder, even a small degree of service use by this large segment of the population will take up a considerable part of the total capacity of mental health services. Thus, Katz *et al.*[50] noted that because of the relatively high rates of perceived need for care and help-seeking among individuals without a CIDI diagnosis in the United States, total mental health outpatient service use was higher in that country than in Ontario. Although diagnosis is only an imperfect indicator of need for care, the results nevertheless suggest that the mismatch between need and care in the population is greater in the United States than in Ontario.

A long-standing debate exists whether and how financing of mental health care can be used to maximize the fit between need and care in the population. A frequently expressed concern is that universal coverage will lead to an increase of people with little need using services of unproven value. The opposite argument, however, is that limitations in coverage will result in service use that is poorly matched to need. Although it is thought that differences in type of insurance system have an impact on demand and utilization of mental health services,[51] systematic comparisons between countries have been lacking. The systems of coverage in the United States, Canada, and The Netherlands are different in many respects. In Ontario, universal and relatively comprehensive coverage for mental health services exists, with no or minimal limits on inpatient stays or outpatient visits for mental health services, and minimal patient cost sharing. In The Netherlands, almost all mental health care is covered under the Exceptional Medical Expenses Act, and is available to the entire population. A comprehensive range of public services exists, with few supply-side controls. In the United States, at least 16 per cent of the population is uninsured, and even for the insured mental health coverage is increasingly limited. Although the public health system provides mental health care at little or no cost to the poor and the uninsured, supply-side controls severely and increasingly limit access. Therefore, the results of the comparisons between the three countries do not support the frequently expressed reservation that expansion of insurance coverage for mental health disorders results in an increase in unnecessary use of services. Of the three countries considered, those with broad mental health coverage actually treated a similar number or more people with severe mental illness, but less people who never had a history of mental illness.

Treatment and response

Culture has an important influence on the type of service received. There are reports that African-Caribbean and African-American patients receive antipsychotic medications in a higher prescribed dose, and more frequent use of injectable preparations is made.[30,52–57] Asian patients have been reported to receive lower doses.[58,59] Some ethnic minority groups may receive less information about side-effects,[60] which may result in less vigilance with regard to onset of problems such as tardive dyskinesia. In the United States and the United Kingdom, ethnic minority patients are less likely to receive psychological treatment.[61,62] In the United States, African-American children have substantially lower rates of receiving methylphenidate.[63,64] Such differences may be related to differences in explanatory models of African-American parents, and differences in the rate with which African-American parents receive appropriate information about attention deficit–hyperactivity disorder from the doctor.[65]

There are several important considerations with regard to outcome in relation to cultural variables.[66] The first is that services offered may not be equally efficacious for different groups of people. For example, Chinese, Japanese, Filipino, Korean, and Southeast Asian Americans who were treated in the same setting in Los Angeles County showed different outcomes. Filipinos were under-represented in the system, whereas Southeast Asians were over-represented and had higher rates of service utilization. Despite this, Southeast Asians showed less improvement than the other groups, even after controlling for diagnosis and initial level of functioning.[67] The second is that treatment uptake may differ between groups.[33] In the United Kingdom and the United States, uptake of treatment with antipsychotic medication may be higher in white patients, though the overall influence of ethnicity remains small.[68] The third consideration is that the expectations about the desired endpoint of treatment may not be the same for different groups of people. For example, the expectations of British Asian and white people relating to the process and outcome of a psychological intervention were shown to be different in one study.[69]

Outcome may improve if therapists receive information about their clients' cultural background and expectations before treatment.[70] Perhaps the most important consideration is that outcome is a multidimensional concept defying summary statements. For example, clinical outcome in terms of usual symptom severity and risk of self-harm may be better in African-Caribbean patients with psychosis as compared with white people, yet risk of imprisonment and compulsory admission may be greater,[71] as may be the frequency of relapse[72] and the rate of dissatisfaction with services.[73]

However, it is interesting to note that a recent pan-European study has concluded that despite the fact that differences in health-care systems may affect service provision and cost, the impact of such differences on outcome may be less marked. More work needs to be undertaken on cultural differences in care pathways and treatment to see if they change outcomes.[74] Moreover, at an individual level, recent work has failed to show differences in the duration of untreated psychosis between African Caribbeans and whites in the UK,[75] even though they have different pathways to care at first admission indicating that the impact of cultural or ethnic differences in pathways can be difficult to predict.

Pathways out of care

Pathways out of care are complex and have multiple influences. An important influence is the pathway into care because the relationship set up with services at first contact determines, in part, the trajectory of the clinical career of a patient. Moreover, in specific circumstances, such as where the criminal justice system is involved, certain responsibilities may be placed on services which constrain the ability to discharge patients. There has been little research which aims to understand ethnic differences in pathways out of care.[76] This reflects the fact that the focus of studies to date has been to document any inequalities in access to care.

Pathways out of statutory sector care are influenced by the effectiveness of treatment strategies, the illness models and treatment preferences of patients, the structure and funding of clinical services, the availability of and access to nonstatutory sector support and also the socio-cultural context in which people live.

Effectiveness is a combination of the efficacy of a treatment and the real world context which influences outcomes. Though there may be differences in the efficacy of drugs by racial group, differences in compliance are more likely to be important,[77] and there are well documented differences in adherence to treatment programs which may lead to differences in rates of patients leaving care.[78]

Adherence has been linked to differences in illness models but in psychosis the level of discord between patient and treatment service illness models are not consistently associated with differences in outcome.[79] This may reflect the fact that preferred alternative treatment outside statutory mental health services are not available or that services are more coercive with patients who do not fully subscribe to their model.

The structure and funding of clinical services is important. Filters out of care can be porous—an example of this is Ontario, where rehabilitation is mainly offered by local community based organizations which may have better links with the community and so make transition out of care easier. They also have limited responsibility for their clients compared to the UK and may be less risk averse. Risk averse service cultures can lead to delay in discharge from care.[80] Moreover, putting the onus on risk can mean that ethnic groups who are considered more risky have particular difficulty in getting out of care.

Prevailing law also shapes pathways out of care. Such laws may be applied differently to some ethnic groups. For instance, in New Zealand, the Maori population is more likely to be detained on community treatment orders thus delaying movement out of statutory service care.[81]

The availability of nonprofessional support and the structure of some cultural groups may affect pathways. Those of South Asian origin with severe mental illness spend less time in hospital and outpatient care. Family support is cited as the reason for this. Socio-cultural mores are important but also geographic concentration; dispersed refugee and asylum groups with limited access to community support may stay longer in services than would be expected from their symptoms. But socially cohesive groups can be a double-edged sword. One study has demonstrated higher rates of re-admission in areas with high social capital which arguably could be a result of high levels of health norm policing and low levels of tolerance for deviance.[82]

Socio-economic factors also need to be kept in mind when considering the capacity of communities to offer care. The decreased resources available to low income groups will be important in determining the level of burden they will be able to accept.

Primary prevention of mental disorders

J. M. Bertolote

Despite the demonstration of the possibility of preventing some forms of mental disorders, many mental health professionals continue to underestimate the possibilities of primary prevention in their field. This is due to:

1 a lack of clear concepts when referring to this issue;

2 the fact that the effective prevention of mental and neurological disorders often falls outside the usual remit of mental health professionals (in many cases it falls outside the health sector altogether).

These two factors are discussed below, in addition to an indication of actions which effectively prevent some forms of mental disorders.

Prevention

In the late 1950s, Leavell and Clark[1] proposed a three-level concept of prevention (primary, secondary, and tertiary), covering almost all medical actions. Their innovative approach must be understood in relation to what they also called the horizon of the natural history of the disease process: under natural circumstances, a disease will proceed from a prepathological period through its early stages, evolving either to partial or full recovery (or cure), or to death; in the case of partial recovery, there may be chronification or sequelae. Prevention, in this sense, refers not only to the appearance of the disease but also to any further worsening or complication of it once it has appeared.

Primary prevention

The primary prevention level covers what is otherwise referred to as both health promotion and specific protection, and is best exemplified by, for example, adequate nutrition and immunization against specific diseases by vaccines. Whereas, in this example, adequate nutrition is totally non-specific (it contributes to enhancing the overall resistance to several diseases without conferring any specific protection against any), vaccination is highly specific in relation to a single condition. Rational-specific protection is fully dependent on a reasonable knowledge of the aetiology of the disease (or, at least, its mode of transmission) in order to be effective.

Secondary prevention

The secondary prevention level refers to early detection and treatment of diseases. Usually the bulk of the medical activity, its main preventive goal is to avoid chronicity and the establishment of irreversible sequelae. It is dealt with more specifically in Part 6 of this book.

Tertiary prevention

The tertiary prevention level largely corresponds to rehabilitation. It enters into operation once the disease process has been established and aims at reducing as much as possible damages caused by the disease process, preserving intact functions, and restoring and/or compensating impaired functions, disabilities, and handicaps.

On one hand, this conceptual model was highly instrumental in providing an impetus towards preventive activities in the medical field as a whole but, on the other hand, it so popularized the term prevention that it almost lost its powerful message. Therefore, it is important to retain the idea of primary prevention as a synonym of specific protection, referring to methods designed to avoid the occurrence of a specific disorder or groups of disorders. It comprises those measures applicable to a particular disease or group of diseases in order to intercept their causes before they affect people, and should be differentiated not only from treatment and rehabilitation, but also from mental health promotion.

The main obstacle for the prevention of many mental disorders is the limited knowledge about their aetiology. Admittedly, there are very promising and exciting hypotheses concerning the causes of three mental disorders which represent the greatest burden, namely, depression, schizophrenia, and dementia. They are, nevertheless, nothing more than hypotheses. The most successful examples of prevention of diseases refer to those whose aetiology (cause and/or mode of transmission) is relatively well-known. There are historical examples of the prevention of some conditions based on false assumptions about or without a good knowledge of their aetiology (for example, the eradication of malaria in ancient Rome, and the control of the London cholera epidemics by John Snow in the nineteenth century). However, it does not seem appropriate for health professionals and scientists to base their actions on chance or false assumptions, even though the result might be opportune to the population.

As implied by the need to intercept causes of a particular disease or groups of diseases (with a common cause), the concept of prevention calls for a high degree of specificity concerning the target condition or conditions. In the medical field, it led to successful programmes for the prevention of, for example, diarrhoeal diseases (such as typhoid), hypertension, coronary heart disease, breast cancer, and unwanted pregnancies, rather than of infectious diseases, cardiovascular diseases, cancer, or obstetrical problems. Unfortunately, in the mental health field there has not been a great concern with the specification of the target condition, and the prevention of 'mental disorders' (as a whole) became a label soon associated with failure and disinterest.

Mental disorders

What is understood as 'mental disorders' comprises a variety of quite diverse clinical conditions in terms of aetiology, symptomatology, clinical course, prognosis, and response to treatment. Therefore, whenever the prevention of mental disorders is referred to, an effort must be made to obtain some precision.

From a nosological point of view, most of the mental disorders are conceptually at a syndromal level; depression, schizophrenia, and dementia are appropriate examples. In this respect, dementia is one step ahead of the other two, in so far as vascular dementia is now clearly differentiated from Alzheimer's disease, with important implications for prevention.

Therefore a strategic shift is necessary in order to obtain greater efficiency in the successful prevention of some mental disorders. The first step is for an effort to be as specific as possible in relation to the target condition: for instance Down syndrome or phenylketonuria instead of intellectual disorder, foetal alcohol syndrome, delirium tremens instead of alcoholism, and vascular dementia and dementia following brain injury instead of dementia in general.

The second step applies to those conditions which cannot be meaningfully broken down into more specific conditions, such as schizophrenia or depression. In these cases, the target is displaced from the appearance of the conditions towards future relapses, once a first episode has occurred; this conveniently applies to schizophrenia, depression, and dependence on alcohol and other drugs.

Finally, there are some violent behaviours, such as suicide, parasuicide, and violence against others, the control (and prevention) of which are largely expected by society to come from the field of mental health. They do not characterize a mental disorder in particular, but are frequently associated with one or more of them. Their prevention, therefore, requires specifically dedicated interventions.

With this wide range of issues considered as mental disorders, it becomes clear that the coverage of their prevention goes well beyond the limits of this chapter. A detailed conceptual approach to the prevention of mental and psychosocial disorders can be found in a recent publication of the World Health Organization (**WHO**).[2]

Prevention of mental disorders

From a practical point of view there are three groups of conditions for which efficient preventive action has been documented.

1 Mental disorders with known aetiology: this mostly includes those disorders demonstrated to have an organic basis, ranging from the 'historical' general paresis and dementing disorders (e.g. vascular dementia, pellagra, and dementias associated with infectious and parasitic diseases such as malaria and HIV infection) to several forms of intellectual disorder (Down syndrome, foetal alcohol syndrome, phenylketonuria, and intellectual disorder due to iodine deficiency).

2 Mental disorders without a well-established aetiology but with a relatively predictable course: these are chronic disorders with a recurrent relapsing fluctuating pattern, such as schizophrenia, mood disorders (unipolar and bipolar), and alcohol dependence syndrome.

3 Psychosocial problems strongly associated with mental disorders: these range from violence (domestic and other) to suicide and staff burnout.

Mental disorders with known aetiology

(a) Infectious diseases

Prevention of this group of disorders has by far yielded the greatest success. The demonstration in 1911 by Noguchi and Moore of the brain infection by *Treponema pallidum* as the cause of general paresis[3] opened the way in 1917 to its treatment by malaria therapy, and later to its prevention with penicillin; this is now a landmark in the history of medicine. The discovery of the aetiology of pellagra also led to its prevention and control, leading to the prevention of one type of dementia associated with alcoholism and avitaminosis.

These two once very frequent diseases have almost completely disappeared and there are many experienced psychiatrists who never come across a single case of either; with them also disappeared the history of their successful control. Although the same success has not yet been achieved in relation to vascular dementia, the control of hypertension and atherosclerosis (e.g. through the reduction of salt and fat intake) can significantly reduce brain damage and ensuing dementia (vascular or multi-infarct dementia).

In some developing countries, meningitis and malaria (and, to a lesser extent, inadequately treated epilepsy) are important causes of permanent brain damage which can also lead to dementing disorders. The environmental control of malaria and other brain infections, of which bacterial meningitis is the most important, and their early and prompt treatment can reduce the impact of the infection on the brain and prevent these forms of dementia (or intellectual disorder, depending on the age of onset).

More recently, it has been demonstrated that in some people infected with HIV, the initial manifestations of AIDS are accompanied by some forms of mental disorder, such as mood disorders or dementia.[4] The prevention of these forms of mental disorders follow the same measures as for the prevention of AIDS in general. However, it is not yet certain if the newer combined treatments (bi- and tritherapy) can alter the course of AIDS when brain damage due to HIV has been confirmed.

(b) Intellectual disorder (mental retardation)

Up to 15 per cent of cases of intellectual disorder could be prevented by dealing with the causes that lead to it. A recent WHO publication[2] has set detailed guidelines for the prevention of some forms of this condition, namely, Down syndrome, foetal alcohol syndrome, phenylketonuria, and iodine deficiency syndrome.

These preventive actions are both efficient and affordable even in very poor regions of the world.

- *Down syndrome*—The primary prevention of Down syndrome can be successfully achieved through the control of the age at which women become pregnant: ideally, the age range during which the risk is minimal is between 16 and 35 years, after which the risk increases almost exponentially, as shown in Fig. 7.4.1. Amniocentesis is a procedure that can be very useful for the *in utero* diagnosis of Down syndrome (as well as of other problems and malformations). Where it is culturally and morally acceptable, and legally permitted, a therapeutic abortion is viewed by some as another primary prevention measure.
- *Iodine deficiency*—The world population at risk of intellectual disability due to iodine deficiency is approximately 1 billion and it still occurs in large numbers in some regions of the globe.[6] However, it can be very efficiently and cheaply prevented through the addition of iodine to salt, milk, flour, or water, or, in special situations, through injections of an oily solution containing iodine.[7]
- *Phenylketonuria*—Intellectual disorder due to phenylketonuria can also be successfully prevented through the early identification of children at risk who then receive a phenylalanine-free diet throughout their lives.[8]
- *Foetal alcohol syndrome* (FAS)—Intellectual disorder and malformations seen in FAS syndrome can be prevented if women stay away from alcohol during pregnancy, more particularly during the first trimester, or at least keep their alcohol intake below the dangerous limit of 15 g of ethanol per day.[9]

Table 7.4.1 summarizes actions which can effectively prevent some forms of intellectual disorder. Prevention of intellectual disorder is discussed further in Chapter 10.3.

Table 7.4.1 Action to prevent mental retardation

Condition	Preventive action
Iodine deficiency disorders	Iodize salt or water supply Treat individuals at risk with iodized oil or Lugol's solution
Down syndrome	Discourage pregnancies in women over the age of 35 years If appropriate, provide amniocentesis to women over the age of 35 years
Foetal alcohol syndrome	Use simple screening test to identify women at risk Discourage women from drinking alcohol during pregnancy Alert women that drinking around the time of conception increases the risk to the child
Phenylketonuria	Screen all newborn babies for phenylketonuria Treat with a special low-phenylalanine diet Discourage pregnancies in women with phenylketonuria

Mental disorders without a well-established aetiology but with a relatively predictable course

In this group of disorders, the target for prevention is not the disorder itself, whose aetiology is not clearly established, but the occurrence of further episodes of the disorder, since these are chronic recurrent disorders. Three good examples of this are mood disorders, schizophrenia, and alcohol dependence syndrome.

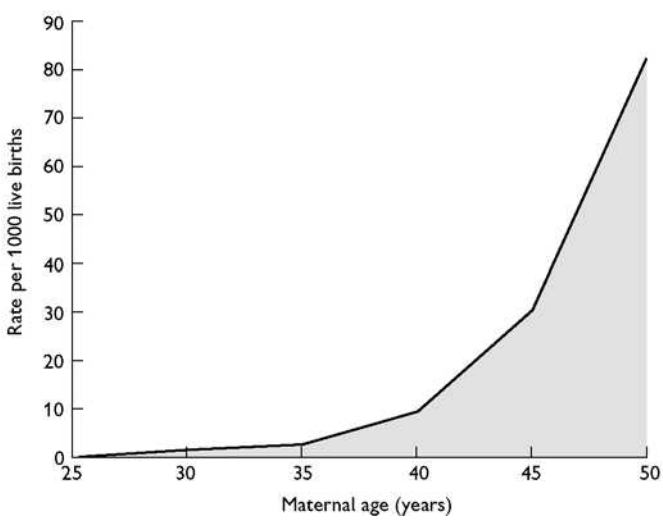

Fig. 7.4.1 Estimated risk of Down syndrome by related age. (Data from Gottesman.[5] Taken from the contribution of genetic factors to the common psychopathologies © World Health Organization, www.who.int)

(a) Mood disorders

In addition to the use of antidepressants and neuroleptics to treat episodes of depression and mania, respectively, it has been demonstrated that the appropriate use of lithium salts can prevent the reappearance of new episodes of disease, or at least increase the disease-free periods and reduce both their duration and severity. The use of lithium salts, also called psychoprophylactics, is now a standard procedure for the treatment and management of mood disorders and this use can be considered as a form of prevention of mood disorders (see Chapter 4.5.8).

(b) Schizophrenia

Although no evidence of a definite cause of schizophrenia is yet available, it can be reasonably controlled through the use of psychopharmacotherapy and psychosocial interventions. Relapse rates (measured by number of hospital readmissions or days in hospital) decrease significantly when persons with schizophrenia adhere to some specific pharmacological regimens and are exposed, together with their relatives, to psychoeducational programmes.[10] These usually include some social skills training for the patient and information about the disease and the management of expressed emotions for the relatives. Unfortunately, schizophrenia is a very long-lasting condition, even lifelong, and most studies on the combination of those two approaches have not yet gone beyond a follow-up of 48 months, thus limiting the full appreciation of its long-term efficiency.

(c) Alcoholism

This term refers to both the alcohol dependence syndrome and other forms of problematic use of alcohol. For people in either category, whenever total abstinence is an unachievable or undesirable goal, the intake reduction, particularly when in connection with risk or dangerous situations, may become the target for prevention. There are several therapeutic techniques usually revolving around brief interventions that are useful to help people significantly to reduce their alcohol and their exposure to problems

associated with it (harm reduction). One should neither forget nor minimize the positive impact of self-help groups (such as Alcoholics Anonymous) in helping some people to achieve sobriety.

Psychosocial problems strongly associated with mental disorders

(a) Violent behaviour

In this category, the immediate target condition is not strictly a mental disorder. However, its close connections with some forms of mental disorder or symptoms make their prevention of immediate concern in the mental health field. Domestic violence (spouse and child beating) is strongly associated with substance abuse;[11] some types of mental disorders are potent risk factors for suicide (see below), and stress and anxiety are at the roots of the burnout syndrome seen in health workers (see below).

Extremely violent behaviour (and crime) is not associated with severe mental disorders (such as schizophrenia) as usually portrayed by the media.[12,13] On the contrary, it is more frequently associated with some types of personality disorders (e.g. antisocial, poor impulse control, aggressive) and with substance use, of which the most prevalent is alcohol. Hence, the control of substance use disorders (in itself a case of secondary prevention) can be seen as an example of primary prevention of domestic violence. The focus of prevention should be broadened from the individual perspective (the substance user) to the social group (the family) which is not exposed to the direct organic effects of alcohol, but nonetheless suffers from its indirect effects.

(b) Suicide

Despite the long-standing sociological tradition of considering suicide as a phenomenon associated with the social condition known as anomia,[14] the medical profession tends to see it primarily as a medical problem. Probably both are right. Among the demonstrated risk factors for suicide there are both social factors (anomy, old age, masculine gender, social isolation) and medical problems (chronic, painful, and incurable diseases and, most of all, psychiatric disorders and psychological problems). Several European studies have indicated that approximately 80 per cent of all cases of suicide are associated with alcohol use and depression combined.[2] This indicates the appropriateness of targeting the treatment of these two conditions (another secondary prevention intervention) regarding the prevention of suicide. However, given the broad social implications of suicide, treatment of mental disorders alone has not yet produced a significant reduction of suicide rates.

Hence the importance of a paradigmatic change which views suicide on a ecological perspective that considers the suicidal act as the immediate target for prevention and not just suicidal intention or ideation as subsumed by the traditional medical (and psychiatric) model.[2] It is now firmly established that the control of the availability of means to commit suicide can greatly contribute to the reduction of mortality rates from suicide. According to WHO,[2] steps to prevent suicide can be taken in the following areas:

- psychiatric treatment
- gun control
- gas detoxification
- control of toxic substances
- responsible media reporting.

Corresponding actions to prevent suicide include:

- identification and treatment of people suffering from depression
- restriction of access to guns
- detoxification of domestic gas and car emissions
- controlling the availability of toxic substances and medicines
- downtoning reports of suicide in the media
- erection of physical barriers to deter jumping from high places.

A more detailed discussion about the prevention of suicide can be found in Chapter 4.15.4.

(c) Staff burnout

Freudenberger[15] first used the term 'staff burnout' to describe a 'syndrome of exhaustion, disillusionment and withdrawal in voluntary mental health workers'. The concept has aroused considerable interest in the caring professions, and the publication of a large number of articles and books on the subject suggests that burnout is a major problem in health services.[2]

Indeed, with the general trend towards community-based care in many parts of the world, burnout is now a problem faced by all caregivers, including the relatives of people suffering from chronic disorders.

There is no single accepted definition of burnout; however, there is general agreement that the syndrome has three major characteristics, which are observed in various caregivers, particularly health workers and family members:

- emotional exhaustion
- depersonalization
- a reduced feeling of personal accomplishment.

The two approaches most frequently employed to prevent staff burnout are:

- Stress management (at the individual level);[16] and
- Supervisor training (at the organizational level).[17]

Table 7.4.2 summarizes actions which contribute to the prevention of burnout among health care staff, at different levels of intervention.

Who is responsible for primary prevention?

As indicated in the introduction of this section, one of the obstacles to a greater involvement of mental health professionals in preventive action stems from the fact that the effective actions for the

Table 7.4.2 Action to prevent staff burnout

Avoid making unrealistically high demands of caregivers
Ensure that all workers have some rewarding tasks
Train caregivers in time-management and relaxation techniques
Modify jobs that are proving too stressful
Encourage the formation of support groups
Consider the possibility of part-time employment
Encourage workers to participate in decisions which affect them

prevention of several mental disorders often falls outside their usual remit and in many cases falls outside the health sector altogether, as indicated in Table 7.4.3. Although this is true, it does not mean that mental health professionals do not have a major role to play in three areas: advocacy, information generation, and supervision.

Perhaps mental health professionals need to reconsider their potential role in primary prevention; for instance, they could develop their potential to act as advocates and advisers to professionals in other sectors. As Eisenberg[18] has argued:

> what matters is not the mode of action of the agent, the venue in which it is applied, or the academic discipline of the practitioner, but the effectiveness of the measure in preventing diseases manifested by disturbances in mental function.

At any rate, prevention is unquestionably a public health priority. Accordingly, WHO has recently published a book on this aspect of prevention, whose reading is strongly recommended.

Table 7.4.3 Agents for prevention

Condition	Effective agents for prevention
Mental retardation	
Down syndrome	Family planning professionals Obstetricians/midwives Women's associations
Foetal alcohol syndrome	General health-care personnel Substance abuse professionals Family planning professionals Obstetrictans/midwives . Educators Women's associations
Phenylketonuria	Obstetricians/midwives Paediatricians Nutritionists
Iodine deficiency	General health-care personnel Nutritionists Groups involved in salt production/trade Water supply personnel Educators
Depression	Mental health workers Rehabilitation officers
Schizophrenia	Mental health workers Rehabilitation officers
Alcohol dependence syndrome	General health workers Mental health workers Self-help groups
Violence	General health workers Mental health workers Paediatricians Justice officers Police officers
Suicide	Mental health workers General health workers Agricultural and environment authorities Journalists Pharmaceutical industry Car industry Traffic authorities Authorities in charge of provision of domestic gas Gun control authorities (including legislators)
Burnout	Occupational health workers General health workers Staff counsellors Trade unions Staff associations Personnel officers Job supervisors Self-help groups

7.5

Planning and providing mental health services for a community

Tom Burns

Introduction

The aim of this chapter is to assist clinicians and managers review and plan services effectively for their local population. Severe psychiatric disorders manifest themselves in social relations and often disrupt social structures; they have wide-ranging consequences and services need to be comprehensive. Health and social care have been intertwined in psychiatry from its origins—it is neither feasible nor sensible to ignore the wider context of their management.

Mental health services research

The last 30 years have seen an explosion of Mental Health Services Research alongside the shrinking and closure of mental hospitals (see Chapter 7.6). Policy considerations, particularly cost containment and public safety, have influenced the research agenda which is disproportionately Anglophone (from the United States, United Kingdom, and Australasia) and focused on new services developed as alternatives to institutional care with staffing and motivation that are not easily generalizable. More routine practices, crucial for safe and effective care, have been relatively neglected by researchers.

Scope of chapter

This chapter is mainly devoted to describing the essential components of a mental health service—its 'building blocks'. It will then consider how they relate to one another, how they can be prioritized, and how integrated into an effective local service linking into other essential services. Lastly it will stress how their inevitable evolution should be monitored.

Services for adults (increasingly referred to as 'adults of working age' indicating 18–65 years) will be used as the template. In many settings these may be the only services, stretching to accommodate all comers. In better resourced health care systems a range of specialized services have evolved from this basic model and are described elsewhere in this section (refugees 7.10.1, homeless 7.10.2, and ethnic minorities 7.10.3).

Building blocks of mental health services: care and treatment

Most mental health treatments (whether psychological, pharmacological, or social) are based on face-to-face interviews and do not require sophisticated equipment or buildings. Institutions (the asylums) evolved for social care of disabled individuals, to protect them while they recovered and, sometimes, to protect society from them. Patients needing long-term institutional care are now relatively few but psychiatry is judged on how they are managed and service planners must pay them due attention.

Inpatient beds

No comprehensive service can survive without access to 24 h nursing supervision for acute episodes of severe illness. These include patients at risk from neglect or suicide or those lacking insight. Wards usually accommodate 10–20 patients. It is rarely possible to effectively staff and run stand-alone units of less than 3–4 such wards (30–60 beds). Ward size is a trade-off between privacy and domesticity against effective supervision. Single rooms are preferable, affording maximal privacy and, while initially expensive, improve flexibility and reduce conflict.

Smaller, more flexible, units such as 'crisis houses' offering 24 h care are a useful complement to inpatient wards, but not a replacement. Ward design and management are increasingly crucial as improved community care concentrates involuntary and disturbed inpatients in them.

How many acute beds?

'How many beds do we need for our local population?' is often the first question asked by planners or managers. Unfortunately there is no reliable or precise answer to this. We know that supply will drive use (perceived as need)—beds are rarely left unfilled despite enormous variation in their availability. It is also surprisingly difficult to collect useable figures on bed usage nationally or internationally because of differences in methods of reporting and also the profusion of overlapping and rarely defined local terms

(e.g. night hospitals, crisis homes, step-down wards). The levels of external accommodation provision (e.g. hostels, day care) clearly also impact the need for acute beds. Similarly need for beds will reduce as community services become more comprehensive and robust.

European provision of general acute beds in 2000 in the public sector ranged from 128 per 100 000 in the Netherlands to 6 per 100 000 in Northern Italy. However, unless we know the pattern of care (in particular the level of private and social services care) these figures tell us relatively little. The United Kingdom has little parallel private care and here acute beds needed for a population of 250 000 have been estimated to range from 50 to 150 plus 5 to 20 secure or intensive care beds[1] dependent on morbidity (generally much higher in large urban settings). London figures for the mid-1990s were very close to this range, averaging 73 for outer and 110 for inner London, but with increased secure provision, particularly in the deprived inner city. The authors predicted a similar range of 24 h supervised hostel need (40–150 per 250 000 population) and London use was somewhat higher (99 and 162 per 250 000, respectively) but with a markedly wider range.

Current bed usage in the United Kingdom is closer to the 50 per 250 000 and well below this in stable communities. This reflects both the establishment of specialized home-treatment and assertive outreach teams and the expansion of forensic care but also a shift in expectations and practice. The average duration for admissions has been steadily reducing over the last three decades. Figures can be misleading as they are heavily skewed by short (1–2 day) admissions but the current admission for an uncomplicated psychotic relapse is likely to be between 3 and 6 weeks.

Longer inpatient care

Acute inpatient wards admit patients for weeks or a couple of months. Rapid discharge is anticipated and regimes emphasize openness and independence. Even within a local service some patients will require longer or more secure care because of illness severity or for legal reasons. Modern rehabilitation practice restricts long-stay wards to patients whose behaviour is persistently unacceptable to local communities. Forensic and secure services are usually a regional or national rather than local responsibility.

Diagnosis-specific wards

Alcohol and substance abuse wards have been long established (especially in Scandinavia and Central Europe) and diagnosis- or disorder-specific wards are increasingly common. Wards for specialized patient groups such as anorexia nervosa or resistant schizophrenia provide highly specific regimes. These are generally an adjunct to acute admission wards rather than an alternative. Some services are organized in disorder-specific wards (e.g. a psychosis unit, a psychosomatic ward) *instead* of general wards. Such specialization is not possible in comprehensive services for populations of less than about 1 000 000. For smaller populations this increased specialization must be balanced against reduced flexibility and energy wasted in 'boundary disputes'.

Day care

Day care is provided either in day-hospitals or day-centres, with little consistency in the terms or practices. Patients attend usually from 1 to 5 days a week for a half or whole day before returning to their homes in the evening. It is particularly valuable when families are out at work but can offer support at evenings and weekends or for very isolated patients.

Generally day-hospitals are provided by health services, include medical and nursing staff and can offer treatments (e.g. the prescription and monitoring of medication, psychotherapies). Day-hospitals were a significant feature in the move of mental health services from mental hospitals to District General Hospital sites. However their role has been more uncertain since community teams have expanded and taken on much of their therapeutic role. Many services have scaled down or even closed their day-hospitals relying more on social services for day care. Day-hospitals have had a problem of isolating themselves from service needs, locked in time with a static patient group. Comprehensive services can, undoubtedly, survive well without them, so if they are to be established it is essential that there are strong links into local teams who can exercise some control over their clientele and their activity.

Day-centres, provided by social care organizations, can rarely provide treatments or employ clinical staff. However overlap is wide with services highly specific to local context (e.g. a drop-in day-centre may be the main provider of psychiatric assessment and treatment in areas of high social mobility and homelessness). Generally day-centres provide long-term social support and day-hospitals focused interventions and treatments.[2] The 'Club House' is a specialized rehabilitation day centre, popularized in the United States, which emphasizes useful normal work and where members take responsibility for running the centre with minimal supervision. Many day units now function in the evening and at weekends.

Acute day-hospitals in Europe and partial hospitalization in the United States have been energetically proposed as alternatives to inpatient care[3] but have had little impact. While day-hospitals never achieved their anticipated prominence they serve specific groups well (e.g. mothers with small children or protracted treatment of eating disorders or personality problems). Day care is problematic in rural settings but adaptations such as travelling day-centres (i.e. a team that moves from setting to setting on specific days) or a weekly open day run by the community team are worth considering.

Supported accommodation and residential care

Many patients remain well outside hospital only with adequate support. At its most basic this implies stable, affordable accommodation. For many, however, supervision is needed to ensure self care, continued medication, and to anticipate and defuse crises. This can be provided by voluntary agencies, social services, or health services. Voluntary agencies tend to be more efficient at providing long-term residential care[4] but they may be reluctant to accept risky patients (e.g. with a history of violence or substance abuse). A mixed economy works best and the need for health services supported accommodation depends on the vigour of local voluntary and social services. While some purpose built units exist, the accommodation is usually shared adapted houses to promote integration and reduce stigma.

Supported or sheltered accommodation is subject to a bewildering terminology but can be considered at four basic levels of increasing need:

1 ***Group homes***. These have no regular staff and are reserved for relatively independent patients visited by staff from their own community teams.

2 ***Day-staffed hostels***. One or two staff are present each day to support and monitor patients (encouraging cooking and cleaning, etc). They would usually not provide specific treatment but liaise with the community team about it.

3 ***Night-staffed hostels***. Non-clinical staff sleep over in the hostel to provide greater safety and availability.

4 ***24 h staffed/nursed hostels***. On-site clinical staff are available overnight either sleeping in or, sometimes, awake. These are expensive hostels and generally restricted to patients with long-term severe illnesses (including sometimes those compulsorily detained). Night-staffed hostels tend to be larger usually with 10–20 residents as opposed to 4–8 in day staffed ones.

Most comprehensive local services provide levels 1 and 2 and most social services undertake to provide level 3. Level 4 is relatively rare and would usually serve a population of 500 000–1 000 000.

Office-based care and outpatient clinics

In insurance-based systems many psychiatrists run individual office practices and manage patients on their own. In state-funded systems this is rare; most work in outpatient clinics or mental health teams. Both approaches should be considered when planning and providing public mental health services, paying particular attention to financial regulations that can inhibit integration and development (comprehensive planning may pose a significant threat to their livelihood and be resisted). Office-based practice remains widespread but neglected in academic and policy publications. It tends to be narrow in remit (usually either psychotherapy or pharmacotherapy) and is poorly equipped for managing severe disorders.

Outpatient clinics ('polyclinics' or 'dispensaries') are an essential part of modern services increasingly replacing office practice. Psychiatrists and psychologists may still operate independently within them but with access to enhanced resources and second opinions. In the public sector outpatient clinics may operate either alongside community mental health teams (CMHTs) or as part of them (which works better for severe illness).[5] They provide an efficient, predicable format for assessments, treatment, and monitoring.

Community mental health centres (CMHCs)

Mental hospitals, for all their faults, had no problems coordinating care; what little was available was all in the same place. Outpatient clinics expanded to Community Mental Health Centres (CMHCs) providing a wide range of services located in shared buildings (e.g. depot clinics, a day-hospital, psychotherapy services). The failure of the early US CMHCs demonstrated that relying entirely on patients to attend fails to engage the more ill and also that down-playing the 'medical model' made it impossible to recruit psychiatrists, further distancing practice from the severely ill.

Most CMHTs are based in CMHCs sharing accommodation with other CMHTs and services (e.g. day care). They provide an important safeguard in sustaining clinical standards and reducing the professional isolation in dispersed community services. This is a particularly important safeguard for community teams which can otherwise easily become idiosyncratic and rigid in their practice if not forced into regular contact with others.

Multidisciplinary Community mental health teams (CMHTs)

Most community mental health services consist of varied forms of multidisciplinary CMHT consisting of psychiatrists, nurses, social workers and often psychologists, and occupational therapists. The staffing of these teams will vary but their strength is that regular meetings to assess and review the management of patients incorporates their varied professional perspectives and allocates tasks based on skills and needs. Developed initially in France and the United Kingdom and championed latterly in Italy they have seen further specialization from North America and Australia.

The generic sector CMHT ('The CMHT')

Who it is for

The CMHT is *the* fundamental building block of modern community mental health services. It originated as mental hospital catchment areas (often covering a whole city or county) were divided into sectors of 50–100 000 inhabitants to permit ongoing care. The aim was that it should be possible for most of the team to have some familiarity with most of its complex and long-term patients and to have some *personal* knowledge of its referrers and community resources. Current sector size in Western Europe ranges from 20–50 000 population, determined both by resources (shrinking as investment increases) and by the local configuration. As more specialized teams are established the CMHTs remit may be reduced and sector size consequently increased keeping its caseload fairly constant. 200–250 is considered the maximum for most teams to exploit multidisciplinary working. The number is less in services for highly complex and difficult patients.

CMHTs offer assessment and care for patients discharged from psychiatric units and those who cannot be adequately treated in primary care or in the private sector. They should prioritize severe mental illnesses (SMI—e.g. psychoses and severe affective disorders). However diagnosis is not all—complications from social adversity, personality difficulties, or substance abuse can make secondary mental health care necessary even for apparently 'minor' disorders. Tools to clarify this threshold[6] have been of limited use and most teams rely on clinical assessments. In countries with limited private care CMHTs also treat mild and transient disorders. CMHTs can be remarkably inefficient if little thought is given to their structure and thresholds. To work well, there needs to be agreement on their purpose, clientele and systems of management and they have often suffered from lack of clarity and leadership.

Staffing and management

CMHT staffing varies enormously and there is no uniform model. Teams of less than 6 can rarely provide comprehensive care or cross-cover while teams of more than about 12–15 start to become

unwieldy, overwhelmed with management and information transfer. CMHTs emphasize skill-sharing and a degree of generic working and have evolved an informal, democratic style[7] which often means confusion over clinical leadership (originally provided informally by senior medical staff). With increased staff numbers and treatment complexity 'team managers' now coordinate workload with a role which varies from the purely administrative to setting clinical priorities and supervising staff. Establishing a clear understanding of clinical leadership in CMHTs (without inhibiting initiative and creativity) is essential for effective functioning. If leadership and management are separated (common with a strong medical presence) the roles need to be well defined and relationships good.

Assessments

The key to good care is accurate assessment (see Chapter 1.8.1). Most commonly psychiatrists conduct initial assessments (usually in an outpatient clinic) and involve the team members in treatment. Increasingly other team members have taken a role in assessments, either individually or jointly with the psychiatrist. Although this issue generates strong feelings there is surprisingly little research into it. With highly developed primary care non-medical assessments may be effective but otherwise medical time should prioritize assessments. With severely ill patients home-based assessments pay considerable dividends.[8,9]

Case management

Most CMHT staff act as clinical case managers[10,11] with responsibility for coordination, delivery, and review of care for their patients. The caseloads of staff members should be explicitly limited (usually 15 to 30) and reviews recorded and systematic. In the United Kingdom this has been formalized as the Care Programme Approach.[12] Fig. 7.5.1 shows a care plan indicating a patient's needs or problems, the interventions proposed to meet them, who is responsible and who is informed, plus an agreed date for review. Such concise structured paperwork (as with the risk assessment and contingency plan (Fig. 7.5.2)) can be adapted to any service, coordinates complex care and serves as a natural focus for clinical reviews. The level of detail needs to be clinically (not managerially) determined.

Team meetings

CMHTs need 1–2 regular meetings (each usually 1.5–2 h) per week for both clinical and administrative business. The degree of structure depends on team style and remit.

(a) Allocation of referrals

Referrals can be allocated by who is first available or by matching the clinical problem against available skill and training. Time discussing allocations before assessment is generally unprofitable and most well-established teams delegate the task to the manager or a senior clinician.

(b) Patient reviews

*R*eviews should be held for (i) *new patients*, (ii) *routine monitoring*, and (iii) *discharge*. Reviews can range from simply reporting the problem and proposed treatment in uncomplicated cases through to detailed, structured, multidisciplinary case-conferences including other services (e.g. GP, housing, child protection). *New patient* reviews are an excellent opportunity for providing a broad, experienced overview, and ensuring rational and fair allocation to caseloads. *Routine monitoring* is often overlooked yet probably the most important for team efficiency. It should be systematic and not only responsive to crises and problems. It shapes and redirects treatment and identifies patients ready for discharge. The burden on individual staff members is regularly monitored. Routine monitoring is a legal requirement of the Care Programme Approach and good practice in all case management. *Discharge reviews* are an excellent opportunity for audit and learning within the team.

(c) Managing waiting lists and caseloads

Effective CMHTs need to guarantee prompt access. *Routine assessments* should be within 2–4 weeks. Sooner is rarely productive and delays above 3 weeks result in a rapidly rising rate of failed appointments.[13] *Urgent assessments* (most psychotic episodes) need to be seen within a week, usually within a couple of days. *Emergency assessments* are for those associated with immediate risk (e.g. hostile behaviour or suicidal intent) and need to be seen the same day.

A practical approach to waiting lists is to count the assessments in the preceding year and allocate routine appointments for 20 per cent more. Thus a team with 400 assessments the preceding year allocating nine slots a week will have one available weekly for emergencies. Rapid routine assessment reduces pressure for urgent and emergency referrals more efficiently than emergency rotas.

Communication and liaison

Team meetings ensure internal communication but CMHTs need good links with a wide network of professional colleagues. Structured liaison is advisable with primary care and general hospitals in addition to routine letters. Hospital links may be between specific CMHTs and wards or CMHTs may provide input to patients from their sectors in the absence of dedicated liaison psychiatry services.

(a) General practice liaison

Much of mental health care is delivered in primary care (see Chapter 7.8) and effective coordination is essential. GP liaison systems range from informal contact through to shared care and co-location of CMHTs in GP Health Centres.[14] An effective system comprises regular, timetabled meetings between the two teams or a 'link' CMHT member attending the GP health centre. Monthly meetings where shared and complex patients are discussed are highly time-efficient because of prompt problem solving and crisis anticipation. However it is important to be clear about responsibilities, fudging boundaries is risky.

(b) Liaison with other agencies

The same principles apply to liaison with other agencies (social services, housing, charitable, and voluntary sector providers). Whether regular meetings are cost-effective will depend on the volume of shared work but showing up and meeting people (even just once) pays enormous dividends in improved relationships and understanding. Professional confidentiality and information sharing is more sensitive.

Assertive Outreach (AO) Teams

The most replicated and researched specialist CMHT is the AO Team. The original US model[9] improved clinical and social outcomes with substantially reduced hospitalization at slightly lower cost.

CPA REVIEW

Patient's name: Jenny T	**CMHT: West Central**
Address: 56 Acacia Avenue	**Phone:**
Phone:	**New patient: ~~YES~~/NO**
Date of birth: 09.06.61	**If NO, date of review: 20.10.07**
GP: Dr Findlay	**Diagnosis:**
Phone:	**1…Major depressive disorder..... F 32 .0**
	2…… F __ __.__

You must consider the following: 1) Mental health, including indicators of relapse; 2) Physical health; 3) Medication; 4) Daytime activity; 5) Personal care / living skills; 6) Carers, family, children and social network; 7) Forensic history; 8) Alcohol or substance misuse 9) Cultural factors; 10) Housing/finances/legal issues.

Complete a **risk assessment** and include: **i) a crisis plan; ii) a contingency plan**

Assessed needs or problem	Intervention	Resp.of
1. Depressed mood, apathetic and self critical	• Regular home visits, assess mental state • Encourage compliance with antidepressants • Encourage activity – take to shops etc	BJ
2. Suicidal thoughts	• Explore severity (+/- plans) at each visit • Support mother and husband who are scared of suicidal thoughts	BJ/ Cons
3. Daughter's school problems	• Maintain links with class teacher • Keep family informed of her progress	BJ
4. Plan for recovery	• Link with support group when mood lightens • Help reapply for part-time cleaning job	BJ

Professionals involved in care:	✓ Dr	Psychologist	✓ CPN	OT	✓ SW	Ward Nurse	ACT	Other
Present at planning meeting:	✓ Dr	✓ Psychologist	✓ CPN	OT	✓ SW	Ward Nurse	ACT	Other

Fig. 7.5.2 Risk assessment and contingency plan.

AO teams (Box 7.5.1) are costly and consequently reserved for the most difficult ('hard to engage' or 'revolving-door') psychotic patients with frequent, often dangerous, relapses and poor medication compliance plus alcohol or drug abuse, significant personality difficulties, and offending behaviour.

AO emphasizes proactive outreach—visiting patients at home even when they are reluctant. It exploits enhanced team working with daily meetings and several members actively involved with most patients both for safety considerations and also reflecting patients' extensive needs. The culture is of very practical working (taking patients shopping, sorting out accommodation, delivering medicines daily if need be) well beyond traditional professional boundaries.

Despite strongly expressed convictions there is little evidence that AO teams need to slavishly follow the original model[15,16] and local clinical adjustments are both sensible and justified. If embedded in a comprehensive system there is little need for a 24 h service, most staff establish strong individual relationships with patients and caseloads are usually more than the recommended 1:10. Where CMHTs function well AO teams take only patients who cannot be stabilized despite their support.

If CMHTs provide outreach and a comprehensive treatment then the extra AO resources may add little. Improved outcomes follow only from additional effective treatments (e.g. daily Clozapine visits in resistant schizophrenia); it is not outreach itself that is therapeutic. Whether AO will improve care (and, if so, how many teams are needed for how many patients) will depend on current services.

Box 7.5.1 ACT core components

- Assertive follow-up.
- Small caseloads (1:10–1:15).
- Regular (daily) team meetings.
- Frequent contact (weekly to daily).
- *In vivo practice* (treatment in home and neighbourhood).
- Emphasis on engagement and medication.
- Support for family and carers.
- Provision of services using all team members.
- Crisis stabilization 24 h a day, 7 days a week.

Ethics in community mental health care

Balancing patients' welfare with their autonomy and their rights with those of their families and the wider community are sharply revealed in AO teams. These teams regularly visit patients who vigorously and clearly reject them. When does intensive support become intrusion? When does professional persistence tip over into coercion or disrespect?

Compulsion was traditionally identified with the buildings of the old asylums or left to the family (as it still is in many parts of the world). With expanded community care, compulsion, and coercion (either explicitly in the form of legal requirements or informally through professional or social pressure[17]) are now a pervasive feature of practice. Improved legal and professional scrutiny makes compulsory treatment possible in the community. Most developed countries have enacted forms of community treatment order ('mandated community treatment', 'outpatient committal') mainly for the care of young psychotic individuals

without insight into their need for ongoing treatment. The introduction of these provisions has generally been controversial but their operation not so.

Community treatment orders have the advantage of legal scrutiny unlike most of the ethical dilemmas facing CMHT and AO staff in their day-to-day work. These require discussion case-by-case. How proper is it to inform neighbours if a patient may pose a risk to them but will not give consent? Is it right for a patient, heavily dependent on his parents, to deny them information on his treatment? What does a case manager do when they know their client is doing something illegal? Most professionals share the goal of maximizing their patient's autonomy while minimizing significant risks. Guidelines exist only for extreme circumstances. Teams should be encouraged in regular discussion of these issues.

Crisis teams

Crisis teams play a crucial role where local services are poorly developed (they may be the *only* community services) or in city centres with many transient and homeless patients. They must prioritize rapid response and accessibility. Most teams will see patients immediately, certainly the same day. Their clinical aims and staffing are essentially similar to the acute functioning in CMHTs. They are best located alongside CMHTs or in the emergency rooms of general hospitals with 24 h availability. Liaison services (see Chapter 5.7) can often incorporate and manage hospital-based crisis teams.

Crisis Resolution/Home Treatment (CR/HT) Teams

The CR/HT team model, developed in Australia[18] and currently implemented in the United Kingdom and Europe, reflects increased consumer demand for access in crises and a desire to reduce inpatient care costs. It draws heavily on AO practice with limited, shared caseloads, flexible working, extended access, and an emphasis on outreach. Reduction in hospitalization offsets much of their cost[19] but this needs to be considerable as with two daily shifts and on call overnight needs a staff of about 15 for a caseload of 30 proposed for a population of 150 000.[20] They target patients who would otherwise be in hospital and focus on the severely mentally ill with intensive visiting (usually daily for a limited period) and considerable practical support and work with patients' social networks; most aim for a maximum of 6 weeks involvement. Such intensive team working requires highly effective communication and the teams meet daily (often twice at shift handovers). Information transfer is burdensome and liaison with CMHTs complex requiring absolute clarity on local arrangements for clinical responsibility.

Variations in practice and sustainability

The CR/HT teams may reduce the need for hospital care[18,21] but how much will vary. The UK model is precisely specified (including who it should and should not care for, Box 7.5.2) but practice varies considerably. A full 24 h service is rarely needed, an on-call facility to the emergency room and police station at night usually suffices. Contact frequencies are generally lower, patients stay with the service longer than anticipated and they are inevitably referred individuals recurrently in crisis (often with alcohol and relationship problems) who cannot easily be refused care but would not be 'otherwise in hospital'. Good medical staffing is needed and CMHT responsibilities need to be carefully negotiated, mutually agreed and crystal clear if to be avoided. These realities need to be carefully considered before deciding to establish such teams.

Box 7.5.2 Remit of UK Crisis Resolution/Home Treatment Teams[20]

'Commonly adults (16 to 65 years old) with severe mental illness (schizophrenia, manic depressive disorders, severe depressive disorder) with an acute psychiatric crisis of such severity that, without the involvement of the CR/HT team hospitalisation would be necessary'.

'The service is not usually appropriate for individuals with:

- *Mild anxiety disorders.*
- *Primary diagnosis of alcohol or other substance abuse.*
- *Brain damage or other organic disorders including dementia.*
- *Learning disabilities.*
- *Exclusive diagnosis of personality disorder.*
- *Recent history of self harm but not suffering from a psychotic or serious depressive illness.*
- *Crisis related solely to relationship issues'.*

Crisis services may have a relatively limited lifespan[22] but can be a very successful way to improve local access, gain familiarity with at-risk populations, and then consolidate as a more comprehensive service. Sometimes, however, they become overwhelmed with inappropriate referrals or patients who cannot be referred on and close.

Crisis houses and respite care

Crisis houses allow admission with a minimum of formality and often with reduced supervision compared to hospitals. They are usually small (4–8 beds) in a domestic setting and take people for days, occasionally a week or two. They are favoured for vulnerable women and early intervention services. Most have one staff member sleeping in overnight and a couple on during the day with support from patients' case managers. They are very welcome for a minority of patients but do not replace inpatient care and need careful supervision to avoid becoming chaotic or blocked.

Adjunct or replacement for CMHTs?

The three teams outlined above comprise the fundamental building blocks of most community services. AO and CR/HT teams have been proposed as substitutes for CMHTs, particularly when there are problems with local CMHTs. However both experience and research evidence[23] suggests that they are rarely durable without effective CMHTs to relate to. They should be considered to improve the quality of care in otherwise well-functioning services rather than cost-saving shortcuts.

Highly specialized and diagnosis-specific teams

There are various specialized teams, generally organized on a regional level. These are not essential local services but impact on

them—both in terms of removing some of the clinical obligations and the need to ensure clear and negotiable thresholds.

Early Intervention Teams (EIS)

Concern that a long duration of untreated psychosis (DUP) confers poorer prognosis[24] has led to the development of EIS teams which many would now argue should be standard provision. Developed mainly from Australian and UK models[25,26] they vary remarkably even despite a detailed prescription for UK teams. Some down-play diagnosis in favour of easy access, others restrict to schizophrenia, some emphasize a 'youth service' while others take all first episode patients irrespective of age.[7] Even more confusing there are three quite different activities which may, or may not, be part of the service (Box 7.5.3).

The core of EIS is a specialized CMHT which case-manages first episode psychosis patients protecting social networks and functioning (keeping patients at college or work, an emphasis on family interventions, etc.) assuming a return to premorbid functioning. Crisis and respite houses are preferred to hospital. Some EIS teams conduct public awareness campaigns, lecturing in schools and colleges.[27] A minority of research teams attempt to identify and treat 'ultra-high risk' patients to prevent progression to psychosis.[28]

Forensic and rehabilitation teams

Community-focused services face particular difficulties in treatment-resistant patients, particularly those with socially unacceptable or offending behaviour. Such patients fit poorly into open wards and specialized forensic teams provide care where offending behaviour and danger to others predominates. Some provide community services (intensive case management of dangerous patients) with an emphasis on risk assessment and management. Integrating them with general services can be problematical.

Rehabilitation

A significant number of patients remain disabled despite best treatments and require long-term management of disability rather than episode-based care. Rehabilitation teams generally serve patients who cannot survive without supervised accommodation even when at their best. They include the diminishing cohort of old long-stay patients and increasingly a very disturbed 'new long-stay' population with comorbid substance abuse and behavioural disturbances.

Diagnostic-specific teams

Highly specialized teams for individual disorders (e.g. eating disorders, personality disorders, bipolar patients) concentrate specific skills and provide specialized treatments and are usually provided at regional level. They usually have stronger advocates than CMHTs, both from professionals and families of sufferers, and the opportunity costs (see below) of establishing them need careful thought.

Box 7.5.3 Components of early intervention teams

- **Case management**—ongoing care of identified patients
- **Early Identification**—awareness-raising campaigns for psychoses
- **High risk and prodromal** patient identification and treatment

Planning services

Step-wise planning and adaptation

Planning mental health services for a given community rarely starts with a clean sheet. In such circumstances there are excellent texts, both general and specific to mental health. Tansella and Thornicroft's 'matrix' model[29] is particularly thorough and structured (see Chapter 7.2). It covers the process from establishing service principles and needs assessment (at national, regional, and local levels) through to monitoring and reviewing the cycle of planning and provision. They propose a hierarchical approach depending on the level of mental health spend.[30] Case identification and outpatient treatments in primary care are the priority for low income countries and only with increased resources the establishment of a secondary care mental health service (usually a form of generic CMHT). Not until these are well-established are specialist and inpatient services indicated. This process must, however, take account of what is already in place.

Local population needs assessment

Psychiatric morbidity varies considerably with social deprivation and is much higher in cities than in stable rural or suburban settings (see Chapter 2.7). At the regional and national level comparative need can be predicted fairly well from established indexes incorporating levels of migrants, overcrowding, poverty, etc. Catchment areas should broadly reflect these differences. At the more local level these figures are of limited value. How does one factor in travelling time or known differences in the quality of primary care? A process of negotiation is best to agree local allocation following these general guidelines. However a concentration of hostels for the mentally ill or homeless or the presence of a railway station or international airport may swamp these differences. These should be provisionally estimated in planning but then regularly monitored and reviewed.

Opportunity costs and unintended consequences

Planning mental health services has become based on international evidence, often including cost-effectiveness analyses, i.e. is there more overall patient health gain for the same input (see Chapter 7.7)? However these rarely address the opportunity costs across a whole system. For example one form of day hospital may be more cost-effective for its patients than another day hospital, but is diverting nurses from an inpatient unit to staff that day hospital a net gain? Rigorous intervention studies of large systems are formidably difficult to conduct and even more so to interpret.

The impact of enthusiasm and the migration of the best staff to such research services can be especially misleading.[31] Successful new services are always reported but there is less consistency in reporting when a service may have lost its efficacy or was abandoned.[5,22] It is best to visit examples of services that are proposed and not to always assume that what works for them will necessarily work for you.[15]

Manpower is often as significant a resource limitation as funding, hence the need for a system-wide appraisal. Also, though expressed as costs, these decisions include wider judgements of values and expectations rather than simply outcomes.[30] Local and national objectives also matter, not just clinical ones (e.g. public safety now dominates much mental health planning).

Cultures and funding

Health care cultures, their structures and their funding systems vary enormously. Services must be congruent with them otherwise they will not survive. Occasionally service planners can influence the system but more often have to adapt to it. Obtaining relatively small changes in funding arrangements (or external governance) can deliver quite major improvements. However caution is needed as unintended consequences and perverse incentives may arise. Enthusiastic clinicians are often blind to the risks of over-prescription which can lock in outmoded practices (e.g. a highly specific form of day hospital or crisis facility) that after opening is found not to have the level of need predicted but may be so rigidly prescribed that it cannot be adapted.

How 'integrated' mental health care should be is a highly local decision. Well-established systems often strive for integration with general medicine or, increasingly, with social services to reduce both discrimination and administrative barriers to integrated care. For less confident services the value of a distinct, separate, identity can be considerable—not least the ability to protect its resources. The 19th century British mental health reformer Lord Shaftsbury wrestled with the same dilemma.

The task of integration is easily underestimated, particularly the energies required to accommodate contrasting health and social care cultures. Social care, for example, tends to rely on very detailed paperwork and a highly structured system of intensive supervision (reflecting political accountability and previously only minimally trained workforce) as opposed to the high levels of professional autonomy in health care. Agreed compromises need to be reached before integration and the negotiations can be exhausting, but preferable to misunderstandings. The costs and benefits will depend very much on the local situation, relationships and history and should be very carefully weighed up.

Relationships with the voluntary sector and patients movement

Relations with local non-health statutory services (housing, education, police) and with the voluntary sector will determine much of the success of MH services. Voluntary and private sectors may fill specialist niches left by a monolithic public health care system (as with the NHS in the United Kingdom) or conversely the public system may act as a safety net, for charitable and private provision. Service planners need to exploit the strengths of local providers. Non-statutory services are often more efficient but less comprehensive and may also be less reliable over the long-term. Both may be equally reliant on public funding, differing only in contracts and degrees of independence. Patient and carer advocacy and support organizations are now a major force; effective working with them significantly will enhance both the design and delivery of services (see Chapter 7.9).

Monitoring and review

Careful monitoring and review are as important as careful planning for several reasons. The long-term, fluctuating nature of disorders, the subjective nature of diagnoses (increasingly self-ascribed) complicate outcome measures and the targeting of services; services can easily drift to those who demand them from those who most need them; treatments (particularly psychological and psychotherapeutic treatments) may evolve over time losing their effective characteristics; needy patients are rarely demanding or well-informed; engaging and motivating them to collaborate in long-term, treatments is difficult.

A consistent effort to deliver even the most basic, proven interventions will make a substantial difference to patient welfare. The PORT study in the United States demonstrated how schizophrenia care was strikingly inconsistent and fell below accepted essentials.[32] Regular audit ensures that services remain targeted on those for whom they were developed and that their application and quality remains good. Monitoring can vary in sophistication—from a simple head count of who is getting what through to careful evaluation of care pathways. The audit review process feeds back into the development process, adjusting and refining it. Even in the most hard-pressed services audit more than rewards its investment.

Routine outcome measures (ROM)

Audit brings rigour and reflection (often lost in the immediacy of the therapeutic relationship) into the care process. Measurement also serves a training purpose by benchmarking interdisciplinary understandings of symptoms and outcomes. Systematic, periodic recording of patients' clinical or social status is increasingly used in both planning and research. Structured outcomes can be generic (e.g. HoNOS[33]) or for specific disorders (e.g. the Brief Psychiatric Rating Scale[34]) or even locally developed. Their value lies in their consistency of use.

Conclusions

Planning and providing mental health services requires flexibility and compromise. Epidemiological and service statistics translate poorly to local planning; this remains primarily a practical and political, rather than academic, activity. The scientific evidence is dominated by Anglophone alternatives to hospital care studies but local history, culture, mental health law, and political imperatives cannot be ignored. Mediterranean societies, for example, with strong family supports and fewer isolated psychotic individuals have less interest in AO teams. A high-profile patient homicide, or a strong public endorsement of services by politician or celebrity, can derail years of careful planning.

This chapter has attempted to draw out some principles (Box 7.5.4) for the process but these can only be guidelines. Inevitably the decision will be based on what is *possible* locally. Despite this most solutions draw on a limited number of tried and tested structures described here in some detail. Their balance and configuration depend on what is available for them and around them. Above all the mentally ill and their families deserve reliable and predictable services. Not all change is innovation and research findings should be judged in terms of their sustainability and demonstrated translation from research efficacy to clinical effectiveness.

Box 7.5.4 Developing local community mental health services

- Make a careful inventory of what services exist, and any special local needs.
- Consult locally and invest heavily in building coalitions with policy makers, statutory services, and voluntary groups.
- Test research evidence for durability and relevance. If possible visit established services and ask 'around the service'.
- Monitor and review regularly. Improved consistency of current practice often delivers more than introducing new treatments.
- Consider carefully opportunity costs. Include both the impact of a specific improvement across the whole service and the costs of system change itself.
- Avoid excessive reorganization—not all change is innovation.

7.6

Evaluation of mental health services

Michele Tansella and Graham Thornicroft

Introduction

Evaluation is the basis for improving care to people with mental illness. It is vital to know whether interventions are beneficial or harmful, and whether they offer value for money. Mental health interventions need to be understood both in terms of their active ingredients and how they fit within their context.[1] Such combined interventions, often including pharmacological, psychological, and social elements, are the epitome of 'complex interventions'[2] and their evaluation poses considerable challenges. In this chapter we shall discuss *definitions* of evaluation, and go on to discuss *why* evaluate, *what* to evaluate, and *how* to evaluate mental health services. In our conclusion we shall offer an indication of the most important trends in this field in the coming years. The overall approach that we take is centred upon the idea that ongoing evaluative research is of fundamental importance in discovering which interventions are effective, neutral, or harmful, and that such information is essential to deliver better mental health care.

Evaluation: definitions and conceptual framework

The *Concise Oxford English Dictionary*[3] gives the following definitions of 'evaluation':

evaluate (*verb transitive*) **1**. assess, appraise; **2a**. find or state the number or amount of; **2b**. find a numerical expression for.

evaluation (*noun*) **1**. appraisal, valuation, assessment; **2**. estimate, estimation, approximation, rating, opinion, ranking, judgement, reckoning, figuring, calculation, computation, determination.

The etymological root of the word therefore refers directly to 'value', although in common usage 'evaluation' now has a more technical connotation. In our view evaluation necessarily requires both the precise measurement of the effects of treatments or services, alongside a contextual understand of the meaning, and value of such results.

A conceptual model that can be used to clarify key issues related to the evaluation of mental health services is the Matrix Model.[4,5] The two *dimensions* of this model are place and time (see Table 7.6.1). Place refers to three geographical levels: (1) country/regional, (2) local, and (3) individual. Time refers to three phases: (A) inputs, (B) processes, and (C) outcomes. In this framework *inputs* relates to all those resources which are necessary before health care can take place (such as financial and human resources, policies, and treatment guidelines), *processes* refers to all those activities which constitute the delivery of health care (such as outpatient consultations, or hospital admissions), while *outcomes* refers to the consequences of health care (such as changes in symptoms, disability, and quality of life). In relation to the evaluation of mental health services, we shall illustrate in this chapter how inputs and processes need to be measured and understood in their contribution to the outcomes of care.

Historically, the first attempts to evaluate psychiatric practice originated in the mid-nineteenth century as the tabulation of admissions, discharges, and deaths in mental hospitals, simply describing the inputs and processes of care. In recent decades, as more sophisticated research methodologies and more valid and reliable research measures have been developed, so the evaluation of mental health services has increasingly focussed upon the analysis of the outcomes of care. As Sartorius has put it, 'In its most classical form, evaluation denotes a comparison between results and goals of activity',[6] indicating that evaluation has now become a purposeful exercise in which measurements are used as tools to answer specific questions, usually defined a priori at the beginning of a scientific study.

Why evaluate mental health services?

In our view, the main purposes of mental health service evaluation are to assess the effectiveness and cost-effectiveness of care, either at the organizational (local) or at the patient (individual) level. In the long-term such evidence can be used to provide better services for people with mental illness. For example, evaluation can be applied to comparing differing models of care, such as studies in England showing that home-treatment teams can provide a realistic alternative to emergency hospital admission.[7–9] Evaluation therefore measures the impact of care (outcomes) and also aims to increase understanding of the active ingredients (inputs and processes) which contribute to better outcomes.[1] In fact, a wider range of purposes can be served by the evaluation of mental health services, as shown in Table 7.6.2.

What to evaluate in mental health services?

In our view the most important focus of evaluation is upon the *outcomes* of care.[10,11] The outcome chosen for any particular

Table 7.6.1 Overview of the Matrix Model, with examples of inputs, processes, and outcomes

Place dimension	Time dimension		
	(A) Input phase	(B) Process phase	(C) Outcome phase
(1) Country/regional level	1A Mental health budget allocation Mental health laws Government directives and policies Training plans for mental health staff Treatment protocols and guidelines	1B Performance/activity indicators (e.g. admission rates, compulsory treatment rates)	1C Overall suicide rates Homelessness rates Imprisonment rates Years lived with disability
(2) Local level	2A Local service budgets and balance for hospital and community services Local population needs assessment Staff numbers and mix Clinical and non-clinical services Working relationships between teams	2B Service contacts and patterns of service use Pathways to care and continuity Targeting of services to special groups	2C Suicide rates among people with mental illness Employment rates Physical morbidity rates
(3) Individual level	3A Assessments of individual needs made by staff, service users, and by families Therapeutic expertise of staff Information for service users Information for family members	3B Content of therapeutic interventions (both psychological, social, and pharmacological) Continuity of clinical staff Frequency of appointments	3C Symptom severity Impact on caregivers Satisfaction with services Quality of life Disability Met and unmet needs

evaluation will depend upon the central question addressed and the level at which outcomes are assessed, as shown in Table 7.6.3.

Directly in relation to the population level, a frequently used outcome measure is suicide rate (see cell 1C in Table 7.6.1). Rates of homelessness among mentally ill people (or rates of mental illness among the homeless) can also be used as an outcome indicator of the effectiveness of mental illness policies at the national (or regional) level.

At the local level, outcome indicators useful for evaluation can be made in three ways: (i) by interpolating from regional/national data; (ii) by measuring directly at the local level; and (iii) by aggregating individual-level information up to the local level. For example, rates of suicide and unemployment can be estimated using the first method, or directly measured using the second approach if the appropriate data and resources exist, which will provide more accurate and up-to-date information. The third approach is to aggregate up to the local level information gathered from individual patients, if institutions providing care to those local patients are willing to cooperate in integrating their datasets.

At the individual level mental health service evaluation increasingly acknowledges the importance of outcomes other than symptom severity.[10,11] Traditionally, **symptom severity measures** have been used most often to assess the effectiveness of the early, mental health treatments. Psychiatrists and psychologists have contributed to the early development of such assessment scales to allow this

Table 7.6.2 Main purposes of mental health service evaluation

- To assess the outcomes of services in experimental conditions (*efficacy*)
- To investigate whether interventions which have demonstrated *efficacy* under experimental conditions are also *effective* in ordinary, routine clinical conditions
- To understand the mechanism of action (i.e. active ingredients) of interventions
- To inform mental health service investment decisions, for example using health economic data on cost-effectiveness
- To raise awareness among planners, policy makers, and politicians of service gaps
- To test a priori or to check *post hoc* the value of planning decisions (for example, the closure of mental hospitals)

Table 7.6.3 Outcome measures suitable for use in routine clinical practice

Outcome measure	Place dimension		
	Country level	Local level	Individual level
Employment status	√	√	√√
Physical morbidity	√	√	√
Suicide and self-harm	√√	√	√√
Homelessness		√	√√
Standardized mortality ratios	√	√	
Symptom severity		√	√√
Impact on caregivers		√	√
Satisfaction with services		√	√√
Quality of life		√	√
Disability		√	√√
Met and unmet needs for care		√	√

Key: √ = suitable for use as an outcome, √√ = commonly used as an outcome.

research to take place.[10,11] While the primary symptoms are clearly important, for most of the more severe mental disorders there is symptom persistence, and, at present, it is unrealistic to see symptom eradication as the sole aim of treatment. Therefore, very often, after the point of maximum symptom relief, when the extent of the ongoing impairments is clear, then the clinical task becomes one of attempting to minimize the consequent disability and handicap.

The importance of the **impact of caring** for people with mental illnesses upon family members and others who provide informal care has long been recognized, but has only been subjected to concerted research relatively recently.[11–13] Such research has shown that it is common for carers themselves to suffer from mental illnesses, most commonly depression and anxiety, and to worry about the future when they may no longer be able to cope. Moreover, many family members are most distressed by the patient's underactivity, and are often poorly informed about the clinical condition, its treatment, and the likely prognosis, as well as being inadequately provided with a practical action plan of what to do in the future should a crisis occur. Indeed, some services continue to convey to families the outmoded idea that carers, especially parents, are in some way to blame for the disorder or for relapses of the condition. The regular provision of information sessions for family members is now a hallmark of a good practice.[14,15]

Patients' **satisfaction with services** is a further domain that has recently become established as a legitimate, important, and feasible area of outcome assessment.[16] This is a recognition of the contribution that service users and their carers can make to outcome assessment. Psychometrically adequate scales in this field are those that adopt a multidimensional approach, assess the full range of service characteristics, are independently administered (so that patient ratings have no consequences upon their future clinical care), and have established validity and reliability.[17]

Quality of life ratings have also become prominent during the last decade, and several scales have been constructed that reflect different basic approaches to the topic.[18] The first distinction is between scales that address subjective well-being, compared with those that also measure objective elements of quality of life. The second main point of differentiation is between scales constructed for the general population and those designed for patients suffering from specific disorders, including the more severe mental illnesses.[19] One advantage of quality of life data is that they tend to be popular with politicians, for whom the concept often has powerful face validity.

Among people with longer-term or more complex mental illnesses, the measurement of **disability** is often an important consideration.[20] Increasing importance is also being attached to the **needs** of people with mental illness, where met needs are difficulties faced by people with mental illness in the presence of appropriate interventions.[21] Needs (both met and unmet) may be defined by professionals/experts, or by service users, and in fact there is emerging evidence that service user ratings may be more informative, for example in predicting quality of life.[22–24]

Psychometric properties of outcome measures

Establishing the psychometric qualities of scales used for service evaluation is a central issue.[4] Among the most important characteristics of outcome scales are validity and reliability. Validity refers to whether a scale actually measures what it is intended to measure. It is conventionally assessed in terms of face validity, content validity, consensual validity, criterion-related validity, and construct validity.

In addition, a rating scale must give repeatable results for the same subject when used under different conditions, i.e. it must be reliable. There are four widely used methods to gauge reliability: inter-rater reliability, test–retest reliability, parallel-form reliability, and split-half reliability. The main issue for the evaluation of mental health services is to use wherever possible scales with known and adequate psychometric properties.

How to evaluate mental health services

In this section we consider research designs that may be applicable to the range of contexts used in mental health service evaluation.[1] Different types of evidence produced using these designs cannot be considered as equivalent. A hierarchical order has been proposed by Geddes and Harrison[25] as shown in Table 7.6.4.

In terms of research methods or designs which can be used to produce such evidence, they can be considered as: (i) randomized controlled trial (RCT), (ii) quasi-experimental studies, (iii) case-control studies, (iv) cohort studies (prospective or retrospective), (v) cross sectional studies, and (vi) case series and single case studies. Since evaluations of mental health services are usually concerned with complex interventions, it is helpful to have an overall scheme linking different stages of research to test treatment interventions. The Medical Research Council (MRC) framework for the evaluation of complex interventions sets out one such sequence, as shown in relation to anti-stigma interventions in Table 7.6.5. The elements in this scheme can be considered as sequential, or stages 0, 1, and 2 can be seen as one larger iterative activity.[1] Nevertheless, although this gives salience to randomized controlled trial designs, it is important to appreciate that research study designs need to be matched to the purpose of each type of evaluation, as shown in Table 7.6.6.

Evidence from a meta-analysis of randomized controlled trials

Meta-analysis can be defined as 'the quantitative synthesis of the results of systematic overviews of previous studies', while systematic overviews, in turn, are methods of collating and synthesizing all the available evidence on a particular scientific question.[26] Since randomized controlled trials are often considered to produce the most sophisticated evidence on the efficacy of medical treatments,

Table 7.6.4 Hierarchy of evidence

1a	Evidence from a meta-analysis of RCTs
1b	Evidence from at least one RCT
2a	Evidence from at least one controlled study without randomization
2b	Evidence from at least one other type of quasi-experimental study
3	Evidence from non-experimental descriptive studies, such as comparative studies, correlation studies, and case-control studies
4	Evidence from expert committee reports or opinions and/or clinical experience of respected authorities

(Reproduced from J.R. Geddes, and P.J. Harrison, Closing the gap between research and practice, *The British Journal of Psychiatry*, **171**, 220–5, copyright 1997, The Royal College of Psychiatrists.)

Table 7.6.5 Phases of the Medical Research Council framework for the evaluation of complex interventions[1,2]

0 Preclinical	1 Modelling/manualization	2 Exploratory	3 Definitive trial	4 Long-term implementation
Explore relevant theory to ensure best choice of intervention and hypothesis and to predict major confounders and strategic design issues	Identify the components of the intervention and the underlying mechanisms by which they will influence outcomes to provide evidence that you can predict how they relate to and interact with each other	Describe the constant and variable components of a replicable intervention and a feasible protocol for comparing the intervention with an appropriate alternative	Compare a fully defined intervention with an appropriate alternative using a protocol that is theoretically defensible, reproducible, and adequately controlled in a study with appropriate statistical power	Determine whether others can reliably replicate your intervention and the results in uncontrolled settings over the long-term
Example: anti-stigma intervention in schools study				
Social contact theory[69]	Yes	Completed[70]	Planned	Potential if preceding phases successful

a meta-analysis conducted on well selected and relevant randomized controlled trials can be seen as the highest order of knowledge. It follows that the quality of systematic overviews is limited by the quality and quantity of the contributory trials (see Table 7.6.7).[27]

Cochrane was the first to emphasize the need to bring together, within specific categories, the results of randomized controlled trials.[28] This approach is now central to evidence-based medicine. Within psychiatric evaluation the first meta-analyses were conducted in the late 1970s, and more information is given on systematic reviews in Chapter 1.10 and 6.1.

An illustration of such an exercise is the systematic overview and meta-analysis is that which reviewed RCTs comparing the outcomes of community mental health teams with those of standard care for patients with severe mental illness and disordered personalities.[29,30] They found 1200 citations using the search strategy: 70 appeared relevant to the review, but only four studies satisfied the inclusion criteria. The main results of this systematic review are that community mental health team management is associated with fewer deaths by suicide, with fewer people being dissatisfied with services or leaving the studies early. No clear difference was found in admission rates, overall clinical outcomes, or in the duration of inpatient hospital treatment. The authors concluded that community mental health team management is not inferior to non-team standard care in any important respects, and is superior in promoting greater acceptance of treatment. It may also be superior in reducing hospital admissions and avoiding deaths by suicide.

The randomized controlled trials

The importance of randomized controlled trials within medical research has been expressed by Korn and Baumrind:[31] 'Randomized clinical trials are the sine qua non for evaluating treatment in man'. According to Barker and Rose: 'the essence of the randomized controlled trial is that the outcome of the treatment given to one group of patients is compared with one or more other groups who are given different treatments or none at all. Allocation of individuals to the treatment and comparison groups is by random selection'.[32]

Table 7.6.6 Research aims and appropriate study designs

Research aim	Appropriate study designs
Service description	Cross sectional survey
Assess intervention	Quasi-experimental study (e.g. controlled before–after comparison) Randomized controlled trial
Identify prognosis for a condition	Cohort study
Establish aetiology of a condition	Cohort study Case-control study

The advantages of the research design of these studies have been extensively described[33] and are shown in Table 7.6.8 (see also Chapter 1.10 in this book). However, the design limitations of such trials also need to be appreciated, particularly in relation to health service research, as shown in Table 7.6.9.[34]

In addition to the technical limitations of the trial design, there are also situations where randomized controlled trials are not applicable to specific research questions. These can be summarized as conditions in which randomized controlled trials are inadequate, impossible, inappropriate, or unnecessary, as shown in Table 7.6.10. Nevertheless, where they are appropriate, it will be necessary to use explicit criteria to assess the quality of such trials, such as those shown in Table 7.6.11.[35,36]

It is now common to distinguish between *efficacy trials* (which tend to be explanatory) and *effectiveness trials* (sometimes otherwise called large simple, pragmatic, practical, or management trials).[33,37–39] This categorical distinction has its uses, although

Table 7.6.7 Characteristics of systematic overviews

Questions to ask about papers for potential inclusion in a systematic overview

- Were the questions and methods clearly stated?
- Were comprehensive search methods used to locate the relevant articles?
- Were explicit methods used to determine which articles were included in the review?
- Was the methodological quality of the primary studies assessed?
- Were the selection and assessment of the primary studies reproducible and free from bias?
- Were the differences in individual study results adequately explained?
- Were the results of the primary studies combined appropriately?
- Were the reviewer's conclusions supported by the data cited?

(Reproduced from S.I. Sackett and J.E. Wennberg, Choosing the best research design for each question, *British Medical Journal*, **315** (7123), 1636, copyright 1997, BMJ Publishing Group Ltd.)

Table 7.6.8 Advantages of RCTs

- Controls for many confounding variables which may exist
- Eliminates the effects of spontaneous remission
- Eliminates regression to mean
- Eliminates placebo effect
- Independent of rater bias if blindness maintained
- Basis for systematic reviews

for some purposes we may rather see efficacy and effectiveness trials as falling along a continuum. Efficacy trials, which usually precede effectiveness studies, refer to those conducted under more ideal, experimental conditions, while effectiveness trials are RCTs carried out in more routine clinical conditions.[28,40–42] Nevertheless, some important questions, for example the impact of clinical guidelines, may only be researchable in real world settings, and will therefore bypass the efficacy study stage.[43]

Cochrane has defined effectiveness, at the patient level, as assessing whether an intervention does more good than harm when provided under usual circumstances of health care practice.[28] At the level of service provision, Wells has defined effectiveness trials as those which 'duplicate as closely as possible the conditions in the target practice venues to which study results will be applied'.[44] The key differences between efficacy and effectiveness trials are shown in Table 7.6.12, although in practice the differences between these types of trial may not necessarily be as great as the differences between pharmacological, psychological, and service interventions

Table 7.6.9 Limitations and disadvantages of RCTs designs

1. Difficulties in choosing the unit or level of random allocation
   - Should allocation be made at the patient level, the clinician level, the clinical team/practice level, or the locality level?
2. Difficulties in achieving random allocation
   - Randomization not possible
   - Particular patient groups excluded
   - Self-exclusion because of non-consent
3. Difficulties in obtaining consent and in maintaining motivation
   - Consent may be inversely proportional to severity of condition
   - Consent may be refused because of patient treatment preferences
   - Retention with the trial may be affected by patient motivation
4. Difficulties in establishing and maintaining blindness
   - Degree of blinding of subjects
   - Degree of blinding of staff
   - Degree of blinding of raters
   - Deactive Hawthorne effect (the effect of being studied upon those being studied)
5. Difficulties related to the experimental conditions
   - Concurrent multiple interventions in health service research trials (without a single potentially active ingredient)
   - Interactions between treatment components
   - Consistency of control ('usual treatment') conditions
   - High attrition rates or loss to follow-up

   Large differences between conditions in which trials can take place and those of routine practice

Table 7.6.10 Situations when RCT designs are not applicable

1. Situations in which experimentation is inadequate
   - Poor generalizability—low external validity
   - Unrepresentative staff included
   - Atypical patients included
   - Treatments not standardized
2. Situations in which experimentation is impossible
   - Refusal of clinicians to take part
   - Ethical objections to the study
   - Political barriers
   - Legal objections
   - Contamination between experimental and control conditions
   - Scale of task—trials are required for too many treatments
3. Situations in which experimentation is inappropriate
   - Studies conducted to reduce the occurrence of events of very low frequency
   - Studies to prevent unwanted outcomes in the distant future
4. Experimentation unnecessary
   - When benefit/risk ratio is dramatic
   - When there is a small likelihood of confounders

(Reproduced from N. Black (1996), Why we need observational studies to evaluate the effectiveness of health care, *British Medical Journal*, **312** (7040), 1215–18, copyright 1997, BMJ Publishing Group Ltd.)

(such as the dissemination, and related barriers, of proven interventions).[45–47]

In planning effectiveness RCTs, seven sets of issues need to be carefully considered: (i) study question (e.g. is the study question expressed in an answerable way?), (ii) reference population (e.g. what is the reference group or subgroup to which the trial results should be generalized?), (iii) patient sample (e.g. how far does the sample reflect the target population?), (iv) study settings (e.g. how representative are the study settings of routine clinical sites?), (v) study interventions (e.g. is the study intervention manualized, acceptable to patients, and suitable for widespread use?), (vi) control condition (e.g. are the key characteristics of the control condition well described, and do they vary within and between sites?), and (vii) bias (e.g. attrition, blinding, concealment, consent, and

Table 7.6.11 Criteria to evaluate the quality of an RCT

Criteria
1. Is the hypothesis clearly defined?
2. Is the study population representative?
3. Was patient assignment randomized?
4. Were patients, practitioners, and assessors blind to the experimental intervention?
5. Were the groups similar at the start of the trial?
6. Were the groups treated equally apart from the experimental intervention?
7. Were all those who entered the trial accounted for at its conclusion?
8. Was this in the groups to which they were originally allocated?
9. Are all clinically important outcomes considered?
10. Whose perspective do they reflect?
11. Is the data analysis appropriate?
12. What is the size and precision of the treatment effect?
13. Do the likely benefits outweigh the harms and risks?
14. Is the conclusion supported by the results?

Table 7.6.12 Key differences between efficacy and effectiveness trials

	Efficacy trials	Effectiveness trials
Goal	To estimate efficacy and safety (if relevant) usually of a specific clinical intervention	To estimate relative benefits and risks of approved treatments, clinical interventions, programmes, or policies
When	Usually before an intervention is introduced	Post-implementation
Diagnosis	Diagnosis by structured interview	Clinical diagnosis or structured interview
Inclusion and exclusion criteria	Strict and multiple inclusion and exclusion criteria, typically excluding patients with comorbid physical and psychiatric disorders	Relatively few inclusion and exclusion criteria to optimize external validity of sample
Patient sample	Typically enrol highly motivated patients	Attempt to include more representative patients, including those who are ambivalent and who may not adhere to the allocated treatment regime
Sample size	At most a few hundred, more often less than 100	Often larger to enable smaller effect sizes to be identified in heterogeneous populations (e.g. in large simple trials with dichotomous outcomes)
Comparator	Placebo and/or single active comparator (for drug trials) Treatment as usual or active control (for psycho-social interventions)	One or more active comparators (for drug trials) Treatment as usual or active control (for psycho-social interventions)
Dosing	Fixed or flexible	Flexible dosing in clinically used range
Blinding	Triple-blind (i.e. patients, staff, and researchers blind), or double-blind	Double-blind (where possible), or single-blind
Duration	1–4 months	6 months or more
Research sites	Small number of experienced research sites	Dozens of routine treatment sites
Delivery of intervention	According to manual or protocol, not a focus of research	Fidelity to manual a key variable, and study may consider barriers to delivery of intervention in routine practice[47]
Research protocol	Strictly defined	Deliberately similar to usual practice
Adjunctive treatments	Not allowed or strictly limited	Allowed as in usual practice
Outcomes	Symptom rating scales and other clinical parameters	A single well-defined, clinically important outcome (for large simple trials) and multiple secondary outcomes, including safety and costs (for practical trials)

(Reproduced from S. Stroup, Practical clinical trials for schizophrenia, *Epidemiologia e Psichiatria Sociale*, **14**, 132–6, copyright 2005 Il Pensiero Scientifico Editore.)

contamination). These issues are shown in more detail in Tables 7.6.13 and 7.6.14.[48]

Quasi-experimental studies

The term 'quasi-experiment' was first used to refer to a situation in which the decision about whether an individual does or does not receive the intervention to be evaluated is not under the investigator's control.[49] Random allocation of patients is therefore not made, so selection bias may occur. In other respects, a quasi-experiment aims to apply the logic of randomized controlled trials to the study design, and the researcher tries to reduce this bias by making the study units, in the groups being compared, as alike as possible in terms of the most important characteristics. This approach is known as ***matching***. Characteristics chosen for matching are those expected to influence the outcome (i.e. confounding factor). Therefore, the overriding aim of matching is to reduce the contribution made by the matched variables to the selection bias, although this method is inferior to randomization in that it cannot reduce the selection bias from all other variables.

There are two main approaches to matching. ***Paired matching*** consists of selecting individuals for the comparison group (or groups) who have closely similar characteristics to those included in the experimental group, for example in terms of age, gender, and occupation. This form of prestratification will need to be taken into account at the data analysis stage. A less rigorous variant is *group matching*, which only ensures that there are similar overall proportions of people, for both the experimental and comparison groups, in the various age bands, occupational groups, or other predefined strata used for the variables chosen for matching.

Non-experimental descriptive studies

The next type of research design included in the hierarchy of evidence is non-experimental descriptive studies. For the sake of clarity and brevity we shall distinguish two types of descriptive study: structured clinical practice and everyday unstructured clinical practice. An example of a descriptive evaluation design is the South Verona Outcome Study.[50,51] This is a prospective study, which aims to

Table 7.6.13 Criteria to plan effectiveness randomized controlled trials[48]

1. Study question
   - Who defines the aim of the study?
   - What process is used to identify the question addressed?
   - Is the study question expressed in an answerable way? (as a clear hypothesis)
   - Prior evidence of intervention effect size
   - Is the answer to this question really unknown?
   - Why is this question important now?
   - Is there initial evidence from efficacy trials or effectiveness studies? (observational or trials)
   - What is the public health importance of the policy or practice question addressed?
   - What is the clinical necessity of the question?
   - Sample size and statistical power for primary/secondary aims and related hypotheses
2. Reference population
   - What is the reference group (or subgroup) to which the trial results should be generalized?
   - What are their socio-demographic and clinical characteristics?
   - What are the ethnic and cultural characteristics of the target group?
   - What is resource level in this population?
   - What is the nature and standard and coverage of health and social care?
   - At what time point is population identified?
3. Patient sample
   - What are their socio-demographic, and clinical characteristics?
   - What are the inclusion criteria?
   - Not invited to participate rate
   - Non-participation rate
   - Patient preferences
   - What are the exclusion criteria?
   - How far does the sample reflect the target population?
   - What level of heterogeneity is there?
   - Selection of incident or prevalent cases (true incidence/prevalence or treated incidence/prevalence)
   - What are the rates of adherence and non-adherence to treatment as recommended?
4. Study settings
   - Characteristics and representativeness of professional staff
   - Levels of resources available
   - Research oriented culture
   - Staff morale and sustainability of intervention
   - Incentives for research collaboration
   - Opportunities for data linkage
   - Centre/professional non-participation
5. Study intervention
   - Is intervention acceptable?
   - Total time needed to deliver intervention
   - Frequency of interventions
   - Simplicity/complexity of the intervention
   - Single/multi-component intervention
   - Is intervention manualized?
   - Do usual professional staff deliver the intervention during the study?
   - Can treatment process be measured? (fidelity)
   - Degree of fit/feasibility for current practice
   - Exit strategy, who pays after the end of study
6. Control condition
   - Treatment as usual or specific control
   - Acceptability to patients of control condition
   - Cost and feasibility of control condition
   - Variation between control condition within and between sites (fidelity)
   - Are the key characteristics of the control condition well described?
7. Bias
   - Does contamination take place?
   - Degree of blinding
   - Choice of primary and secondary outcomes
   - Perspectives prioritized in outcome choice
   - Time(s) at which outcomes measured
   - Total length of follow-up and late effects
   - Sources of outcome data
   - Respondent burden
   - Consent rate
   - Recruitment rate
   - Attrition/drop-out and follow-up rates

(Reproduced from Tansella, M. Thornicroft, G., Barbui, C. *et al.* Seven criteria for improving effectiveness trials in psychiatry. *Psychological Medicine*, **36**(5) 711–200, copyright 2006, Cambridge University Press.)

assess the outcome of mental health care. Data from this study have been analysed using a multidimensional perspective. Among 354 patients followed up after 6 years of treatment in routine clinical settings the study revealed a complex pattern of emerging and disappearing clinical and patterns of exacerbation and remissions, with both changing frequently over time, but changes in both clinicial and social domains were not associated with diagnosis.[52]

Conclusions

Over the course of the next decade we expect that the following key trends will be of paramount importance. In relation to the focus of research, in many countries a degree of contestability may well develop, in which those who have traditionally identified questions to be addressed by research (investigators) will be challenged by research funders (such as governments and charities) and by the intended beneficiaries of the research (people with mental illness and their family members) to set the research agenda.[53] We can expect governments to direct their research investment towards policy challenges, such as barriers to the implementation of evidence-based practice.[54–56] This may well include the commissioning of research not just on new treatments and services, but also to evaluate already or even long-established models of care. For example, there is relatively little mental health service evaluation about: outpatient services (clinics), inpatient services, or forensic service provision.[57,58] In future, it will be important to evaluate *post hoc* current but unproven service configurations, particularly those that are widespread and expensive, as well as innovative interventions. This will necessitate providing sufficient long-term funding for health service research.

In terms of study design, we anticipate that there will be a relative growth of effectiveness studies, especially RCTs, which attempt to balance internal and external validity.[48] These will more often than in the past specify the precise nature of the control condition, use representative patient samples, and standardized outcomes measures. Less common study designs, such as cluster and preference RCTs will be necessary to tackle complex interventions.[59,60] The recent trend to more often include qualitative assessments

within RCTs we expect to accelerate, for example to identity the acceptability of interventions to patients, and to identify the active ingredients (and barriers) to treatment effectiveness.[61–65]

How will the conduct of evaluations of mental health services evolve in the coming years? We can identify a trend for study interventions to be increasingly often manualized. At the same time the patient populations treated will be more often similar to those treated in routine clinical practice. As a consequence, more attention will need to be paid to ways to incentivize clinical staff to participate in research.

Although traditionally research scientists have seen the dissemination of research findings largely in terms of publications in scientific journals,[66] it is likely that research funders will increasingly encourage or even insist upon using effective and target-specific communication methods to reach key audiences with the results of research and their implications, including non-traditional methods such as social marketing.[67] This will be intended to alter the behaviour of service planners, commissioners, practitioners, and service users, so that the results of research do influence the behaviour of these key groups in terms of service decisions, so that they increasingly reflect the evidence both of effective interventions and where the evidence shows lack of effect then to stop ineffective practices and services. Such behaviour change (and an established evidence base for this) may include methods as social marketing, as well as carefully combined interventions such as those used in case management in the treatment of depression.[68]

Table 7.6.14 Key challenges to the evaluation of mental health services

Focus of research
◆ Clarifying who is defining research questions
◆ Including service users and family members in setting research questions
◆ Asking clear research questions to answer important clinical challenges
◆ Evaluating already established as well new services
◆ Providing sufficient funding for long-term health service research
Study design
◆ Balancing internal and external validity of mental health service evaluation
◆ Moving from efficacy to effectiveness trials
◆ Specifying the precise nature of the control condition
◆ Using representative patient samples
◆ Using standardized outcome measures
◆ Combining qualitative and quantitative information
Conduct of research studies
◆ Manualizing the interventions to be evaluated
◆ Specifying the key characteristics of the patient groups to be treated
◆ Incentivizing clinical staff to participate in research
Data analysis and interpretation of findings
◆ Identifying the active ingredients of effective interventions
Dissemination of research findings
◆ Using effective and target-specific communication methods to reach key audiences with the results of research and their implications
Implementation of effective interventions
◆ Implementing the results of evaluation when the evidence is strong enough and decommissioning ineffective practice

Economic analysis of mental health services

Martin Knapp and Dan Chisholm

Introduction

Economics is concerned with the use and distribution of resources within a society, and how different ways of allocating resources impact on the well-being of individuals. Economics enters the health sphere because resources available to meet societal needs or demands are finite, meaning that choices have to be made regarding how best to allocate them (typically to generate the greatest possible level of population health). Economics provides an explicit framework for thinking through ways of allocating resources.

Resource allocation decisions in mental health are complicated by the fact that disorders are common, debilitating, and often long-lasting. Epidemiological research has demonstrated the considerable burden that mental disorders impose because of their prevalence, chronicity, and severity: globally, more than 10 per cent of lost years of healthy life and over 30 per cent of all years lived with disability are attributable to mental disorders.[1] Low rates of recognition and effective treatment compound the problem, particularly in poor countries.

However, disease burden is not in itself sufficient as a justification or mechanism for resource allocation or priority-setting. A disorder can place considerable burden on a population but if appropriate strategies to reduce this burden are absent or extremely expensive in relation to the health gains achieved, large-scale investment would be considered misplaced. The reason is that scarce resources could be more efficiently channelled to other burdensome conditions for which cost-effective responses *were* available. For priority-setting and resource allocation, it is necessary to ask what amount of burden from a disorder can be avoided by using evidence-based interventions, and at what relative cost of implementation in the target population.

Cost and cost-effectiveness considerations enter into health care reform processes, priority-setting exercises within and across health programmes, and regulatory decisions concerning drug approval or pricing. Two broad levels of economic analysis can be distinguished: macro and micro.

Economic analyses at macro level: the mental health system

Macro-level economic analyses are concerned with how health systems function and what they achieve. What, for example, are the motivations and behaviour of key 'stakeholders', with what implications for access, quality, and costs? What roles do economic forces play and can they be shaped to improve health outcomes and cost-effectiveness? Do different organizational or financial arrangements produce different resource configurations? For example, do markets achieve fairer or more efficient allocations than state bureaucracies? Through their macro analyses, economists can contribute to a better understanding of how health systems can improve utilization of resources (for example, see Box 7.7.1).

While improved psychological well-being in the population is likely to represent the primary goal of the mental health system, there are other (social) goals that could also feature prominently, including quality improvements in service provision, and financial (as well as human rights) protection for people with mental health problems.[2] Meeting these goals is achieved via a number of key health system functions, including resource generation, their allocation via appropriate modes of financing, actual provision of services, and overall stewardship and evaluation of these various functions.[3] Economic analysis contributes to policy formation relating to each of these functions.[4–6]

There are barriers to implementation of evidence-based mental health care in even generously resourced health systems. An insidious barrier is resource insufficiency: mental health services are often grossly under-funded in comparison to both needs and the

Box 7.7.1 The relevance of a health systems perspective

The need for a systems approach to mental health policy and planning is made apparent from a simple illustration: cheap, effective drugs exist for key neuropsychiatric disorders, including tricyclic antidepressants, conventional neuroleptics, and antiepileptic drugs, which are affordable even to resource-poor countries. The availability and prescription of these drugs to those in need, however, are determined by the extent to which such drugs have been distributed and by the ability of health care providers to detect and appropriately treat the underlying condition. Access to and use of such medications may further be hampered by the private cost of seeking and receiving health care, particularly if it is out-of pocket. User fees, provider incentives, and clinical practice are in turn influenced by the availability of national legislation, regulation, and treatment guidelines.

cost-effectiveness of interventions to meet them. This is a major issue for countries where the proportion of national income devoted to health care is low, or where the proportion of the health budget allocated to mental health is minimal. With limited funds it is difficult to build any kind of service system, because it is difficult to recruit, train, and retain skilled staff.

Even when resources are committed, available services might be poorly distributed, available at the wrong place or time relative to the distribution of needs. They may only be delivered by specialist clinics or concentrated in big cities, or affordable only by wealthier individuals. Improvements to practice take time to work through to improved health outcomes, cost-effectiveness gains or fairer access, even when suitable professionals can be recruited or new facilities opened. Decision makers must think long-term, for the immediate consequences of many interventions could be modest but longer-term benefits immense.[7]

A more general difficulty is that available services do not match what is needed or preferred. Indeed, there may be scant information on population or individual needs, and patients may have few opportunities to participate in treatment decisions. Another problem could be poor coordination of services because of professional rivalry, stultifying bureaucracy or 'silo budgeting' (resources held in one agency's 'silo' cannot be allocated to other uses).

Economic analyses at micro level: cost-effectiveness

The most frequently posed micro questions relate to the cost-effectiveness of interventions, such as an emphasis on community-based care, the use of new drugs, or the development of secure accommodation. For example, consider what happens following development of a new treatment (say a new medication for schizophrenia). Decision makers want answers to two questions when considering whether to use or recommend this drug. The first is the clinical question: is it effective in alleviating psychotic symptoms and generally improving health-related quality of life? If the answer to the clinical question is 'yes', then there is a second question: is it cost-effective? That is, does the drug achieve the improved outcomes at a cost that is worth paying? The meaning of 'worth' is far from straightforward to establish and laden with controversy.

These two questions sit at the heart of economic evaluation: outcomes must be assessed (and compared between different treatments) and the (relative) costs of achieving them must be examined. Looking only at costs is *not* an economic evaluation.

There are different variants of economic evaluation. They share a common approach to the conceptualization, definition, and measurement of costs, but adopt different approaches when considering and measuring outcomes, primarily because they seek to answer slightly different questions. We set out these differences by discussing the questions a study might address, measuring costs and outcomes, making trade-offs between them, and utility and benefit measurement.

Question and perspective

The choice of evaluative approach depends on the question to be addressed. If the question is essentially clinical—what is the most appropriate treatment for someone with particular needs in particular circumstances—information is needed on the comparative costs of alternative treatments and comparative outcomes measured in terms of symptom alleviation, improved functioning, and so on. A cost-effectiveness analysis would be appropriate (see 'Effectiveness measurement' below).

If, to take a broader stance, the question is whether to treat depression rather than spending the funds elsewhere in the health system, then decision makers need to know the costs, but now need an outcome measure that uses a common metric across different health domains. The most common such metric is 'utility' and a cost-utility analysis would be undertaken (see 'Utility measurement' below).

To widen the perspective further, if the question is whether to increase expenditure in the health system or in (say) improving transport or launching a new environmental policy, then an evaluation needs to ask about the comparative costs and impacts of the different options, where 'impact' will need to be measured in a common unit across all public policy areas. The usual choice of broad measure is monetary, leading to cost–benefit analysis (see 'Benefit measurement' below).

The question to be addressed thus influences the type of evaluation needed, but the choices are not mutually exclusive: a single study can support more than one approach if the right measures are used. The broader the question, the lower the likelihood that the outcome measure will be sensitive to the particular circumstances of a specific disorder such as depression, but the greater the usefulness in terms of resource allocation decisions.

Linked to specification of the question to be addressed is the *perspective* of a study. Is the evaluation needed to help resource allocation within a particular agency (such as primary care clinic), or a particular system (such as the health care system), or the whole society? The perspective will determine the breadth of both cost and outcome measurement.

Cost measurement

Some costs are directly associated with a disorder or its treatment, such as the money spent on medications and services used by patients, and some are more indirect, measuring lost productivity because ill-health can disrupt someone's employment pattern or the social cost of unpaid care provided by families. How broadly the costs are measured will depend upon the purpose of the study.

In carrying out evaluations in practice, economists need data on service use patterns by patients. This information might come from organizational 'billing' systems (recording amounts transferred between purchasers and providers for services used), or from routine information systems that record service contacts, or from research instruments that specifically collect data on service use patterns through interviews with patients, caregivers, or service professionals. One widely used instrument is the Client Service Receipt Inventory.[8]

The next task is to attach unit cost estimates to these service use data. In England, there is an excellent annual compendium of health and social care unit costs, which provides just such figures.[9] In other countries, it might be necessary to estimate unit costs anew. A range of data sources could be used, including government statistics, health system expenditure figures, and specific facility or organization accounts. The main cost categories to be quantified would be:

- salaries of staff employed in patient treatment and care
- facility operating costs (e.g. cleaning, catering)

- overhead costs (e.g. personnel, finance)
- capital costs for buildings and durable equipment

Effectiveness measurement

The most intuitive mode of economic evaluation is cost-effectiveness analysis (CEA): it measures costs as set out above, and outcomes along the dimensions that would be recognized by clinicians and used in clinical studies (changes in symptoms, behaviour, functioning, and so on). A CEA can help decision makers choose between interventions aimed at specific health needs. A cost-effectiveness analysis looks at a single outcome dimension—such as change in symptoms—and computes and compares the difference in costs between two treatments and the difference in this (primary) outcome. If one treatment is both more effective and less costly than another, then it would clearly be the more cost-effective of the two. But if it is more effective and *more* costly then a trade-off is needed (see below).

Often the economist will compute cost differences and a range of effectiveness differences (one for each outcome dimension)—an approach sometimes called cost-consequences analysis—which has the advantage of breadth but poses a challenge if one outcome is better and another worse for a particular treatment. It is then not always obvious which treatment is to be preferred, and the decision maker must weigh up the strength of evidence.

Making trade-offs

If an evaluation finds a new intervention to be both more effective but simultaneously more expensive than an older intervention, which is the more cost-effective of the two? A trade-off must be made between the better outcomes and the higher costs necessary to achieve them.

The classical way of determining this trade-off has been via the derivation of a incremental cost-effectiveness ratio (CER), which divides the extra cost associated with a new intervention by its additional effect (see Box 7.7.2).

More recently, health economists have developed the 'net benefit approach' to explicate the nature of the trade-off (see Box 7.7.3 for an example). It is commonly seen today in the construction of *cost-effectiveness acceptability curves* (CEACs). These curves show the probability that an intervention will be cost-effective for each of a number of pre-specified or implicit valuations of an outcome improvement by the decision maker.

Utility measurement

One way to overcome the potential problem of different outcome dimensions pointing in different directions is to employ a single, over-arching measure. A preference-weighted, health-related quality of life measure could be used. The value of the quality of life improvement is gauged in units of 'utility', usually expressed by a combined index of the mortality and quality of life effects of an intervention. The best known such index is the Quality Adjusted Life Year (QALY).

A cost-utility analysis (CUA) measures the outcome difference between two interventions in terms of QALY gain, and compares this with the difference in costs. CUAs have a number of attractions, including a unidimensional, generic outcome measure that allows comparisons across diagnostic groups, based on an explicit methodology for weighting preferences and valuing health states. But the utility measure may be too reductionist and insufficiently sensitive to changes expected in a particular clinical area such as depression treatment.[11] Nevertheless, cost-utility analyses produce estimates of cost-per-QALY gain from one therapy over another, which can then inform health care resource allocation decisions, such as by the National Institute for Health and Clinical Excellence (NICE) in England and Wales.

Box 7.7.2 Calculation of the incremental cost-effectiveness ratio

For example, evaluation of a new antidepressant may show that the cost per treated case of major depression is an extra £500 per year but also results in a lower average symptom score over this period (such as a ten point reduction on the Beck Depression Inventory); the resulting incremental CER would therefore be £50 [£500/10], meaning that each additional unit improvement on the BDI cost £50.

Box 7.7.3 Example of the net benefit approach in mental health services research

An example of the use of cost-effectiveness acceptability curves comes from a study of computer-delivered cognitive behavioural therapy (CCBT) for anxiety and depression.[10] CCBT was more expensive in health service terms than standard primary care services, but more effective in reducing symptoms. The fitted CEACs showed that, even if the value placed by society on a unit reduction in the Beck Depression Inventory (the primary clinical measure used in the trial) was as little as £40, there was an 81 per cent probability that CCBT would be viewed as cost-effective. Similarly, assigning a societal value of just £5 to each additional depression-free day would result in an 80 per cent probability that CCBT would be cost-effective. The CEAC makes transparent the trade-offs faced by decision makers.

Benefit measurement

Cost–benefit analysis asks whether the benefits of a treatment or policy exceed the costs, helping decision makers to allocate resources across a wide area, for example comparing health care with housing, education, or defence. All costs and outcomes (benefits) are valued in the same (monetary) units. If benefits exceed costs, the evaluation would provide support for the intervention or programme, and vice versa. With two or more alternatives, the intervention with the greatest net benefit would be deemed the most efficient. Cost–benefit analyses are thus intrinsically attractive, but conducting them is especially problematic because of the difficulties associated with attaching monetary values to health outcomes, and especially mental health outcomes. Methodological advances in health economics offer ways to obtain direct valuations of health outcomes by patients, families, or others,[12] but they will not be easy to apply in mental health contexts.

Design issues

As in clinical evaluation, an important consideration for the review, assessment, and interpretation of economic evidence is research

design. Generally speaking, the ideal type of study upon which to base decisions on cost-effectiveness and resource allocation is the one conducted prospectively with two (or more) appropriately sized randomly allocated groups of patients, for whom all conceivable costs and outcomes are measured appropriately, including a comparable measure of outcome (monetized benefits or, more realistically, a utility metric).

Looking across the mental health field, the accumulation of new cost-effectiveness evidence has been uneven, tending to be greater in diagnostic areas where new classes of medication have been launched: the pharmaceutical industry looks to economic evidence to support its marketing. At the same time, health care funding and delivery bodies also want their own independent evidence on new therapies. Consequently, a lot of economic studies of depression followed the licensing of the early selective serotonin-reuptake inhibitors (SSRIs) and later antidepressants with other mechanisms of action. Similarly, the arrival of the atypical antipsychotics and the cholinesterase inhibitors for Alzheimer's disease stimulated a lot of economics research.

We cannot cover all mental health areas here. Instead, in the next three sections, we look at areas where there has been some interesting activity:

- cost-utility analysis of depression treatment in primary care
- cost-effectiveness of interventions for child and adolescent mental health problems
- sectoral cost-effectiveness analysis of mental health interventions in developing countries.

Cost-utility analysis of depression treatment in primary care

Ten years ago, examples of the application of the cost-utility approach to mental health were hard to find.[11] Since then, there has been an increasing use of the so-called cost-per-QALY approach in mental health evaluations, following recommendations for such analyses by regulatory bodies in Australia, Canada, the United Kingdom, and the United States. In the field of depression, for example, cost-utility analyses have now been carried out for: screening in primary care[13] (annual and periodic screening cost more than $50 000 per QALY, one-off screening below this threshold); newer versus older antidepressant drugs[14]; maintenance treatment for recurrent depression[15,16]; guideline-concordant primary care treatment for women[17]; primary care practice-initiated quality improvement programmes[18]; computerized cognitive behavioural therapy[10]; and ECT versus transcranial magnetic stimulation for 'treatment-resistent' depression.[19] Many of the cost-utility analyses carried out to date employ secondary data and modelling techniques to estimate costs and effects, others have constructed cost-per-QALY estimates alongside clinical trials.

An example of a cost-utility analysis using modelling is that by Revicki *et al.*[14] who compared treatment for major depression with (a) newer antidepressants (nefazodone and fluoxetine) (b) tricyclics (imipramine) and, for treatment failures, (c) a step approach involving initial treatment with imipramine followed by nefazodone. A decision analysis model was developed to simulate the clinical management pathways and pattern of recurrences of major depression for these alternative treatment strategies to estimate lifetime medical costs and health outcomes (expressed as QALYs). There were only minor differences in costs and QALYs between nefazodone and fluoxetine, and both these newer antidepressants were estimated to be cost-effective compared to imipramine treatment and the imipramine step approach. The ratios of cost to QALYs gained for these newer antidepressants were deemed to be sufficiently low (below $20 000 per QALY gained) to merit adoption of these treatments in the health system. For example, the extra lifetime cost of nefazodone over imipramine ($1321) resulted in 0.32 added QALYs, giving a ratio of $4065 per QALY gained. Since decision models and their findings are only as good as their underlying assumptions and the quality of the data used to estimate key model parameters, extensive sensitivity analyses were conducted, but these did not alter the conclusions. However, the results did not include indirect costs such as changes in work productivity—important for a societal perspective—and are not readily generalizable to groups other than the targeted population (in this study, 30-year old women with one previous depressive episode).

An example of the empirically based generation of cost-per-QALY information is the randomized controlled trial of practice-initiated quality improvement (QI) for depression,[18] which involved group-level randomization of 46 clinics in six community-based US managed care organizations, either to medication or psychotherapy quality improvement programme (in addition to training and enhanced educational resources). Two QALY measures were derived, one from the Short-From, 12-Item Health Survey (SF-12) plus a standard gamble utility weighting exercise among a local convenience sample, the other with reference to estimated time spent depressed plus values from the literature for lost utility due to depression. Relative to usual care, average health care costs increased by $400–500 per treated patient, while QALY gains were less than 0.025, resulting in an estimated cost per QALY of $15 000–36 000 (QI-medication) and $9500–21 500 (QI-therapy). In addition to these health gains, patients exposed to the quality improvement programmes were employed more days than those receiving usual care.

The envisaged benefit of expressing the results of economic evaluation in these terms lies in the ability to line-up cost-per-QALY estimates for a range of different interventions and disorders, with a view to determining acceptable efficiency against a pre-defined threshold (of, say, $50 000 in the US context), or even constructing 'league tables' summarizing best and worst buys in the health sector. In practice, there remain significant problems in relying on league tables for allocating resources (due to the heterogeneous and context-specific nature of cost-utility studies), while there may be criteria unrelated to efficiency that determine whether a particular intervention is deemed acceptable for reimbursement or inclusion in a defined package of basic health care.

Cost-effectiveness of interventions for child and adolescent mental health problems

There are hundreds of completed economic evaluations in the depression field, almost all confined to adults of 'working age'. But there is surprisingly little economic evidence on child and adolescent mental health interventions. A systematic review a few years ago found only 14 published economic evaluations, some of rather poor quality.[20] Common problems included small sample sizes, narrow cost measures, short follow-ups, and limited outcome measures. (Guidelines and quality checklists are available for health economist researchers and readers of their outputs.)[21]

Another drawback is that most of the completed economic studies have been undertaken in North America, the United Kingdom, and Australia. But the results of economic evaluations generally do not transfer easily from one health system to another because of differences in system structure and financing, leading to differences in relative costs. It is infeasible and certainly unnecessary to carry-out an evaluation every time a policy decision needs to be taken, but it is also difficult to assess the relevance of economic evidence from another country, especially if its mental health system is markedly different.

An example of a well-conducted cost-effectiveness analysis is the evaluation of a home-based social work intervention for children and adolescents who have deliberately poisoned themselves.[22] The researchers measured suicidal ideation, hopelessness, and family functioning as the main outcomes, and costs were based on patterns of utilization of health, education, social care, and voluntary sector services. Within a randomized controlled trial, involving 162 children aged 16 years or under, they found no significant difference in the main outcomes or costs, although parental satisfaction with treatment was significantly greater in the group that received a new social work intervention compared to those who received routine care.

In another pragmatic randomized trial, a parenting intervention for parents of children at risk of developing conduct disorder (the Incredible Years programme) was compared to wait-list controls. The perspective for cost measurement was the public sector (health, social care, special education); effectiveness was measured by reductions in intensity of behaviour problems.[23] The Incredible Years programme was more effective but also more costly. The researchers found that it would cost £1344 to bring the average child in the intervention group (in terms of behaviour intensity score) to below the clinical cut-off point. A cost-effectiveness acceptability curve was plotted to show the trade-offs between cost and effectiveness.

Sectoral cost-effectiveness analysis of mental health interventions in developing countries

Cost-effectiveness analysis can also be used to evaluate mental health programmes for whole populations (countries or even world regions). While the burden of neuropsychiatric disease is very high, the resources available to address that burden are extremely low. Given the consequent tension between the need for and the availability of mental health care, plus the fact that effective interventions do exist, the job of cost-effectiveness analysis is to show how much of the burden can be reduced or averted, by doing what, and at what cost.

Through its CHOICE project (choosing interventions that are cost-effective), WHO embarked on an initiative to assemble databases on cost-effectiveness of key health interventions in 14 epidemiological sub-regions of the world.[24] A comparative cost-effectiveness analysis of interventions for reducing the burden of major neuropsychiatric disorders formed part of this programme.[6,25,26] WHO-CHOICE advocates a 'generalized' form of cost-effectiveness analysis, in which costs and effects of current and new interventions are compared to the starting point of 'doing nothing'. Accordingly, the costs and effectiveness of pharmacological and psychosocial interventions in primary care or outpatient settings for psychiatric disorders were compared in a population model to an epidemiological situation representing the untreated natural history of these disorders. Effects are measured as disability adjusted life years (DALYs) averted (i.e. reduced burden), and costs in international dollars (I$; one international dollar should buy the same quantity of health care resources in China as in the United States).

Compared to no treatment (natural history), the most cost-effective strategy for averting the burden of psychosis and severe affective disorders in developing regions of the world is a combined intervention of first-generation antipsychotic or mood-stabilizing drugs with adjuvant psychosocial treatment delivered by community-based outpatient services, with cost-effectiveness ratio of I$4200–5500 in Sub-Saharan Africa and South Asia, rising to more than I$10 000 in middle-income regions[25] (see Fig. 7.7.1). Currently, the high acquisition price of second-generation antipsychotic drugs makes their use in developing regions questionable on efficiency grounds alone, although this situation stands to change as these drugs come off patent. By contrast, evidence indicates that the relatively modest additional cost of adjuvant psychosocial treatment reaps significant health gains, thereby making such a combined strategy for schizophrenia and bipolar disorder treatment more cost-effective than pharmacotherapy alone.

For more common mental disorders treated in primary care settings (depressive and anxiety disorders), the single most cost-effective strategy is the scaled-up use of older antidepressants (due to their lower cost but broadly similar efficacy to newer antidepressants). However, as the price margin between older and generic newer antidepressants continues to narrow, generic SSRIs should be at least as cost-effective and may therefore represent the treatment of choice in the future. Since depression is commonly recurring, there are also grounds for thinking that proactive care management, including long-term maintenance treatment with antidepressant drugs, represents a cost-effective (if more resource-intensive) way of significantly reducing the enormous burden of depression in developing regions.[27]

The purpose of such an exercise is to locate the relative position of effective and applicable interventions within a wider cost-effectiveness and priority-setting framework. Using the affordability criteria of the WHO Commission for Macroeconomics and Health,[28] this analysis indicates that (a) the most efficient interventions for common mental disorders can be considered very cost-effective (each DALY averted costs less than 1 year of average per capita income), and (b) community-based interventions for severe mental disorders using older antipsychotic and mood-stabilizer drugs meet the criterion for being cost-effective (each DALY averted costs less than three times GDP per capita). These findings therefore provide relevant information regarding the relative value of investing in neuropsychiatric treatment and prevention, and so may help to remove one of many remaining barriers to a more appropriate public health response to mental health needs.

Conclusion

Economic evaluation provides a means of comparing the costs and outcomes of mental health interventions or programmes, enabling decision makers to assess whether they offer good use of (scarce) resources. An analysis of costs alone, or indeed of outcomes alone,

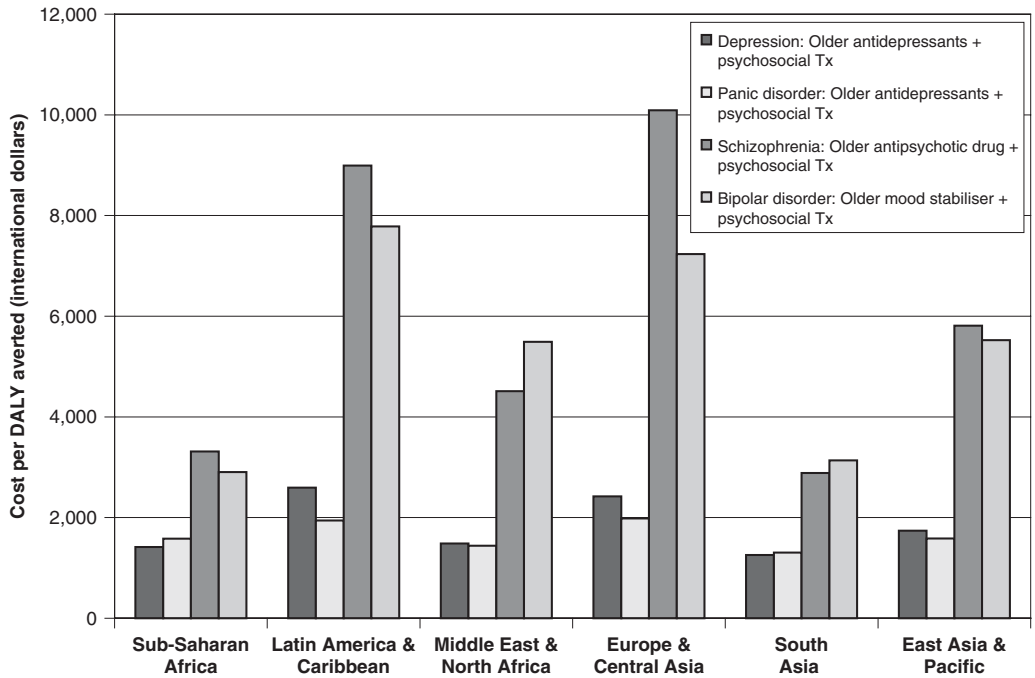

Fig. 7.7.1 Cost-effectiveness ratios for a basic mental health package in low and middle-income regions of the world.

does not provide such information. The results of well-conducted economic evaluations can be channelled into decision-making processes at a succession of levels.

Patients, users, and caregivers

Economic evidence can complement clinical decision-making at the patient, user, and caregiver level by comparing costs and consequences of particular treatments. One very pertinent question about any treatment is whether the additional acquisition costs associated with (say) newer antidepressants or second-generation antipsychotics are compensated by better symptomatic response or fewer side effects. Our earlier examples of economic evaluations of treatments for depression and for child and adolescent mental health problems provide this kind of evidence.

Purchasers and providers

At another decision-making level, those who commission or purchase mental health services need economic data. A core element of local needs assessment and strategic service development by (say) a state health care system or a health maintenance organization concerns the resource implications of changes to, for instance, the hospital/community balance or investment in a new clinic or training of therapists.

Government and society

Economic evaluations should influence national-level policy and resource allocation decisions. Such evaluations have influenced policy with respect to the substitution of community-based for long-term hospital care, the development of 'assertive outreach' models, the expansion of early intervention initiatives for psychosis, and the overall level of funding. The CHOICE programme aims to provide this kind of evidence.

While adding economic analysis to mental health evaluations introduces an extra dimension that offers a wider assessment of the implications of new or existing courses of action, there can also be limitations. Many economic evaluations fall short of the ideal, whether in terms of sample size, comprehensiveness of cost measurement, outcome assessment, or evidence interpretation. Conclusions based on small-sample randomized trials can often only be tentative, while failure to measure the wider (non-health and non-service) costs associated with two or more treatments may produce misleading and partial results.

Even when it overcomes these limitations, an economic evaluation can never resolve difficult allocative and policy issues; rather, it is one additional tool that, together with evidence on the clinical and social dimensions, can facilitate explicit evidence-based decision-making.

Psychiatry in primary care

David Goldberg, André Tylee, and Paul Walters

Epidemiology

In recent years, major epidemiological surveys have been carried out in the community in many different countries, in the United Kingdom most recently by the Office of National Statistics (to find this and other surveys go to http://www.statistics.gov.uk/STATBASE/Product.asp?vlnk=8258). The findings in such community surveys can be compared with findings in primary care surveys, when it will be found that the list of common mental disorders is not quite the same, although conditions characterized by symptoms of depression and anxiety are the most common. Rather than considering the detailed diagnoses, it can be helpful to distinguish between 'internalizing disorders', which besides anxiety states and depression, also include the fear disorders like phobias and panic disorder, obsessive-compulsive disorder and many cases of somatization disorder; and 'externalizing disorders' consisting of conduct disorder in childhood, and antisocial behaviour, as well as drug and alcohol disorders in adult life. The former group of disorders are characterized by subjective distress, and typically high levels of anxious and depressive symptoms; while in the latter group abnormalities are in externally observed behaviour.[1]

In community surveys it can be seen that rates of internalizing disorders rise sharply after puberty, are highest between the ages of 35 and 55 and fall thereafter, and that females rates are higher than males at all ages., while rates of externalizing disorders reach their maximum between the ages of 15 and 34, and fall sharply after that, with males rates much higher than female rates at all ages. This is shown in Table 7.8.1 (which does not include antisocial behaviour as reliable data are not available in the community).

The Goldberg-Huxley Model[2]

This was devised as a framework for comparing the characteristics of patients seen in the community with those in other medical settings, and describing the pathway which people usually follow to mental health care in places where GPs act as 'gatekeepers'. It consists of five levels, separated by four filters. The figures for psychiatric morbidity over 1 year necessitate using estimates of incidence rates, and are therefore much higher than the point prevalence rates reported in community surveys. The essence of the model is the demonstration that most distressed patients will see a doctor over the course of 1 year (filter 1), but only about half of them will have their distress detected (filter 2). Most common mental disorders are treated in primary care, so filter 3 is relatively impermeable, only allowing one in five to pass. Psychiatrists only have any part in the process with the fourth filter, which also holds back most patients. Psychiatrists therefore form their ideas about mental disorders from a highly skewed section of all those with disorders.

Prevalence of psychiatric disorder in primary care

In the United Kingdom, about 80 per cent of the population consult their doctor in the course of a year, and prevalences among attenders are higher than among the general population.[2] In contrast, specialist mental health services see between 1 and 2 per cent of the population in the course of a year, and admit only about 0.5 per cent to inpatient care, so that primary care deals with the major part of the burden of common mental disorders.

The World Health Organization (WHO) carried out the largest primary care survey in 14 countries[3] but for purposes of comparison only the UK data will be shown here. Table 7.8.2 compares the frequencies and types of mental disorders seen in the community, in primary care, and in psychiatric practice. Mental disorders

Table 7.8.1 Annual prevalence of mental disorders in the community by type and age, rates per 100 at risk

Disorder	Gender	5 to 16	to 34	to 54	to 74	All (16–75)
Internalizing	Male	3.1	11.70	16.75	9.87	13.5
	Female	4.3	20.55	21.35	14.80	19.4
Externalizing	Male	10.05	11.6; 18.9	2.25; 10.4	0.4; 3.8	6.0; 11.9
	Female	4.35	5.3; 5.7	0.75; 2.1	0.4; 0.5	2.3; 2.9
Other	Male	1.9	0.33	0.78	0.23	0.5
	Female	0.75	0.42	0.73	0.52	0.6

Internalizing = any neurotic disorder. *Externalizing* = conduct disorder for age 5–16; for the remaining age groups the rate for drug dependence is shown first, followed, after the semicolon, by the rate for alcohol dependence. *Other* = psychotic disorders in adults. seen in primary care settings are more severe on average than those seen in community surveys, and different disorders predominate. The figures shown are for practices in Manchester with a fairly high prevalence of mental disorders, but the spread of diagnoses is fairly similar in other countries. The ICD-10 criteria only counted somatoform disorders if they were severe and long-standing, and do not count the many patients presenting with unexplained somatic symptoms, which are often accompanied by symptoms typical of anxiety or depression. A more recent study from Denmark[4] has estimated that almost a half of their patients were diagnosed cases of mental disorders, with somatoform disorders being found in about one-third. Patients with established physical illnesses are also at greater risk of mental disorders, and this is especially so if they are disabled by their illness. It can be seen from Table 7.8.3 that disorders admitted to psychiatric hospitals in the United Kingdom are different again from those typically seen in primary care, with organic states, drug and alcohol dependence, schizophrenia and severe depressive states accounting for the majority of cases (Source: http://www.hesonline.nhs.uk/Ease/servlet/ContentServer?siteID=1937&categoryID=202).

A study in 10 European countries shows 28 per cent of consecutive attenders in the United Kingdom to be distressed on a screening interview, but only 6 per cent presented psychological symptoms to their GP. Most of these (5.5 per cent) received a psychiatric diagnosis, but the GPs also diagnosed others as 'psychiatric'—so that their total rate was 15 per cent.[5] These figures are fairly similar to those in Switzerland and the Netherlands, but in stark contrast to those in Eastern Europe. In the Russian Federation, for example, 27 per cent were distressed, but none reported psychological distress to their GPs, and none were diagnosed: however, the GPs identified 3 per cent of their patients as 'psychiatric'. Fairly similar figures were reported in Estonia, Poland, and Belgium; while figures in Germany, Spain, and Sweden are intermediate (*ibid* 2007; see Fig. 7.8.1). This study also showed that GPs who discuss psychosocial matters with their patients, and look at them are better at diagnosing them—a finding that echoes previous research in the United Kingdom.[2]

It can be seen from Fig. 7.8.1 that most distressed patients—who may well be found to have a mental disorder if interviewed with a research interview—do not mention their distress to their doctor, and that this accounts for failure to diagnose the disorder. Many patients who have not endorsed feelings of distress are nonetheless assessed as mental unwell, either because they are presenting with

Table 7.8.3 The Goldberg-Huxley Model: Data for Manchester, UK

Level 1: Community samples *First Filter: The decision to consult*	**250–315/1000/year**
Level 2: All those seeing GPs found to have a mental disorder *Second filter: GPs ability to detect*	**210–230/1000/year**
Level 3: Cases recognized by the GP As 'mental disorders' *Third filter: GPs decision to refer*	**101/1000/year**
Level 4: All those seeing mental health professionals *Fourth filter: Psychiatrist's decision to admit to hospital*	**20.6/1000/year**
Level 5: Those admitted as inpatients	**3.4/1000/year**

unexplained somatic symptoms or because they are under treatment for a mental disorder that has responded to treatment.

Clinical presentations

Somatization

Somatization is broadly defined as the expression of psychological distress through physical symptoms. In primary care, most patients present physical symptoms at the onset of an episode of anxiety and depression. This is actually the usual way that new episodes of common mental disorders present in general medical settings, as only about 15 per cent of new episodes present purely in psychological terms.[2]

Primary care somatizers can be subdivided into 'facultative somatizers', who admit to their psychological symptoms and accept a mental disorder diagnosis if appropriately interviewed, and 'pure somatizers' who, despite such an enquiry, still deny the presence of psychiatric symptoms. People have many reasons for preferring to present somatic symptoms to their doctors—they are understandably worried that they may have a new physical disease, they give priority to pains over other symptoms because it is pain that hurts, and they often wish to avoid the stigma of being thought psychologically distressed.

Somatizers may be compared with 'psychologisers', who directly present their psychological problems to their doctors. The former are more likely to report adverse childhood events and periods of childhood illnesses, while the latter have more abnormal attachment behaviours.

Hidden versus conspicuous morbidity

The ability of GPs to detect psychological disorders among their patients forms the second filter that patients must pass through in order to receive a diagnostic label. This ability varies a good deal between places as well as between disorders. In the WHO study[3] the overall average detection rate was 48.9 per cent, but rates varied from 75 per cent for Verona to 15.9 per cent for Shanghai (62.9 per cent for Manchester). Recognition rates for individual diagnoses followed these overall rates, with somatization disorder being best recognized, followed by depression. However, these detection rates do not reveal whether the GP is identifying the same patients as the research assessment. In fact, the exact agreement between the two (measured by κ) is rather poor, at only +0.18 for all centres (+0.38 for Manchester).

The second filter is passed when the GP recognizes a mental health problem in the patient, although this will often be without a precise ICD-10 diagnosis. Those recognized by the GP make up the '**conspicuous' morbidity**—in fact, just under half of that estimated to be present in the waiting room population by a two-stage case-finding procedure: so that the patients who are not identified can be thought of as the '**hidden morbidity'**. These undetected patients continue to consult, but an outsider's inspection of notes and prescriptions, or even discussion with the relevant doctor, will not identify them as patients with psychiatric morbidity. In practice, the 'conspicuous' morbidity may be greater than 50 per cent, as the longitudinal nature of primary care means that patients may be diagnosed in subsequent visits, and this is missed in cross-sectional waiting room studies.[6,7] Kessler *et al.* followed up a cohort of primary care patients over 3 years and found only 14 per cent of patients with depression remained unrecognized at the end of this period.[8] Rost *et al.* followed up 98 depressed patients who had made at least one visit to their GP and found 32 per cent were undetected at 1 year.[9] Despite this, GPs are good at recognizing severe depression, and unrecognized depression tends to be mild.[10–12] The severity of depression in primary care, rather than being defined categorically, may therefore be better conceptualized as running along a continuum from mild to severe. Using a dimensional approach Thompson *et al.* calculated GPs only miss one 'probable' case of depression every 29 consultations.[13]

Doctors better able to detect disorder have the following characteristics:[2]

- Make eye contact with the patient
- Make empathic comments
- Pick up verbal cues
- Pick up non-verbal cues
- Ask directive questions, with a psychological content
- Do not read notes, or look at their computer, while the patient is speaking
- Deal with over-talkativeness
- Deal with today's problem

Data from the WHO study indicate that these 'undetected illnesses' are on an average less severe than those detected by GPs and have a somewhat better outlook. However, the data does not support the view that failure to detect these less severe disorders has serious long-term consequences for the patient[14] although this does not mean that there are not individuals would be better served if their distress was acknowledged.

The elderly

Mental illness in the elderly is common in primary care. Between 5 and 10 per cent of older adults attending primary care will suffer from depression, though this may be higher in areas of socio-economic

deprivation.[15] Older people are less likely to admit to psychiatric problems and more likely to emphasize somatic concerns and present behavioural changes. One study found that only 38 per cent of those identified as depressed through screening in the community had discussed feelings of depression with their GP.[16] This may lead to under-recognition in primary care. Crawford *et al*. found that only 52 per cent of 62 patients identified with clinical depression from a community survey were correctly diagnosed by their GP.[17] The elderly may attribute their symptoms to 'normal ageing', grief, or physical illness, or may fear sigmatization more than younger patients making recognition more difficult. Elderly depressed men may be particularly likely to go unrecognized.[17]

A systematic approach using a collaborative care model may improve depression management for the elderly in primary care. The Improving Mood-Promoting Access to Collaborative Treatment (IMPACT) trial in the United States demonstrated that a primary care collaborative model for late-life depression was more effective than usual care in improving depressive symptoms. It also decreased pain due to osteoarthritis, increased functional abilities, and improved quality of life.[18] The collaborative care model was highly cost-effective[19] and continued to show benefits over a 2-year follow-up period.[20]

The other major condition with which the GP will be involved is dementia. In the United Kingdom, the prevalence rate is approximately 5 per cent for all those over 65, but there is an age-related rise within this band to 25 per cent for those aged over 85. Consultations for organic psychoses reflect this: 370 consultations per 10 000 years at risk for those aged over 75, and 888 per 10 000 years at risk for those aged over 85. However, the management of people with dementia in primary care has been criticized.[21] Up to 75 per cent of patients with moderate to severe dementia and up to 97 per cent of patients with mild cognitive impairment go unrecognized by their GP.[22] Again there may be a number of reasons for this. Dementias have an insidious onset, and sometimes the doctor's familiarity with the patient can militate against spotting change. If a relative also accepts that the changes associated with dementia reflect normal ageing, the diagnosis may be delayed or never made. Only 40 per cent of GPs in the United Kingdom use a specific test to detect dementia, and in a survey of 8051 GPs in England 40 per cent thought an early diagnosis of dementia was not important.[23] Turner *et al*. surveyed GPs knowledge, confidence, and attitudes about dementia and found that despite GPs overall knowledge about diagnosis and management being good, a third lacked confidence in their diagnostic skills and two-thirds lacked confidence in their management of behavioural problems and other associated problems in dementia.[24]

Downs and others conducted a trial of an educational package to improve detection and management of dementia in primary care.[25] In the United States, a trial of collaborative care versus care as usual for patients with dementia in primary care has produced encouraging results.[26] Compared with care as usual, collaborative care (consisting of case management though a senior practice nurse working with the patient's family and integrated in the primary care team, and the use of standard protocols to guide and monitor treatment) resulted in significant improvements in the quality of care and in the symptoms of dementia, without an increase in psychotropic medication use.

Classification of mental disorders in primary care

Difficulties with conventional psychiatric taxonomies

The main problem with the International Classification of Diseases, 10th Edition (ICD-10)[27] or Diagnostic and Statistical Manual, 4th Edition (DSM-IV)[28] classifications used by psychiatrists is that they were devised to describe a very different consulting population, they are needlessly complicated, and they do not lead directly to management. Patients usually present a mixture of physical, psychological, and social symptoms expressed in any order, although somatic symptoms are usually first. Some symptoms are repeatedly mentioned and some are mentioned only in passing. Symptoms left to the end may be the most important of all. Symptoms may not fit a psychiatrist's taxonomy. In primary care, patients often have several concurrent problems of a medical, psychological, and social nature.

Most psychologically distressed patients show symptoms of both anxiety and depression. The ICD-10 classification has a mild disorder called 'mixed anxiety depression', since some patients have symptoms of each which together seem sufficient for a diagnosis, although not satisfying the criterion for either disorder on its own. However, this does not solve the problem of the many patients who are above the threshold for both disorders, who are declared 'co-morbid' for two different disorders by conventional psychiatric taxonomy.

An alternative view points out that the two groups of symptoms are strongly correlated with one another (about +0.7) in the consulting population,[2] and thus views them as two related dimensions of symptomatology which tend to co-vary over time. GPs themselves rarely emphasize the distinction between the two groups of symptoms, and there appears to be no evidence that any adverse consequences follow this neglect. For the GP, the diagnostic task can be one of separating the symptoms of depression and anxiety from those of an accompanying physical illness, or of probing for psychiatric morbidity in patients where apparent physical symptoms do not have an organic cause. In primary care settings, 'co-morbidity' refers to patients who have both physical disorders and mental disorders.

Solutions to the classification problem

Both the major psychiatric classifications—ICD-10 and DSM-IV—offer special versions produced in collaboration with primary care physicians which are deemed suitable for this setting, and roughly correspond to the parent classification. The WHO offers '**ICD10-PHC**'[29] which consists of 26 common conditions, with advice on how they present, the diagnostic features, the differential diagnosis of similar symptoms, essential information for the patient and the carer, advice and support for the patient and the carer, the role of medication, and indications for referral to the mental health services. Information is given about national organizations, and self-help materials, to assist people with particular diagnoses, and advice is given to GPs in particular areas about customizing the system by including information about self-help and support groups for local people.

The '**DSM-IVPC**'[30] on the other hand is organized by symptoms that branch out into diagnostic algorithms. The GP assesses the

patient's symptoms and, in workbook fashion, determines the relevant psychiatric diagnoses. The manual is formatted to be concise and practical, with limited use of psychiatric jargon. As a key feature, the chapter devoted to 'Algorithms for Common Primary Care Presentations' presents nine algorithms, headed by the presenting symptoms, for the most common psychiatric concerns encountered in primary care. No advice is given on management or on information to be given to carers.

Given the quantity of printed material that floods into GPs offices, it is doubtful whether many GPs keep such systems on their desks—although they may be incorporated in their computer programs. It is more realistic to use such systems in training new doctors, so that ways of approaching patients and their carers become incorporated in their usual routines, with the system only consulted when an unusual problem presents itself. It can be seen that whereas the DSM-IV system is aimed at formal diagnosis, the ICD10-PHC system is aimed at management once an assessment has been completed.

The International Classification for Primary Care, (ICPC-2-R)[31]

The classification most widely used by GPs is of course their own, devised under the auspices of the World Organization of National Colleges & Academies ('WONCA'), called the International Classification for Primary Care, '**ICPC-2-R**'. This is a system which classifies all patient data and clinical activity in primary care, taking into account the frequency distribution of problems commonly encountered.

It allows classification of

- the patient's reason for encounter (RFE),
- the problems/diagnosis managed,
- interventions,
- test results, and the
- ordering of these data in an episode of care structure

It has a biaxial structure and consists of 17 chapters, each divided into seven components dealing with

- symptoms and complaints
- diagnostic, screening, and preventive procedures
- medication, treatment, and procedures
- test results
- administrative
- referrals and other reasons for encounter, and
- diseases

It is not clear to what extent all GPs work their way through this complex system, but should they reach the seventh component, there is a rough correspondence with the ICD. Note that multiple disorders can be coded in the same episode, but the extent to which this is done is not clear. Nor does the system provide advice on the management of the various conditions—it is assumed that the clinician knows how to do this.

The Read codes[32]

The most widely used system in the United Kingdom since the advent of computerization, are the Read codes. This meets the needs of the generalist by including diagnoses, symptoms, and problems. Some very broad reasons for consultation—such as 'anxiousness', 'depressed', and 'headache' are provided. A letter of the alphabet is followed by up to four numerical codes, and there are also about 50 codes for diagnoses such as E204. 'Depression' or E2003 'anxiety with depression', which correspond very roughly to ICD diagnoses. However, no criteria are given, nor any advice on management for these various diagnoses.

None of the above four systems take into account functional impairment and disability, yet clinicians need to consider this in conjunction with the set of symptoms presented by an individual patient. Both diagnosis and current impairment are essential, and may help to explain why up to a quarter of patients with schizophrenia are managed solely in primary care settings[33] whilst some patients with adjustment disorder need referral to the community mental health team.

Improving the identification of some common disorders

(a) Aids to accurate detection of depression

Rather than using routine screening questionnaires to all patients, it is more practical to ask the following questions in six groups of patients:

- all those who look or sound depressed, or mention depressive symptoms
- all those with a past history of depression
- all those with significant physical illness causing disability
- all those with diabetes and coronary heart disease, where the risk is higher
- all those with other mental health problems, such as dementia or heavy drinking
- mothers of infants who are either single or are unsupported by a partner or family

Both these questions should be asked:

- During the past month, have you been feeling down, depressed or hopeless?
- During the last month, have you often been bothered by having little interest or pleasure in doing things?

(b) Aids to accurate assessment of severity of depression

If positive replies are obtained to either of these, assess severity of using the Patient Health Questionnaire-9 (PHQ-9) a questionnaire with nine questions validated for use in primary care,[34] which may assist in ensuring that antidepressant medication is better targeted on those with moderate and severe degrees of depression.

(c) Aids to the accurate detection of alcohol problems

Other, more recent tools, such as the Drug Abuse Problem Assessment for Primary Care (DAPA-PC),[35] were designed specifically to be administered via computer. While currently popular in the areas of depression and substance abuse, the audience for assessment tools is expanding for a number of reasons, including: convenience, privacy, high-patient satisfaction,[36] decreased provider time, improved validity, and reliability,[37] and decreased expense.

The management of mental disorders within primary care

(a) Stepped care

With the introduction of mental health guidelines there has been a shift towards stepped care for mental health problems.[38] Stepped care 'provides a framework in which to organize the provision of services supporting both patients and carers, and healthcare professionals in identifying and accessing the most effective interventions' (see Fig. 7.8.2). Stepped care allows treatment to be provided in steps according to the severity of problems and/or response to treatment, aiming to provide the greatest benefit to most of the people from the resources available. Patients who fail to respond are given the next step on the treatment plan. Stepped care can be delivered by starting at the least invasive step and gradually 'climbing' the steps according to response, thus targeting more intensive treatments to those that that need them, or by 'stratifying' care so that the first treatment step is determined by severity of disorder and thereafter by response.[39] Stepped care was developed in the United States, initially for the management of depression.[40] In the United Kingdom, this model of care has now been recommended for depression,[38] anxiety disorders,[41] obsessive-compulsive disorder,[42] and self-harm.[43]

(b) Mental health workers based in primary care

Several new possibilities have emerged recently with the advent of the new *graduate mental health workers* in primary care. The NHS plan (DH 2000) was to have 1000 such workers in England and indications are that there are 600–700 in post. Mostly, the posts are similar to assistant psychologists and they generally are trained on a one-day release scheme at local university level in primary care mental health. Many are conducting initial assessment, providing brief psychological interventions such as brief cognitive behaviour therapy (CBT) or problem-solving for common mental health problems and medication management. Many are overseeing the use of self-help written materials and computerized help such as 'Beating the Blues', a computerized CBT programme for depression, which has been shown to be cost-effective.[44] Graduate primary care mental health workers (PCMHWs) also act as advisors on the range of other local services (for example, local library bibliotherapy schemes, and support groups). They have been proved to be effective at increasing patient satisfaction with episodes of care but were found not to improve mental health symptoms or to use the voluntary sector more than usual care.[45] Many PCMHWs are psychology graduates, and they tend to move on after a year or two into much wanted clinical psychology posts, so corporate memory can be diminished. Many other interventions described in level two of the National Institute for Clinical Excellence (NICE) Depression guideline[38] are increasingly applied in primary care—such as exercise schemes, befriending schemes, brief problem-solving, brief CBT, self-help materials, and sleep restoration.

Practice primary care counsellors may in reality be psychologists, psychotherapists, or counsellors depending on their training, expertise, and accreditation. They mostly see adults with common mental health disorders which may include adjustment disorders and losses. They often integrate different models of brief psychotherapeutic treatment depending on their training and the particular patient, and they receive regular supervision. These services may be provided in-house or in a neighbouring practice depending on

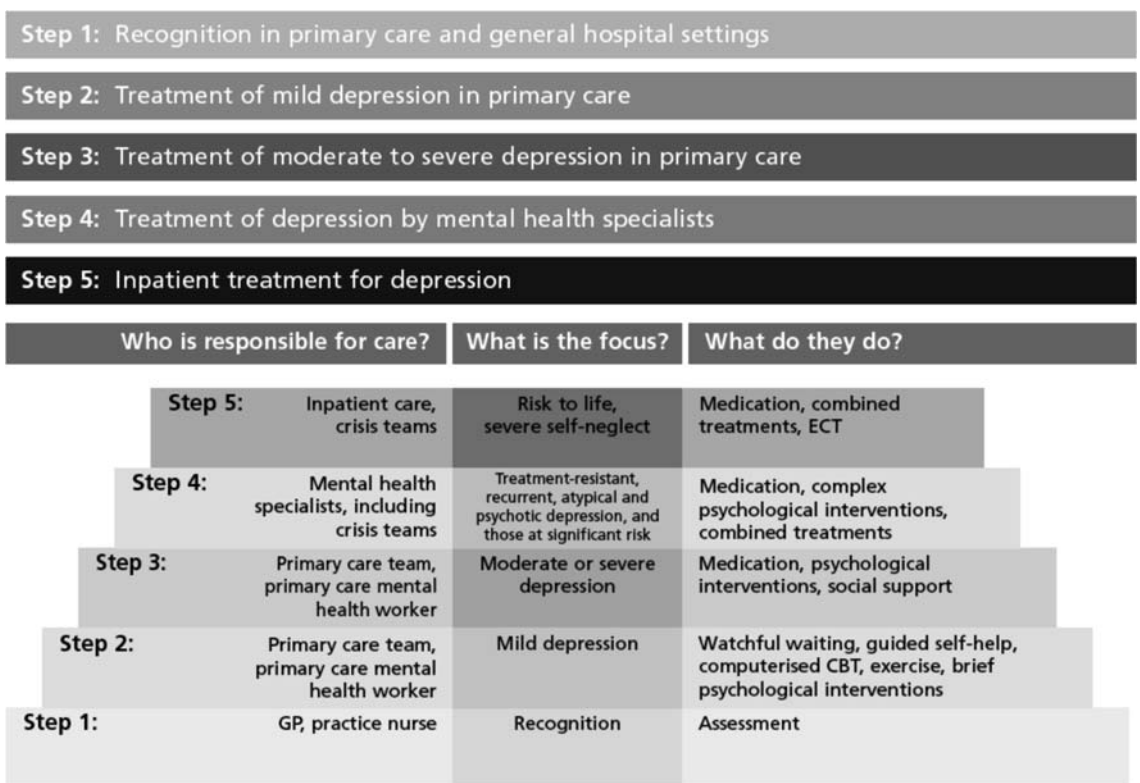

Fig. 7.8.2 The stepped care model applied to depression. Reproduced with permission.[38]

available space. Some counsellors specialize in providing services for non-English speaking groups and certain patient subgroups such as eating disorders, domestic violence, etc.). Whilst resources are usually limited on occasions they may see patients for longer courses of treatment.

(c) The role of the primary care nurse

Practice nurses are increasingly involved in chronic disease management within practices and this includes managing mental health conditions whether severe or common. From April 2006, practices have been rewarded in England under the Quality and Outcomes Framework of the General Services Medical Contract[46] for screening their patients with coronary heart disease (CHD) and diabetes for depression and with any newly depressed patients for using a recommended patient self-report instrument to assess baseline severity of depression. The recommended instruments are the Patient Health Questionnaire-9 item (PHQ9),[34] the Hospital Anxiety and Depression Scale (HADS),[47] or the Beck Depression Inventory (BDI).[48] Practice nurses are expected to undertake much of this work as they see the patients with CHD or diabetes for review and therefore they need proper training and supervision. Also rewarded in the GP contract is an annual physical review of all patients on the Severe and Enduring Mental Illness registers (SEMI or SMI)—again usually conducted by practice nurses. Such nurses have traditionally administered depot medication for such patients without much training on the procedure or the accompanying health checks. This training has been improving lately. Expecting an untrained practice nurse to administer depot without support and training is unacceptable, and training is needed in how to give the injection, how to review the suitability of this form of medication, how to monitor for side-effects, how to assess mental state for signs of deterioration, when to involve colleagues or refer to the community mental health team, and crisis management.

Practice nurses have been successfully trained in the assessment and management of depression[49,50] and the use of problem-solving in major depression.[51] Practice nurses have been successfully trained in chronic disease management of the severely mentally ill,[51] whereby they constructed a disease register, a care plan, and 3-monthly structured reviews encompassing psychological, physical, and social well-being. Whilst the practice nurses were diligent and detected problems, there was little evidence that they communicated these to the GPs. There was also a failure to increase health promotion in this group, despite their recognized increased standardized mortality.

Health visitors trained in counselling have been shown to benefit women with postnatal depression,[52] and Appleby *et al.*[53] have targeted the same group of patients with a nurse-led intervention.

Primary care mental health services

The primary care team provides the majority of care to people suffering from mental health problems. Though many services remain GP-led, many are becoming increasingly sophisticated with a growing number of professionals involved in the care of people with mental health problems. In England, the Department of Health has produced a guide for improving primary care mental health services.[39]

A number of models for primary care mental health services are described reflecting the need for services to provide care to populations with different needs, resource availability, and relationships with secondary care. Examples include the 'opt-in' or self-referral model, proactive models such as a collaborative care model, 'one-stop shop' models, and focused service models (i.e. services are developed for a specific remit such as common mental disorder or psychosis). The 'opt-in' model is one in which the patient initiates care and follow-up and is the traditional primary care model. In a collaborative care model there is active follow-up and collaboration between patient, primary care health professionals, and when required secondary care professional with the health professional coordinating care. A 'one-stop shop' model provides a single point of access to all mental health services with a triage system determining resource allocation. There is no perfect model, and all have advantages and disadvantages depending on the population needs and availability of resources.

As services develop so the range of primary care mental health professionals is expanding. As well as the traditional primary care professionals—the GP and practice nurse—many practices now have others, including primary care graduate mental health workers and health visitors. Their roles include making assessments, facilitating referrals and movement through the health care system, and delivering treatments. In the United Kingdom, the availability of counselling services is now commonplace in primary care and up to 50 per cent of general practices have on-site counselors.[54] They are referred people with a wide range of common mental disorders and other psychosocial problems such as adjustment disorders. Bower and Roland reviewed the evidence for the effectiveness of counselling in primary care and found it was associated with a modest improvement in short-term outcomes compared to usual care, but was no better than usual care over the longer-term. It did not appear to be any more cost-effective than usual care but patients appeared satisfied with it.[55]

The primary–secondary care interface

What GPs expect of psychiatrists

GPs expect psychiatrists to possess and exhibit specialized skills of assessment and management not possessed within the primary health care team. The primary care team may include primary care mental health workers ranging from graduate workers to counsellors, psychotherapists, or psychologists, although if present these are usually extremely thinly spread (i.e. 1–2 sessions per practice per week). GPs do expect their psychiatrists or a named person from the mental health team to be available when they are needed, and they should also make themselves available for incoming telephone calls from the key contact. Because of sheer numbers (in England and Wales there are 12 times as many GPs as psychiatrists) the GP must protect this valuable resource by not overloading it with inappropriate referrals and by obtaining and maintaining certain assessment and management skills that can be used in primary care as well as sharing the care of certain patients under the leadership of secondary care. Referrals will vary widely from practices depending on their own 'in-house' expertise and the presence or absence of any primary care mental health workers or local counselling services. Larger practices often have more in-house expertise and are more likely to have at least one of their GPs who possess more specialized mental health skills. Small practices with one or two partners are less likely to have such skills and may need

more support. GPs expect the psychiatrist to provide inpatient care when needed (e.g. serious self-neglect, suicide intent, etc.) and day-patient facilities to provide a place of care, respite, and safety. They can also expect the psychiatrist to use diagnostic facilities and investigations (e.g. scans) as necessary and to provide highly specialized treatments when indicated (e.g. electroconvulsive therapy). Less frequently, the GP may need respite from particular doctor–patient relationships for the longer-term good of both. Referral is also sometimes a result of pressure by the relatives or patient. Where good communication exists between primary and secondary care, these often 'covert' reasons for referral can be openly discussed.

Access to specialist assessment when appropriate is paramount for a primary care service. GPs are not usually trained in specialist assessment and therefore, to match need to services, a psychiatrist, community psychiatric nurse, or psychologist from the community mental health team can perform this function, often in a primary care setting or the patient's home. Other community mental health teams operate an outpatient clinic (which may be moved into the surgery). Often 'true consultancy' is being sought by the GP, whereby he or she may receive advice only. Other practices operate a joint consultation system whereby the specialist and generalist see the patient together and formulate a plan. With recent changes in the configuration of mental health teams in the United Kingdom to provide acute care, early intervention and assertive outreach, in some places the more traditional community mental health teams are being reduced which is often confusing and can be unsettling for practices which have developed relationships with individual psychiatrists and colleagues. Also, if crisis teams work 9 to 5 p.m., yet the GP surgeries are open until 6 or 7 p.m., this can create difficulties for making urgent referrals.

Ways of organizing the interface

The interface between primary and secondary care is of key importance in the delivery of mental health care. Bower and Gilbody[56] have described a continuum of specialist involvement in primary care mental health with least involvement of secondary care professionals in the education/training model, and increasing involvement through the consultation-liaison model, the collaborative care and the replacement/referral model. In practice, these models are not mutually exclusive. They can complement one another and be adapted to take into account local workforce issues and staff availability.

There are at least four models of working across the interface between primary and secondary care:

1 A **replacement/referral model** is the traditional way in which primary care interfaces with secondary care. In this model, the patient's care is handed over to specialist services by way of a referral, the specialist service only relinquishing care when the patient had been treated. However, over the last 25 years other models have developed.[57] These include:

2 The **consultation-liaison model** allows secondary care professionals to develop ongoing relationships with primary care professionals, not only providing expert advice but also actively liaising with the primary care team, and often attending team meetings or seeing patients jointly with the GP.

3 The **collaborative care model**, as described above has primary care mental health professionals working between primary and secondary care to improve the overall care of patients. These link-workers can provide active follow-up and access to specialist advice and care as needed.[59]

4 In the **training/education model**, secondary care provides education and training to the primary care team which otherwise functions autonomously utilizing secondary care services when needed via a referral system.

How health services negotiate the interface between primary and secondary mental health services is likely to get increasingly complex as secondary care moves away from centralized care through the community mental health teams, to specialist teams such as assessment and brief treatment teams, early intervention teams, and continuing care teams. It is likely that each of these teams will develop its own model of interfacing with primary care. This may allow for a more fluid interface and closer working relationships between primary care and secondary care teams.[59] However, it needs to be managed appropriately or could lead to confusion of roles and responsibilities.

Shared care registers and shared care plans

A **shared care register** is usually a computerized record of all patients jointly cared for by the two services. It might consist of all those who have been discharged from hospital in the past 2 years, all those who have been on a psychotropic drugs for longer than a year, and all psychotic patients known to the GP who have not had an admission to the hospital. The record gives information about the key worker, outpatient clinics are held in the surgeries, and 'good practice protocols' can be developed, so that the case register can be audited against what other teams agree is good clinical practice.

Shared care plans follow on from this development. Such a plan gives the primary care staff information about symptoms which they may expect while the patient is well, likely symptoms in relapse, the name of the key worker, and full details of whom to contact in an emergency both during the day and at night. The plan makes clear who is responsible for medication, and gives an acceptable alternative should the GP find it necessary to vary the medication. It is essential that these plans are mutually agreed between the two teams, rather than being imposed by one team on the other. GPs in England are now being remunerated for keeping registers of patients with psychotic illnesses, dementia, and learning disabilities.

Improving the mental health skills of GPs

About half of GP trainees have a 6-month psychiatry hospital attachment, many of which are considered to be unhelpful for a future generalist career.[59] Many GPs have had no higher professional training in mental health and are not required to do so. There are several GPs who may have previously trained in psychiatry or psychotherapy (e.g. cognitive analytic psychotherapy, CBT, family therapy, etc.) before entering general practice and there is a growing national network of GPs with a special interest in psychiatry (GPsis) with the development of a national course for GPsis to Diploma/Masters level organized by PRIMHE, the National Primary Care Mental Health charity for professionals (www.primhe.org). The GPs network covers most regions and greatly overlaps with the National Trailblazer network (www.iop.kcl.ac.uk). Trailblazers was developed 10 years ago by one of the authors (AT) to bring together professionals from primary and secondary care to work together in pairs to build bridges and

enhance local services by working on a local service development project together with supervision. Trailblazer courses bring pairs together for tutor and peer supervision of projects for up to a year. To date nearly 1000 GPs, psychiatrists, CPNs, PNs, etc., have participated in this way and trailblazer training centres now run in every region in England, supported by the Regional Care Services Improvement Partnership Development Centres (www.csip.org.uk/regions) of the UK Department of Health. International trailblazers is now part of the International Initiative for Mental Health Leaders (www.IIMHL.org) and runs in New Zealand, United States, and England where there is the added interest of comparing service systems by participants who have exchange visits as modules rotate in the three countries. Trailblazers has been positively evaluated for the adult-centred learning approach.[60] Another well-recognized Quality Improvement Programme with a long history of working in primary care has recently focused its methods on common mental health disorders. The Improvement Foundation (www.improvement foundation.org.uk) formerly known as the National Primary Care Development Team (www.npdt.org.uk) have been working with 20 PCTs in England using a Plan Do Study Act cycle (PDSA) to help practices improve their depression care.

As there are few opportunities for primary care workers to obtain mental health skills training, one successful distance learning method involves the use of training DVDs. 'Micro-skills' of assessment or treatment of mental health disorders can be demonstrated by real-life general practitioners with actor–patients in 10 min consultations. The learner is then encouraged to practice these skills using role-plays supplied with the DVDs. A series of existing training materials have been put together for the World Psychiatric Association (WPA) which involves two of the authors (DG and AT) and colleagues from the Institute of Psychiatry, and Prof. Linda Gask and her colleagues at Manchester University. The materials in this WPA package cover depression, somatization, chronic fatigue, schizophrenia, anxiety, and dementia (see www.iop.kcl.ac.uk or www.man.ac.uk for further details).

Summary

At one time, it was asserted that the 'worried well' were treated in primary care, while true mental illnesses were seen by the mental illness services. This was not true when it was asserted, and is even less true now. The great majority of patients with common mental disorders are cared for within primary care, and many of those with severe mental illnesses are only seen in primary care. 'Stepped care' is a model for distributing clinical problems between the services, and 'shared care' refers to the care of patients seen by both primary care and specialist mental health services. Many other workers in primary care now assist GPs with the treatment of mental disorders, and special administrative arrangements within primary care are necessary to ensure that clinical services are available to those with special needs.

In summary, mental disorders in primary care:

- Are an important public health problem
- Frequently present with somatic symptoms
- Are more likely to be detected if the doctor has better communication skills
- Those with disabling physical illnesses are also at greater risk
- Are on average less severe than those seen in specialist care

7.9

The role of the voluntary sector

Vanessa Pinfold and Mary Teasdale

What is the mental health voluntary sector?

The voluntary sector plays an important role in the mental health field across the world. Originally set up and run by volunteers, the prime motivation and purpose for this sector is improving the lives of people affected by mental health problems by doing things differently, tirelessly pushing for change, never giving up hope and working alongside service users (also known as patients and consumers) and their families every step of the way. In some countries it has been labelled the 'third sector' to distinguish it from other organizational sectors namely industry (private sector) and government (public or statutory sector).

The voluntary sector is not, however, a cohesive group of organizations and across the mental health community each one operates with its own specific remit. Some of these organizations have become large businesses providing a wide range of services under contract with statutory agencies. Others choose to avoid employing staff and are still run entirely by committed volunteers. Many rely on voluntary donations in order to remain fiercely independent of government. Each has its own aims and mission, core stakeholder group, trustee and membership structures, management systems, governance procedures, and a unique portfolio of activities.

Some mental health organizations focus activities on mental health or emotional well-being specifically (e.g. Finnish Association for Mental Health). Others target a social problem and support all those affected such as charities working with the homeless, refugees, victims of domestic violence, or young offenders, including people with mental health problems. There are organizations that primarily campaign, educate, advocate, lobby, and promote self-help resources such as EUFAMI—an association for families across Europe and SANE Australia. In parts of the world, including Eastern Europe, there are particular challenges in mental health resulting from poverty, dislocation of the population, and insufficient resources for health. Some states, like Armenia, have no mental health services. Here, the Catholic Agency for Overseas Development (CAFOD) is working with Armenia's Association of Child Psychiatrists and Psychologists to provide therapy and mental health care and to increase awareness and understanding in order to overcome prejudice.

Wherever they work, key characteristics of voluntary sector organizations include an independent position, a strong values base, empowerment principles, non-profit distributing of resources, passionate commitment to the work focus, rooted to service user, and carer experiences and they are always striving for changes to provide people with mental health problems better provision and opportunities. Most started as local support groups but some have grown into large national organizations with considerable political leverage. The National Schizophrenia Fellowship (known today as Rethink) was founded in 1972 by a group of families concerned that relatives of people with schizophrenia had no support for themselves. In this chapter we draw on the Rethink experience to illustrate how the voluntary sector contributes to, and shapes, modern psychiatry. Although the English experience does not directly map onto those in other countries across the world, there are similarities and we seek to highlight these through the use of international examples where possible.

Rethink severe mental illness

Rethink is a membership charity with 7500 members (service users, carers, mental health professionals, the general public) whose mission is 'to support everyone affected by severe mental illness recover a better quality of life'. It adopts a recovery-orientated approach to supporting the individual and their family through periods of ill health and their journey of recovery. This perspective is significantly different from that of clinicians and statutory providers, who have not been through the experiences common to people who suddenly have to cope with severe mental illness. Rethink staff descriptions of their role include:

> *Bridging: linking a person with non-judgemental delivery of services connected with service user and carer experience*
>
> *Ensuring service users are heard and needs met more holistically*

Initially providing mutual support, the organization later offered information resources which address the problems commonly encountered by service users and carers, like difficulty in gaining access to services or funding for appropriate care. The emphasis is on finding successful strategies which achieve solutions. Advocacy is provided for individuals and families whose needs are not being met. The experiences of service users struggling to cope provide detailed evidence which is used to develop Rethink's policy on the mental health issues which reach the political arena and also as the basis of campaigns on stigma and discrimination. Research and

surveys of service user and carer views form the basis of reports on vital issues, like how information can be provided to carers with due respect for the service user's privacy and autonomy. Guidance on good practice may be developed and sometimes training for professionals. Media activity has publicized Rethink's campaigns and using the internet has made dissemination of information cheaper and easier than it used to be.

Rethink's activities also include the provision of front-line services in partnership with the National Health Service and Social Services (statutory sector) for example supported housing schemes, advocacy projects, community resource centres, carer support services, employment and training programmes, school education projects, and mentoring programmes for young people. In 2007, Rethink ran 350 front-line mental health services and employed approximately 1300 staff.

Does the voluntary sector make a difference?

The voluntary sector makes a substantial contribution to both the image of psychiatry and its practices. For example in New Zealand, the Mental Health Foundation has worked in partnership with the Ministry of Health and other agencies to run a successful anti-discrimination campaign—like minds, like mine (whakaitia te whakawhiu i te tangata) for the past 10 years. This is an internally renowned mental health awareness programme that is transforming how the New Zealand public engages with mental health issues. Non-Governmental Organizations (NGOs) can also bring influence to bear at a national level and bring people together to plan new service models. The World Fellowship for Schizophrenia and Applied Disorders (WFSAD) supported a workshop in East Africa in 2003 where service users and families could meet with government ministers and medical professionals to discuss plans for achieving effective health care delivery. In England, the voluntary sector has collectively ensured that the published clinical guidelines describing best practice for the treatment of schizophrenia in 2002 took note of service user and carer treatment preferences. In India, Action for Mental Illness (ACMI), an advocacy initiative has achieved tax concessions for those with mental illness and their carers and also maintenance allowances equivalent to those provided to people with physical disabilities.

Standards of mental health care delivery vary dramatically—with cases of human rights abuses in psychiatry being documented in some countries and innovative services emerging in others in response to local demands. The voluntary sector can, and does, bring the spotlight on both ends of the service delivery spectrum (good and bad) and demand better for everyone. It also leads the way by developing innovative solutions both in terms of service delivery, public education, and self-management techniques. In the United States, NAMIs Peer-to-Peer Education Course is a 9-week experiential education course on the topic of recovery for anyone with serious mental illness who is interested in establishing and maintaining wellness. In Canada, a family to family network was established for first episode psychosis families by the Canadian Mental Health Association. The recovery model is being pioneered and embraced by the voluntary sector across the world. However, this relatively new approach requires a change of attitude by both service users and professionals as shown by the Scottish recovery network programme.

Common themes tend to emerge through the campaigns of voluntary organizations across the world, in spite of differences in wealth and varying stages of development. In most places the demands are for earlier intervention, better crisis response, more support for families, and less use of physical restraint on the ward when coping with challenging behaviour. The transition to care in the community presented a new set of problems, not least the need for different professional skills and adequate resources. And in the later part of the last century, the controversy over community treatment orders was raging in many countries. Changes in government policy and concerns over access to newer treatments resulted in new alliances in many countries, and the voluntary sector, clinicians and other professionals often learned to work together, recognizing how in alliance they could lobby more effectively for better law and more resources.

An excellent example of successful partnership working in England and Wales has been the formation of a coalition known as the Mental Health Alliance involving 80 organizations. Professional bodies have joined, including the Royal College of Psychiatrists as prominent and active members. The Mental Health Alliance has opposed the government's proposals for reforming the Mental Health Act 1983 for the past 8 years and has managed to achieve some change in the content of the legislation as well as delaying the whole process.

The role of critical friends

The independence of organizations is an essential characteristic of the voluntary sector. These bodies do occupy the territory of 'critical friends' to both the statutory and private sectors of the mental health community, monitoring activity and speaking out in praise of positive developments but also highlighting when things are wrong.

For example at Rethink experience shows that misdiagnosis can result in inappropriate care and treatment with tragic consequences like imprisonment, suicide, or even homicide. Therefore Rethink supports service users in obtaining expert second opinions. Providing families or individual service users with accurate but understandable information enables them to challenge the opinion of a psychiatrist or medical team if this seems appropriate.

Rethink also advocates for families by using the complaints procedures or by providing legal representation at inquest hearings in order to draw attention to deficiencies in support, care, and treatment. They focus efforts on cases where systemic problems played a part, like a poor approach to risk assessment or refusal to accept information from families. The aim is to persuade the Ombudsmen or coroners to recommend improvements in the local policies and procedures in order to improve the quality of services.

In recent times there has been a spotlight on mental health services' engagement with people from Black and Minority Ethnic groups (BME) in England. The BME voluntary mental health organizations have formed a network which aims to reduce inequalities and promote good practice in mental health for racialized groups. The Network has been very critical of the Government's proposals to amend mental health legislation and has criticized the statutory health sector for failing to meet legal requirements on race equality. Similar issues arise in the United States where the National Council of La Raza (NCLR)—the largest national Hispanic civil rights and advocacy organization in the United States—works to improve

opportunities for Hispanic Americans. They report that Latinos are at a disproportionately high risk for depression and other conditions associated with mental illness, and are also much less likely to seek treatment or receive quality culturally and linguistically competent care.

Conclusion

The voluntary sector is a dynamic and vital part of any mental health system. Rooted in the experiences of mental health service users and carers, voluntary sector organizations across the world ensure that the voices of 'experts by experience' directly influence campaigns, policy debates, service redesign, and project planning and treatment guidelines. The sector is, however, fragile and in some countries organizations are increasingly dependent on state funding which could undermine their autonomy and independence. Psychiatrists can support their local voluntary organizations by joining them—as members, as campaigners, and as educators. The sector can also support psychiatrists, helping to transform the public image of psychiatry and encouraging young people to take an interest in mental health as a career option. The alliances forged with psychiatrists and their representative bodies are crucial for improving the quality of mental health services and to effectively tackle stigma and discrimination. We do need each other in order to deliver better outcomes for mental health service users and their families.

7.10.1 The special psychiatric problems of refugees

Richard F. Mollica, Melissa A. Culhane, and Daniel H. Hovelson

While the forced displacement of people from their homes has been described since ancient times, the past half-century has witnessed an expansion in the size of refugee populations of extraordinary numbers.[1,2] In 1970, for example, there were only 2.5 million refugees receiving international protection, primarily through the United Nations High Commission for Refugees (**UNHCR**). By 2006, UNHCR was legally responsible for 8.4 million refugees. In addition, it is conservatively estimated that an additional 23.7 million people are displaced within the borders of their own countries. Although similar in characteristics to refugees who have crossed international borders, internally displaced persons do not receive the same protection of international law. Adding all refugee-type persons together, the world is forced to acknowledge the reality that over the past decade more than 10 000 people per day became refugees or internally displaced persons.

The sheer magnitude of the global refugee crisis, the resettlement of large numbers of refugees in modern industrial nations such as Canada, the United States, Europe, and Australia, and the increased media attention to civil and ethnic conflict throughout the world has contributed to the medical and mental health issues of refugees becoming an issue of global concern. This chapter will focus on a comprehensive overview of the psychiatric evaluation and treatment of refugees and refugee communities. Although this mental health specialty is in its infancy, many scientific advances have been made that can facilitate the successful psychiatric care of refugee patients.

Definition

The definition of a refugee as outlined in the 1951 Convention and 1967 Protocol relating to the Status of Refugees is presented in Box 7.10.1.1.[3] A person or persons who has passed over from one country into another seeking protection from violence and who cannot return to his country of origin because of fear of persecution or injury is considered a refugee according to international law.

The 1951 Convention Relating to the Status of Refugees was drawn up by the United Nations parallel to the creation of UNHCR. This Convention and the subsequent 1967 Protocol establishes

Box 7.10.1.1 Definations according to the 1951 convention and 1967 protocol relating to the status of refugees

Article 1—Definition of the term 'refugee' A(2) [Any person who] . . . owing to well-founded fear of being persecuted for reasons of race, religion, nationality, membership of particular social group or political opinion, is outside the country of his nationality and is unable or, owing to such fear, is unwilling to avail himself of the protection of that country; or who, not having nationality and being outside the country of his former habitual residence . . . , is unable or, owing to such fear, is unwilling to return to it. (As amended by Article 1(2) of the 1967 Protocol.)

Article 33—Prohibition of expulsion or return (refoulement)
(1) No contracting state shall expel or return (refouler) a refugee in any manner whatsoever to the frontiers of territories where his life or freedom would be threatened on account of his race, religion, nationality, membership of a particular social group or political opinion.

international law for the definition of refugees as well as the protection accorded to them. It also articulates the important principle of *non-refoulement* (Box 7.10.1.1), which states that no refugee can be returned to his or her country of origin or any other location where there is any probability that he or she will be harmed. These legal definitions indicate that a refugee is not an economic migrant or a traditional immigrant. Sadruddin Aga Khan, in a seminal report, was one of the first High Commissioners to acknowledge the human rights violations that are primarily responsible for the generation of refugee populations.[4] Corresponding to these international covenants, the international community has focused on the protection of refugees. There are two components to protection that are classically viewed by UNHCR as an essential aspect of its mandate. These two elements include protection against:

1 ongoing violence and potential injury to the refugee including being denied proper asylum and involuntary repatriation;

2 lack of adequate food, water, clothing, and other forms of material assistance.

The UN Declaration of Human Rights adopted by the United Nations in December 1948 and the United Nations Convention against Torture and Other Cruel Inhuman or Degrading Treatment or Punishment adopted in December 1984 extends the basic principles of refugee protection and asylum, and reaffirms the principle of *non-refoulement*. In most refugee crises, not withstanding the political and military barriers to protection, UNHCR and the international community strive to offer refugees a safe asylum and basic humanitarian aid.

Trauma and torture

By definition, most refugees have experienced traumatic life events of extraordinary brutality. Since the Second World War, empirical studies have investigated the relationship between mass violence, the refugee experience, and psychiatric morbidity. The earliest research focused on survivors of the Nazi concentration camps.[5–8] Shortly after the Second World War, Eitinger and his colleagues gave a detailed account of their medical and psychiatric examinations of concentration camp survivors. They postulated that the traumatizing process had a dual nature. They described the somatic traumas of captivity, such as head injury, hunger, and infections, as leading to a 'psycho-organic syndrome', and the predominately psychological traumas as leading to other psychiatric disorders such as depression. Thygesan's studies of concentration camp survivors in Denmark revealed similar results.[9,10] These early pioneering investigations of the psychosocial sequelae of the Nazi concentration camps established a preliminary baseline of traumatic outcomes for future generations of refugees, many of whom had experienced the trauma of similar experiences in Cambodia, Bosnia-Herzegovina, and elsewhere.

Increasingly, civilian populations carry the burden of ethnic conflict and mass violence. It is now estimated that more than 80 per cent of casualties caused by the recent violence in Africa, Asia, and Europe have primarily affected non-combatants.[11] Extensive research has revealed the major trauma events experienced by refugee populations fall into the eight groups below:

1 material deprivation

2 war-like conditions

3 bodily injury

4 forced confinement and coercion

5 forced to harm others

6 disappearance, death, or injury of loved ones

7 witnessing violence to others

8 brain injury

Every refugee situation will have a range of traumatic events that will fall into each of these categories that are unique or characteristic of a specific conflict. It is essential that the specific types of violence experienced by a given refugee population are well known to the psychiatric clinician who can use this knowledge to assess potential traumatic outcomes.[12] In addition to many unique forms of violence occurring in different refugee settings, the meaning of violent events also differs across cultures. Anecdotal, clinical, and epidemiological evidence suggests that certain categories of refugee trauma are more potent than others in producing psychiatric morbidity and other traumatic outcomes. Brain injury, sexual violence, torture and other forms of bodily injury, coercion, and forced confinement have great potential of causing psychiatric harm in refugees exposed to these events. Consistent with indicators of the 'potency' of specific trauma events, there evidence of a dose–effect relationship between cumulative trauma and psychiatric symptoms.[13] The personal aspects of human suffering associated with specific types of trauma, such as the murder of a child or the disappearance of a family member are still relatively undefined but obviously very difficult.

Many refugees have actually experienced torture. Recent research states that the most significant finding in the last 7 years may be that either torture has become more prevalent worldwide or the total number of events reported has increased, likely as a result of advocacy and elevated media attention.[14] After 25 years of research on treatment work with torture survivors, still no consensus exists for effective interventions within the field.

Conceptual model of traumatic outcomes

Research on refugees has revealed the persistence of negative health and social outcomes decades after their initial experience of violence and dislocation. Emergence of standardized criteria for psychiatric diagnoses and disability and the demonstrated ability to elicit trauma events through simple screening instruments in culturally diverse populations have allowed evidence to accumulate suggesting a model of traumatic outcomes associated with the refugee experience. This model is primarily based upon the classic epidemiological triad which describes the interaction between host (i.e. the refugee), agent (i.e. traumatic life experiences), and environment (e.g. refugee camp) in the pathogenesis of psychiatric disorders.[15,16] This model, illustrated in Fig. 7.10.1.1, allows equal attention to be given to all aspects of the refugee experience.

The model in Fig. 7.10.1.1 has three major elements. First, it suggests that the major medical outcomes associated with the refugee experience are medical illness, psychiatric disorders, and disability. Second, trauma and the personal and environmental characteristics of the refugee describe the major risk factors associated with violent outcomes. Third, the direction of the causal arrows in the model do not imply a lack of reciprocal relationships where none is indicated; instead they indicate what most investigations consider

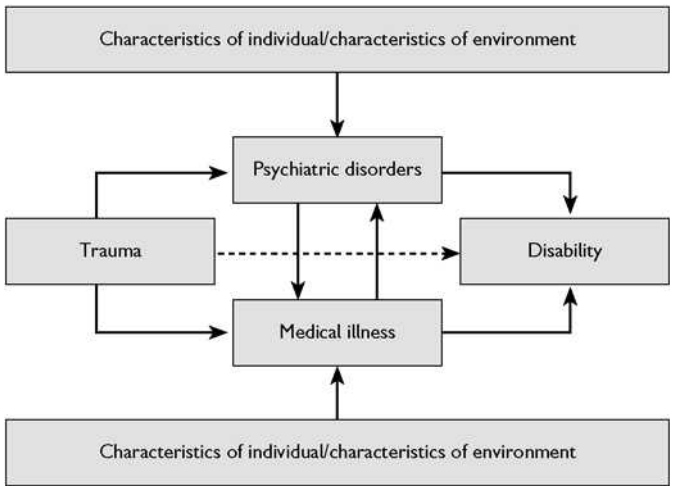

Fig. 7.10.1.1 Conceptual model of refugee risk factors and traumatic outcomes.

to be the most dominant causal relationship. Despite its limitations, this simple conceptual model can provide the psychiatric professional with a scheme for approaching the refugee patient from either a clinical or public health perspective. The importance of the socio-cultural and political context unique to each refugee situation and its impact on each of the model's pathways cannot be overstated, since refugees come from diverse cultural groups and political experiences.

Health status and medical illness

Refugees experience many diseases and chronic debilitating conditions, such as starvation and landmine injuries that have both immediate and long-term effects on their physical health. Every refugee situation involves many unique but common acts of violence leading to major medical sequelae. For example, gender-based violence and rape, which were instruments of ethnic cleansing in the Balkans, resulted in pregnancy, medically complicated self-administered abortions, and sexually transmitted diseases.[17] Extensive documentation of refugee survivors of torture describes the medical sequelae of torture and the causal link between refugee trauma and medical mortality and morbidity over time.

Throughout the process of migration, refugees are frequently exposed to infectious diseases and physical or psychological trauma that can have a profound impact on their overall health and well-being. Refugees are at increased risk for diseases such as obesity, diabetes, and heart disease, and often encounter significant barriers to employment and health care when attempting resettle. For these reasons, programmes implemented in the refugees' country of resettlement designed to improve health-seeking behaviours and overall self-care can have a positive, lasting impact on refugees' physical and mental health.[18]

Psychiatric symptoms and illness

Observations since Kinzie *et al.*[19] and Mollica *et al.*[20] first diagnosed PTSD in Cambodian refugees, have made the cultural validity of PTSD seem almost certain. However, this reality does not negate the importance of culture-specific symptoms related to trauma that are independent of PTSD criteria. Recent large-scale epidemiological studies of refugee populations have confirmed the high prevalence of major depression and PTSD in Western (e.g. Bosnian[21]) and non-Western (e.g. Cambodian[22] and Bhutanese[23]) refugee communities. The mental health impact of major depression, which presents both as a comorbid disorder with PTSD and alone, is chronic, severely disabling and demands the attention of the clinician working with refugees. Longitudinal data indicates that 45 per cent of Bosnian refugees who met criteria for PTSD, depression or both continued to meet criteria for these disorders 3 years later.[24] Similar results were found in a longitudinal study of Cambodian refugees 20 years after resettling in the United States.[25] As with Western populations, depression in refugees tends to be under-diagnosed and can be expressed as somatic complaints. A study of Vietnamese refugees showed high prevalence based on self-report, but high rate of physician under-diagnosis. Most patients with depression (95 per cent) presented with physical complaints.[26] These finding underscore the importance of depression screening especially in the primary care setting.

New research indicates that there may be memory problems in refugees with PTSD. When asked to recall traumatic events refugees with PTSD reported an increased number of traumatic or torture events over their baseline report, as compared to those with other psychiatric disorders who showed no change or decreases in number of events reported.[27] Substance use disorders are often overlooked in refugee populations but are often comorbid with PTSD.[28] Early in the 1980s reports of Hmong refugees using opium emerged.[29] Substance use disorders have been shown to have a delayed presentation of 5 to 10 years after the initial settlement of the refugee.[30] However, substance use disorders may vary by population. One recent study of Cambodian refugees in the United States reports low rates of alcohol use in the past 30 days.[31] Screening for substance use disorders especially in primary care is important. Complex grief reaction and chronic insomnia are also prevalent in this population.

(a) Head injury

Clinical evidence is also emerging identifying head injury as a cause of significant psychopathology in refugee survivors. Head trauma is one of the most common forms of torture, so much so that reports of torture almost always imply that some kind of head trauma occurred. Many head injury survivors experience seizures and headaches, as well as behavioural disturbances such as aggressiveness, irritability, and sleep disturbances. Recent research on Vietnamese ex-political detainees who experienced head trauma while in captivity indicates that the number of head injuries is related to a decrease in executive functioning, those with head injury have increased risk of developing PTSD, and had decreased cortical thickness in several brain regions (Mollica *et al.* 2007, unpublished). The long-lasting effects of head trauma are serious and pervasive, affecting both the injured individual and their family. The presence of head trauma in torture victims has been overlooked in past research, but awareness is growing.

(b) Functional status and disability

Although the functional status of refugees at the emergency and long-term ends of the continuum of the refugee experience has received little attention, the significance of this traumatic outcome is beginning to emerge. Until recently, the standard operating model of refugee protection has not been asked to determine the long-term socio-economic damage caused by the refugee experience. The answer to this question is extremely important to the

recovery of societies in which the majority of the population has been displaced. In many societies, the refugee experience is the majority experience, which has strong implications for future socio-economic development. While the prevalence of functional impairment and disability is unknown in refugee populations, a recent epidemiological study of Bosnian refugees in Croatia reveals that functional disability may, in fact, be extremely high, especially in elderly refugees.[21] Furthermore, disability may be exacerbated in refugee survivors who have both chronic medical and psychiatric disorders.

Psychiatric assessment

This section reviews key factors unique to the psychiatric evaluation and diagnosis of the refugee patient.

Primary care: the proper setting for a refugee clinic

The psychiatric literature has generally stressed the importance of evaluating and treating refugee patients in a primary health care setting, whether in a refugee camp or in a country of resettlement. Four factors seem to support this viewpoint:

1 refugee patients seldom self-refer to psychiatry;

2 in many societies considerable stigma is associated with psychiatry but not with primary care medicine;

3 the majority of refugees seek out the care of their local medical doctors and indigenous traditional healers for the relief of their emotional suffering;

4 most refugees have associated medical and psychiatric disorders.

Considerable field experience has shown that establishing a mental health programme within a health facility where refugees already seek medical care can result in the highly successful utilization of psychiatric professionals and treatment.

Cross-cultural psychiatric assessment and diagnosis

Early research describing the psychiatric status of refugee survivors, especially those who had been tortured, refrained from the use of psychiatric diagnoses because of a prevailing perception that the observed symptoms were a normal response to horrific life experiences.[12] Similarly, many medical anthropologists believed that Western psychiatric diagnostic classifications were not relevant to the assessment of suffering in non-Western populations.[32] Despite these reservations, the emergence of standardized diagnostic criteria for major depression and post-traumatic stress disorder (PTSD) have allowed for the cultural validity of these diagnoses to be tested in a number of refugee settings. Cross-cultural research suggests that assessments of psychiatric illness should begin with phenomenological descriptions of folk diagnoses or culture-specific syndromes.[33] Important methods of exploring the validity of DSM-IV diagnoses in cross-cultural settings have included using culturally valid definitions of functioning and mental health problems based on local views of maladaptive thoughts and behaviour in response to distress, not preconceived Western diagnostic categories[34]; however, to date, not a single culture-specific illness associated with the mass violence and torture experienced by refugees has been defined.[35] On the contrary, the criteria for the two major diagnoses associated with violence in Western society, i.e. major depression and PTSD, have been successfully applied to refugees from many parts of the world. While high rates of PTSD can be measured in refugee patients and traumatized civilians, it is not known if other culture-specific symptoms not part of the DSM-IV criteria that may have greater clinical relevance and meaning to a specific refugee group. A general principle demonstrated by the World Health Organization cross-cultural study of depression,[36] i.e. that while some depressive symptoms may be present across cultures, they may not be the symptoms most strongly endorsed by the patient; this principle may also apply to PTSD. Figure 7.10.1.2 provides an illustration, which can help to address the problem of psychiatric diagnoses in refugee patients. This figure suggests that, until further research is forthcoming, the psychiatric provider needs to determine clinically whether the refugee patient is presenting with scenario A, B, or C.

The high prevalence of psychiatric symptoms associated with trauma in refugee populations neither affirms nor negates the 'normalization' of these symptoms. A narrow medical viewpoint could create a psychiatric redefinition of refugee mental health problems that would place the majority of refugees in a 'mentally ill' box without any access to individual psychiatric care; on the other hand, the hostility of many humanitarian aid workers toward psychiatry has denied the seriously mentally ill refugee legitimate access to psychiatric treatment. There will probably be a compromise at the intersection of public health objectives and the protection goals of humanitarian aid workers. In future, the presence of chronic and severe disability in refugee survivors will be the gold standard which drives the psychiatric and humanitarian rehabilitation of refugee survivors.[37,38]

Psychiatric screening

If mental health practitioners are to treat refugee patients, they must be able to assess the refugee's major risk factors and traumatic outcomes. Simple screening instruments culturally adapted to the language, trauma, and symptoms of refugee patients have been found to be extremely effective as well as being well received by refugees themselves.[39–41] For example, a simple well-known

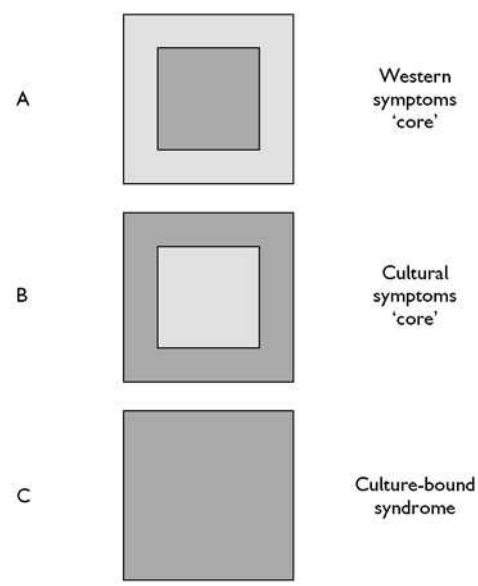

Fig. 7.10.1.2 Comparison of diagnostic classifications.

screening instrument adapted from the Hopkins Symptom Checklist allowed Indochinese patients for the first time to provide their symptoms with little distress. The development of the Harvard Trauma Questionnaire further revealed that these same patients could provide answers to lists of possible trauma events and symptoms without becoming retraumatized. Overall, two major lessons have been learned from the use of simple checklists with refugee survivors.

1 The checklist acknowledges the traumatic life experiences of the refugee survivors and *de facto* gives them permission to elaborate on the details of their trauma.

2 The checklist, as a simple medical test, helps refugees to 'put words around' events and symptoms that would be too emotionally overwhelming for them in an open-ended interview.

Extensive research regarding appropriate methods of development, translation, and validation of the clinical screening instruments such as the Hopkins Symptom Checklist and Harvard Trauma Questionnaire has been widely disseminated.[29,42]

Understanding somatic complaints

For years it was considered standard psychiatric wisdom that emotional distress, especially in non-Western patients, was primarily somatic in character; and that, because of their dominant expression of suffering through somatization, these patients were not psychologically minded, making them incapable of participating in psychotherapy or counselling. Extensive clinical experience and scientific studies with refugee patients throughout the world have led to a revision of these previously dominant professional attitudes. While it may be valid that some refugees primarily present their emotional suffering through somatic complaints, it has also been found that it is fairly easy for the medical practitioner to obtain from refugee patients deeper insights into their feelings and their beliefs as to the causes of their emotional distress. Often because of severe victimization, refugees as a group will not readily share their experiences of trauma and related medical and psychiatric injuries unless they are in a highly confidential environment where it is clear that the medical team can be trusted. In fact, the ability of refugee patients to extend themselves beyond their initial somatic complaints, as well as participating in clinical dialogue with the psychiatric practitioner as to the nature of their mental distress, is more the rule than the exception and is a major goal of assessment.[43]

Psychiatric treatment

The trauma story

The trauma story emerges as the centrepiece of any treatment approach. Every refugee patient has at least one traumatic experience that figures prominently in his or her life history. The trauma story is a living reality and is present for every patient. The trauma story is also present for the clinician. Yet, the story can be elusive and difficult for both patient and doctor to share. Often times when the patient is ready to tell the trauma story, the clinician is not ready to hear it. More frequently, when the clinician is ready for the patient to tell his or her story, the patient is unwilling. Therefore, one of the major goals of psychotherapy with refugees is to allow the trauma story to emerge gently and become a familiar and acceptable theme, which the refugee is not shamefully hiding from his or her therapist and ultimately his or her family and community.[44]

(a) Debriefing

Although commonly conducted within populations who have experienced trauma, typically by relief workers or crisis counsellors, debriefing has been shown to have negative effects on psychiatric outcomes and should be avoided at all costs.[45] As described above, the trauma story should be allowed to emerge naturally and at the patient's own pace.

(b) Treatment

Psychiatric treatment of refugee patients should primarily be based upon standard psychiatric practices for mentally ill patients, including the appropriate use of psychotropic medicines. However, a number of novel therapeutic approaches have been used with refugees. Recent research in refugee populations has indicated that cognitive behavioural therapy (CBT) is efficacious for treatment-resistant PTSD and panic attacks[46,47] and in refugees who have experienced torture.[48] Interpersonal psychotherapy for depression has been found to be useful in rural Uganda.[49] This approach may also be effective with resettled refugees in Western countries. In female veterans of war, prolonged exposure therapy was more effective over time than other interventions for reducing symptoms of PTSD in female veterans of war. It may be possible and beneficial to use prolonged exposure therapy for others with PTSD.[50] Similarly, although no research has specifically examined the effects of therapies such as eye movement desensitization and reprocessing (EMDR) for refugees, positive results have been seen in a variety of different studies done with traumatized populations, including individuals with PTSD. Traditional medicine, which includes diverse health practices, knowledge, and beliefs is widely accepted and practiced worldwide. Traditional medicine typically relies upon local classifications of emotional distress and its treatment can incorporate plant-, animal- or mineral-based medicines, as well as spiritual therapies or massage.[45] Traditional healing approaches were widely used for the Cambodian refugee crisis of the 1990s.[51–53] Although widely used, no conclusive research has yet been done using complementary treatments such as massage, acupuncture or herbal medicine in the treatment of torture survivors.[14] Recent research with Cambodian refugees it was shown that interventions supporting work, altruism, and spirituality for refugees might serve as protective factor for the onset of psychiatric disability.[54]

Special considerations

A number of special considerations have emerged from the many therapeutic approaches that have been tried with refugees.

Family focus

Treatment should be directed at the entire family of the identified refugee patient. The refugee crisis tends to initiate a process in which surviving family members become each other's major social support system. The disruption and disintegration of stable communities and traditional social supports place the entire burden of survival upon family members. Sometimes in extreme situations that affect the family unit such as when a refugee is experiencing symptoms of depression, psychosis, or social withdrawal, the psychiatrist must reach out to the patient and establish a one-to-one therapeutic relationship until family members can be of assistance.

Cultural sensitivity

The cultural sensitivity of refugee mental health practitioners is essential to the proper therapeutic relationship to the refugee patient. This means that the refugee mental health practitioner must be informed as to the type of trauma experienced by the refugee and its socio-cultural meaning, the cultural idioms by which human suffering is expressed in a given community, and the social stigma associated with mental illness. Despite the refugees' own adversity, long-standing social prejudices against mental illness will persist throughout the refugee crisis.

Little cross-cultural literature exists on the relationship between refugee patient, Western professional, and bilingual interpreter. The use of refugees as interpreters can be problematic. Ideally, health professionals from the refugee communities should be recruited to participate in psychiatric intervention. These individuals have had professional medical training as to the importance of confidentiality and can also provide insight into the cultural nuances of the doctor–patient relationship. The use of untrained interpreters from the refugee community should be avoided if at all possible. This is especially true of family members or members of a community or government institution that has previously threatened the security of the refugees. In addition, medical practitioners must respect patient dignity by not allowing young people to interview community elders or males from the community to ask refugee women explicit sexual questions and/or witness or be exposed to an undressed refugee woman during a medical examination. The more the bicultural interpreter can function in the role of a trained mental health paraprofessional, the more successful will be the therapeutic experience of all involved.

Caring for the seriously mentally ill

Despite numerous biases against psychiatric intervention in refugee populations, psychiatrists are well positioned to treat the seriously mentally ill refugee. In most refugee camps, those in immediate danger are the psychotic and depressed refugees with suicidal ideation. These individuals have difficulty coping with their ongoing crisis and have high mortality rates. Once resettled, these refugees with serious mental health issues need appropriate medical and mental health services.[55]

Special treatment needs of gender-based violence

Many colleagues in the field of refugee mental health have sought to break the 'conspiracy of silence related to sexual violence'.[32] While this issue has been well documented in refugee communities, it was not until the Bosnian conflict that rape was finally accepted by the international community not as a criminal act but as a crime against humanity. This recognition of gender-based violence as the most common type of torture of women, as well as a major terrorist instrument of war, has contributed to the protection and psychiatric care of sexually abused refugee survivors. While the political will now exists to condemn rape, and to protect refugees from it, the cultural stigma and corresponding social punishments of women considered 'tainted' by sexual violence, sometimes including their murder ('honour killing') by relatives, continues to make the psychiatric care of these survivors extremely difficult. In most cultures, rape remains a secret issue caused by the refugee's extreme resistance to reveal any details to the physician. Psychiatric practitioners must approach this issue with extreme caution in a strictly confidential manner. They must also be aware of the severe consequences to the patient if the rape experience becomes public knowledge, even to the patient's family members.

Risk and resiliency factors

The pre- and post-conflict personality characteristics of refugees that increase resiliency and reduce psychiatric distress and disability are not known. While certain demographic characteristics have been associated with negative traumatic outcomes, these characteristics may be confounded by other risk factors. Women, especially widows, seem especially vulnerable to negative refugee effects. UNICEF has extensively reviewed those risk factors associated with the vulnerability of refugee children and adolescents.[56] Data from Bosnian refugees correspondingly reveal the high rates of disability associated with trauma and psychiatric comorbidity in the elderly.

Lessons learned from studies of political prisoners in Turkey reveal the importance of a well-established political world view as a major protection against the long-term human suffering associated with torture.[57] Studies of Bhutanese refugees in Nepal confirm the possible protective function of Buddhism in devout refugee practitioners of this religion.[23] Anecdotal reports by refugees themselves consistently confirm the emotional safety that they have found in their spiritual and religious beliefs and practices. Finally, recent research findings concur with the earlier research in concentration camp survivors and prisoners of war that prior psychiatric history and premorbid personality factors may have little effect on the psychiatric sequelae of traumatic refugee experiences. In resettlement countries, opportunities related to family unification, learning to speak the new country's language, and employment have clearly been shown to be associated with decreased psychiatric morbidity over time. Those who provide psychiatric care for refugees must keep in mind the environmental opportunities that can increase their overall resiliency.

Reducing risk and maximizing resiliency

Figure 7.10.1.1 provides a readily accessible model for psychiatric practitioners to determine how they can reduce the risk factors associated with psychiatric disorders as well as promote the resiliency of the refugee patient. The section on risk factors provides many useful insights into the importance of enhancing the refugee's active role in work, spiritual participation, involvement in altruistic behaviour, and the many other personality and environmental factors that can directly reduce depression and other forms of psychiatric distress.

7.10.2 Mental health services for homeless mentally ill people

Tom K. J. Craig

Definition and demography of homelessness and its link to mental illness

The term 'homeless' has been used to describe populations as diverse as those sleeping in the shelter of a cardboard box, to those sleeping on a friend's floor. Given such wide definition, it is not surprising that estimates of the numbers involved vary greatly from survey to survey and from one country to another. But regardless of the definition, there is consensus that the numbers of homeless people in most Western urban areas increased during the past two decades, reflecting a scarcity of low-cost housing, the erosion of traditional family networks, and downsizing in the organization and delivery of supportive services. Of all these factors, the shortage of affordable accommodation is the most important. For example, in England there has been a 40 per cent increase since 2002 in the number of households on waiting lists for social housing with estimates that a minimum of 20 000 housing units above current government targets are required to simply meet newly arising urgent need.[1]

Compared with a domiciled population, homeless people are less likely to have completed basic education, less likely to have ever held employment, and more likely to have experienced parental neglect and abuse in their childhood.[2]

Given the evidence linking homelessness to poverty and social disadvantage, it is hardly surprising that homeless people report higher rates of psychiatric disorder relative to the general population. While rates vary depending on the particular measure of mental illness adopted by each study and by the homeless population being investigated, most report major psychiatric disorder in 30 to 60 per cent of those using emergency shelters and sleeping rough. The prevalence of schizophrenia and other psychoses is particularly high amongst the middle-aged residents of long-stay hostels, while depression, generalized anxiety, and impulsive self-harm are more typically encountered in younger runaways and adolescent populations. Alcoholism and drug dependency are present in as many as two-thirds of men and a third of homeless women. Co-morbidity of mental illness and substance use disorder is the rule rather than the exception as are the co-occurrence of respiratory disease, infections, trauma, and the physical consequences of poor diet, poor hygiene, and the complications of substance abuse. Of growing concern is the accumulation of older multiply disabled populations in some North American cities.[3]

The typical pattern of service utilization of the severely mentally ill among the homeless population is one of extremes—bursts of involuntary hospital admissions and compulsory treatment interspersed with long periods of neglect and isolation. Many of those who are found sleeping rough or resident in temporary shelters have found their way to these locations as a conscious effort to avoid contact with health and social care professionals and remain unwilling to be part of any structured rehabilitation programme.

Barriers to care

Poverty and isolation

Very few homeless mentally ill people have satisfactory links to family or other supportive social groups. Unemployment is the norm and many have histories of contact with the criminal justice system. The lack of supportive kinship networks mean that there is seldom anyone who has an interest in their welfare and no one on whom services can rely for informal care giving. Affordable housing is likely to be of poor quality and unsupervised. Landlords are reluctant to rent property to someone with a history of destructive behaviour, a criminal record, or manifest mental illness.

Barriers arising from the illness

Severe mental illness contributes to incompetence in many aspects of daily life, with impaired social function and problems initiating and executing daily living tasks that require a degree of forward planning. Co-morbid cognitive impairment or substance abuse compound these problems. Many homeless patients will have lost their accommodation as a direct result of their illness, being evicted

for failing to keep up with rent payments, neglecting or damaging the property, or following complaints from neighbours.

Barriers put up by services

The lack of common purpose and co-ordination of social welfare, health, and criminal justice agencies lies at the heart of many difficulties faced by homeless mentally ill people. A young homeless person, for example, may be too chaotic to undertake the retraining programme that is his only route to welfare support, may be unable to register with a local family health centre because of his lack of a permanent address, and may be summarily rehoused without reference to health services involved in his care. Finally, the prejudices of professionals can make services unacceptable and the emphasis on treatment is seldom attractive to a homeless person whose immediate needs are for food, shelter, and security.

Principles of service organization and delivery

To state the obvious, the solution to problems of homelessness lies in the provision of suitable accommodation, targeted efforts to re-house the most vulnerable, and sufficient longer-term tenancy support to prevent a return to the streets. While many countries have social welfare legislation to assist homeless people, only a minority provide a legally enforceable right to suitable accommodation for vulnerable populations. The Rough Sleepers Initiative in England, provides emergency accommodation for the roofless population and follows this emergency re-housing with a Tenancy Sustainment Programme of flexible practical and emotional support to prevent future accommodation breakdown.[4] This has been very successful in reducing the numbers of rough sleepers though gaps remain, particularly for people suffering from severe mental illness and substance dependency. For these populations, a further tier of service involving specialized mental health provision is needed either as part of an intensive initial stabilization[5] or in the longer-term. While the detail of specialized services varies according to local circumstances, they are all based on a small number of ideological and organizational principles (Table 7.10.2.1).

Improved inter-agency co-operation

As a first step, most involve a steering group comprising senior representatives of the key stakeholders in health, housing, social services, police, and voluntary sectors. These groups oversee the development of services across a wide geographical area—a large sector of a city or state. The members carry sufficient political and managerial authority to be effective in dealing with bureaucratic obstacles that are bound to arise from time to time.

Table 7.10.2.1 Services for homeless mentally ill people

Essential components for rehousing
Availability of temporary accommodation with a pathway to permanent housing
Capacity to deliver basic needs (shelter, food, income support)
Ongoing practical support to maintain tenancy
Specialized mental health service
Steered by a partnership of key stakeholders (housing, health, welfare, etc.)
Multidisciplinary front-line team
Assertive outreach model
Capable of managing mental illness and substance-use disorder
Wider context
Community-orientated mainstream psychiatric services
Influence of central and local government policies on health, welfare, and criminal justice

Providing local multidisciplinary specialist teams

This co-ordination is replicated at the local level through multidisciplinary clinical teams, joint working, and case management. Such partnership ventures have been established in several cities in North America, Europe, and Australia using a variety of organizational approaches ranging from a single multidisciplinary team through 'one-stop shops' where professionals from a variety of backgrounds come together to provide services at a common location.

Essential components of the specialist service

The management of a homeless mentally ill person involves stages of engagement, stabilization, resettlement, and the eventual transfer of care to mainstream providers. Engagement can take a long time, staff must be prepared to leave the clinic and go to where homeless people congregate. Help with welfare and practical problems may be all that can be done at first but the duty to maintain a therapeutic focus must always be maintained. Stabilization requires the specialist assessment and treatments provided to any mentally ill person, including hospital admission if necessary. The task of resettlement typically involves a compromise between personal preferences, available resources, and the level of support needed to promote rehabilitation. For example, independent accommodation may be a person's first choice but may only be a viable prospect if it can be backed up by weekly visits from the mental health team. Core and cluster arrangements, in which residents have their own flat but receive supervision from an on-site warden within the complex is a particularly effective model for those who have failed in independent accommodation but who reject shared facilities.

The eventual transfer of care to mainstream services can be quite difficult to manage and most follow-up studies suggest that fewer than half of those transferred remain in treatment.

Conclusion

Specialist multidisciplinary teams for homeless mentally ill people provide an essential safety net for those who have fallen out of the wider mental health care system. They offer distinct advantages in terms of their capacity to work across traditional geographical and bureaucratic barriers, to take the longer-term view of the task of engagement, and to bring together the multiple strands of care across different provider agencies. Introduced as a temporary measure over a decade ago, they are still with us and likely to remain a permanent fixture of urban mental health care.

7.10.3 Mental health services for ethnic minorities

Tom K. J. Craig and Dinesh Bhugra

Ethnicity, culture, and health care need

Services aimed at minority ethnic populations are all too often developed on the basis of conspicuous morbidity than on any real understanding of the diversity of ethnic minority communities and their wider health needs. For example, in England, while much has been written about ethnicity and psychiatric morbidity, the literature remains largely focused on African-Caribbeans and Asians, while the needs of the Irish, who comprise the largest ethnic community by migration in many parts of the UK are seldom explicitly addressed despite evidence of high rates of suicide and unexplained death many times in excess of the indigenous population.[1] In addition, the large numbers of asylum seekers and refugees who move around the world, brings an increased need for culturally sensitive services. But very few models exist for developing these. The principles of good practice indicate that the start has to be a clear knowledge of the population that will be accessing services and an appreciation of the complicating factors of social disadvantage, material deprivation, and poverty.

There is no doubt that social disadvantage and racial prejudice whether real or perceived are pivotal in determining not only the mental health of minority populations but also the pathways individuals and their families use in seeking help for ill health. Delays in help-seeking can also be due to the stigma of mental illness and to sufferers' fears that they will be misunderstood and mistreated because of differences in culture, language, and racist attitudes within the services. These factors may be more apparent in older individuals and those who were born outside the country who may not be aware of various options available to them. Studies over the past 30 years or more in Britain, the Netherlands, the United States, Canada, and Australia have shown that minority groups have lower access to mental health services, are less likely to receive care, and when they do this is more likely to be of a lower quality. Black people in the UK and the United States are more likely than white people to be compulsorily detained in hospital, to be screened for drug abuse, to receive higher doses of medication and physical rather than psychological therapies. They are over-represented compared with their numbers in the general population, whether in general wards, locked wards, secure units, court diversion schemes, special hospitals, or prisons.[2]

Some of these problems can be attributed to a lack of understanding on the part of mental health practitioners of the cultural beliefs, values, and practices of minority groups with consequent shortcomings in assessment, diagnosis, and the provision of care. While language can be a major obstacle, for many people from minority ethnic groups who speak English the problem is of communication rather than language. The power dynamic that is always present in any clinical consultation is magnified and both patient and doctor will have predetermined expectations of how their interaction will turn out depending upon their experience of previous consultations. Problems in the interaction are likely to be interpreted as arrogance and racism on the one hand and indifference, wariness, or docility on the other. Thus, both missed diagnoses and misdiagnosis may result. A lack of recognition of the personal, social, and cultural problems which influence the presenting patterns of symptoms in different ethnic groups can contribute to the tendency of clinicians to make assumptions and listen out for stereotypical triggers which then prompt a particular therapeutic response. Such triggers include religious euphoria, use of Cannabis in African-Caribbeans, and the 'fatalistic attitude' attributed to Asian patients.

Culturally competent services

The past decade has seen an emerging consensus that the way forward lies in the development of fully integrated multicultural services with good working links with the local minority community rather than separate services. Such services would provide staff who can understand their client's cultural background and the ways in which this influences the presentation of distress and disorder. There would be closer working links with religious leaders and healers of local ethnic minority communities, female-only areas on wards, and a greater involvement and support of the family in understanding the problems and developing solutions.

In North America,[3,4] Britain,[5] and Australia[6] there has been a significant 'top–down' pressure to shift health care organizations in this direction and several large-scale programmes such as the European 9-country 'Migrant-Friendly Hospitals' initiative[7] have been reported. Although differing in detail, all these programmes share common elements. These principles are outlined in Table 7.10.3.1 setting out the main conclusions in a 'bottom–up' approach in order to emphasize the importance of changes in the attitudes, knowledge, and skills of front-line managerial and clinical staff.

Commonly referred to as 'cultural competence' these attributes include attention to obvious language differences but go further to include history, traditions, beliefs, and values even if the latter differ from those held by the professional. A culturally competent clinician is sensitive to a patient's cultural influences, expressions of distress and help-seeking, and is also aware of their own attitudes and prejudices and how these are in turn shaped by their own cultural background. This objective is achieved through

Table 7.10.3.1 Organizational steps towards a culturally competent mental health service

1 **Workforce level**
Training in 'cultural competence' should be mandatory for all mental health professionals
(a) Undergraduate programmes
(b) Post-graduate as continuing professional development
2 **Health care provider level**
Provide accommodation, washing, and living space facilities that take into account different cultural and gender definitions of ordinary social behaviour, dignity, and respect.
Senior management responsibility and accountability for:
(a) Active race equality policies
(b) Recruitment policy—to increase presence of minority staff and provision of training and support as needed
(c) Ensure staff have received relevant cultural competency training
Ensure adequate data collection includes a robust estimate of the numbers of ethnic minorities using services with a focus on key areas such as disparities by ethnicity in the use of coercive treatments, dropout from follow-up; differences in the uptake of psychological and pharmacological treatments.
Specialized outreach services targeting mentally ill people in the criminal justice system, homeless, and refugee populations.
Partnership arrangements with NGOs including the provision of volunteer advisors and of translation services that do not rely on relatives or other informal carers.
3 **Wider health service level**
At the appropriate Regional or National HMO or Statutory Organization:
(a) Policy and practice commitment to removing barriers to access, e.g. extend health insurance to the uninsured and closer integration of primary and secondary mental health care
(b) Collection of good quality demographic information and ethnic monitoring for planning and overseeing services
(c) Minority representation at all levels of health service planning and delivery
Continue to expand the science base to determine what works best for whom

training and a plethora of different cultural competency/diversity courses have sprung up in recent years. A search of the Internet identifies courses in undergraduate nursing, medical, and pharmacy programmes, in post-graduate continuing professional development and as part of wider organizational change and development. While the moral argument for improved cultural competence is hardly contestable, whether or not these training courses are sufficient to effect lasting change in behaviour and the delivery of health care is less certain. The very limited empirical evidence base is predominantly from the United States and shows efficacy in terms of short-term changes in attitudes and knowledge. Evidence is still lacking on which elements of this training are essential and on the downstream effects on service quality that is the real target.

Table 7.10.3.1 also shows the other key steps that have been taken towards developing more culturally sensitive services. Most health service providers have gone some way to providing female-only inpatient wards, more community-orientated service settings and addressing the need for expanding the numbers of people from minority backgrounds in their workforce though it is still all too easy to think that problems with cultural sensitivity can be solved with this alone. Simply hiring people on the basis of nationality, ethnicity, or skin colour will not necessarily ameliorate problems in the service. Typically these staff are the lowest in the hierarchy of power and have the least capacity for influencing either the care of the patient or wider attitudes within the institution. Even when employed in a position of power there is a danger of their appointment being seen as tokenistic.

Another important step involves the elaboration of performance indicators to assess the impact of training and service changes and ethnic monitoring with a focus on key areas such as the use of coercive treatments, treatment discontinuation, and ethnic differences in the uptake of psychological and pharmacological treatments. In the most sophisticated systems this includes both quantitative epidemiological and economic data as well as qualitative inputs from consultation with users, carers, and the general public including community and religious leaders.[8]

Finally, at the wider community level, NGOs have often become the champion of good practice, seen by their users as an antidote to inadequate mainstream care. These small organizations are generally based on consultation with users, carers, and local mental health professionals and are more in tune with the expressed needs of the community. The best have good working relations with mainstream services, and are generally seen as making an important contribution to wider community care. They provide a range of supportive services and are ideal vehicles for health promotion and dissemination of health-related information. Given the need to develop ways of working which promote inclusion of patients, their families, and the community in general, it is impossible to overstate the importance of effective liaison between the voluntary sector and mainstream psychiatric services. People often come into contact with the emergency services because there is a lack of knowledge of the availability of community alternatives and of where to go when distressed. Working with voluntary services will not only contribute to their longevity but also ensure that the complementary treatment modalities they offer are part of the service provided.

Even where these system-wide initiatives are absent or not yet fully implemented, individual clinicians can do a lot to improve the care of minorities within their own service. Finding out the scale of the problem is a good place to start. Are population estimates available from a recent census, is information available from a recent census or from local government sources? More importantly, are there known problems of access for these populations in general or particularly within local mental health services? Are significant numbers not treated because they are held in 'inappropriate' settings in the criminal justice system or because they are mobile populations? In terms of delivering the service, outreach is likely to be the key and this will almost always involve partnership arrangements, developing understanding of key cultural influences including the importance of alternative health perspectives, spirituality and traditional healing. Several innovative services have been developed alongside organizations that 'hold' significant numbers of the minority population such as the Church or the local Mosque or NGOs dealing with specific communities, which can provide a wider social or housing service to minority populations. It is the near universal experience of these services that initial progress is slow with many barriers of mutual misunderstanding and suspicion to overcome. Developing a relationship or even employing someone from the minority culture as a go-between, advisor, or 'cultural consultant' can be helpful though it needs careful preparation to avoid selecting a consultant from the wrong tribal

background or at the wrong level of seniority, gender, or language group. Culture broker models have been used in the United States, whereas cultural consultation services happen in parts of the UK and cultural liaison officers are used in parts of Australia. Whatever the choice, it is likely to take time and patience to develop a high level of 'visibility' in the target community as well as a sound understanding of its culture, taboos, and historical context. Where available, cultural supervision from a more experienced practitioner is also helpful. The underlying principle has to be a two-way process, which deals with information from the patient's community and the service provider to ensure that communications are clear.

A few further points can usefully be taken into account in planning the service. First an understanding of local models of illness that determine when and how and of whom help will be sought, second use of local epidemiological data to assess the impact of age and gender on service demand and finally the involvement of the local community to promote a sense of ownership and involvement in the delivery of services.

In conclusion, the diagnosis and treatment of mental ill health among multiethnic populations is probably one of the most complex and contentious challenges in psychiatric service provision. At the heart of this complexity are problems of ignorance, attitude, and failures of communication on all sides. It is also potentially one of the most rewarding endeavours if got right. No one service model is likely to apply to every community, even if people belong to the same ethnic group. The development of specialist psychiatric services may not always be possible or even essential. Instead, the requirements are for approaches that are flexible, sensitive, accessible, and accountable to the people they serve.

SECTION 8

The Psychiatry of Old Age

This page intentionally left blank

8.1

The biology of ageing

Alan H. Bittles

Introduction

Although old age is readily recognizable, methods to define and measure the underlying biological processes are much less amenable to study. For this reason, **life expectancy** has been widely used as a surrogate measure of ageing, as well as to monitor economic progress at national and regional levels. It is generally acknowledged that lifespan is a constitutional feature of the human phenotype, and twin studies have indicated that 25–33 per cent of the variance in human **longevity** is genetic in origin.[1,2] External factors including lifestyle can also exert a major influence, as illustrated by the current mean life expectancies of 79 and 86 years for males and females in Japan, whereas the comparable figures for Botswana are 35 and 33 years, respectively.

The importance of genetic inheritance as a determinant of extended survival has been illustrated by population level studies in Okinawa, an island prefecture of southern Japan with a very high prevalence of long-lived individuals. On the island, the mortality rates of the male and female siblings of centenarians were approximately half those of birth cohort-matched, non-centenarian siblings.[3] These findings parallel an earlier study of the family of Jeanne Calment, who died in France in 1997 aged 122 years. Of her 55 relatives, 24 per cent had lived to >80 years compared to just 2 per cent of a matched control group.[4] However, it remains unclear whether the enhanced lifespan of individuals who exhibit above average longevity is due to a slowing of the overall ageing process or is primarily associated with resistance to major life-threatening pathologies.

The concept of an '**allostatic load**', potentially involving the neuroendocrine, sympathetic nervous, immune and cardiovascular systems, and metabolic pathways, has been advanced to describe the lifetime costs of adapting to physical and psychological stresses. According to this hypothesis, while the actions of biological mediators of **stress** can be initially beneficial to health, chronic stimulation results in regulatory imbalance and subsequent pathophysiological changes.[5] Empirical studies have indicated increased physiological dysregulation and functional decline at >70 years of age, which would imply that predicted global increases in the numbers of older persons will be accompanied by disproportionately larger groups of individuals with major age-related pathologies.

Theories of ageing

While initially popular, it became apparent that single, 'magic bullet' causes of ageing were inappropriate to complex biological species, and with this recognition earlier organ- and system-based theories have gradually been discounted. Conversely, the observation that ageing appears to be initiated at different ages and can proceed at different rates in individual members of a species provides presumptive evidence for the interaction of multiple genetic and non-genetic influences. Two main groups of theories have been formulated, genomic and stochastic, each subdivided into a number of discrete topic headings.

Genomic theories of ageing

Genomic theories premise that ageing is primarily associated with changes in the genetic constitution of the organism. Support for genomic theories stems largely from the characteristic life expectancies of mammalian and non-mammalian species, and theories proposing a primarily genetic basis for ageing were greatly strengthened by the demonstration that human diploid cells exhibited a highly reproducible lifespan when cultured in the laboratory. Although strong evolutionary advantages can be envisaged for genetic control of developmental changes up to and including reproductive adulthood, the existence of genes uniquely encoding ageing seems improbable since few free-living animals or humans have ever succeeded in attaining the maximum lifespan of their species.

(a) Information transfer

The ability to synthesize functional proteins is dependent on the fidelity of genetic information encoded in the DNA, its unimpaired transcription from DNA to RNA, and translation into peptides and proteins. As each of these processes is subject to inaccuracy, and during the life course of an organism the sequence of information transfer steps is continuously operational, the error potential is large. With increasing chronological age the probability of errors increases, resulting in the accumulation of deleterious mutations late in life.[6] Since a number of the proteins synthesized may be involved as surveillance enzymes to maintain the accuracy of the entire system, feedback mechanisms could lead to its collapse, resulting in a phenomenon initially termed **error catastrophe**.

(b) Somatic mutation

With the demonstration of an inverse correlation between the lifespan of mammalian species and the incidence of chromosome abnormalities, age-related physiological changes were originally ascribed to accumulated mutations in the nuclear DNA (**nDNA**) of somatic cells. Findings of this nature could, however, be explicable in terms of the ability of an organism to tolerate DNA damage via the repair of damaged molecules, with more than 130 human **DNA repair genes** identified.[7] The capacity of nDNA to resist attack by endogenous reactive species and environmental agents is therefore considerable, which casts doubt on the general applicability of the theory.

(c) Epigenetic mechanisms

Epigenetic errors, i.e. errors in the control of gene expression rather than mutations in DNA or protein, have been proposed as major primary causal factors in senescence.[8] In promoter regions of genes, hypermethylation silences a gene whereas the hypomethylation of previously methylated sequences permits their expression. The pattern of **DNA methylation** is established during development and is cell type-specific, and changes in methylation can occur both during ageing and in cancer cells. The advantage of epigenetic models of ageing is their lack of requirement for the evolutionary preservation of genes encoding ageing, which in former generations would seldom have been expressed.

(d) Mitochondrial decline

Mitochondria are subcellular organelles responsible for aerobic energy production in humans and many other species. The mitochondrial genome of ~16.5 kb is characterized by its extremely compact organization, with no protective histones, a lack of excision or recombinational repair mechanisms, and a virtual absence of introns, all of which make it highly susceptible to mutation. Mitochondrial DNA (**mtDNA**) plays a central role in mitochondrial propagation and the maintenance of cellular respiration, but a majority of proteins involved in the regulation of mtDNA transcription, translation and replication, and the mitochondrial respiratory chain, are encoded in the nuclear genome. This design requires the operation of a highly coordinated mechanism for the expression of the nuclear and mitochondrial genomes. The central role of mitochondria in energy production means that defects may be of major metabolic significance, and the demonstration of increased levels of mtDNA deletions and base-substitutions in aged human neurones, heart, and skeletal muscle suggest a causative role for mtDNA mutations in ageing.[9]

(e) Telomere loss

Telomeres are specialized structures located at the terminus of the DNA helix and critical to the maintenance of DNA stability and replication. The enzyme telomerase which is responsible for telomere synthesis is active during early embryonic and foetal development but its activity is down-regulated in all human somatic cells before birth. As human diploid fibroblasts in culture were shown to progressively lose telomeres, it was hypothesized that telomere length could act as a predictor of the potential *in vitro* lifespan achievable by a cell strain.[10] Humans have a common telomere profile found on lymphocytes, amniocytes, and fibroblasts which appears to be preserved throughout life. However, the rate of telomere loss with ageing varies between chromosomes and there is evidence that, in addition to the common human telomere profile, each person exhibits an individual profile.[11]

Besides ageing, telomere loss has been implicated in a wide range of disease states, including heart disease, stroke, infection, long-term chronic stress, and obesity. Given the apparent relationship between telomere loss and both ageing and age-related pathologies, pharmacological activation of telomerase has been proposed as a potential treatment for chronic or degenerative diseases.[12] As tumour tissue and transformed cells constitutively produce telomerase, any therapeutic intervention of this nature would require careful monitoring.

Stochastic theories of ageing

Stochastic theories of ageing propose that cumulative adverse random changes at the cellular level ultimately overwhelm the capacity of an organism to survive, with ageing representing the preceding period of functional decline.

(a) Rate of living

An optimum lifespan was achieved by a variety of non-mammalian species when the organisms were maintained at suboptimal temperatures. The further demonstration of an inverse relationship between basal metabolic rate and longevity in mammals was interpreted as evidence that a species lifespan was governed by its **rate of living**, which in turn was correlated with its level of energy expenditure. Theories of this type tend to be imprecise in defining the nature of the factor(s) controlling ageing and lifespan, although it was subsequently proposed that the rate of living theory could be reformulated as a **stress** theory of ageing, with stress resistance and longevity positively correlated.

(b) Waste product accumulation

Ageing has been ascribed to interference by accumulated waste products in normal cellular metabolism and function, ultimately resulting in dysfunction and death at cellular and organ levels. Lipofuscin, a highly insoluble, pigmented compound derived by auto-oxidation from incompletely degraded cellular materials and detected with advancing age in neurones, cardiac muscle fibres, and the adrenal cortex, has been particularly implicated. Alternatively, the build-up of lipofuscin in older organisms may be secondary to an age-related decline in the function of cellular catabolic processes.

(c) Macromolecule cross-linkage

Many macromolecules of biological importance develop cross-links with increasing chronological age. The establishment of cross-linkage, whether covalent in nature or due to hydrogen bonding, alters the chemical and physical properties of molecules. Thus cross-linkage of the extracellular protein collagen is believed to be responsible for the loss of elasticity in mammalian blood vessels and skin with advancing age, even though collagen is subject to turnover throughout the lifespan. DNA and RNA also are believed to be potential intracellular targets for cross-linking agents, and changes in their structure could have serious functional implications for cellular information flow.

(d) Post-synthetic modification

In addition to cross-linkage, molecular aggregation and immobilization that compromises cellular metabolism and function could be caused by post-synthetic modification of proteins, with non-enzymic glycosylation (glycation) particularly associated with ageing. Glycation is initiated by the reaction of glucose with the amino group of lysine residues, which then proceed to form a Schiff

base, and progressively more complex compounds collectively termed advanced glycosylation end (AGE) products. As little variation was found in the glycation levels of lens crystallin proteins in subjects aged between 10 and 80 years, post-synthetic mechanisms may be as much an effect as a cause of ageing.

(e) Free radical damage

The role of **free radicals** in ageing was first proposed over 50 years ago.[13] A wide range of highly reactive free radicals are derived from molecular oxygen, including the superoxide and hydroperoxyl radicals, hydrogen peroxide, hydroxyl radical, and singlet oxygen. The polyunsaturated fatty acid side chains of cell and organelle membranes form highly susceptible targets for the action of **reactive oxygen species (ROS)**, and the resulting lipid peroxidation can result in severe membrane damage and eventual death of the cell. DNA may also be a critical target molecule for free radical damage, with mtDNA especially susceptible because of its proximity to the site of free radical production in the inner mitochondrial membrane.[9] Although a wide variety of antioxidants have been identified in humans, including ascorbate, α-tocopherol, β-carotene, glutathione, and the enzymes superoxide dismutase, peroxidase, and catalase, there has been little experimental evidence that these antioxidants can produce a significant extension in maximum lifespan. However, transgenic mice expressing the free radical scavenger enzyme catalase targeted to mitochondria showed an approximately 20 per cent extension in their mean and maximum lifespans, and concomitant delays in cardiac pathology and cataract development.[14]

Ageing as an energy crisis

From an evolutionary perspective, it was suggested that senescence was the end-result of an energy conservation strategy operating in somatic cells. During the course of a lifespan, total available energy has to be allocated to a variety of functions, including macromolecular synthesis and degradation, cell and organ maintenance, and reproduction of the species. Since the energy supply is finite, and to ensure propagation of the species by the successful transmission of genes to future generations, a compromise has to be reached between the energy made available for each of these functions. According to the **disposable soma theory**, this accommodation in energy saving is achieved by maintenance of absolute or near absolute accuracy in germ cell replication but less rigorous error correction in somatic cells.[15]

As an organism ages, the demands placed on the free energy pool alter and increase from a primarily anabolic role to meeting the requirements of ever-increasing repair and catabolic functions, including those imposed by specific disease-related insults. If the mitochondrial inner membrane and/or mtDNA is damaged, an organism must increasingly rely on alternative, less efficient pathways for its energy needs, ultimately resulting in a critical shortfall in the energy supply needed to sustain life. In such an **energy crisis**, the somatic cells primarily affected would be post-mitotic cells with high energetic demands, typified by the heart, skeletal muscle, and the brain.

Dietary modification of ageing

Inherited factors clearly play a major role in ageing, and in determining the human lifespan. But if ageing also is stochastic in nature then it should be possible to modify development of the ageing phenotype by altering the relative influence of contributory environmental variables, including diet.

Dietary (or calorie) restriction, based on a diet reduced in total amount but otherwise nutritionally adequate, is the only method so far proven to increase maximum lifespan in mammals. The original dietary restriction experiments conducted in the 1930s resulted in animals that remained prepubertal as a result of their retarded growth and development.[16,17] In more recent food restriction experiments, rodents have typically been fed a diet corresponding to approximately 60 per cent of the food ingested by *ad libitum* fed controls, commencing either soon after weaning or in young adulthood. Under these circumstances, besides a increase in maximum lifespan the development of tumours and other chronic diseases of late adulthood was slowed.

DNA microarray studies into the effects of **calorie restriction (CR)** in mice have indicated a shift in transcriptional patterns towards increased protein turnover and decreased macromolecular damage. Rats maintained on a restricted diet (representing 60 per cent of the control diet) for 36 weeks showed increased transcription of muscle genes involved in ROS scavenging, tissue development, and energy metabolism, with decreased expression of genes involved in signal transduction, stress response, and structural and contractile proteins.[18] CR also was able to maintain ATP production but at the same time reduce age-dependent endogenous oxidative damage.[19]

Preliminary studies conducted on rhesus macaque monkeys aged approximately 20 years and maintained on a reduced caloric intake for 9–10 years have suggested that long-term CR produced beneficial alterations in glycogen metabolism and mitigated the development of insulin resistance in older animals. Although restricted numbers of primates have been studied and few have attained extreme old ages, a wide range of potentially beneficial outcomes have been reported, in particular an improvement in glucose tolerance, a lower core body temperature, an attenuated decline in dehydroepiandrosterone (DHEA) sulphate levels, decreased triglycerides and increased HDL2b, in combination with lower weight, lean body mass and fat, and lower energy expenditure (reviewed in Bittles 2008).

A number of small-scale human studies have been reported, including a 6-day investigation on eight adults and eight pubertal children involving a 50 per cent caloric reduction that resulted in a significant reduction in the nitrogen balance of both adults and children and a decrease in their insulin-like growth factor-1 (IGF-1) levels. Individuals who had voluntarily adopted a restricted food intake for 6 years displayed a wide variety of physiological, metabolic, and biochemical changes, all of which would be consistent with protection against atherosclerosis,[20] and CR alone or with accompanying exercise regimes significantly increased the numbers of mitochondria in skeletal muscle cells while decreasing both energy expenditure and the frequency of mtDNA damage in overweight healthy adults.[21]

Ageing and the concept of healthy life expectancy

Active Life Expectancy (ALE) is defined as the period of life free of disabilities which interfere with basic Activities of Daily Living (ADL), e.g. eating, getting in and out of bed, bathing and toiletry needs, dressing, and indoor mobility. The concept of healthy life expectancy has been extended by weighting specific physical and

cognitive dysfunctions to measure Disability-Adjusted Life Years (DALY) and Quality-Adjusted Life Years (QALY). **Disability Adjusted Life Expectancy (DALE)** is now widely used in epidemiological studies to estimate the number of years that might be expected to be spent in 'full health'. A common finding in developed countries was that although females enjoyed higher DALE scores they also could expect more years of disability at advanced ages. Although measures such as DALE, DALY, and QALY have been criticized on methodological grounds, given global increases in the numbers of elderly individuals, the concept of healthy life expectancy may be increasingly useful in identifying the health and support needs of the aged.

Discussion

As in other areas of medical science, the Human Genome Project has impacted strongly on research into biological aspects of ageing, and DNA analysis now offers major insights into the development of the ageing phenotype. During the last decade, DNA microarray studies have been adopted to investigate changes in gene expression that accompany ageing.

Initial studies on rodent tissue showed differential gene expression patterns with advancing age, indicative of a marked stress response and lower expression of metabolic and biosynthetic genes. An 'ageing transcriptome' conserved across mammalian species has been identified, comprising deregulation of mitosis, cell adhesion, transport, signal transduction, mitochondrial function, and inflammatory response, and accompanied by a reduction in processes dependent on energy metabolism and mitochondrial function.[22] Subsequent analysis of human tissue based on large-scale DNA microarrays has revealed diverse patterns of both increased and decreased gene expression. However, a study of ~32 000 muscle tissue genes obtained from volunteers aged 16 to 89 years confirmed the existence of a common ageing signature, with altered levels of expression in 250 age-regulated genes and three genetic pathways that correlated both with chronological and physiological age.[23]

Research on adult stem cells may provide key future insights into ageing. Adult stem cells mainly undergo chronological ageing, as in skeletal muscle, or exhibit a combination of chronological and replicative ageing, typified by haematopoietic stem cells.[24] What remains to be determined is whether the overall decline in tissue regenerative capacity with advancing age is caused by intrinsic ageing of stem cells, or is due to increasing impairment of stem cell function in an aged tissue environment. Until this basic question is resolved, the prospect of stem cell therapy as a potential 'treatment' to correct the functional declines and degenerative diseases typical of human ageing will remain a theoretical possibility.

8.2

Sociology of normal ageing

Sarah Harper

Introduction

Research on the sociology of normal ageing has focused on understanding the paradigms of '*successful ageing*'. In an apparent reaction to '*disengagement theory*'[1] which proposed that to withdraw from roles and relationships in old age was normal, a new conceptual framework was developed in the late 1960s and 1970s which attempted to explain how individuals adapted to the constraints of ageing and old age. This has been variously measured in terms of good health, high levels of physical and mental functioning, and active engagement with one's social and physical environment. While post-modernism and critical gerontology have attempted to refocus the debate, the emphasis of most research and writing has remained within the framework of understanding, explaining, and even facilitating, 'success' in old age.

There is also a body of research which recognizes the importance of the *life course perspective*, and that throughout an individual's life, he or she is faced with *continuities* and *discontinuities* which have to be negotiated and resolved. Old age is but part of this lifelong process. Changes which occur in later life, such as retirement and widowhood, will lead to discontinuities in roles and relationships, other aspects of our lives will undergo little change allowing continuity. Alongside this, perspectives from anthropology, history and the social constructionist school of thought have also been recently influential.

This chapter will discuss concepts of age, generation, and cohort. It will consider the contribution of the life course approach to understanding ageing, and the manner in which other perspectives, such as social constructionism, narrative psychology and anthropology, have contributed to the sociology of normal ageing.

Structuring the life course through age

According to Hazelrigg,[2] the concept of age introduces signposts which link memory and anticipation, an iteratively remembered past and an iteratively expected future. Age classification is thus integral to normal organization of consciousness. As Mead's extensive work on life history, reminiscence and autobiography informs us,

> *one interacts retrospectively with one's younger selves, recalling earlier states of selfhood in the productive functioning of memory, and interacts prospectively with ones' older selves, anticipating conditions, actions, goal realizations and the like of late states of selfhood.*[1]

For both the individual and society, age conveniently dissects the life course into more manageable components. As a capitalist, industrial system emerged, and individuals moved from domestic units to bureaucratically organized corporations, so age was used to define adulthood and thus labour force participation. Age became the basis for regulating a large population. It defined the responsibilities of citizenship, and for each age related transition there is a stage of preparation, a stage of participation, and a stage of retirement.

Various anthropological studies[2] have highlighted alternative ways in which the life course might be structured. One of the most influential anthropological studies on the sociology of ageing was Cowgill and Holmes[3] work on ageing and modernization, which argued that the marginalization of older people was directly linked to modernization. While extensively debated ever since, this work highlighted the importance and complexity of cultural diversity. The burgeoning of anthropological studies around the concept of age and ageing since the Cwgill and Holmes study have contributed significantly to our understanding of this diversity.

Neither the !Kung nor Herero, hunter-gather and Bantu pastoralist peoples respectively of Botswana, have a concept of chronological age, marking age by physical transitions. Alternatively, the Tuareg, a semi-nomadic peoples in northern Niger, noted age by social transitions—courtship, marriage, childbirth, and grandchildren. Here, life transitions defining the ageing process are predominantly social rather than biological. A girl becomes a women not at menstruation, but at marriage; a women becomes an older women not at menopause but on having a child marry. For the Sukama of north-west Tanzania, ageing is defined through life course events. This emphasizes the social status of elderhood, measured by the wealth of alliances, offspring and livestock, which could not be diminished through ill health or loss of mental capacity. The Gussui of south-western Kenya have a similar notion of elderhood. However, they have adapted this traditional seniority gradation based on networks and affiliations to modern demands,

---

1 G.H. Mead, quoted in Hazelrigg p. 105[2]

2 See Harper for a full reference list to these studies[5]

incorporating such aspects as the role of entrepreneur to the criteria for achieving successful seniority status.

Modern Japanese society still applies a wide variety of terms to different points of the life course indicating complex relationships between chronological age and life transitions and physical appearance. For example, mid-life men and women with children whether or not they are married, will commonly be referred to as uncle and aunt, (*oji-san* and *oba-san*). Similarly, old men and women are frequently given the name of grandfather or grandmother, (*ojii-san* and *obaa san*) regardless of the presence of grandchildren, a characteristic also found in some European countries such as Greece. It is therefore clear that the domination of chronological age, has less salience in some other cultures.

Generation and cohort

Two further important concepts are generation and cohort. Individuals born within the same time period may be perceived as having a shared history and a common biography. The concept of *generation* is thus the link between an individual life course and the social changes that occur during the historical time of that life course. A generation may thus be thought of as *embodied history*.

Many of these draw on ideas from Mannheim who explored the creation of society through the continuous emergence of new age groups or generations. He argued that if social processes were always carried on and developed by the same individuals then once established, any fundamental social pattern, attitude or intellectual trend would probably be perpetuated. Culture was thus developed by individuals who come into contact anew with the accumulated heritage, that is the role of generations and while the continuous emergence of new individuals results in some loss of accumulated possessions it facilitates re-evaluation of our inventory and teaches us both to forget that which is no longer useful and to covet that which has yet to be won.

The problem for quantitative social scientists is how to disentangle those factors pertaining to the individual life course from those emerging from the historical context. It is here that the concept of cohorts, and cohort analysis has been refined by some to form a more analytical tool in the understanding of age and generational change.

A cohort begins with a particular demography at birth, that is its sex, race and economic composition. Differential mortality may lead to a higher proportion of some sub-groups surviving to old age; social mobility may lead to changes in cohort social status composition; and different historical periods will allow or enhance differential migration in and out of specific cohorts. A more sophisticated analysis places cohorts within specific historical contexts.[4] The *life-stage principle* suggests that disruptive social changes have enduring consequences on the subsequent lives, a particularly marked effect on those vulnerable at the time of occurrence.

Life course perspective

The life course perspective views old age as part of a life-long process of continuity and change. These can be addressed within four main frameworks: *context, transitions, roles*, and *relationships*.

Context

A starting point for life course analysis is the acknowledgement of the historical *context* within which different cohorts experience different aspects of the life course to life course perspective. As Harper[5] explores, while, most older men experienced a long period of economic activity followed by abrupt retirement, many older Western women experienced their younger lives within a framework of primary domestic duties, supplemented by intermittent economic activity. As a result, most older women replaced low earning capacity or economic dependence in younger life, with low incomes in old age. Cohorts in mid life, however, have had very different social and economic frameworks within which to live out their lives. Half the labour force in many countries is now female and full-time economic employment, with or without domestic, in particular childcare responsibilities, is becoming a widespread experience for many women. Despite this, there are still considerable income disparities in earning capacity of mid-life men and women. However, it is likely that future cohorts of older women will have higher incomes relative to older cohorts, and a lower gender income disparity.

Transitions

The processes which occur within these contexts can be understood as a series of life transitions.[6] Key transitions associated with later life are the end of active parenting, grandparenthood, widowhood and retirement. Each of these phases of life which may overlap, may be understood in relation to prior phases, and are mediated by other variables such as gender, class, and race. The transition to grandparenthood, for example, is experienced very differently by men and women, while the end of active parenting and transition to parent of a non-dependent child, the so-called *empty nest syndrome*, is mediated both by gender and by the experience of active parenting itself.

The transition to *widowhood* is one of the most stressful events of later life, with a high prevalence of depression both immediately before (presumably due to anticipation of the event and/or associated care giving) and in the first year following bereavement. Widowhood is likely to lead to lower income but higher social contacts for women, while men maintain their income, but are more likely to lose social contacts, unless they remarry. Over half women over 65 are widowed, rising to four-fifths at 85. Only 17 per cent of men are widowed over 65, rising to 43 per cent by their late 80s. Nearly three-quarters of older men in the UK are married, compared with less than a half of older women. This is explained both by differential life expectancy and the tendency of men to remarry following divorce or widowhood.[7]

The transition to *Grandparenthood* is the current normal experience of old age. US data suggests that more than half the population aged over 55 are in four-generation families and three-quarters of this population are or can expect to be as grandparents, with a prediction that one-third of current grandparents will live to be great grandparents, and one-fifth of all women who reach 80 will spend some time in a five-generation family as great-great-grandmothers. A similar picture may be found in the UK with estimates that three-quarters of adults over 66 years of age are grandparents. The transition from parenthood to grandparenthood, and even great-grandparenthood, determines both an individual's self-identity and subsequent roles and functions as

grandparenthood. In addition, the experience of the relationship that the grandchild has with his or her grandparent earlier will partially determine the way they take on the role and relate to their own grandchildren later on in life. Other sociological theories have been applied to the study of grandparenthood. *Role theory* suggests that a successful transition to grandparenthood requires both some socialization to the role, and appropriate life course timing. *Social stress theory* is used to argue that stress associated with transition to grandparenthood is related to the number, type, and context of the transitions and moderated by gender, education, income, and race.[9]

For many individuals, especially men, the transition to *retirement* is abrupt. Although early retirement has increased in Europe over the past twenty five years, most men still retire from full time work in their early-to mid-60s. A successful transition to retirement requires securing both financial security and personal adjustment. Atchley[10] identifies several phases of retirement. Pre-retirement, which may include a combination of both negative and positive feelings towards the impending event; a honeymoon period immediately following the event, which may extend for several years depending on the adjustment and resources, social, financial, and personal, available to the individual; disenchantment and reorientation; and eventually (if successful) stability. This latter stage occurs with the development of a well established set of criteria for making choices and dealing with the challenges and opportunities of this new life phase.

Roles and relationships

The above transitions—retirement, widowhood, grandparenthood - are also, of course, phases of life with specific roles and relationships. Thus, the transition of retirement also has an associated phase of being retired; that of grandparenthood of being a grandparent; that of widowhood of being a widow or widower.

We can examine two of these—late-life parenting and grandparenting—in the context of negotiating transitions and continuities in family roles and relationships as individuals age.[11] Intergenerational solidarity—shared values, normative obligations and enduring ties—and intergenerational conflict—whereby issues are resolved and relationships move on have been long seen as important components of this. More recently the concept of intergenerational ambivalence has been introduced. This, it is argued, reflects the contradictions which occur with ageing within family relationships These arise both through the desire of parents and children for both help and freedom, and conflicting norms regarding family relationships especially around the issue of care giving.

(a) Late-life parenting

Increasing longevity also means that most parent-child relationships will be lived out as predominantly non-dependent adult dyads, this is despite the delaying of child birth. The common experience for many parents and children is around 60 years of joint life, of which under one-third is spent in the traditional parent/dependent-child relationship. Around one-quarter of UK women and nearly 40 per cent of US women aged 55–63 still have a surviving parent. These women have thus spent around 60 years a child, some 40 of them in an adult relationship with a living parent. This relies on *re-bonding* in adulthood sometimes also referred to as 'reverse bonding'.[12] Under such experiences we see a loosening of the association between marital and parental roles. As the common experience of parenthood moves to more than 50 years of shared life, parents and children are adjusting to spending most of their relationship as independent adults. Similarly, husbands and wives are spending fewer of their joint lives as parents of young children. Relationships which have been historically based on a hierarchy which existed in part to support successful reproduction must move to greater equality, both child-parent, and husband-wife, as traditional roles based on parenthood give way to companionate relationships.[12]

(b) Grandparenting roles[3]

Currently, women can expect to become grandmothers in their 50s and 60s due to the early first age of births in the 1960s and 1970s. In addition, grandparental roles are lasting far longer due to increased longevity, the grandparent is thus more likely to be able to build a relationship with their grandchild into their adulthood. As a result many grandmothers, in particular, now face simultaneous demands as children of frail and dependent parents, mothers and grandmothers, as well as still being in full or part time economic employment.[13]

Grandmothers, in particular maternal grandmothers, are repeatedly attributed with having more influence in almost every value domain over their grandchildren than grandfathers. Research into the role of grandfathers has been limited.[14] However, it has been proposed that men become more nurturing as they get older and it could be hypothesized that these qualities might be expressed in relationships with their grandchildren. Similarly, the need to consider grandfathers as important resources for teenage mothers who are rearing their children, has been stressed. Harper also found that grandfathers could act as replacement partners and replacement fathers in female single parent households.[13]

Various roles of grandparenthood have been identified.[15] Bengtson (1985) for example, identifies five separate symbolic functions of grandparents: being there; grandparents as national guard; family watchdog; arbiters who perform negotiations between (family) members; and participants in the social construction of family history. Harper's study of grandmothers identifies grandmother as carer, replacement partner (confidante, guide and facilitator), replacement parent (listener, teacher and disciplinarian), and as family anchor (transferring values, attitudes and history).[13]

Complementary perspectives

Our understanding of ageing from a life course perspective has drawn on valuable insights from narrative gerontology and the social constructionist perspective.

Narrative gerontology

Narrative gerontology's main contribution to the field of ageing has been to the role of the life story in the development of theoretical and empirical approaches to ageing. It presumes that individuals think and act on the basis of stories, which have an external structure and an internal reality. Individuals retell their stories as they progress through their lives to make sense of their lives, and from a sociological perspective this retelling when carried out publicly provides considerable insights into various aspects of an individual's experience of ageing across the life course. There are

[3] A full reference list on grandparenthood may be found in Harper.[5]

four dimensions to this: the structural story, which reflects the wider societal context inhabited across the life course; the sociocultural story, which reflects other identities such as ethnicity and gender; the situational story which reflects an individual's roles and relationships; and the interpersonal story, the meanings which the individuals place themselves on their life story.

Writers in this genre of theory have further suggested that individuals experience two types of time. Achenbaum[16] describes this as a *physical outer time* and *a psychological inner time*, or as Kenyon and Randall[17] state *clock time* and *story time*. There may be a tension between the two types of time described as *on time* and *off time*.[18] Hazelrigg[19] suggests that the tension between the two times has been become more extreme within modern society, so dominated by rigid timekeeping. He argues that modern life is lived in two separate registers. On the one hand, most of a life experience is formed directly and indirectly in a highly standardized sequence of institutionalized events—schooling, work, parenting, retirement. These events are regulated by procedural rules and recognized routines, with predictable durations and regulated transitions between events. On the other hand, those aspects of life experiences that are not institutionalized and structurally stabilized in recognized life course sequences tend to have little or no connection to status dimensions or specific locations in the life course. These would include self-image, personal satisfaction, existential aesthetics etc.

Tensions arise when the two registers fail to coincide—*off time*.[18] Examples include middle-aged couples falling in love and publicly exhibiting displays of physical affection and romance, or older people adopting student style lives. Off time may also include the experience of being externally forced, through illness for example, to fall outside the normal behaviour range as defined for one's age. This also includes examples where society takes an individual and places them within a situation which is unusual for their chronological age–for example, a very young person being rapidly promoted within an institution which is very highly age regulated, such as a university, and taking on a professorial mantle.

Social constructionist approaches

The sociology of ageing has also recently enveloped social constructionist approaches, including phenomenology, symbolic interactionism, and ethnomethodology. These approaches share a subjective orientation to social reality, focusing on describing how individuals negotiate their worlds, rather than trying to explain why. A key area of interest here is the management of identity across the life course and in particular as we age. Examples include, Matthew's[20] seminal work using symbolic interactionist approaches to explore how old women negotiate their own identities when they are continually deluged with negative public stereotypes of infirmity and worthlessness. This is a theme taken up later by Featherstone and Hepworth[21] in their work on the Masks of Ageing. Similarly, Karp[22] uses symbolic interactionist approaches to explore the impact of social messages on the emerging consciousness of men and women in their 50s of their own ageing.

Conclusion

The sociology of, so-called, normal ageing thus combines perspectives from diverse traditions of thought. This actual measurement of ageing, in terms of health, physical and mental functioning, and active engagement with one's social and physical environment, has combined quantitative social science, epidemiology and political economy. The understanding of these interactions, draws on perspectives from sociology, psychology, and anthropology. In both cases, however, there is now recognition of the importance of context and process, and that, in reality, there is perhaps no single construct of 'normal' ageing. Given this perspective, it is essential that care for older adults is person-centred rather than imposed by professionals.

8.3

The ageing population and the epidemiology of mental disorders among the elderly

Scott Henderson and Laura Fratiglioni

In the last decades the ageing of the populations has become a worldwide phenomenon.[1] In 1990, 26 nations had more than 2 million elderly citizens aged 65 years and older, and the projections indicate that an additional 34 countries will join the list by 2030. In 2000, the number of old persons (65+ years) in the world was estimated to be 420 million and it was projected to be nearly 1 billion by 2030, with the proportion of old persons increasing from 7 to 12 per cent.[2] The largest increase in absolute numbers of old persons will occur in developing countries; it almost triples from 249 million in 2000 to an estimated 690 million in 2030. The developing regions' share of the worldwide ageing population will increase from 59 to 71 per cent. Developed countries, which have already seen a dramatic increase in people over 65 years of age, will experience a progressive ageing of the elderly population itself (see Fig. 8.3.1). The global trend in the phenomenon of population ageing has dramatic consequences for public health, health care financing, and delivery systems in the whole world. The absolute number of chronic diseases as well as psychiatric disorders is expected to increase. In this chapter, the epidemiological aspects of the most common psychiatric disorders of the elderly are summarized and discussed.

Depressive disorders

The epidemiology of depression in the elderly can be approached at three levels: its occurrence in the elderly living in the community, in those reaching primary care, and in the residents of hostels and nursing homes.

The community

It might be expected that, overall, the prevalence of depressive symptoms and disorders might increase in old age due to the loss of partners, friends, social status, retirement, income, and, above all, declining health. It is surprising, therefore, that surveys of the elderly in the general population have recurrently found rates that are significantly lower than in younger adults. Many of the large national surveys have not included persons aged over 65 years, but two exceptions are Australia, which found a 12-month prevalence of 1.7 per cent for the 65 years and over group compared with 5.8 per cent for all adults; and the New Zealand survey with rates of 2.0 and 8.0 per cent, respectively. It must be emphasized that these data refer to depressive symptoms in the elderly living in the community.

What is so far unproven is that such findings are indeed valid, and if they are, what might explain them.[3] They could be due to sample bias, in which elderly respondents with depressive symptoms may be more likely to decline to be interviewed than younger depressed people. Selective mortality has also been proposed, but cannot account for the size of the difference. It could be due to an error in case ascertainment, by which the interview instrument is not equally valid across age groups. For example, questions about depressive symptoms may be responded to differently by persons aged 20 and 80 years. Another possibility is a cohort effect in much of the Western world, where people born in the second half of the twentieth century have higher rates for depression.[4,5] This seems increasingly likely and may be due to a combination of social and environmental factors.

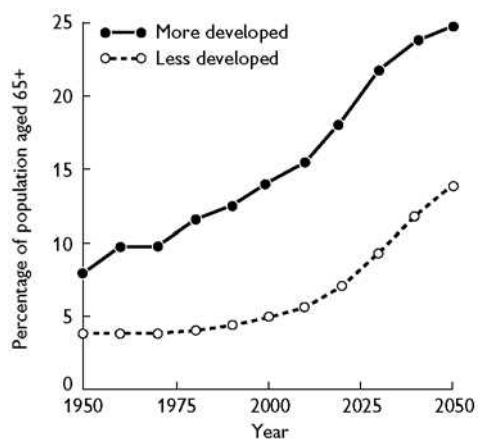

Fig. 8.3.1 Percentage of the population aged 65+ for more developed and less developed countries. (Reproduced from Kinsella, K. and Velkroff, V.A. The demographics of aging. *Aging Clinical and Experimental Research*, **4**, 59–69, copyright 2002 with permission from Editrice Kurtis S.r.l.)

Primary care

Unsurprisingly, the prevalence of depressive symptoms is considerably higher in elderly persons consulting their doctor than in the general community. One study in London found a point prevalence of about 30 per cent. Where it has been possible to compare the rates for those cases recognized by their doctor with cases independently ascertained by a research measure, such as a screening instrument or standardized interview, a typical finding is that the general practitioner recognizes about two thirds of the mild cases, rising to some 90 per cent of the moderate to severe ones. Some cases are considered to be depressed when they are not. Another finding is that elderly persons with depressive symptoms may not mention them to their doctor, attributing them to their age and circumstances. These findings have led to programmes offering additional training for GPs and to recommending the use of brief screening tests in primary care. Because diagnosis would lead to appropriate treatment being given earlier in an episode of depressive disorder, its duration would be shortened. Since prevalence is the product of incidence and duration, the prevalence of depression would therefore be expected to fall. This is an example of the application of epidemiology to prevention, which is its ultimate service.

Depression in hostels and nursing homes

Prevalence rates are also higher in hostels and nursing homes. In the United States, levels as high as 30 to 50 per cent have been reported. It might be thought that the context of living in a nursing home would account for having depressive symptoms. But one study found that the excess over the general population rates was largely accounted for by medical disorders, environmental factors contributing little to the variance. This needs to be studied further because it seems counterintuitive that the social and physical environment, both of which can be modified, could be of little relevance.

What is important is that only about one quarter of cases are recognized. To compound the situation, those cases that are recognized tend to be treated with too low doses of antidepressants. Depressive symptoms are well known to occur comorbidly with cognitive decline and the dementias. These findings from clinical epidemiology have pointed to the need for better case recognition through education of medical and nursing staff, and to the use of routine screening of residents in such settings.

Suicide

For many decades across the world, the traditional pattern has been for the highest rates of suicide to be in elderly men. This has now changed. In over a third of countries, both developed and less developed, it is younger people who have come to carry the highest rates. The World Health Organization provides a valuable resource for such data, showing rates by age and gender for nearly all countries from 1950 onwards.[6] The pattern varies considerably between countries. For example, in the United Kingdom in 2002, men aged 75 and over had a rate of 10 per 100 000, whereas the highest rate was 18 per 100 000, in men aged 35–44 years. In the United States and in the Russian Federation, the rates for men aged 75 and over were 41 and 89 per 100 000, respectively.

The main risk factors for suicide in the elderly are a past history of an attempt, depressive disorder, physical illness or disability, chronic pain, recent losses, social isolation, and access to lethal means. While universal interventions are more powerful than selected factors in prevention,[7] these attributes can be used in selective intervention to identify groups at increased risk. Furthermore, being multiplicative, these markers are of great value in individual cases by alerting the clinician to a person needing particular attention. Here is another example of the use of epidemiology for prevention. A systematic review of suicide prevention strategies for all age groups concluded that two interventions did reduce rates: physician education in recognizing and treating depression; and restricting access to lethal means.[8] Both of these interventions have close relevance to the elderly.

Personality disorders

The subject matter here refers to older people who have enduring attitudes and behaviour that bring difficulties for themselves or for others.[9] There is only sparse information on the prevalence of personality disorders in the general population, let alone specifically in the elderly. One exception, based on a national survey of mental health, found a lifetime prevalence of 6.5 per cent across all age groups with a trend towards lower rates with increasing age.

In clinical practice, it has long been suggested that traits such as impulsivity and externalizing behaviours tend to become less frequent in later life, whereas anxiety-prone, dependent, schizoid, paranoid, or obsessional persons are likely to change little as they age, or to become more so. Bergmann's pioneering enquiries among the elderly of Newcastle upon Tyne found that it was the anxiety-prone and insecure types that had late-onset neurotic disorders. A more recent study of late-life depression found an overall prevalence of comorbid personality disorder of 10–30 per cent. The group formerly known as neurotic and more recently as Cluster C in the DSM classification, had the higher prevalence. The Cluster B group, those with borderline, narcissistic, histrionic, and antisocial traits, were rare. What is not yet established, however, is if this lower prevalence also exists in the general population of the elderly, not just among cases with depressive disorder who have reached treatment in specialist services.

The epidemiology of personality disorders in later life is therefore significant for two reasons. First, some types are associated with increased risk of anxiety, depression, or paranoid states (*vide infra*). Second, there remains much yet to understand about the natural history of the personality disorders across the lifespan.

Psychosis of late onset

For the functional psychoses of late life, epidemiological information comes from two sources: studies of persons who have reached psychiatric services; and surveys of elderly persons living in the general community.[10] Psychotic symptoms probably exist as a continuum of severity, with only the more developed cases meeting diagnostic criteria. These often, but not always, reach psychiatric services, not uncommonly through being brought to the attention of the police. States phenomenologically similar to those found in clinics do occur in the community in non-trivial numbers. For cases that reach the threshold for a diagnosis by virtue of the range and severity of symptoms and behaviour, it has been proposed that cases with onset after the age of 60 years be called 'very-late-onset schizophrenia-like psychosis'. The syndrome has a 1-year prevalence

of 0.1 to 0.5 per cent. For advancing knowledge about the aetiology of schizophrenia, any information on it might be useful in explaining why people with this syndrome have reached the seventh decade or later in life without becoming psychotic, and only then develop it. It is more common in women. This is unlikely to be due to different social visibility or access to services. It is associated with a better premorbid level of social and occupational functioning. Premorbid paranoid or schizoid traits have been implicated and both clinical and community-based studies have found an association with sensory impairment such as deafness or poor eyesight. Personal and environmental factors associated with ageing have been considered, such as physical ill health, bereavement, loss of friends, and loss of income, but these have not been shown to contribute significantly. Genetic factors appear to be less important than in earlier onset schizophrenia.

Alcohol and drug dependence

It is generally believed that the prevalence of alcohol abuse and dependence declines during adult life and that the elderly have low rates in most communities. This may well be the case, but some other factors have to be considered. Whatever the prevalence, the absolute numbers will rise in the future because of the unprecedented growth in the elderly population. Next, the assumption may be false. In community surveys, errors in the ascertainment of alcohol abuse may lead to an underestimate for older persons. Most screening instruments were developed for use on younger adults, so their validity in the elderly is largely undetermined. Measures of the quantity drunk may mislead because smaller amounts may have an intoxicating effect in persons whose body fat, lean tissue, cerebral reserve, and metabolic function have declined. So the usual cut-off for problem drinking may be set too high for the elderly. One review of screening instruments concluded that the CAGE and MAST-G scales were appropriate, whereas other widely used instruments were not.[11] Next, all the studies have been cross-sectional. The elderly may have lower rates because of a cohort effect, whereby people born in the first half of the twentieth century may have been more moderate drinkers for all their life, compared to the high levels of consumption that are now found in the young of both sexes.

The actual values for prevalence are dependent on the instrument used and the definition used to define problem drinking, alcohol abuse, or dependence.[12] One review of community studies gives a figure of 5.1 per cent using various definitions. Invariably, men have higher rates than women. There is also considerable variation between countries and across different cultures. In identifying cases, a distinction of clinical significance needs to be made between late-onset and long-standing alcohol abuse. In primary care, accident and emergency departments, hospital in-patients, and nursing homes, the prevalence is much higher, yet cases are consistently under-recognized. The use of screening instruments in all of these settings has been advocated to improve this.

Alcohol abuse carries important comorbidity. In addition to all the established medical complications, it is associated with falls, subclinical delirium, cognitive decline, and depression. One study demonstrated a five-fold increase in the risk of developing a psychiatric disorder, especially depression and dementia. Simultaneous use of benzodiazepines, itself common in older persons, is clearly an additional and important factor. Against all this, it should be recalled that moderate alcohol use has been found in population studies to be associated with better mental and cardiovascular health, as well as being subjectively enjoyable.

Alzheimer's disease and other dementias

In the last two decades the dementia field has registered a tremendous scientific progression in many research areas including aetiology, pathogenesis, clinical aspects, treatment, and prevention. These advances have opened new perspectives, especially concerning definitions and diagnostic criteria, which have a relevant impact on epidemiological research.

Dementia is still defined as a syndrome which includes memory deficits and disturbance of other higher cortical functions; these major symptoms are commonly accompanied, and occasionally preceded, by deterioration in emotional control, social behaviour or motivation. However, it has become apparent that memory impairment may not necessarily be the major or first symptom for dementia subtypes such as frontotemporal dementia (FTD) and vascular dementia (VaD). Furthermore, as the current definition requires impairment severe enough to interfere with daily functioning, in several cases a delay of the diagnosis occurs. For that reason, a new research line has emerged with the aim to detect early Alzheimer's disease (AD) and other dementias, and the terms mild cognitive impairment (MCI) and cognitive impairment no-dementia (CIND) have been proposed to identify those subjects that show a clear cognitive deficit but do not fulfil diagnostic criteria for dementia. Finally, it is well known that dementia syndrome can be induced by many different underlying diseases, and that a differential diagnosis may be difficult for several reasons. AD as well as other dementia subtypes shows heterogeneity with distinct clinical and pathological characteristics; many different dementing disorders overlap in clinical and pathologic features; and different dementing disorders may make a common contribution or interact in causing dementia symptoms. Thus, rather than viewing, for example, AD and VaD as dichotomous entities, it may be more relevant to consider the role of their additive or synergistic interactions in producing a dementia syndrome.[13,14]

Following these new perspectives, in this chapter we will summarize the major findings from the most recent epidemiological research according to three major topics: early detection of AD and other dementias, incidence and risk factors for AD and dementia, and prevalence and impact of the dementing disorders at the individual and societal levels.

Early detection

As diagnostic criteria for AD require gradual onset of cognitive deficits, it is expected that cognitive disturbances are present already before the diagnosis can be rendered. Cognitive deficits are observable up to 10 years before dementia diagnosis with a sharp decline more evident in the final 3 years,[15] and occurring in episodic memory as well as in other cognitive domains such as executive functioning, verbal ability, visuospatial skills, attention, and perceptual speed.[16] However, our capability to use such early disturbances as a predictive tool of incipient dementia is strongly limited by several concomitant facts: (1) cognitive decline is also present as a function of the normal ageing process; (2) several conditions other than AD may lead to cognitive disturbances in the elderly; and (3) dementia-free patients with cognitive impairment observed in specialized clinical settings are different from cognitively impaired persons detected in the general population.[17]

To overcome these difficulties, different definitions have been proposed, with MCI and CIND being the most commonly used. MCI definition was originally derived in a clinical setting to identify subjects with isolated memory loss (now referred to as the 'amnestic' type) who may be in a preclinical phase of AD. Since then, the view has widened to cover a broader range of cognitive disturbances, and other MCI subtypes have been proposed.[18,19] CIND is derived essentially from population-based studies, and operationalized in slightly different items. Unfortunately, not one of the proposed definitions has shown a sufficiently good predictivity at the community level. Even a highly selected algorithm including subjective memory complaints, and global, and specific (memory/language) cognitive deficits could identify only 18 per cent of the incipient AD cases.[20,21] Although elderly persons with cognitive impairment have a high risk of developing dementia with a rate of about 11 to 50 per cent over 1 to 5 years, not all persons with CIND or MCI develop dementia. A substantial proportion of these persons (24–42 per cent) even improve in their cognitive performances over time.[22] This diverse prognosis supports the notion that AD is not the only causal mechanism underlying cognitive impairment in the non-demented elderly population. Cognitive psychologists have detected lower cognitive performances in elderly persons with deficiency in vitamin B_{12} and folate, elevated homocysteine, thyroid stimulating hormone deficiency, and cardiovascular disease. Physicians found an association between CIND and a number of factors including frailty-related factors such as history of hip fracture and high consumption of multiple drugs, history of psychoses, and depressed mood occurring 3 years before CIND development.[23] Other studies have identified older age, low education, depression, APOE ε4 allele, medicated hypertension, mid-life elevated serum cholesterol, and high diastolic blood pressure, as well as diabetes and anticholinergic medication use as risk factors for MCI.[17]

The prevalence of cognitive impairment—no dementia varies depending on diagnostic criteria with a maximum of 30 per cent.[24] In the younger elderly (e.g. 65–75 years old) cognitive impairment is actually more frequent than dementia disorders.[25] Annual incidence rates vary from 15 per 1000 among persons aged 75–79 years to 98 per 1000 among nonagenarians, when the estimates are corrected for dropouts due to death (Fig. 8.3.2; Ref.[26]). Regardless of the aetiology underlying the cognitive deficits, the high prevalence and incidence highlight the importance of this syndrome in the ageing population. Given that the criteria for cognitive impairment in non-demented persons are still under construction, and that there is no efficacious treatment to stop the possible progression to AD, at the moment we must be cautious with diagnosing MCI, which may cause an unnecessary burden on patients and relatives due to the unclear prognosis. However, it is clinically relevant to identify all persons with cognitive deficits due to treatable conditions such as depression, low-level vitamin B_{12}, and use of drugs.

Incidence and risk factors

Dementia incidence is similar in all continents and from different regions of the world (Table 8.3.1). Slightly lower rates detected in US in comparison with those in Europe and Asia are likely to be due to differences in study designs and case ascertainment.[27] AD accounts for 60–70 per cent and VaD accounts for 15–20 per cent of all dementia cases. The incidence of both AD and dementia increases almost exponentially with age. However, there are inconsistent findings regarding whether the rates continue to increase even in more advanced ages. The apparent decline found in some studies may be an artifact of the poor response rates, survival effects, and nature of populations previously sampled in these very old age groups.[28]

Age is the strongest risk factor for dementia and AD, suggesting that ageing-related biological processes could be implicated in the etiopathogenesis of AD. Further, the strong association with increasing age can be, at least partially, explained by a lifetime cumulative risk to different risk factors. Using this approach, the risk of dementia in late life is considered as a result of complex

interactions of genetic susceptibility, biological factors, and environmental exposures experienced over the lifespan. A summary of all these factors is reported in Table 8.3.2, according to different biological mechanisms and grade of scientific evidence. As a part of an initiative of the Swedish Council on Technology Assessment in Health Care, specific criteria to summarize the scientific evidence concerning risk and protective factors for dementia have been proposed. Similar to criteria adopted for other diseases, these criteria first integrate the internal validity with basic causal criteria to weight the study quality, and then they take into account also number and proportion of the included studies reporting a specific association.[29] Moderate or strong evidence supports several genetic, vascular, and psychosocial factors as significantly related to both AD and dementia risk. Whereas implementing preventive strategies targeting the genetic susceptibility is limited, the other two hypotheses can easily lead to prevention programmes.

(a) Genetic hypothesis

First-degree relatives of AD patients have a higher lifetime risk of developing AD than the general population or relatives of non-demented subjects. Both genetic and environmental factors contribute to the phenomenon of familial aggregation. Twin studies have shown that heritability of AD is about 58 per cent, whereas other variance may be attributable to non-genetic factors.[30] The APOE ε4 allele is the only established susceptibility gene factor for both early- and late-onset AD. The risk effect of APOE ε4 allele decreases with increasing age, and after age 75 years, 15–20 per cent of AD cases are attributable to APOE genotype.[31] Familial aggregation of dementia and AD can be only partially explained by APOE polymorphism, implying that other genetic factors may be active and need to be detected.[32] Several other genes have been examined as possible candidates, but the reports are sporadic or the results are inconsistent.[33]

(b) Vascular hypothesis

Whereas the reported association between vascular risk factors and dementia risk is expected, due to vascular dementia, several explanations have been proposed for the association between vascular risk factors and Alzheimer-type dementia: (1) coexistence of vascular factors and AD pathology in the elderly; (2) precipitating effect of cerebrovascular disease or interactive effect between Alzheimer-type and vascular lesions in the brain; and (3) misclassification of mixed dementia as AD. Even if the mechanisms are still not fully understood, prevention may be possible as most vascular risk factors and diseases are modifiable or amenable to prevention and treatment. Controlling high blood pressure in middle age, avoiding mid-life obesity, and appropriately treating diabetes are the major intervention actions. Some studies also show that people who maintain tight control over their blood glucose levels tend to score better on tests of cognitive function than those with poorly controlled diabetes. Indeed, borderline diabetes or impaired glucose tolerance is also linked to an increased risk of dementia and AD in very old people.[34] Finally, to postpone clinical expression of the dementia syndrome in old people, preventing recurrent cerebrovascular disease as well as maintaining sufficient cerebral perfusion by adequately managing heart failure and avoiding very low blood pressure seems to be critical.

(c) Psychosocial hypothesis

Evidence from both epidemiological and biological studies indicates that factors acting at different periods across life course and having an intellectually stimulating nature may contribute in increasing the neural reserve and therefore promote functionally more efficient cognitive networks to cope with brain pathology and delay the onset of clinical manifestations of dementia. These factors include education, adult-life occupational work complexity as well as late-life social network and intellectually stimulating activities.[29,35] Although physical exercise may reduce the risk of brain damage due to atherosclerosis, the relevance of physical activity itself remains in debate, as most physical activities include also social and mental components. Complex leisure activities with physical, mental, and social components seem to have the most beneficial effect.[36] In addition to the reserve hypothesis, other mechanisms such as premorbid cognitive ability, vascular damage,

Table 8.3.2 Scientific evidence supporting risk and protective (in italic) factors of dementia and AD by different aetiological hypotheses.

	Risk and *protective* factors			
	Vascular	**Psychosocial**	**Genetic**	**Others**
Insufficient or limited scientific evidence	High cholesterol Cigarette smoking Obesity Late life high BP Late life low BP Heart failure Silent stroke *Moderate alcohol intake* *Dietary factors (e.g. fish and vegetables)*	Depression Low SES *Midlife physical activity* *Late life social network*	Several susceptibility genes	Head trauma Inflammatory markers *NSAIDs* *HRT* Folate and vitamins B12, A, E, and C deficiency Occupational exposure to toxics *Antioxidants*
Moderate or strong scientific evidence	Midlife high BP Diabetes mellitus Clinical stroke Atherosclerosis *Antihypertensive drugs*	Low education *Late life mentally stimulating activities* *Physical activity*	APOE ε4 allele* Familial aggregation	

Abbreviations: AD = Alzheimer's disease; APOE = apolipoprotein E gene; BP = blood pressure; HRT = hormone replacement therapy; NSAIDs = non-steroidal anti-inflammatory drugs; SES = socioeconomic status.

neuroprotection, or detection bias may be possible explanations. The most likely effect of a mentally, physically, and socially active life is to postpone the onset of clinical dementia: even delaying dementia onset by 5 years would halve dementia prevalence and substantially decrease the number of dementia cases in the community.

Prevalence and impact

Despite different inclusion criteria, several meta-analyses of prevalence studies have resulted in strikingly similar results (Ref.[27]; Table 8.3.1). Currently, more than 24 million people in the world have dementia and this number will double in 20 years.[37]

The prognosis of dementia is dramatic. In 3 years, more than 50 per cent of the dementia cases progress to the severe stage. In the Kungsholmen Project, the proportion of severe dementia among prevalent cases increased from 19 per cent at baseline to 48 per cent after 3 years, and to 78 per cent after 7 years. This progression is due to both cognitive and functional decline. The mean annual rate of cognitive decline as measured with the MMSE varies from –4.0 to –2.0 points. Many predictors of a more rapid cognitive decline have been reported such as initial higher cognitive function, functional disability, and brain lesions. The APOE ε4 allele seems not to act as relevant prognostic factor.[38]

Dementia is strongly associated with disability being the major determinant of developing dependence and functional decline over 3 years. Approximately half of the persons who developed functional dependence in a 3-year period can be attributable to dementia.[39] In industrialized countries, mental disease and cognitive impairment are the most prevalent disorders among older adults living in nursing homes or other institutions. However, institutionalization of dementia patients varies depending on age structure, urban or rural residence, and other cultural aspects. In the 75+-year-old population, 70 per cent of incident dementia cases die during the 5 years following the diagnosis, accounting for a mortality rate specific for dementia of 2.4 per 100 person-years. Dementia triplicates the risk of death.[40]

Conclusion

Mental disorders are common chronic conditions among the elderly people, and the absolute number of subjects with psychiatric disorders will increase dramatically worldwide in the near future due to the ageing of the populations. In addition, the mental disorders have a high impact both at the individual and societal level. Prevention may represent one answer to these challenging conditions. The scientific advances of the last few years have provided sufficiently strong evidence supporting two possible preventative strategies: an active and stimulating lifestyle in late life as well as optimal control of other chronic disease both at middle and late age may decrease the risk of relevant psychiatric disorders such as AD and other dementias.

8.4

Assessment of mental disorder in older patients

Robin Jacoby

The assessment of older people is not fundamentally different from that of younger patients. The principles of taking history and mental-state examination are the same at any age. But if the goals are common, the routes taken to reach them are not necessarily so. For example, an assessment adequate enough to begin treatment of a 30-year-old woman presenting to an outpatient clinic with a depressive illness might take about an hour and involve speaking only to the patient and perhaps briefly to her partner, whereas the equivalent assessment of an 81-year-old woman in whom uncertainty exists as to whether the diagnosis is that of a depressive or a dementing illness may require more than one interview and necessitate enquiry from several informants. This section will not repeat what can be found in Chapter 1.8.1, but cover only those points which are specific to or need to be emphasized for older patients.

The referral process

Who refers?

Whilst the referral process might be the same as for younger patients, it is more often different. In many cases the patient has no idea why, or indeed does not even know or has forgotten that she has been referred. (The feminine gender is used in this chapter because older women are more likely to develop a mental illness and to survive longer than men. However, what is written applies also to men.)

The process has most often been initiated by family members who might not have discussed it with the patient. Many old people live alone with no relatives nearby or even in the same country or state, so that referrals are frequently initiated by friends, neighbours, or other acquaintances, such as local shopkeepers, social services care workers, and people who run luncheon clubs.

Reasons for referral

In the case of a woman of 30 with a depressive illness, she is referred to a psychiatrist for treatment to effect a remission. However, an older woman of 80 with a similar condition may be referred for a variety of reasons including the following: the primary care doctor might be uncertain of the diagnosis, that is whether it could be dementia; the grown-up children might have removal from home to residential or nursing care as the first item on their agenda; the patient's condition may not be the primary issue—there may be greater concern for her husband who is failing to cope, perhaps to the extent of physically abusing her.

The informants

A large number of older people seen by psychiatrists are unable to give complete or reliable information about themselves. Frequently, but not invariably, there is a spouse or adult offspring living with the patient. In other cases, however, it is necessary to track down someone less obvious. Neighbours are often helpful at relating recent history, but may know little of past personal or family history. Effort spent in telephoning relatives, even those on the other side of the world, can be invaluable in giving an account of such items as family history or premorbid personality. If an informant is not readily available, for example, because it is night-time in Australia, the psychiatrist should not shelve the task of phoning, but only defer it to the next available opportunity.

Where conflicting information is given by a variety of informants it might be necessary to weigh up the particular 'hidden agenda' of each one. For example, the husband of a demented woman may minimize his wife's behaviour disturbance for fear that she would be 'put away'; whereas the daughter may overstate it in order to support a case for her mother's transfer to a nursing home because her father repeatedly phones her for assistance at all hours of the day and night. Each one of the two informants has cogent reasons for weighting the information, but the psychiatrist and his or her team cannot help to resolve the situation until they understand those reasons.

Professional informants

Psychogeriatrics is as dependent on multi-disciplinary working as any other branch of psychiatry. Many patients seen for the first time will already be well known to their primary care doctor who will be able to provide invaluable information. The same frequently applies to community psychiatric nurses who now take referrals directly from general practitioners and may themselves be making referrals to the old-age psychiatry service. The psychogeriatrician can save a great deal of time and effort by consulting community psychiatric nurses and general practitioners before seeing the patient or relatives.

Where to assess the patient

The patient needs to be placed at her maximum advantage to provide clinical information in whatever setting the assessment takes place. This has to be stated explicitly because the doctor is often required to take active steps to ensure it. Account has to be taken of special sensory impairment. Poor vision may need lights to be switched on so that the patient can see who is asking her questions. Distracting noises will make it even more difficult for someone with hearing impairment to grasp what is said. Surprisingly often, this may require a request that the television be switched off. Most importantly, examiners need to sit facing the patient with the lips visible, to speak slowly, and to enunciate words carefully. The patient should then be asked if she can hear properly. Simply shouting at her is not a substitute for these simple steps.

Social customs vary within and between societies. For instance, in the United Kingdom and the United States the use of first names is much more acceptable with younger adults than it was 40 years ago. With the current generation of older patients it is not. For them to be called by their first names unbidden is disrespectful and infantilizing. Even if nurses and other non-medical staff do so, doctors should not use first names, unless specifically invited. Instead, the surname plus appropriate title (Mr, Mrs, etc.) is correct.

At home

The preferred place to assess older patients is in their own homes, although circumstances sometimes dictate that it will be elsewhere. At home patients feel less intimidated and can be seen within an environment which tells the psychiatrist a great deal that he cannot know in the clinic. If a house is filthy and cold and the patient in a similar state, and if there is reliable information that this is only a recent phenomenon, then it is a powerful descriptor of the patient's inability to cope. However, the converse is not always true; a clean and tidy home may only reflect someone else's willingness to support and care for the patient who could not otherwise do it herself (e.g. a daughter or neighbour). Another advantage of a home assessment is that cognitive disabilities, such as dyspraxia and agnosia, can be tested in an ecologically valid way (making tea, recognition of family members from photographs) that is more acceptable to a patient than being formally tested with the Mini-Mental State Examination.[1]

Assessments at home require more preparation for the doctor than is necessary at outpatient clinics where equipment for physical examination and blood tests are available, for example. It is an obvious courtesy to the patient to let her know of the visit beforehand, but it is also wise to arrange for a suitable informant to be present. Furthermore, some older patients are incapable of letting visitors into their houses and the informant might well first have to facilitate the doctor's access. Elderly patients are much more likely to be suffering from comorbid physical illness which may be the fundamental cause of the mental disorder, for example, pneumonia or a urinary tract infection manifesting delirium. The old-age psychiatrist does not therefore need to adhere rigidly to lines of specialty demarcation but rather be aware of the possibility of and prepared to search for physical illness. The basic equipment for a medical examination, such as a stethoscope, sphygmomanometer, and patellar hammer are items to be taken on home visits. Urine testing strips and a thermometer, especially a low-reading thermometer, are also sometimes useful.

In a psychiatric hospital

Patients who are assessed after admission to psychiatric beds lack the advantages of being in their own environment, although the opportunity for physical examination is much easier. Another advantage for hospital inpatients is that the assessment can be carried out over a longer period of time, since older people tire more easily and cooperation varies from day-to-day. For example, some demented patients will object to undergoing full cognitive assessment in one go, especially because they are often aware that they are failing. If a few questions are asked in the course of several short sessions, a more accurate and complete picture of the patient's abilities eventually emerges. If the Mini-Mental State Examination is administered in this way, a higher total can be achieved than if an attempt to administer it all at once meets with sullen refusal after the first few questions, with all subsequent ones having to be scored zero.

Information from other informants is as crucial for hospital inpatients as it is for those seen at home. It is usually the responsibility of the house officer or resident to collect the history, and they may be required to telephone several informants in distant and local parts to obtain a full picture which the patient is incapable of providing.

Liaison visits in general hospitals

Liaison visits to patients in general hospitals make up a considerable part of the old-age psychiatrist's work because comorbid mental and physical illnesses are very common. In spite of the fact that the host nurse's instinct is to lead the visiting psychiatrist straightaway to the patient's bedside, the latter should insist on first reading the case notes (charts) and speaking to the nursing staff who know her best. From the case notes and the prescription cards (medication orders) invaluable information on current and past drug therapy as well as details of the patient's medical history are obtained. Clues as to the patient's mental state are often best gleaned from the records written by the nurses. Nevertheless, non-psychiatrist doctors, surgeons, and nurses are not accustomed to assessment of the mental state and statements such as 'confused' should not be taken at face value, since they stand for anything from slight difficulty in answering complex questions due to anxiety at being in a strange environment to major mental disturbance. As in most other settings, time spent telephoning informants from the general hospital ward is well invested and may permit the visiting old-age psychiatrist to express an opinion on the patient's condition more firmly than would otherwise have been possible.

A useful final step before going to talk to the patient is, if possible, to observe her from a suitable distance. In this way signs of delirium, disruptive behaviour, social interaction, and other phenomena such as dyskinesias may be seen.

When seeing the patient herself, wherever possible she should be taken to a separate room and not examined in an open ward where there are other patients. If it is impossible for the patient to leave her bed, then it is usually feasible to move the bed to a more private place.

Nursing and residential homes

Much of that which is required for liaison visits to general hospitals applies to assessment in residential or nursing homes, most notably trying to see the patient in a private room away from other residents. Since abuse of elderly people is sometimes an issue in these

settings, it is preferable to have at least some time completely alone with the patient first, and if indicated, to check for bruises or other injuries, and secondly to allow the patient to tell the doctor things which she might be frightened to do in front of the staff of the home. Another problem in some nursing and residential homes is that the psychiatrist finds that an untrained or unqualified member of staff accompanies him, the quality of whose information may not be at the level of trained nurses. Careful questioning of several members of staff, attention to written records, and telephone calls to appropriate informants should all improve the quality of the assessment.

The history

Family and personal history

As has already been made clear, for many older patients a complete history may have to be obtained from a variety of informants. With the patients themselves a more flexible approach than is taken with younger ones is often needed. Whether intellectual failure is obvious and global or there is only relatively mild cognitive impairment (MCI), for some to give a history that is fully chronologically correct can be too great an effort. The examiner must accept these limitations and try to keep the atmosphere as relaxed as possible. Much more than the young, elderly psychiatric patients perceive the psychiatric interview as an ordeal or a form of trial in which it is easy for them to acquire a sense of failure. This in turn induces anxiety and a vicious spiral of ever worsening performance. One way in which the patient can be put at ease is to reassure her that you will come to her main problem in due course but that it would be good to hear something of her background first. For most older patients the family and personal histories are easier to recall than the confusing events which have led up to the referral. This is not simply good for the patient but for the examiner as well. Amongst the most profitable of pleasures in old-age psychiatry are the life stories of people who have lived during some momentous periods of world history. Furthermore, these stories put patients into a context which makes it much easier to understand why and how they have reacted to the mental illness with which they have presented.

As regards the family history specifically, the examiner needs to be alert to mistakes which could indicate cognitive impairment. A patient may confuse family relationships or misidentify family members quite early in the course of a dementing illness. In other words, inaccurate information from the patient can be as clinically informative as that which is correct. Older patients are not necessarily as sophisticated in medical vocabulary as their children and grandchildren. Therefore, to obtain facts about a possible family history of dementia (an important issue), it may be necessary to ask if any blood relative had 'memory problems' in late life or 'had to go into a home'.

In eliciting the personal history the examiner might need to be aware of the historical context at the time in question. Some older patients, however affluent they may be now, grew up in poverty or other adverse circumstances (e.g. a parent died of tuberculosis during their childhood) which could still be affecting their psychological lives. Similarly, education may have been disrupted in a way that is more unusual nowadays. Some patients, notably women, relate how they missed education because they had to look after their younger siblings after mother died or father was killed, because the remaining parent had to go out to work for the family to survive. A precise enquiry should be made as to educational attainment, and especially the level of literacy and numeracy which may be the only 'baseline' appraisal obtainable for a patient with current dyslexia or dyscalculia.

Whilst it is often very obvious to the examining doctor that a patient has cognitive impairment because of her errors and inconsistencies in giving her personal history, it is very unwise to foreclose on a diagnosis at this stage. Patients with severe depressive illnesses can be even more hesitant than those with, for example, Alzheimer's disease, or show such retardation and lack of concentration on what is being asked that they can portray a clinical picture that is not easily distinguishable from a state of advanced dementia.

Medical and psychiatric history

The nature of the information required is no different from that in younger patients. However, of particular importance in the older population is past and present medication. Drugs taken at the prescribed dose, at a wrong dose (due to dementia), or drugs no longer intended to be taken and prescribed sometimes quite a long time ago but of which a residual supply remains, are all potent causes of confusion and even frank delirium in old people. It is therefore good practice to ask to see where all medication is kept and to examine each pack or bottle to check that the amount left is approximately proportionate to that which one might expect given the date the drugs were dispensed. Since elderly people are frequently the victims of clinically injudicious polypharmacy, it is common to find a large quantity of current and prescription-expired drugs which the patient is taking on a random basis. To counter this problem proprietary boxes which dispense drugs in daily amounts, such as the Dosette or Nomad systems, are used and can more easily be checked for compliance or overdosing.

Premorbid personality

Personality is one of the prime determinants of outcome in mental illness at any age, but where older people are concerned too little effort is made, partly for lack of reliable informants, to give a valid assessment of personality. False assumptions are made that someone has always been awkward or cantankerous, whereas it is shown later that they have become so because of frontal-lobe impairment. Similarly, it is sometimes assumed that a woman has always exhibited attention-seeking or manipulative behaviour, when to the surprise of doctors and nurses alike such behaviour disappears following effective treatment for a depressive illness. Every effort should be made to find a reliable informant before reaching such conclusions.

The mental state examination

Appearance, behaviour, and the environment

A great deal can be learnt from the appearance of the patient and her home environment. Signs of neglect in both are commonly found. A brief tour of the home may reveal rotten food, little or no food, empty bottles of liquor, evidence of poor hygiene or incontinence, and inadequate heating. The patient may be dirty and unkempt, and clothes may have been put on in the wrong order (dressing dyspraxia). Particular attention should be paid to relatively mild impairment of attention and concentration, since it

might betray a delirium which can be treated to achieve a remarkable improvement in the patient's condition. Agitation is another sign to be carefully sought. Sometimes agitation is obvious with behaviour such as pacing and sighing which make it almost impossible to communicate with the patient, but at other times it can be allied to psychomotor retardation and perceptible only in tireless movements of the fingers.

Talk

Dysphasia in any of its guises is a frequent manifestation of dementia. Sometimes it is obvious, but not always. For example, it may be difficult at first to differentiate between an expressive dysphasia (Broca's dysphasia) and retardation. It is relatively mild or moderate receptive dysphasia (Wernicke's dysphasia), however, which traps the unwary clinician. In such cases the patient may appear to be obtuse, unintelligent, or hard of hearing until it is appreciated that she simply does not understand a considerable proportion of what is said to her.

Even if the patient is not dysphasic, she may be evasive and given to circumlocution. Again, this should not be taken automatically as evidence of a premorbid lack of intelligence or pompousness, since it is frequently used as a camouflage for cognitive impairment. A patient with dementia might say 'Oh of course I know that' or 'I never paid any attention to that sort of thing' when asked to give an item of current affairs.

In manic or hypomanic illness in old-age slow flight of ideas is sometimes missed by inexperienced clinicians or mistaken for evidence of cognitive impairment. Here the normal coherence of thought is disrupted because the patient is distracted from one idea to another, just as in characteristic flight of ideas, but they are delivered at a normal or even slower pace. The latter can occur if a mixed affective state is present.

Thought content

Much of that which applies to younger patients applies also to older ones and does not need to be mentioned here. However, subtle changes in thought content amounting to a restriction in breadth and a repetitiveness of themes may be noticed. Formal thought disorder which is found in young patients with schizophrenia is extremely rare in the old.

Mood

Depressive illness is commonly missed in older patients. This is partly because the clinical picture can mimic a dementing illness, so that a history from a reliable informant, as has already been stressed, is mandatory. Another reason is so-called *masked depression* in which the patient denies depressed mood but presents with other symptoms, such as those of apparent physical illness. In this sort of case a reliable account of sleep and appetite disturbance, weight loss, and anhedonia give clues as to the presence of an affective disorder. It should also be remembered that dementia and depressive illness are common disorders and not infrequently occur together, so that the diagnosis of one does not rule out the other.

Older men are still the group most at risk of suicide in most countries of the world where statistics are recorded (see Chapter 4.15.1). The psychiatrist does not shrink from specific enquiry about suicidal thinking in patients of any age, but it can sometimes be difficult to differentiate between a rational desire to die when the time comes and active suicidal ideation. In-depth probing is therefore mandatory and the examiner should not be put off by the patient's attempts to leave the topic, if he or she thinks that there is likely to be risk of self-harm.

Cognitive examination

In assessing elderly patients more emphasis is usually placed on the cognitive examination than in younger patients. In theory it can be as exhaustive and thorough as assessment by a neuropsychologist, but in the routine practice of old-age psychiatry it usually has to be feasible within the constraints of a consultation which lasts about an hour.

It is in this part of the assessment that the examiner is most likely to lose the patient's cooperation, principally because of the humiliation experienced by some at their own failures. Some patients become angry, indignant, or defensive. Others become anxious and their performance deteriorates. One way to pre-empt this is to preface testing by stressing that this is not a competitive examination and that most people have difficulty answering some of the questions. Correct answers are praised without excessive emphasis and incorrect ones are either treated in a neutral way or given a positive spin by saying, for example, 'Well it's…, but you weren't far off'.

Many old-age psychiatrists and other members of their multidisciplinary team prefer to use standardized questionnaires, such as the Mini-Mental State Examination,[1] the questionnaire in widest use. It has the advantage that results between and within patients can be compared and progress can be monitored. However, no off-the-shelf test is exhaustive and none produces an adequate cognitive assessment by itself. The clinician therefore needs to have some sort of schema for covering the main areas of cognitive function which would include: memory (in its various aspects) and general information, and naming; the understanding and production of language; praxis (ideomotor and constructional); sensory recognition (gnosis); abstract reasoning; verbal fluency; calculation; left/right orientation; and executive function (the ability to integrate mental processes for goal-directed activity). The list is not exhaustive and some areas may need to be covered in greater detail as the clinical situation demands. Table 8.4.1 gives a guide to cognitive examination based on an extended Mini-Mental State Examination. Clinicians vary in the order and way in which they test individual cognitive functions, and the list in Table 8.4.1 is not intended to be prescriptive.

Other aspects of the mental state examination

These do not differ in essence from that in younger adults and are not covered in this section.

Physical assessment

Since physical comorbidity is extremely common, the old-age psychiatrist needs to be able and willing to conduct a basic physical examination. In the patient's home this may not always be easy. For instance, it may not be kind to ask a frail person who takes an hour or more to dress and come downstairs in the morning to return to her bed and undress, but it is usually possible to make a reasonable examination of the arterial pulse, blood pressure, and jugular venous pulse, and to auscultate the heart and lungs when

Table 8.4.1 Schema for testing cognitive functions based on an extended mini-mental state examination

Function	Subfunction	Examples
Orientation	Time	Year, month, date, day, season
	Place	Own address or that of hospital, city, county/state, country
	Person	Own name (married women sometimes cannot give married name); recognize others by name or function (e.g. you are a doctor)
Memory	Immediate recall	Immediate repetition of three objects or a name and (local) address
	Delayed recall	Repetition as above but after a distractor task
	Long-term recall	Give historical or personal events (that can be verified)
	General information	Names of politicians or other VIPs
Concentration		Months of the year in reverse order, counting from 20 back to 1; spelling WORLD forwards then backwards
Praxis	Construction	Copy diagram of interlocking pentagons
	Ideomotor	Draw a clock and set the hands at a specified time (also a test of executive function)
	Dressing	Put on a jacket; undo, and refasten buttons
Sensory recognition (gnosis)	Visual including prosopagnosia	Recognize photographs taken from unusual angles and of familiar faces
	Auditory	Recognize the doorbell
	Tactile	Recognize objects placed in the palm, e.g. coins
	Reading	Any sample *but* use large print, e.g. newspaper headlines
	Olfactory	Recognize something from the kitchen, e.g. coffee
Language	Expressive	Repeat 'no ifs ands or buts'
	Understanding	Carry out a three-stage command
	Naming	Naming objects of increasing complexity
Verbal fluency		List as many items from a category as possible in 1 min, such as boys' and girls' forenames, or as many words beginning with a specified letter
Writing		Write an ordinary English sentence
Calculation		Not too complex—subtraction of serial sevens from 100 is too difficult for many. A simple sum involving money is better
Left–right orientation		Face–hand test (e.g. left hand to left ear, right hand to left ear); finger recognition on own and examiner's hand
Abstract reasoning		'In what way are an apple and a banana alike?'
		'In what way are a boat and a car similar?'
		Interpretation of simple proverbs

Testing one function usually depends on one or more others; for example, most tests depend on understanding of language. Examples are neither prescriptive nor exhaustive.

the patient is seated. Similarly, a partial neurological examination for signs of focal deficits is also possible. However, if something alerts the doctor to the need to examine an undressed and supine patient, the duty should not be shirked, lest a hitherto unsuspected abdominal mass, or a strangulated hernia are missed.

Patients admitted to psychiatric hospital or nursing home beds should all undergo a physical examination. Focal neurological signs may indicate the cause of dementia. Carcinoma of the breast which either dementia or fear has prevented the patient from declaring may be much more treatable than she has believed. All the physical disorders which may be revealed are too numerous to mention, but their detection and treatment nearly always contribute to an improvement in mental function.

Laboratory investigations

Owing to tight budgetary constraints it is sometimes argued that routine laboratory investigations, such as full blood count and chest radiography, are unnecessary for younger adults. Whether or not this is true, with older patients such tests are strongly advised because the treatment of comorbid physical illness improves mental disorder. Furthermore, a treatable or arrestable cause of dementia may be found. For patients with dementia the following are recommended: full blood count; serum electrolytes, and creatinine; liver and thyroid function tests; syphilis serology; vitamin B_{12} and red cell folate; chest radiography. Medical and nursing staff should also have a low threshold for sending urine for microbiological examination (see superimposed delirium below). The vexed question of neuroimaging, an expensive procedure, is much discussed and the debate is not easily summarized or resolved. Most space-occupying lesions can be detected, as can many vascular changes. However, there is nothing pathognomonic for Alzheimer's disease on CT, magnetic resonance imaging, or single-photon emission tomography. In Alzheimer's disease, scans may support the diagnosis but not establish it.

General considerations in the assessment of older psychiatric patients

Falls

The causes of falls in older people are many and the reader is referred to textbooks of geriatric medicine for a full discussion. However, the old-age psychiatrist needs to be aware that many

psychotropic drugs precipitate falls through postural hypotension, with tricyclic antidepressants and neuroleptics being particular offenders. Neuroleptics induce parkinsonism, putting the patient at risk of tripping against rugs or items of furniture. The clinical implications of falls, especially in older women, are serious because patients are at risk of a fractured neck of femur or (less commonly) a subdural haematoma, both of which carry a high mortality.

Nutrition

Poor nutrition is commonly found in patients presenting to old-age psychiatry services. Even in affluent societies many older people are amongst the most impoverished or feel that they cannot afford good food. Some are too frail to get out to the shops. Others lack motivation to shop and eat because of depressive illness. Patients suffering from dementia may be incapable of shopping and preparing food. Widowers might never have learned to cook. A vitamin B_{12} or folate level at the lower end of the reference range, or even below it, is as often a reflection of poor nutrition as an indication of pernicious anaemia.

Superimposed delirium

Here it is mentioned only that subacute delirium superimposed on another condition is at risk of not being recognized because it is taken to be a manifestation of the underlying illness, usually dementia. This is particularly the case when a subclinical urinary tract infection occurs in a demented patient. It is of clinical relevance because treatment of the urinary tract infection results in a great improvement in the patient's mental state. On routine assessment particular attention should therefore be paid in the history to evidence of sudden worsening of a stable or only slowly deteriorating condition, and to nocturnal disturbance especially with (usually visual) hallucinations. On examination of the patient herself the level of consciousness, awareness of the environment, attention, and concentration should be noted.

Delirium is described in Chapter 4.1.1, and special features in older people are considered in Chapter 8.5.1.

Reassessment after treatment

Because so much of psychiatry is practised in the community, it is impossible for all patients to be reassessed by a psychiatrist after treatment. In hospital or outpatient clinics it is feasible, but not for the majority of older patients who live at home. Furthermore, in areas where the population is geographically widespread, it is very difficult if not impossible for many older people, who may be frail and infirm, to travel long distances to attend clinics. Much of the follow-up assessment in old-age psychiatric services is therefore carried out by other members of the multi-disciplinary team, such as psychologists or occupational therapists, but mostly by community psychiatric nurses. It is essential for the psychiatrist to meet regularly with members of the team seeing patients in the community to discuss the progress of individual patients following treatment.

Special features of clinical syndromes in the elderly

Contents

8.5.1 Delirium in the elderly

James Lindesay

Note Dementia in people of all ages is considered in Part 4, Section 4.1, where the following topics are considered: Chapter 4.1.2 Dementia: Alzheimer's disease; Chapter 4.1.3 Frontotemporal dementias; Chapter 4.1.4 Prion disease; Chapter 4.1.5 Dementia with Lewy bodies; Chapter 4.1.6 Dementia in Parkinson's disease; Chapter 4.1.7 Dementia due to Huntington's disease; Chapter 4.1.8 Vascular dementia; Chapter 4.1.9 Dementia due to HIV disease; Chapter 4.1.10 The neuropsychiatry of head injury; Chapter 4.1.11 Alcohol-related dementia (alcohol-induced dementia; alcohol-related brain damage); Chapter 4.1.13 The management of dementia.

Introduction

Although delirium occurs at all ages, it is most frequently encountered in late life. This is because delirium is the result of an interaction between individual vulnerability factors (e.g. brain disease, sensory impairment) and external insults (e.g. physical illness, medication), the rates of which both increase with age. Our current concept of delirium derives principally from the florid clinical stereotype that has evolved from centuries of clinical observations on younger patients, and it may not be applicable to our historically unique ageing population. In younger adults, a major physical insult is usually necessary to precipitate delirium, which is often a dramatic disturbance. This is not the case in vulnerable elderly patients when relatively mild physical, psychological, or environmental upsets may be sufficient to bring about acute disturbances of mental functioning. These disturbances may be less obvious than in younger patients, particularly if they occur in the context of pre-existing cognitive impairment. Consequently, despite being common and problematic, delirium in elderly patients is frequently missed or misdiagnosed as dementia or depression by medical and nursing staff.[1] This is unfortunate, because delirium is an important non-specific sign of physical illness or intoxication, and if left untreated there may be costly consequences, both for the patient and for health services.

Clinical features

The clinical features of delirium are described in Chapter 4.1.1. Most delirium in elderly patients is of the quiet hypoactive variety, lacking the more florid disturbances in mood, perception, and behaviour that bring the disorder to clinical notice. Reversible cognitive impairment in elderly patients is associated with reduced conscious level, poor attention, poor contact with the patient, incoherent speech, reduced psychomotor activity, lack of awareness of surroundings,

poor orientation, and poor memory.[2] Hyperactive delirium does occur in elderly patients, but it is less pronounced, with the overactivity usually confined to purposeless behaviour such as pulling at the bedclothes. Violent behaviour is uncommon; elderly patients are more likely to injure themselves than others.

Classification

The ICD-10 and DSM-IV diagnostic criteria for delirium are described in Chapter 4.1.1. They are not entirely concordant; ICD-10 is more restrictive, resulting in the diagnosis of fewer cases.[3] However, the two systems agree on four essential features: disturbance of consciousness, disturbance of cognition, rapid onset/fluctuating course, and evidence of an external cause. Unfortunately, none of these features is specific for delirium as opposed to dementia, and the current diagnostic criteria are poor predictors of outcome, defined in terms of improvement in cognitive function. Reversibility of cognitive impairment may be the most discriminating feature of delirium,[2] but is problematic as a diagnostic criterion since outcome is unknown at the outset.

Another shortcoming of the current classifications of delirium is that they do not recognize the partial and transitory disturbances that are commonly observed in elderly patients. Subsyndromal delirium is common, and is part of a continuum between normality and the full syndrome. Subsyndromal cases are clinically significant, since they have the same risk factors and the same increased mortality as syndromal cases.[4]

Diagnosis and differential diagnosis

The diagnosis of delirium is a two-stage process: first, diagnose the delirium, and second, identify the underlying cause or causes. The diagnosis of delirium in elderly patients can be problematic, given the predominantly hypoactive clinical picture and the unreliability of 'positive' symptoms. However, it is important to consider the possibility if cognitive decline is rapid, and if any of the recognized signs and symptoms are present. A good informant history from relatives or ward staff is essential to establish the onset and course of the disorder. Routine screening procedures may be useful in identifying patients who develop delirium while in hospital. Brief instruments such as the Mini-Mental State Examination[5] are not diagnostic, but will alert the clinician to any sudden decline in cognitive function. More extended diagnostic instruments are also available, such as the Delirium Rating Scale,[6] the Confusion Assessment Method,[7] and the Delirium Symptom Interview.[8] Another approach to screening for delirium is to identify those at particular risk of developing the disorder. Predictive factors related to the patient include: visual impairment, severity of illness, cognitive impairment, and a blood urea nitrogen/creatinine ratio of 18 or more.[9] Hospital- and treatment-related factors include: use of restraints, malnutrition, use of more than three medications, bladder catheterization, and the number of iatrogenic events.[10] These factors are multiplicative in their effect.

The differential diagnosis of delirium includes most other psychiatric disorders in this age group. These disorders are themselves risk factors for delirium, so the possibility of co-morbidity must always be considered. When in doubt, investigate and manage as delirium until the situation is clear.

Dementia

Dementia is a major risk factor for delirium, and in practice co-morbidity commonly occurs. However, differential diagnosis is important, as episodes of delirium need to be identified in order for them to be managed effectively. Recent onset and rapid decline of cognitive functioning, from whatever baseline, indicate an episode of delirium until proved otherwise. Delirium in elderly patients can be prolonged, and failure to recover quickly following treatment of the cause does not necessarily indicate an underlying dementia. It is important to have a good history of pre-morbid functioning.

Depression

Delirium can be difficult to distinguish from severe depression in elderly patients, cognitive impairment associated with severe depression is usually relatively mild in comparison with the affective disturbance, whereas the reverse is true of delirium. The pattern of diurnal variation also varies in the two disorders, with depressed patients tending to be worse in the mornings, and delirious patients in the evenings. Elderly depressed patients are at increased risk of delirium, either through self-neglect or because of the antidepressant treatment they are receiving. Anticholinergic tricyclic drugs are particularly troublesome in this respect. Adverse life events, such as bereavement, may precipitate both depression and delirium in vulnerable individuals.

Mania

Mania is much less common than delirium in old age, and is often mistaken for it. There may be a previous history of manic-depressive illness, but a proportion of cases of mania in late life are first presentations, usually in association with underlying organic brain disease. Elderly manic patients are often exhausted and dehydrated, and so 'manic delirium' is a common presentation.

Other disorders

Anxiety states in elderly patients are unlikely to be mistaken for delirium, unless they are particularly severe. Similarly, paranoid states and schizophrenia rarely lead to diagnostic difficulty, although it should be noted that patients with these disorders are at an increased risk of developing delirium, either through self-neglect, or the effects of neuroleptic and anticholinergic medications. A number of other rare conditions in which cognitive, perceptual, affective, and behavioural disturbances occur, such as amnesic syndromes, epilepsia partialis continua, twilight states, the Charles Bonnet syndrome, neuroleptic malignant syndrome, and catatonia, may also resemble delirium. If the history and clinical examination are inconclusive, EEG may be helpful in making the diagnosis.

Epidemiology

The community prevalence of delirium increases with age, rising to 14 per cent in those aged 85 years and older. In medical and surgical inpatients, the rates of delirium vary considerably (prevalence, 10–30 per cent; incidence, 4–53 per cent), because of methodological and population differences. Similar rates are also found in studies of acute psychogeriatric admissions.[11] Some patient groups, such as those with hip fractures, have consistently higher rates. Other at-risk populations, such as nursing home residents, have received less systematic investigation, but the available evidence

suggests that they also have rates of delirium comparable to those found in elderly inpatients.

Aetiology

Almost any physical illness can give rise to delirium in elderly patients. The most common physical causes are listed in Table 8.5.1.1. In many cases the underlying cause is not obvious, and the delirium may be the most prominent presenting feature. The aetiology is commonly multi-factorial, and all contributory factors need to be identified and treated. As a rule, hyperactive delirium is more commonly due to infection and toxic/withdrawal states, whereas hypoactive delirium is more commonly due to metabolic abnormalities.

Table 8.5.1.1 Common causes of delirium in elderly patients

Drugs
Psychotropics
Hypnotics
Anticonvulsants
Anticholinergic drugs
Dopamine agonists
Analgesics
Anaesthetics
Alcohol withdrawal
Infection
Urinary tract infections
Pneumonia
Septicaemia
Ulcers, pressure sores, gangrene
Endocarditis
Postsurgical wound infection
Metabolic and endocrine
Electrolyte abnormalities
Uncontrolled diabetes
Hyper/hypothyroidism
Renal failure
Hepatic failure
Hypothermia
Malnutrition
Cardiovascular
Cardiac failure
Myocardial infarction
Vascular disease
Anaemia/polycythaemia
Respiratory
Pulmonary embolism
Pneumothorax
Pleural effusion
Intracranial
Trauma
Subdural haematoma
Stroke
Tumour
Epilepsy
Gastrointestinal
Perforation
Pancreatitis
Cholecystitis/cholangitis
Haemorrhage
Constipation

Drugs are an important cause of delirium in elderly patients, due to age-associated changes in their distribution, metabolism, and excretion. These pharmacokinetic changes are very variable, with the result that toxicity at apparently therapeutic doses is unpredictable. Certain drugs are particularly prone to cause delirium in elderly patients, for example those with anticholinergic activity. Tricyclic antidepressants, thioridazine, and benzhexol are particularly toxic in this respect, but many of the drugs commonly prescribed to elderly patients have some degree of anticholinergic activity, for example, digoxin, prednisolone, cimetidine, ampicillin, and warfarin. Individually, this activity may be small, but the cumulative effect can be significant if patients are on multiple medications.[12] Patients with Alzheimer's disease are particularly prone to develop delirium when given anticholinergic drugs, perhaps because their central cholinergic function is already impaired. In a minority of particularly vulnerable elderly patients, purely environmental and psychological insults are sufficient to cause delirium. The mechanisms of action in these cases are not known, but may involve factors such as sensory deprivation and stress responses via the hypothalamic-pituitary-adrenal axis.

Course and prognosis

Traditionally, delirium has been regarded as a transient condition that proceeds to either recovery or death. In the majority of cases, the delirium is brief, but about one-third of patients have prolonged or recurrent episodes.[13] Delirium is associated with increased short-term mortality in elderly patients, mainly because of the severity of the underlying illness. Delirium interferes with the processes of diagnosis, treatment, and rehabilitation, and as a result patients have longer hospital stays and higher rates of functional decline and discharge to nursing homes.[14] Increased length of stay and mortality are particularly associated with hypoactive delirium. In general, patients with hyperactive delirium appear to be less severely ill than those with hypoactive delirium; this may be due to differences in the cause of the delirium, or to the fact that hyperactive delirium is more likely to be identified and the causes treated.

Prospective studies have shown that the prognosis, in terms of persistent or recurrent symptoms, is relatively poor in elderly patients.[15] This is probably because those who experience delirium are a vulnerable group who are likely to develop the condition provided there is sufficient external insult. A proportion will also be suffering from a form of dementia, which will increase the vulnerability to delirium as it progresses. There is evidence that delirium is followed by persistent cognitive decline,[16] which raises the possibility that it (or the underlying cause) is a risk factor for the development or exacerbation of dementia.

Evaluation of treatment

Evidence regarding the efficacy of treatments for delirium is sparse (Chapter 4.1.1). The cholinergic hypothesis of delirium raises the possibility that cholinergic agonists, such as the cholinesterase inhibitors licensed for the treatment of Alzheimer's disease, may be of value in the prevention and treatment of delirium.

Management

There are four important steps in the management of delirium[17]:

Address the underlying causes (see above)

Behavioural control

This aspect of delirium management can be divided into pharmacological and non-pharmacological strategies. Non-pharmacological interventions in delirium are aimed at reducing the confusing, frightening, and disorienting aspects of the hospital environment in which most patients find themselves. They have received little formal evaluation, but features such as good lighting, low noise levels, a visible clock, and the reassuring presence of personal possessions and familiar individuals, such as relatives, are thought to be helpful. Any invasive intervention, including personal care tasks, should be introduced and explained simply, slowly, clearly, and repeatedly before it is carried out. Holding the patient's hand while talking helps to focus attention and provides reassurance.

The drug treatment of the symptoms and behaviours of delirium in the elderly is similar to that of younger patients, although it is necessary to start with lower doses, such as haloperidol 0.5 to 2 mg orally, or intramuscularly if necessary, repeated until the disturbance is controlled. Prescriptions should be for short periods only (up to 24 h) to encourage review of the effects and the necessary dosage. Once the delirium has resolved, the medication should be reduced/discontinued over a period of 3 to 5 days. If the patient cannot tolerate typical or atypical neuroleptic drugs, then a benzodiazepine (for instance, diazepam, lorazepam, or alprazolam) should be used instead.

Prevent/treat complications

The complications that befall patients with delirium probably contribute to the adverse outcomes associated with this condition. For example, hyperactive delirium is associated with falls during the hospital admission, whereas hypoactive delirium is associated with the development of pressure sores. Other complications of delirium include urinary incontinence, sleep disturbance, malnutrition, and immobilization; all of these problems should be anticipated and prevented where possible.

Rehabilitation and family support

Given the risk of functional decline following delirium, every effort should be made to return the patient to their pre-morbid level of functioning. ADL capacity should be assessed regularly, and independence encouraged where possible. The patient's family need to be involved in the rehabilitation process, as they will be largely responsible for aftercare following discharge. They should know that delirium is often recurrent, and be advised about the early signs of this. Indeed, delirium is a useful marker of vulnerability, and of the need for more intensive community aftercare.

Prevention

The modern hospital environment contributes significantly to the development of delirium in elderly patients, and multi-component interventions to improve poor clinical practice have been shown to reduce cost-effectively the incidence of delirium in elderly inpatients.[18] The following areas are important:

- *Prescribing*

Avoid where possible any drugs with known deliriogenic potential, particularly in at-risk individuals such as those with Alzheimer's disease. There should be regular review of the drug chart, with the aim of keeping the number of drugs to the minimum necessary. Non-pharmacological sleep-promotion strategies should be used in preference to hypnotic drugs.

- *Ward environment and routines*

These should aim to minimize disorientation, sensory impairment, and sleep deprivation. Patient mobility should be encouraged, as should adequate food and fluid intake. Medical and nursing staff should be trained to recognize and manage delirium.

- *Surgical routines*

Good preoperative, perioperative, and postoperative care (especially with regard to infection control, blood pressure, and oxygenation) will reduce the risk of postoperative delirium.

8.5.1.1 Mild cognitive impairment

Claudia Jacova and Howard H. Feldman

Introduction

Within the cognitive functioning continuum from normal ageing to dementia three broad states can be distinguished: normal functioning for age, clear-cut impairment meeting diagnostic criteria for dementia, and mild cognitive impairment (MCI), which falls below normal but short of dementia in severity (Fig. 8.5.1.1.1). There is active debate over what MCI is, how to define and classify this state, and where to set its borders on the described continuum.[1] Some definitions depict MCI as the tail-end of normal cognitive ageing whereas in other definitions MCI embodies the early clinical manifestation of Alzheimer Disease (AD) and other dementias. In 2003, the key elements of different MCI definitions were integrated into a consensus diagnostic and classification framework,[2] thus establishing some common ground in a field that is still evolving. MCI has also been positioned as a potentially important target for early treatment interventions to delay progression to dementia.

Nosologically, MCI is not currently included as a diagnostic entity in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR)[3] and the *International Classification of Diseases*, 10th revision.[4] The diagnostic categories of *Mild Neurocognitive Disorder* (DSM-IV-TR) and *Mild Cognitive Disorder* (ICD-10) are similar to MCI because they require the presence of cognitive impairment but these categories can only be assigned if a specific neurological or general medical condition can be identified to account for the cognitive symptoms. Much of the current condition

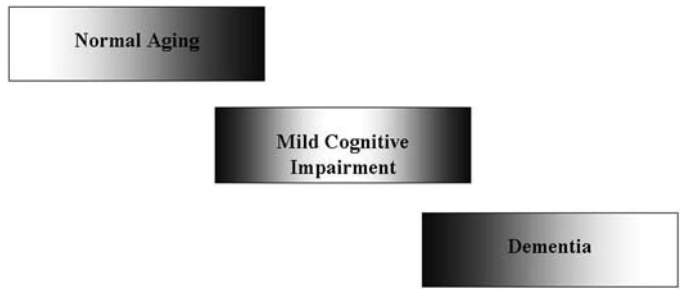

Fig. 8.5.1.1.1 Theoretical continuum from normal ageing to dementia: darker shading indicates areas of overlap between adjacent states and increased diagnostic challenge. (Reproduced from R. Petersen *et al.* Apolipoprotein E status as a predictor of the development of Alzheimer's disease in memory-impaired individuals, *The Journal of the American Medical Association*, **273**, 1274–78, copyright 1995, The American Medical Association.)

of MCI does not fit as it has no aetiologic specification. Nevertheless, MCI is increasingly a presenting condition in primary and specialized settings of care. Medical practice guidelines have recognized MCI as a risk state for dementia and recommend careful clinical evaluation and monitoring of individuals with this diagnosis.[5,6]

Nosology

The current nosological entities within the general MCI framework include a variety of definitions and capture overlapping but not identical conditions in the ageing population (Fig. 8.5.1.1.2).

Age-associated memory impairment (AAMI)

AAMI describes healthy individuals over the age of 50 that experience memory decline. Formal diagnostic criteria require complaints of memory loss, performance on objective memory tests falling at least 1 SD below norms for young individuals, and intellectual functioning normal. AAMI cannot be diagnosed if there is a

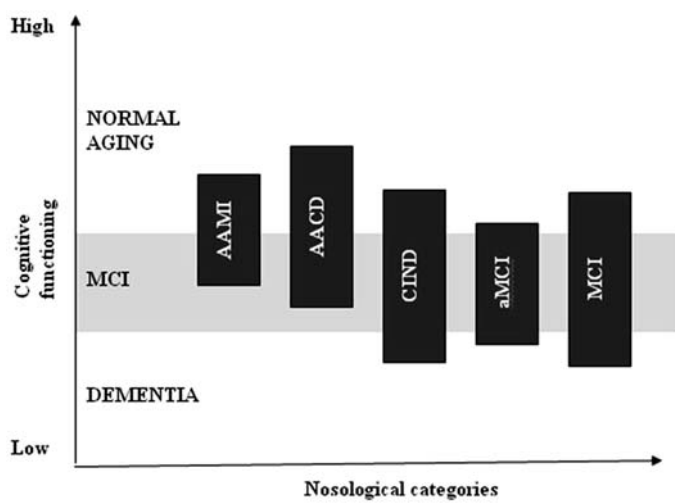

Fig. 8.5.1.1.2 MCI nosological entities on the continuum from normal ageing to dementia. (Reproduced from H.H. Feldman and C. Jacova, Mild cognitive impairment, *The American Journal of Geriatric Psychiatry*, **13**(8), 645–55, copyright 2005, American Association of Geriatric Psychiatry, Lippincott Williams & Wilkins.)

neurological, psychiatric, or medical condition that can account for the impairment.[7]

Age-associated cognitive decline (AACD)

The AACD category covers impairments in any domain affected by ageing, including learning, memory, attention, thinking, language, and visuospatial function. There must be self- or informant-reported cognitive decline over at least 6 months and performance on objective cognitive tests at least 1 SD below age- and education-appropriate norms. The cognitive impairment cannot fulfil dementia criteria and is not accounted for by systemic, neurological, or psychiatric disorders.

Cognitive impairment not dementia (CIND)

CIND includes all individuals that cannot be classified as cognitively normal or as demented. CIND has been applied both in population- and clinic-based studies.[8,9] This diagnostic label is assigned by clinical judgement when there is memory and/or cognitive impairment insufficient to meet DSM criteria for dementia, without exclusions related to underlying aetiologies. There are to date no operational criteria for this category. Because of its inclusiveness CIND encompasses a range of aetiologies that must be disentangled to be clinically meaningful.[8,9]

Amnestic mild cognitive impairment (aMCI)

This amnestic condition is defined as a clinical disorder that describes a transitional state between normal ageing and AD. It is characterized by memory impairment in the context of otherwise preserved abilities. The diagnostic criteria for aMCI require memory complaint preferably corroborated by an informant, objective memory impairment for age and education, largely normal general cognition, essentially intact activities of daily living (ADLs), and the absence of dementia. Objective memory impairment, though not anchored to a specific cut point, is generally ≥1.5 SD below appropriate norms.[10]

Mild cognitive impairment (MCI): international working group criteria

The MCI concept has recently been broadened to encompass multiple patterns of cognitive impairment including amnestic, non-amnestic, single- or multiple-domain deficits.[2] In this framework the classification of MCI requires multiple steps. First, individuals should be judged as neither normal nor demented. Second, there should be evidence of cognitive decline, supported by self and/or informant reports, impairment on objective cognitive tests, or evidence of decline over time on these tests. Third, activities of daily living should be mainly preserved, with the provision that complex ADLs can be minimally impaired.[2] Like CIND, this MCI category recognizes multiple aetiologies underlying impairment, and requires their identification.

Clinical staging scales

Studies of MCI frequently utilize clinical staging scales both to define the inclusion criteria as well as to track outcomes. The Clinical Dementia Rating (CDR) scale[11] distinguishes five stages of dementia severity, with a stage of questionable dementia (CDR 0.5), between the stages of healthy (CDR 0) and mild dementia (CDR 1). CDR 0.5 is most often applied to MCI; however, this stage also can include those with functional impairment who meet dementia criteria. Similarly, the Global Deterioration Scale (GDS),[12] which distinguishes seven stages of impairment, overlaps with MCI at stage 2 (normal with a subjective complaint) or stage 3 (subtle deficits in cognition and occupational/social activities), whereas individuals with mild dementia may receive a GDS stage 3 or 4. The mapping of MCI onto these staging scales has not yet been fully reconciled.

Epidemiology

Prevalence

Prevalence estimates for MCI will naturally vary according to the definition, to age and to the setting. In population-based studies, AAMI has been estimated to affect up to 38.4 per cent, and AACD between 21 and 35.2 per cent, of individuals aged 60 or older.[13] CIND has been reported to affect between 16.8 and 23.4 per cent of individuals aged 65 or older. The prevalence of aMCI has been much lower, at 3 to 6 per cent in similar age groups.[13] Within the broad MCI classification, the multiple domains and single non-memory domain subtypes have been described as roughly twice as frequent as the amnestic subtype, with multiple domain impairment estimated to affect 16 per cent of individuals.[14,15] The prevalence of AACD, aMCI, MCI, and CIND varies with age, with a two- to threefold increase from age 65–74 to >85 in CIND (Fig. 8.5.1.1.3).[8,16] The prevalence of MCI and related conditions within the referral clinic setting is much higher than population estimates.[17]

Natural history

(a) Progression rates to dementia

While the rate of progression to dementia is 1 to 2 per cent per year for cognitively normal individuals aged 65 or older, the rates for all MCI entities are systematically higher and quite variable (Fig. 8.5.1.1.4). Whereas AAMI has low progression rates (1 to 3 per cent per year) and is closest to a normal population, for all other categories most studies report rates between 10 and 15 per cent per

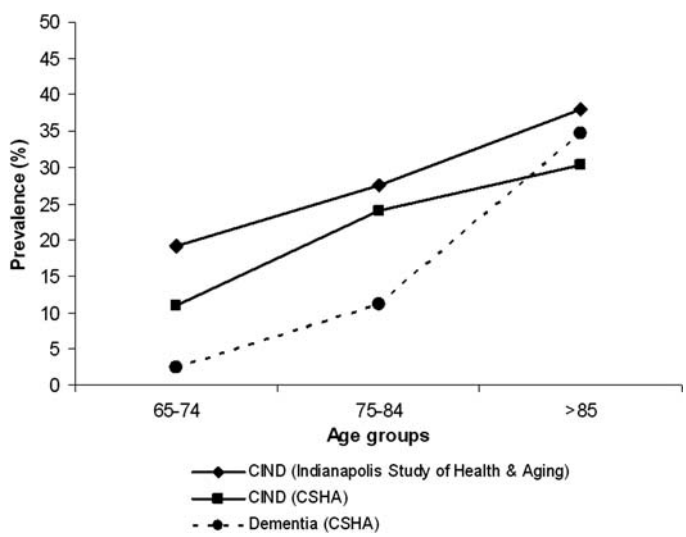

Fig. 8.5.1.1.3 The prevalence of CIND with increasing age reported in the Canadian study of health and ageing (CSHA)[8] and the Indianapolis study of health and ageing.[16]

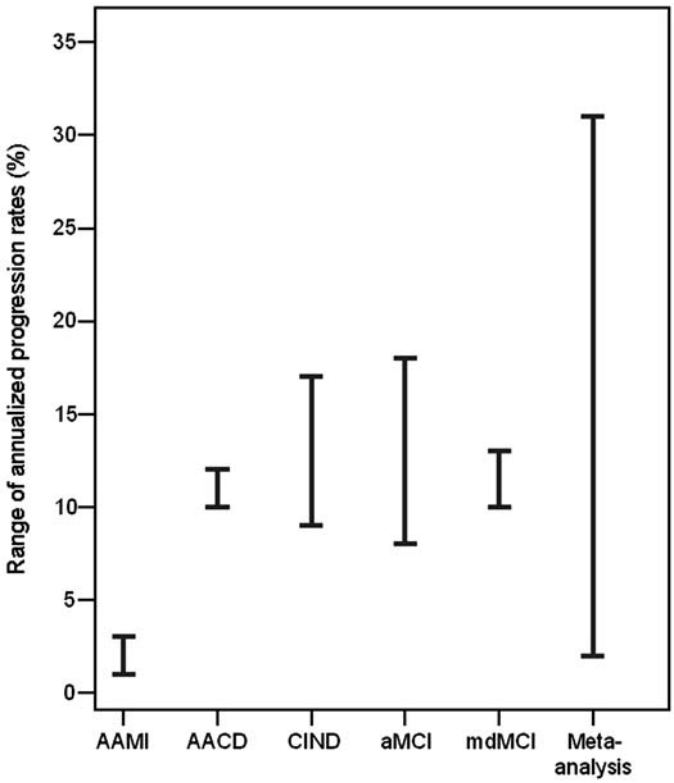

Fig. 8.5.1.1.4 Range of annualized estimates of progression to dementia in various MCI groups, reported in Refs.[13,14,18]

annum, generally over 5-year periods. A meta-analytic study indicated a mean annual conversion rate of 10.24 per cent, with a range of 2 to 31 per cent. The single most important factor accounting for this heterogeneity was the source of the participants, with subjects referred to specialist services, either geriatric or memory/dementia clinics, progressing to dementia at roughly twice the rate found for community volunteers.[18] In studies of CIND annual rates have been 17 per cent for a dementia clinic-referred cohort, 9 per cent for a population-based cohort.[1,9]

An unresolved question is whether all subjects with MCI eventually develop dementia. In a highly selected aMCI sample with CDR 0.5 followed over 10 years, all subjects eventually progressed to meet dementia criteria.[19] This evidence has been proposed to support the belief that aMCI represents early-stage AD.[19] Other studies with similar length of follow-up have not found as high rates of progression and neuropathologic evidence also suggests more heterogeneity, with up to 50 per cent of subjects with aMCI meeting criteria for AD, and the remainder having varied non-AD abnormalities including vascular lesions, argyrophilic grain disease, or other conditions.[20]

(b) Reversion rates to normal

There are consistently proportions of individuals with MCI that will revert back to normal cognitive functioning during follow-up. In population-based studies, this backcrossing has sometimes been particularly high (range 4 to >40 per cent after 1.5 to 5 years).[1] In clinic-referred samples, reversion rates for CIND appear to be lower (14 per cent after 2 years).[9] Reversion may in part be a reflection of an inherent instability in the MCI condition, particularly when it is defined exclusively by psychometric cut points.[1] Reversion appears to be more common when there is no clearly identified aetiology for MCI.[9]

(c) Mortality risk

The mortality risk of MCI is near twice the risk of cognitively normal individuals. The estimated relative risk has been 1.5 for AACD, 1.5–1.9 for CIND, and 1.3–1.7 for aMCI while there has been no increased risk reported for AAMI. There is no clear explanation for this increased mortality risk. It is independent of health conditions such as cardiac disease, cerebrovascular disease, diabetes, and malignancies, and it may be related to incipient and eventually full-blown dementia.[21]

Diagnosis: clinical approach

Overview

Figure 8.5.1.1.5 depicts a flow chart for the clinical diagnosis of MCI.[2] The diagnostic process begins with an expressed concern about cognitive functioning from the patient and/or informant. The assessment then requires a careful history from the patient and informant, as well as the mandatory administration of objective cognitive testing. An evaluation of social function and ADLs, both instrumental and basic, is performed to determine whether there is impairment sufficient for a dementia diagnosis. A clinical judgement must be made of whether the impairment falls outside of the normal range for age and whether it falls within MCI or dementia. The cognitive profile can further be classified into single amnestic, multiple domains, or single non-memory domain. The final step in the diagnostic process is the determination of the aetiology of MCI.

Cognitive assessment

The identification of MCI requires evidence of impairment on objective cognitive testing. Generally, a cognitive screening test is needed as a first step. It should be recognized that the most widely used Mini Mental State Examination (MMSE) lacks sensitivity for MCI diagnosis. In turn, two novel instruments (the Montreal Cognitive Assessment, MoCA, and the DemTect) have been shown to reliably discriminate MCI from normal ageing.[22] The effects of age and educational achievement on test performance and the consequent risk of misclassifications must be kept in mind in the clinical assessment. Irrespective of the instrument that is chosen, there should be coverage of episodic memory, executive functioning and language, which are the most frequent presenting problems in MCI.

Neuropsychological testing (NPT) can be helpful where a clear-cut determination of MCI is difficult following the initial assessment. NPT provides information on the pattern of impairment, with identification of the domains affected and reference to standardized scores. Serial NPT may be particularly useful in defining the progression from MCI to mild dementia. The rate of decline on tests of memory, executive functioning and language accelerates during the 3- to 5-year time window before diagnosis of full-blown dementia.[22] NPT also has some predictive utility in addressing the risk of progression from MCI to dementia. Deficits on tests of episodic memory and executive functioning have consistently been found to characterize those with MCI that will develop dementia.[22]

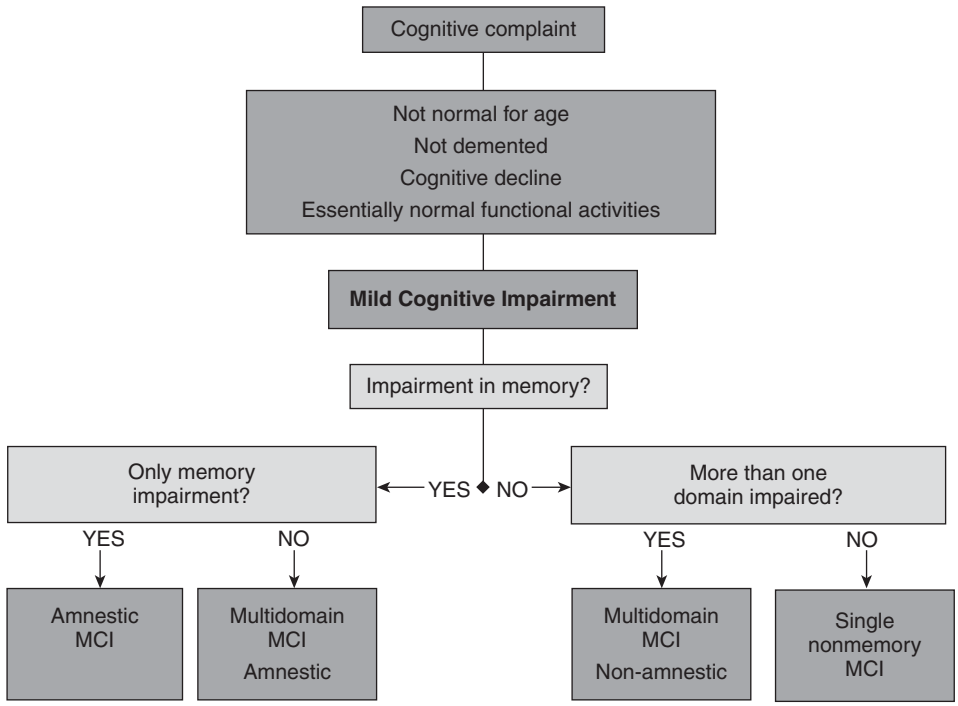

Fig. 8.5.1.1.5 Diagnostic flow chart proposed by the International Working Group on MCI. (Reproduced from B. Winblad *et al.* (2004), Mild cognitive impairment—beyond controversies, towards a consensus: report of the International Working Group on mild cognitive impairment, *Journal of Internal Medicine*, **256**, 240–6, copyright 2004, John Wiley & Sons, Inc.)

Neuropsychiatric symptoms (NPS)

NPS may provide a very useful additional domain for evaluation. An estimated 50 to 70 per cent of subjects with MCI have informant-reported NPS. Symptoms of depression, agitation/aggression, anxiety, apathy, and irritability, while at a low level of intensity, nevertheless each have a frequency of >30 per cent. NPS are associated with greater MCI severity and may be predictive of progression to dementia.[23] The evaluation of NPS is recommended within an MCI assessment.

Aetiology

The determination of aetiology is a final key step in the assessment of MCI. It requires additional laboratory studies as well as consideration of neuroimaging results. Within a cohort of individuals with CIND, the most prevalent aetiologic subtypes were pre-AD, vascular cognitive impairment, cognitive impairment with psychiatric illness, and not otherwise specified (NOS) (Table 8.5.1.1.1). These CIND aetiologic subtypes differed in their functional and psychobehavioural profiles, and in their 2-year prognosis. Pre-AD and vascular CIND had the highest rates of progression to dementia (~40 per cent), with pre-AD subjects developing exclusively probable AD. Psychiatric CIND and CIND NOS had the highest rates of reversion to normal (20 to 30 per cent). Progression to dementia occurred in all aetiologic subtypes (Table 8.5.1.1.1).[9]

Biomarkers

There are no widely accepted MCI biomarkers at the present time. Research has focused on neuroimaging with MRI and FDG-PET as well as on tau and β-amyloid (Aβ) protein levels in cerebrospinal fluid (CSF).

Neuroimaging

On structural MRI, individuals with MCI may show volume loss in the medial temporal lobe (MTL) that may presage AD. The key structures of the MTL include the hippocampus and the entorhinal cortex. MTL structures can be rated on visual scales that may

Table 8.5.1.1.1 Aetiologic subtypes of CIND and their 2-year progression to AD/dementia

Subtype	Prevalence (% within cohort)	Dementia at 2-years (% within subtype)	AD at 2-years (% within dementia)
Pre-AD	24.6	40.9	100
Vascular	18.1	40.0	33.3
Psychiatric	17.3	25.0	75
Non-AD degenerative	2.3	33.3	0
Neurological	7.3	25.0	25
Medical	3.5	60.0	100
Mixed	7.6	33.3	100
Not otherwise specified	19.3	24.2	62.5

(Reproduced from G.Y. Hsiung et al. (2006), Outcomes of cognitively impaired not demented at 2 years in the Canadian cohort study of cognitive impairment and related dementias. *Dementia and Geriatric Cognitive Disorders*, **22**(5–6), 413–20, with permission from S. Karger A.G, Basel.)

reasonably predict AD.[24] MRI-based predictive algorithms may be better when MTL measures are combined with measures of lateral temporal lobe or anterior cingulate structures, or with performance scores on episodic memory.[24] Both whole brain and MTL atrophy rates are greater in MCI subjects that progress to AD than in those who do not.[25]

The characteristic pattern of AD is to have metabolic reductions in temporoparietal and posterior cingulate regions on [^{18}F-]-fluorodeoxyglucose (FDG) PET. This pattern may be seen in individuals with MCI ahead of full-blown disease. Serial PET may show further metabolic deterioration in these areas as well as abnormalities in the ventrolateral prefrontal cortex in subjects who progress to AD.[1] Recently, PET radioligands that bind to cerebral amyloid and potentially to tau proteins have been developed. These include Pittsburgh compound B (PiB) (*N*-methyl-[^{11}C]2-(4′-methylaminophenyl)-6-hydroxybenzothiazole) for amyloid and FDDNP (2-(1-[6-[(2-[^{18}F]fluoroethyl)(methyl)amino]-2-naphthyl]ethylidene)malononitrile) for amyloid and tau. Studies with these ligands have revealed higher than normal retention in subjects with MCI, with a pattern that follows the anatomical distribution of AD pathology.[26,27] If longitudinal follow-up confirms that these MCI cases develop AD, PET with PiB or FDDNP could become a diagnostic test for the early identification of AD.[24]

Cerebrospinal fluid markers

CSF markers can reflect the AD pathogenic process including a reduction in Aβ42 as it aggregates into senile neuritic plaques, as well as an increase in total tau (t-tau) and phospho-tau (p-tau), which signals the hyperphosphorylated state of tau. In MCI, the combination of abnormal Aβ42, t-tau, and p-tau 181 is associated with a 17–20 increased risk of developing AD over 4–6 years. Currently, the utility of these markers is limited by the lack of a standardized assay and the variability in measurements obtained at different laboratories.[28]

Management and treatment

There are no standard therapies for MCI. A clinical management plan is formulated on an individual basis in consideration of the cognitive pattern of MCI and its aetiology. There are two goals for treatment: first, to alleviate the cognitive symptoms of MCI, and second, to attempt to delay the onset of dementia in those at risk.

Symptomatic treatment

(a) Pharmacotherapy

A 24-week trial of the cholinesterase inhibitor (ChEI) donepezil did not benefit subjects with aMCI on its primary endpoints of delayed recall and global impression of change. There were benefits on secondary measures including the ADAS-cog, neuropsychological tests of attention, and patient-rated global function (Patient Global Assessment, PGA).[29]A longer term trial of donepezil with subjects with aMCI (the Alzheimer's Disease Cooperative Study-Memory Impairment Study, ADCS-MIS) demonstrated benefits on the ADAS-cog, memory and language scores, and global measures including the CDR sum of boxes but these were confined to the first 18 months of treatment.[30]

(b) Non-pharmacologic therapies

Cognitive and lifestyle interventions may help the cognitive and behavioural difficulties in MCI. An 8-week cognitive intervention programme to improve memory strategies produced benefits on tests of delayed recall and face-name association, and on self-assessed everyday memory function in subjects with aMCI.[31] A 14-day healthy lifestyle programme with memory training, physical conditioning, relaxation techniques, and a diet plan, showed benefits in subjects with mild self-reported memory complaints. These benefits included improved word fluency and metabolic changes on FDG-PET in dorsolateral prefrontal cortex.[32] Therapeutic approaches of this type require considerable resources, and confirmation in randomized controlled trials (RCTs) is needed before large-scale implementation in MCI can be recommended. Nevertheless these approaches hold some promise.

Delaying the onset of AD

(a) Pharmacotherapy

A considerable number of long and large trials of ChEIs and non-steroidal anti-inflammatory drugs (NSAIDs) have been directed at delaying the time to diagnosis of AD in those with aMCI. In the 3-year ADCS-MIS trial, treatment with donepezil did not have an effect on the primary outcome measure of progression to AD after 36 months. An interesting observation in the study was that carriers of the apolipoprotein E ε4 allele treated with donepezil had a reduced risk of progression to AD at all time points.[30] Similarly, rivastigmine was unsuccessful in delaying the time to diagnosis of AD.[33] A 4-year trial of the COX-2 inhibitor rofecoxib did not show treatment benefits on the primary endpoint of percentage of subjects that were diagnosed with AD nor on secondary measures of cognition and global function.[1] Based on the available data, the long-term use of ChEIs or NSAIDs in MCI, with the goal of delaying AD onset, cannot be recommended.

(b) Non-pharmacologic therapies

An expanding literature supports the hypothesis that a cognitively, socially, and physically active lifestyle in late life may reduce the risk for AD.[34] Evidence from RCTs to support this hypothesis is not currently available and it is premature to recommend organized interventions. There would be little perceived harm in promoting an engaged lifestyle as part of the management of MCI.

The future of MCI

MCI has been a useful construct to focus attention on the cognitive impairment that is going to increase exponentially within our greying societies. It is recognized that MCI is a risk state for developing AD and other dementias. A natural next step will be to develop criteria to diagnose AD earlier. A proposal of research criteria for the early diagnosis of AD has recently been published.[24] The diagnosis builds on a clinical core of early and significant episodic memory impairment and requires in addition the presence of at least one biological footprint of the disease: medial temporal lobe atrophy on structural MRI, abnormal CSF, or reduced temporoparietal glucose metabolism on FDG-PET.[24] Similar frameworks are already in place or will be developed for non-AD dementias. As these frameworks will advance, the concept of MCI will likely be significantly refined and could look quite different by the next edition of this textbook.

8.5.2 Substance use disorders in older people

Henry O'Connell and Brian Lawlor

Introduction

This chapter is divided into three main sections, focussing respectively on alcohol use disorders (AUDs), medication use disorders (MUDs), and use of illegal substances and nicotine, in older people. In each section we focus in detail on definitions and diagnosis, epidemiology, aetiology, clinical features, investigations, screening, management, and prognosis. More is known about AUDs in older people, hence this section is the longest, but MUDs in older people is also a significant problem and abuse of illegal drugs may become increasingly important in future years.

Alcohol use disorders (AUDs) in older people

Introduction

The ageing of populations worldwide means that the already significant problem of alcohol use disorders (AUDs) in older people is likely to become even more important in future years. However, AUDs in older people are neglected and underdiagnosed, for the reasons outlined in Table 8.5.2.1, and unless these factors are tackled proactively there exists a real danger of AUDs in older people becoming a silent epidemic, with negative impacts on all aspects of health and well-being[1] (see Table 8.5.2.2).

Definitions and diagnosis

AUD is a general and broad term, used to include a wide range of alcohol-related problems, as outlined in Table 8.5.2.3. Alcohol status may also change throughout life, with one-third of older people with AUDs developing such problems for the first time in later life (late-onset AUDs). A more severe course of AUD, higher levels of antisocial personality and stronger family histories of AUDs are seen in those with early-onset AUDs.

Because of the effects of physical and cognitive ageing, pharmacokinetic changes, the increased prevalence of comorbid illness, and interactions with prescribed medication, older people are likely to encounter AUDs at levels of intake lower than the general population. Therefore, the recommended levels of intake for the general population (i.e. up to 21 and 14 units per week for men and women, respectively[2]) may be inappropriately high for older people. However, apart from the NIAAA recommendations of no more than one drink per day for older people,[3] there is a lack of guidance on safe levels of alcohol intake, and the pursuit of obvious and 'down and out' drinkers may lead to a significant amount of more subtle and clinically 'silent' AUDs being missed.

Furthermore, the diagnostic criteria used by ICD-10 and DSM-IV used to describe harmful use and alcohol dependence syndrome may not be applicable to older people, as evidence of diagnostic criteria such as craving, compulsion, tolerance, and withdrawal features may be less clear-cut and masked by other medical conditions, and older people may be less likely to encounter the financial, occupational, family and legal consequences of AUDs (see also Table 8.5.2.1 and section on screening).

Table 8.5.2.1 Reasons for the neglect and underdiagnosis of AUDs in older people

Patient factors
Older people may be less likely to volunteer information on alcohol intake/AUDs
Recall of alcohol intake may be inaccurate due to cognitive impairment
Features of AUDs may be atypical or masked (e.g. presenting as falls, confusion)
Pharmacokinetic changes, comorbid illness, and drug-interactions mean alcohol-related problems may arise even at relatively low levels of intake
Health service factors
Health care professionals less likely to ask older people about alcohol intake and AUDs
Health care professionals less likely to refer older people for treatment, even when AUD detected
Inappropriate screening and diagnostic tools used
Therapeutic pessimism in treating older people
Inappropriately high levels for 'recommended' or 'healthy' levels of intake
Family and societal factors
Family members may be less likely to perceive AUD as a problem in older relatives
Ageist attitudes lead to risk of AUDs in older people being perceived as 'understandable'
AUDs in older people less 'noisy', with less impact on absenteeism, antisocial behaviour, crime

Epidemiology

The prevalence of AUDs in older people varies depending on the screening and diagnostic criteria used, clinical and socio-demographic characteristics (men having levels 4–6 times higher than women) and the level of severity of AUD being defined. In community-based studies, for example, 2–4 per cent of older people have been estimated to have alcohol misuse or dependence,[4] with higher rates of 16 per cent (men) and 2 per cent (women) when looser criteria such as excessive alcohol consumption are used.[5] Clinical populations of older people have higher levels of AUDs, with emergency department, nursing home and psychiatric inpatients being described as having levels of 14, 18, and 23 per cent, respectively.[6–8]

The true prevalence of AUDs in older people is often underestimated, for the reasons outlined in Table 8.5.2.1. It is likely, however, that the actual levels of alcohol consumption and AUDs do decline with age.[9,10] This decline may be due to factors such as premature death of those with AUDs, reduced physiological reserve and comorbid medical illness leading to reduced alcohol intake, age-cohort effects and age-related changes in social networks, occupational, and financial status.

Aetiology, risk factors, and associations

These factors can be broadly described as being biological/medical, social, and psychological in nature. Genetic factors are likely to be important in relation to both early-onset[11] and late-onset AUDs.[12] The genetic risk for AUDs may also overlap with risk for other mental disorders such as antisocial personality disorder, other drug use problems, anxiety disorders, and mood disorders.[13] AUDs may have a cause and effect relationship with medical illness.

Important social aetiological factors are likely to include male gender, bereavement, age-cohort effects, culture and ethnicity, religion, and marital status (higher levels of AUDs in divorced and single). Some social factors, such as marital problems, may have a two-way relationship with AUDs.

Table 8.5.2.2 Physical, neuropsychiatric, and socio-demographic aspects of AUDs in older people

1. Physical factors
Gastrointestinal
Hepatic problems: elevated liver enzymes; fatty liver; alcoholic hepatitis; cirrhosis; malignancy
Gastritis, peptic ulcer disease, and bleeding
Oesophageal varices
Acute and chronic pancreatitis
Malignancies
Mouth, pharynx, larynx, oesophagus, hepatic, colorectal, pancreatic
Cardiovascular
Ischaemic heart disease
Hypertension
Alcohol-induced arrhythmias
Congestive heart failure
Alcoholic cardiomyopathy
Haematological
Macrocytosis (acute effect of alcohol intake and due to vitamin B12 and folate deficiency in chronic AUD)
Anaemia (due to gastrointestinal problems)
Musculoskeletal
Falls and fractures
Reduced bone density
Myopathy
Metabolic
Hypoglycaemia
Hyperuricaemia
Elevated lipids
Diabetes more difficult to control
2. Neuropsychiatric factors
Cognitive impairment and dementia
Frontal lobe impairment
Wernicke–Korsakoff syndrome
Cerebellar cortical degeneration
Central pontine myelinosis
Marchiafava–Bignami disease
Depression
Psychosis
Intoxication
Withdrawal syndrome (may be more difficult to treat in older people)
Suicide
3. Socio-demographic
Male gender
Divorced, widowed, and single status
Social isolation
Upper and lower ends of socio-economic spectrum
4. Other
Alcohol–drug interactions
Aspiration pneumonia
Road traffic and other accidents

Relevant personality factors include the stronger association between antisocial personality, hyperactivity, and impulsivity in 'early-onset' compared to late-onset AUDs, who may have higher levels of 'neuroticism' and depression.[14]

AUDs in older people, as in all populations, may also have a two-way relationship with psychiatric disorders such as depression and anxiety disorders. For example, an older person may begin drinking in an effort to self-medicate depressive symptoms, or they may become depressed because of their drinking.[15]

Table 8.5.2.3 Types/levels of severity of AUDs

- Excessive alcohol consumption (i.e. drinking above recommended levels)
- Binge drinking (i.e. episodic bouts of excessive alcohol intake)
- Problem drinkers/harmful use/abuse
- Alcohol dependence syndrome
- 'Early-onset' versus 'late-onset'

Clinical features and comorbidity

AUDs in older people are linked to significant morbidity and mortality, affecting practically all aspects of physical, neuropsychiatric and social health and well-being,[1,16] as summarized in Table 8.5.2.2.

Pharmacokinetic changes (reduced physiological reserve, reduced metabolic efficiency, and increased volume of distribution due to a higher fat to lean muscle ratio, leading in turn to relatively higher blood alcohol concentrations in older people) along with the general effects of physical and cognitive ageing, increasing frailty, reduced functional ability, and higher levels of concomitant prescription drug use means that alcohol is relatively more toxic to older people than younger people. Furthermore, as outlined earlier, such toxic effects may be subtle and may be missed or mistaken for other conditions.

AUDs in older people are associated with a wide range of mental disorders, such as depression, psychosis, withdrawal syndromes, cognitive impairment, and dementia[17] (see Table 8.5.2.2) and are also associated with an increased risk of suicide.[18] The relationship between alcohol use and brain damage and dementia is complex,[19] in that AUDs may increase the risk for different types of dementia[20] and there also exist diagnostic entities known as 'amnesic syndrome associated with alcohol use' (ICD-10) or 'alcohol-induced persisting dementia' (DSM-IV). In contrast, light to moderate alcohol use may protect against dementia.[21]

(a) Clinical assessment

The assessment of AUDs in older people begins with a thorough clinical interview and history of alcohol use (quantity and frequency of drinking, beverage type, drinking context), mental state examination, physical examination and collateral history if available, and with the patient's consent. If indicated by the initial history, additional questions should be asked about features of alcohol dependence syndrome, as they relate to the patient's physical and psychosocial health. Questions should be framed in a sensitive and non-judgemental way, as patients may disengage and be lost to treatment and follow-up if they feel threatened by the assessment procedure.

(b) Further investigations in AUDs

Following a detailed history and examination, other investigations may be indicated and should be directed by the patient's clinical status. These may include: blood tests to check the following: urea and electrolytes; full blood count; liver function tests; vitamin B12 and folate levels; neuroimaging (CT or MRI brain); gastrointestinal investigations such as ultrasound, CT, or MRI examinations of the abdomen, upper gastrointestinal endoscopy, and liver biopsy; basic cardiovascular investigations such as electrocardiogram and other

more detailed investigations if indicated, e.g. echocardiogram and 24 h blood pressure monitoring.

(c) Screening for AUDs in older people

Screening programmes should aim to detect both clear-cut and subtle cases of AUDs in older people. It must be remembered that screening tests are not diagnostic in themselves, but positive results should lead on to further investigations. Screening methods may be based on self-report alcohol screening instruments such as the CAGE,[22] the AUDIT,[23] and biophysical measures such as blood tests checking mean corpuscular volume and liver function tests.

A systematic review of self-report alcohol screening instruments in older people[24] revealed that the CAGE was the most widely studied, but that sensitivity and specificity varied depending on the clinical characteristics of the population in question. However, the CAGE is the most well recognized alcohol screening instrument and is quickly and easily administered, so the authors would recommend use of at least this instrument, along with further investigations and assessment scales if problems are detected.

The utility of biophysical screening measures such as carbohydrate-deficient transferrin, liver function tests or the mean corpuscular volume may be less reliable in older people,[25] because of higher levels of comorbid physical illnesses leading in themselves to false-positive and abnormal results. However, they may prove useful when combined with other clinical information, both in the detection of AUDs and monitoring of progress through treatment.

Management and prevention

Primary prevention strategies should focus on individual older people (especially considering that one-third of older people have late-onset AUDs) and can also be directed at the entire population, targeting factors such as ease of access to alcohol, restrictions on alcohol advertising, and education about the adverse effects of drinking. Such primary prevention and public health initiatives tend to be directed towards younger individuals, but they should also take into account the more clinically 'silent' AUDs that may develop in older people.[26]

Secondary prevention strategies should focus on older people who already have 'at-risk' drinking, either currently or in the past, and who are at risk of developing worsening problems in the context of diverse factors such as bereavement, social isolation, adjustment to retirement, and physical or psychiatric health problems.

Tertiary prevention involves treatment of existing AUDs. Treatment modalities can be divided into biological/medical, social, and psychological. Biological/medical treatments are most important in the acute setting, where detoxification may be required.

Care should be taken with benzodiazepine-assisted withdrawal in older people, in view of the elevated risk of oversedation, confusion, and falls. There are no elderly-specific guidelines on benzodiazepine-assisted alcohol withdrawal in older people. Lorazepam has been identified in one review[27] as the safest choice of benzodiazepine for treatment of alcohol withdrawal in older people, in view of the fact that advancing age and liver disease have little impact on its metabolism, and absorption by the intramuscular route is predictable. In practice, however, it is likely that there is more clinical experience with use of long-acting benzodiazepines such as chlordiazepoxide. The choice of benzodiazepine used should be based on individual patient characteristics such as previous treatments, current medical status (e.g. degree of hepatic impairment) and an objective measure of withdrawal may help guide the dosing regimen (see Table 8.5.2.4).

Parenteral or oral thiamine should be given to prevent development of the Wernicke–Korsakoff syndrome. A recent review has concluded that, in the emergency department setting, oral thiamine administration is as effective as parenteral administration.[28] Again, however, there are no elderly-specific guidelines, and individual patient characteristics must be taken into account, such as general health, ability to take oral medication, and compliance.

The three medications that are approved by the US Food and Drug Administration to promote abstinence and reduce relapse are Disulfiram, Acamprosate, and Naltrexone.[29] However, the limited efficacy of Disulfiram, combined with the potential for a more severe side-effect profile means it is best avoided in this age group. In contrast, Naltrexone and Acamprosate have been suggested as suitable agents for use in older people.[30]

Psychosocial aspects of treatment should also be explored. This may include addressing social circumstances that may be contributing to the AUD (e.g. personal finances and housing). There is a dearth of evidence on psychotherapeutic approaches to AUDs in older people, but there is some evidence that older people may respond better to psychotherapy in same-age settings,[31,32] and consideration should also be given to support groups such as Alcoholics Anonymous.

Prognosis

The available literature on the topic suggests that older people are at least as likely, if not more likely, to benefit from treatment of AUDs as younger people.[33,34] However, prognosis in older people is likely to vary widely depending on a number of factors relating to the individual themselves and the nature of their AUD, the presence of family and other support systems and the availability of treatment services, particularly services that are tailored to older people.

Table 8.5.2.4 The Clinical Institute Withdrawal Assessment for Alcohol-Revised Version (CIWA-Ar) (Reproduced from The South London and Maudsley NHS Trust Prescribing Guidelines, 2005–2006, copyright South London and Mandsley NHS Foundation Trust)

1. Nausea and vomiting
2. Tremor
3. Paroxysmal sweats
4. Anxiety
5. Agitation
6. Tactile disturbances
7. Auditory disturbances
8. Visual disturbances
9. Headaches and fullness in head
10. Orientation and clouding of sensorium

Severity of alcohol withdrawal	
Mild:	<10
Moderate:	10–20
Severe:	20+

(Items 1–9 are scored from 0–7 and item 10 from 0–4. Maximum possible score is 67)

Medication use disorders (MUDs) in older people

Introduction

High levels of prescribing of all types of medications for older people, which may at times be inappropriate, along with factors such as variable compliance, altered pharmacokinetics, reduced functional ability, and increased levels of physical, psychiatric, and cognitive morbidity mean that older people are at higher risk of developing MUDs than any other age group.[35] As with AUDs, clinical features of MUDs may be atypical and masked by other conditions and thus go undetected and untreated.[36]

Definitions

As with AUDs, older people are affected by a wide range of types and severity of MUD.

The ICD-10 uses the same general principles of intoxication, harmful use, dependence, and withdrawal state that apply to alcohol for use of sedative and hypnotic medications. As with AUDs, elderly-specific criteria are not cited, but the same general principles apply: older people are likely to experience harm at lower levels of use and clinical features guiding diagnosis are more likely to be atypical and masked by other health problems.

Iatrogenic factors are also important, as drugs may be inadequately or underused for treating or preventing conditions, or drugs may be overused, leading to unnecessary exposure of the older individual to adverse effects.[36]

Epidemiology

Older people comprise 13 per cent of the US population, but they have been estimated to use more than 30 per cent of prescription[37,38] and 35 per cent of OTC drugs:[37] it has been estimated that older people use prescription and OTC medications approximately three times as much as the general population. Furthermore, we know that the risk of MUDs increases with polypharmacy, which is common in older people.[39,40]

Benzodiazepines are the most commonly prescribed psychotropic drugs in older people, with one study of community-dwelling older people in Ireland demonstrating that 17 per cent of participants were prescribed benzodiazepines, with use in females being twice that in males, and 18 per cent of benzodiazepine users taking at least one other psychotropic drug. Furthermore, 52 per cent of benzodiazepine users were prescribed a long-acting benzodiazepine.[41] It has also been reported that depression in older community-dwelling people is more likely to be detected if accompanied by anxiety symptoms, and such individuals are at risk of inappropriate treatment with benzodiazepines.[42]

Use of opiate analgesia is common in older people and is liable to give rise to MUDs. Therefore, use of these medications should be carefully monitored, with due consideration of dose and careful tapering.[43]

Aetiology, risk factors, and associations

The general principles for aetiology, risk factors, and associations for substance misuse outlined above (see Table 8.5.2.5) also apply to MUDs. Further MUD-specific factors are outlined below in Table 8.5.2.6.

Table 8.5.2.5 Risk factors for substance abuse in the elderly (Reproduced from R.M. Atkinson (2002), Substance abuse in the elderly, In *Psychiatry in the elderly* (3rd edn.) (eds. R. Jacoby and C. Oppenheimer), copyright 2002, with permission from Oxford University Press).

Predisposing factors
Family history (alcohol)
Previous substance abuse
Previous pattern of substance consumption (individual and cohort effects)
Personality traits (sedative–hypnotics, anxiolytics)
Factors that may increase substance exposure and consumption level
Gender (men-alcohol, illicit drugs; women-sedative–hypnotics, anxiolytics)
Chronic illness associated with pain (opioid analgesics), insomnia (hypnotic drugs), or anxiety (anxiolytic)
Long-term prescribing (sedative–hypnotics, anxiolytics)
Caregiver overuse of 'as needed', medication (institutionalized elderly)
Life stress, loss, social isolation
Negative affects (depression, grief, demoralization, anger) (alcohol)
Family collusion and drinking partners (alcohol)
Discretionary time, money (alcohol)
Factors that may increase the effects and abuse potential of substances
Age-associated drug sensitivity (pharmacokinetic, pharmacodynamic factors)
Chronic medical illnesses
Other medications (alcohol–drug, drug–drug interactions)

Clinical features and comorbidity

Clinical features and comorbidities associated with MUDs in older people will vary widely depending on the drug being used and patient characteristics such as age, gender, and presence of other physical and neuropsychiatric problems. An outline of clinical features and comorbidities are listed in Table 8.5.2.7.

(a) Clinical assessment

As with AUDs, a standard clinical assessment involving a history, mental state, and physical examinations and collateral history will form the basis of an MUD assessment. A list of all prescribed and over the counter medications being used, along with their indications for use, should be recorded. Ideally, the patient should be asked to bring with them all medications in their containers, as this will also give an indication as to levels of adherence or compliance. Any reported adverse effects should be recorded, along with

Table 8.5.2.6 Aetiology, risk factors, and associations of MUDs in older people

Biological/medical factors
Genetic predisposition
Chronic medical conditions (e.g. pain)
Age-related pharmacokinetic changes
Interactions: other medications and alcohol
Type of medication (e.g. benodiazepines, analgesics)
Psychosocial factors
Depression
Anxiety disorders
Personality disorder
Older age
Female gender
Lower educational level
Separated or divorced status

Table 8.5.2.7 Clinical features and comorbidity associated with MUDs in older people

Neuropsychiatric (all psychotropic drugs; benzodiazepines may be particularly problematic)
Delirium
Daytime drowsiness
Sleep disturbance
Depression
Anxiety
Physical
Falls
Fractures
Drug–drug and drug–alcohol interactions
Problems related to drug metabolism (e.g. renal and hepatic impairment)

symptoms and signs indicating underuse, overuse, or intermittent use of medication.

(b) Investigations in MUDs

Blood levels of the patient on some prescribed medications may be checked in order to assess levels of compliance and to establish if the blood level is within the therapeutic window for the drug in question (e.g. lithium, carbamazepine). Other biophysical measures may also be indicated that provide proxy measures of medication compliance, such as random or fasting glucose levels and levels of glycosylated haemoglobin, to assess for level of diabetes control and compliance with hypoglycaemic agents or insulin.

(c) Screening

There are no routinely used screening measures for MUDs in older people. However, use of a measure such as Beers' criteria[44,45] may be a useful addition to the overall assessment of an older person if an MUD is suspected.

Management and prevention

(a) Primary and secondary prevention

Along with patients themselves, health care workers, family members, and carers all have important roles in the primary and secondary prevention of MUDs in older people. Prescriptions should be reviewed regularly with a view to simplification and rationalization if possible, and the practice of giving 'repeat prescriptions' without clinical assessment should be discouraged.

Community pharmacists have an important role in providing education and advice on the use of both prescription and over the counter medications.

As older people may have physical and cognitive disabilities that interfere with appropriate use of medication,[46] devices such as dosette boxes and combination packs may be helpful.[47,48] Secondary prevention of MUDs in older people should focus on those with a past history of MUD.

(b) Tertiary prevention

Tertiary prevention of MUDs in older people will depend on the medication in question and the clinical and socio-demographic profile of the patient. Admission to a medical or psychiatric ward may be required to facilitate reduction or stopping of certain medications, e.g. benzodiazepine detoxification, as outpatient detoxification in older people may be hazardous.

Prognosis in MUDs

Similar prognostic indicators that apply to AUDs are likely to be relevant to MUDs, and centre on the individual's clinical and socio-demographic characteristics, levels of support, and available services. The duration of abuse and the medication or medications being abused is also of relevance.

Illicit drug use and nicotine use in older people

Illicit drug use in older people is far less of a problem in comparison to AUDs and MUDs. Lifetime prevalence rates for illicit drug dependence have been estimated as 17 per cent for 18–29 year olds, 4 per cent for 30–59 year olds, and less than 1 per cent for those over the age of 60.[49] Epidemiological Catchment Area data suggest a lifetime prevalence rate for illegal drug use of only 1.6 per cent for older people.[50]

Several other sources of data suggest similarly low rates of illegal drug use among older people. However, the ageing of the 'Baby-boomer' generation is likely to result in a cohort of older people who are healthier and have higher life expectancies than previous generations of older people, but who also carry with them higher rates of illegal drug use.[51]

Principles similar to those seen with AUDs and MUDs apply, in that lower levels of drug intake are required to cause harm and presentation may be atypical and thus go undetected. There is a dearth of evidence in the literature on detoxification and opiate replacement therapies in older populations.

Nicotine use (primarily through cigarette smoking) in older people arguably causes more significant morbidity and mortality than AUDs and MUDs, but the problem tends not to be addressed by psychiatrists, because of a lack of significant neuropsychiatric effects of nicotine use, and a more obvious impact on many aspects of physical health. As with AUDs and MUDs, smoking in older people is treatable, and any comprehensive approach to improving the health of older people, at the individual clinical level or public health level, should involve education about the adverse effects of smoking and efforts at active treatment through the use of nicotine replacement therapies[52] or antidepressants such as nortriptyline or buproprion.[53] However, an important and circular relationship has been described between depression, smoking, and medical illness that complicates smoking cessation in those who have a history of depression.[54]

Conclusions

In this chapter we have highlighted the importance of AUDs and MUDs in older people, in terms of their prevalence and their important but often underrecognized contribution to morbidity and mortality. AUDs are underdetected, misdiagnosed, and often completely missed in older populations. However, despite ageist and therapeutically pessimistic assumptions, AUDs in older people are as amenable to treatment as in younger people, and treating an AUD in an individual of any age can lead to significant benefits in their quality of life.

Likewise, the wide variety of MUDs in older people may be associated with addiction to medication and the undertreatment and inappropriate treatment of medical and psychiatric conditions. Considering that older people are the highest consumers of

prescription medications, screening and treatment programmes for MUDs should also lead to considerable improvements in quality of life, along with financial and other savings.

Misuse of illicit drugs by older people is not generally a major problem at present, but it is virtually certain that consumption of illegal substances by people over 65 will increase in the future.

Greater awareness amongst physicians and other health care providers of the possibility of AUDs and MUDs in their older patients should lead to the development of more comprehensive and age-appropriate prevention and treatment strategies. At the levels of everyday clinical practice and public health policy, greater emphasis should be placed on AUDs and MUDs in older people and further evaluation of dedicated 'same-age' treatment services and settings should be performed.

8.5.3 Schizophrenia and paranoid disorders in late life

Barton W. Palmer, Gauri N. Savla, and Thomas W. Meeks

Introduction

Estimates of the point-prevalence of paranoia and other psychotic symptoms among persons age ≥ 65 years have ranged from approximately 4 per cent to 6 per cent,[1–3] and may be as high as 10 per cent among those age ≥ 85 years.[4] Although the majority of these symptoms occur as secondary psychoses in the context of Alzheimer's disease or related dementias,[5] the population of people with schizophrenia is ageing along with the general 'greying' of the industrialized world, and mental health care for older adults with schizophrenia is expected to be an increasingly important public health concern.[6]

Clinical features

Schizophrenia is typified by the presence of two or more of the following categories of core symptoms: delusions, hallucinations, disorganized or catatonic behaviour, disorganized speech (or formal thought disorder), and negative symptoms (such as affective flattening, avolition, or social withdrawal).[7] Older patients tend to have less severe positive symptoms (hallucinations, delusions, disorganized behaviour) than their younger counterparts, but there are few age-related differences in presence or severity of negative symptoms.[8,9]

Most patients with schizophrenia and related primary psychotic disorders also have mild to moderate neurocognitive deficits.[10] There is considerable interpatient heterogeneity in terms of the severity of neuropsychological deficits, but the level of these deficits is a consistent and strong determinant of impairments in everyday functioning[11] and competence or decisional capacity.[12]

In terms of late-life schizophrenia, one common division is between those with earlier onset in adolescence or early adulthood (prior to age 40 or 45 years) versus later-onset (onset ≥ age 40 or 45 years). The latter group may comprise as many as 24 per cent of people with late-life schizophrenia.[13] Relative to similarly aged patients who had earlier onset, those with later-onset schizophrenia tend to have a higher prevalence of paranoid subtype and persecutory delusions, but better premorbid social-occupational functioning, fewer current disorganized symptoms, less severe (although not an absence of) negative symptoms, and less severe neuropsychological impairment. They are also more likely to be women, and tend to respond to lower doses of antipsychotic medication.[3,14,15] The two groups are similar in terms of severity of thought disorder,[16] although patients with very late onset schizophrenia-like psychosis (age of onset ≥ 60 years) tend to have less severe formal thought disorder.[17]

Classification systems

The term 'schizophrenia' was coined by Eugen Bleuler in the early 20th century, but he wrote of 'the schizophrenias' (plural)[18] as an

explicit acknowledgement of the substantial heterogeneity that characterizes this condition. Efforts to group 'the schizophrenias' into meaningful subtypes have been a key part of efforts to define the syndrome itself.[19] Most of the terms describing different subtypes of schizophrenia in the current *Diagnostic and Statistical Manual* (DSM-IV-TR)[7] and in the International Classification of Diseases (ICD-10)[20] [such as paranoid, catatonic, hebephrenic (disorganized), and undifferentiated (simple) subtypes] overlap with the subtypes identified by Kraepelin and or E. Bleuler a century ago. Other subtyping efforts have focused on a variety of dimensions such as positive and negative symptoms, cognitive functioning and/or course, but as true of the clinical subtypes in the DSM-IV-TR and ICD-10, there is invariably substantial intrasubtype heterogeneity.[21]

In regard to late-life schizophrenia, one of the key nosological controversies over the past century has been whether or not the late onset form is actually schizophrenia. Kraepelin's conception of *dementia praecox* in 1896 was that the disorder was defined by onset in adolescence or early adulthood. By 1913, Kraepelin came to acknowledge that early onset was not a universal feature, but the emphasis on early onset remained a potent belief in the field throughout most of the 20th century.[22] On the other hand, interest in late-onset schizophrenia has a long history, including seminal work by Manfred Bleuler, begun in the early 1940s with patients whose symptoms emerged at or after age 40 years.[23]

The term 'late-onset schizophrenia' has occasionally been used interchangeably with the term *late paraphrenia*, although the latter was originally conceptualized as a more circumscribed psychosis with onset at age 60 or 65.[24,25] Unfortunately, the terms 'late-onset schizophrenia,' and *paraphrenia* (with or without the epithet 'late'), and a variety of age cut-offs have been used interchangeably and inconsistently over the years, resulting in considerable confusion in the literature.[22,25] In a 1998 international consensus meeting on this topic, the group consensus suggestion was that the term 'late onset schizophrenia' be reserved for those with onset between ages 40 and 59 years, whereas the term 'very late onset schizophrenia-like psychosis' be used with those whose symptoms first manifest at age 60 or later.[3]

None of the above schizophrenia onset-related categories is represented in the contemporary formal diagnostic systems. The 1980 version of the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM-III)[26] arbitrarily excluded the diagnosis of schizophrenia if symptoms did not emerge prior to age 45. This exclusion was dropped from the subsequent revision (DSM-III-R),[27] although the DSM-III-R required the specification of 'late onset' if the prodromal phase of illness developed after 45. The latter is the only instance of 'late-onset schizophrenia' appearing as a named condition in one of the major nosological systems. Based on mounting empirical evidence that 'real' schizophrenia could manifest after age 45,[13] the age of onset restrictions as well as the 'late onset' specifier were dropped in the DSM-IV [28] and DSM-IV-TR.[7] Similarly, there is no age-of-onset related restriction or specification under the ICD-10.[20]

Diagnosis and differential diagnosis

The diagnostic criteria for schizophrenia in the DSM-IV-TR and ICD-10 mention neither current age nor age of onset.[7,20] A key differential diagnosis with older adults is to rule out presence of a secondary psychosis.[29] For instance, among elderly patients, psychotic symptoms most commonly present in the context of dementia, such as Alzheimer's disease, Parkinson's disease, or dementia with Lewy Bodies.[5] The pattern in any one patient may of course vary from normative trends, but in general among those with dementia-related psychotic symptoms, there is a greater propensity for visual over auditory hallucinations, and bizarre content is less common in the delusions than in those of patients with primary psychotic disorders such as schizophrenia.[30]

Delirium may also present as acute psychosis;[31] as with dementia, visual hallucinations and delusions tend to be more common than auditory hallucinations, but the psychotic symptoms associated with delirium can be of any form.[32] Given the high rates of polypharmacy among the elderly as well as age-related changes in pharmacokinetics, it is also important to consider potential acute mental effects of the medications in isolation and in combination.[33] Other differential diagnoses to consider among elderly patients are non-psychotic hallucinations related to bereavement or sensory deprivation.[34,35]

Among the primary psychotic conditions, the standard differential diagnoses and considerations apply in terms of differentiating among schizophrenia, schizoaffective disorder, delusional disorder, brief psychotic disorder, substance-induced psychotic disorder, bipolar disorder with psychotic features, and major depressive disorder with psychotic features.[7]

Epidemiology

As was noted above, prevalence estimates of paranoia and other psychotic symptoms among persons age ≥ 65 years have ranged from approximately 4 per cent to 6 per cent,[1–3] but these symptoms are most commonly in the context of a dementia or other medical condition. Estimating the lifetime prevalence of schizophrenia is a methodologically complex endeavour needing additional research attention; recent estimates have ranged from approximately, 0.4 per cent to 1.0 per cent although estimates as high as 1.6 per cent have also been reported.[36,37] The lifetime prevalence of schizophrenia is similar among men and women, and the majority of patients of either gender experience onset in adolescence or early adulthood.[37] However, a consistent finding noted a century ago by E. Bleuler,[18] is that women tend to show later onset than men.[38]

Estimates of the lifetime prevalence of schizophrenia for persons over age 65 have also varied, although the 95 per cent confidence interval estimate from one recent comprehensive study was 0.58 to 1.45 per cent.[37] There have been some epidemiological studies suggesting that the prevalence (current and lifetime) of schizophrenia among elderly persons is lower than that for the younger population. People with schizophrenia have higher mortality due to suicide and physical disorders,[39,40] so there are probably proportionally fewer people with schizophrenia who survive to older age. However, the prevalence of schizophrenia in elderly patients may also have been underestimated in some of the earlier major epidemiological studies.[41] For instance, the Epidemiologic Catchment Area study used the DSM-III criteria, but as was noted above, the DSM-III criteria for schizophrenia arbitrarily required onset of prodromal symptoms prior to age 45, so any cases of later-onset schizophrenia would have been excluded.[41]

Aetiology

The cause(s) of schizophrenia remains unknown. Both Kraepelin and E. Bleuler correctly suspected that there is a heritable vulnerability to schizophrenia, confirmed by the substantially higher concordance rates among monozygotic twins (estimated at 40 to 50 per cent) relative to dizygotic twins (estimated at 5 per cent to 25 per cent).[42,43] The elevated risk of schizophrenia among first-degree relatives is present among those with schizophrenia onset in middle-age as well as those wither earlier onset relatives.[3] Although some candidate genes have been identified,[44] these efforts remain in an early stage of development. Also, given that even the monozygotic twin concordance rate is substantially below 100 per cent, non-genetic factors clearly have a role in the ultimate expression of the schizophrenia phenotype.

At present, the prevailing model of schizophrenia is that of neurodevelopmentally based aberrations in connectivity of key brain regions and systems.[45,46] Evidence for the neurodevelopment component includes an elevated risk of schizophrenia associated with certain pre- or peri-natal insults or stresses, an increased prevalence of minor facial anomalies among patients with schizophrenia, and an increased prevalence of subtle childhood abnormalities in motor, cognitive, and/or psychosocial development among those who later develop schizophrenia.[45] At the level of neuropathology, Kraepelin expressed some suspicion of involvement of the prefrontal and temporal lobes;[47] these remain areas of interest in schizophrenia research although the current focus is on functional (rather than gross structural) impairments related to the connections among such brain regions or systems.[46]

Course and prognosis

Schizophrenia is generally a chronic condition, but not necessarily a constantly sustained one in that many patients experience one or more periods of several years of sustained recovery over their lifespan, but periods of relapse are also common.[48] As with other dimensions of this disorder, the long-term course of schizophrenia is also characterized by heterogeneity among patients, as well as methodological challenges in interpreting varied findings in the empirical literature.[49] Some of the factors that have been cited as associated with worse prognosis include poor premorbid functioning, very early and gradual/insidious onset of symptoms, male gender, and a relative prominence of negative symptoms.[49,50] In a recent review of ten long-term longitudinal outcome studies, Jobe and Harrow[48] found that the estimates of 'good outcome' ranged from 21 to 57 per cent. Since most of the long-term research on the course of schizophrenia has been of younger patients as they age, there remains a clear need for longitudinal research to document changes among patients as they age from their 60s, 70s, and 80s. Nonetheless, empirical data do not seem to support Kraepelin's initial suggestion that *dementia praecox* is characterized by a course of progressive decline.[49] In fact, there may be some modest age-related improvements in positive symptoms and perhaps other aspects of psychopathology.[8] Although there is a small subset of 'poor outcome'/ chronically institutionalized patients who seem to be at added risk for cognitive and functional decline in older age,[51] for most patients there is generally no increased (beyond age normal) decline in cognitive functioning among those with early or middle-age onset.[52,53]

Treatment

Contemporary treatment guidelines for schizophrenia in older adults parallel those for younger adults in that a combination of pharmacological and psychosocial interventions is recommended.[54] Although treatment with antipsychotic medications is a mainstay of effective treatment and management of late-life schizophrenia, selection of the appropriate type and dose of antipsychotic medication in the elderly may be complicated by age-related factors. One of the primary concerns with conventional neuroleptic medications is that they can cause iatrogenic motor abnormalities; older adults are at even greater risk than younger patients to develop tardive dyskinesia and extrapyramidal symptoms, or EPS, (especially parkinsonism) from conventional neuroleptics.[55] The newer ('atypical' or 'second generation') antipsychotic medications have lower (although not absent) associated risk of tardive dyskinesia and EPS, though risks for these motor side effects also vary from one atypical antipsychotic to another.

The current APA treatment guidelines for schizophrenia indicate '*Second-generation antipsychotics are generally recommended over first-generation agents because of their significantly lower risk of inducing extrapyramidal symptoms and tardive dyskinesia in older persons . . . However, the second-generation agents have other clinically significant and common side effects* (pp. 33–34).' In addition to concerns about potential sedation, orthostatic hypotension, and other potential physical or medical side-effects from the newer medications, there has been recent concern about the potentially serious metabolic and cardiovascular side effects.[56] Overall, atypical agents (with the exception of clozapine) have not shown superior efficacy for schizophrenia in direct comparisons with typical antipsychotics.[57] This fact, combined with the lower cost of typical agents, has prompted some experts to question the use of atypical antipsychotics as first-line pharmacotherapy for schizophrenia. In the absence of more definitive evidence, clinicians should discuss these various advantages and disadvantages of specific drugs with patients when choosing drug therapy.

For most antipsychotics (typical or atypical), older adults with schizophrenia generally respond to 50–75 per cent of the doses needed in younger patients and often cannot tolerate the full young adult dose.[58] Side effects that are especially problematic in older adults include anticholinergic effects (e.g. constipation, confusion, urinary retention), orthostatic blood pressure changes (which may lead to falls), and reported increases in stroke and death among persons with dementia receiving antipsychotics (as dementia, of course, becomes more prevalent with increasing age).

Antipsychotic medications are helpful in managing the psychopathologic symptoms of schizophrenia, especially the so-called 'positive symptoms' such as delusions and hallucinations, but they are not a cure. Medications also tend to have little benefit for the 'negative' (e.g. apathy, anhedonia) and cognitive symptoms of the illness. Furthermore, many patients continue to have residual functional disability despite resolution of positive symptoms of psychosis. Thus, the importance of adjunctive treatment with evidenced-based psychosocial interventions in schizophrenia is being increasingly recognized.[59] For instance, investigators at our Research Center have developed or adapted, and validated a number of effective adjunctive psychosocial interventions for older patients with schizophrenia or related psychoses; these include Cognitive Behavioral Social Skills Training,[60]

Functional Adaptation Skills Training,[61] diabetes management/lifestyle modification,[62] and vocational rehabilitation/supported employment.[63] These efforts address a number of dimensions of schizophrenia that are unaffected by pharmacologic treatment alone.

Management

As noted above, schizophrenia is a chronic condition. In addition, to specific therapies previously described, managing this complex and devastating illness requires careful attention to clinician-patient rapport. This is especially true in persons with severe paranoia and in those who lack insight into their illness. Providing care for someone who does not trust anyone or who sees no reason for treatment can be challenging, but these obstacles can often be overcome by involving family, listening empathically, avoiding premature confrontation about delusions, respecting the increased interpersonal distance many patients require, and identifying the patient's goals and priorities. Management of schizophrenia may often be optimized by multi- and interdisciplinary care to address the many ways in which the illness affects patients' lives. Because there tends to be a high degree of medical comorbidity in persons with schizophrenia (especially older adults), integration of primary care and psychiatric care is often needed. Due to normal age-related physical changes, polypharmacy, and the higher risk of medication side-effects, the long-term management of schizophrenia in older adults demands frequent monitoring of symptoms, overall health, and side-effects. Cross-discipline collaborative care and continuity with the same clinicians can help ensure older persons with schizophrenia achieve the best possible outcomes.

8.5.4 Mood disorders in the elderly

Robert Baldwin

Introduction

This chapter considers some of the commonly asked questions about mood disorders in later life. Is depression in later life a distinct clinical syndrome? How common is it? Is there an organic link, for example to cerebral changes, and if so, is there an increased risk of later dementia? Is it more difficult to diagnose and treat late-life depression, and once treated, is the outcome good, bad, or indifferent? The emphasis will be on depression but bipolar disorder and mania will also be considered.

Classification

The main mood disorders which older people suffer are classified as: depressive episode, dysthymia, bipolar disorder, and organic mood disorder. Depressive illness and major depression are terms often used synonymously with depressive episode. Current classificatory systems, notably The World Health Organization ICD10 and the DSM Version IV of the American Psychiatric Association, are described in Chapter 4.5.3.

Depressive episode

Clinical features

Other than more frequent somatic and hypochondriacal complaints, patients with depression in later life are little different, symptomatically, to younger adults.[1] An exception may be the recently described 'vascular depression' (depression linked to small vessel disease of the brain), in which depressive ideation is less but cognitive impairment and apathy greater. In most cases then the pathoplastic effects of ageing and ill-health are what mainly influence the presentation of depression in later life (Table 8.5.4.1).

An overlap of symptoms due to *associated physical ill-health* may lead to diagnostic difficulty, and determining whether a symptom has arisen predominantly because of affective disorder or a medical condition can be difficult for those without the necessary experience.

Older depressed patients may *minimize feelings of sadness* and instead become *hypochondriacal* (morbidly preoccupied with a fear of illness).[1] Late-onset *neurotic symptoms* (*severe anxiety*, *phobias*, *obsessional compulsive phenomena or hysteria*) are usually secondary to depressive illness. Any act of *deliberate self-harm* suggests depression, as elderly people rarely take 'manipulative' overdoses. An overdose in an older person should never be dismissed because its effects, in purely medical terms, were trivial. *All* require psychiatric assessment. Severe depression may mimic dementia. Table 8.5.4.2 highlights the main differences between progressive dementia and the pseudodementia of depression. Pseudodementia is a term which is perhaps waning in use as it has become clear that depressive disorder is commonly associated with cognitive impairment, which may not be reversible, even with adequate treatment of depression. Pseudodementia is often applied to an older depressed patient who, on presentation, appears very confused, with frequent 'don't know' responses. However, the onset of confusion is acute, easily dated, the patients convey their despair non-verbally, and, unlike the person with degenerative dementia, complain vociferously about their memory. Cortical signs (aphasia, apraxia, etc.) suggest a primary dementia with a super-added depression rather than depressive pseudodementia. Wandering off and getting lost suggests dementia but occasional cases are seen of fugue states caused by severe depression mimicking disorganized behaviour in dementia. The key is a good history.

An unusual *behavioural disturbance* may occasionally be a leading symptom of depression. Examples include the onset of incontinence in an older person who feels trapped in a situation of resented dependency in a residential or nursing home, late-onset alcohol abuse or, rarely, shoplifting.

Table 8.5.4.1 Factors influencing the presentation of depression in older people

Overlap of symptoms of physical disorder with those of the somatic symptoms of depression
Tendency of older people to minimize a complaint of sadness and instead become hypochondriacal
Late-onset neurotic symptoms (severe anxiety, obsessional compulsive symptoms, hysteria) which mask depression
Deliberate self-harm which seems medically trivial
Pseudodementia
Behavioural disturbance such as alcohol abuse or shoplifting

Table 8.5.4.2 Characteristics distinguishing depression ('pseudodementia') from dementia

Dementia	Depression
Insidious	Rapid onset
Symptoms usually of long duration	Symptoms usually of short duration
Mood and behaviour fluctuate	Mood is consistently depressed
'Near miss' answers typical	'Don't know' answers typical
Patient conceals forgetfulness	Patient highlights forgetfulness
Cognitive impairment relatively stable	Cognitive impairment fluctuates greatly
Higher cortical dysfunction evident	Higher cortical dysfunction absent

(a) Vascular depression

In vascular depression, vascular disease is judged to predispose, precipitate, or perpetuate depressive symptoms. Evidence (summarized by Baldwin[2]) includes the following. There is a high rate of structural brain abnormalities in both white matter and basal ganglia grey matter on imaging and on post-mortem examination of older patients with depressive disorder, notably with a late age of onset. Psychomotor change, apathy, and executive dysfunction (leading to slowed responses, failure of initiation, impersistence in tasks, and inefficient memory) occur characteristically in such patients. Strategic lesion location, sufficient to disrupt subcortical-frontal circuitry, is associated with poorer depression outcomes, and progression of such lesions is associated with later incident cases of depression in those not already depressed. The concept of vascular depression is discussed critically under aetiololgy.

Diagnosis and differential diagnosis

(a) Assessment

The psychiatric history should include a collateral history as well as drug evaluation (prescribed, 'borrowed', and over-the-counter) and alcohol intake. A cognitive screening test should always be undertaken. A physical evaluation should focus on possible disorders causing an organic mood disorder (Table 8.5.4.3), including medication. Non-selective β-blockers, calcium antagonists, benzodiazepines, and systemic corticosteroids were the main culprits in one study.[3]

Screening questionnaires can be used to help diagnose depression, especially in settings such as medical wards where the prevalence is high, but their results must be informed by clinical judgement. The Geriatric Depression Scale (GDS) (Geriatric Depression Scale website http://stanford.edu/~yesavage/GDS.html) is widely used. It focuses on the cognitive aspects of depressive illness rather than physical depressive symptomatology, and has a simple 'yes/no' format (Table 8.5.4.4). It loses specificity in severe dementia but performs reasonably well in mild to moderate dementia. For rapid screening four questions (1, 3, 8 and 9) can be used.

(b) Investigations

Table 8.5.4.5 summarizes investigations appropriate for a first episode of depression and a recurrence. A guiding principle is that elderly people are in a more precarious state of homeostasis with their environment because they have less physiological reserve.

Table 8.5.4.3 Common medical illnesses and drugs that may cause organic mood syndromes

Medical conditions	Central-acting drugs
Endocrine/metabolic	*Anti-hypertensive drugs*
Hypo/hyperthyroidism	β-blockers (especially non-selective)
Cushing's disease	Methyldopa
Hypercalcaemia	Reserpine
Sub-nutrition	Clonidine
Pernicious anaemia	Nifedipine, calcium channel agents
Organic brain disease	Digoxin
Cerebrovascular disease/stroke	*Steroids*
CNS tumours	*Analgesic drugs*
Parkinson's disease	Opioids
Alzheimer's disease and vascular dementia	Indomethacin
Multiple sclerosis	*Anti-parkinson*
Systemic lupus erythematosus	L-Dopa
Occult carcinoma	Amantadine
Pancreas	Tetrabenazine
Lung	*Psychiatric drugs*
Chronic infections	Neuroleptics
Neurosyphilis	Benzodiazepines
Brucellosis	*Miscellaneous*
Neurocysticercosis	Sulphonamides
Myalgic encephalomyelitis	Alcohol
AIDS	Interferon

Severe depression in a 75-year-old may lead to quite serious metabolic derangement which would be unlikely in a fit 35-year-old.

An electroencephalogram (EEG) can help in differentiating depression from an organic brain syndrome such as delirium or an early dementia. A brain scan is only performed if clinically indicated, for example a rapid-onset depression with neurological symptoms or signs. The Dexamethasone Suppression Test (DST) is less specific for depressive illness than was first thought. It cannot reliably differentiate dementia from depression.

(c) Differential diagnosis

Organic mood disorder is diagnosed when a direct aetiological link can be established between the onset of the mood disorder and an underlying systemic or cerebral disorder (including dementia), or an ingested substance such as medication or alcohol.

Bipolar disorder is covered later. **Psychotic illness** (schizophrenia or delusional disorder) may present with marked depressed affect but other symptoms are present. A common depressive delusion in old age is hypochondriasis and sometimes it is difficult to decide whether the patient has a psychotic or an affective disorder. Interpretation depends on which symptoms predominate; if they occur together, it may be appropriate to use the term schizoaffective disorder.

Table 8.5.4.4 Geriatric Depression Scale

Instructions: Choose the best answer for how you have felt over the past *week*.

1. **Are you basically satisfied with your life?** No
2. **Have you dropped many of your activities and interests?** Yes
3. **Do you feel your life is empty?** Yes
4. **Do you often get bored?** Yes
5. Are you hopeful about the future? No
6. Are you bothered by thoughts you can't get out of your head? Yes
7. **Are you in good spirits most of the time?** No
8. **Are you afraid something bad is going to happen to you?** Yes
9. **Do you feel happy most of the time?** No
10. **Do you often feel helpless?** Yes
11. Do you often get restless and fidgety? Yes
12. **Do you prefer to stay at home, rather than going out and doing new things? Yes**
13. Do you frequently worry about the future? Yes
14. **Do you feel you have more problems with your memory than most?** Yes
15. **Do you think it is wonderful to be alive now?** No
16. Do you often feel downhearted and blue (sad)? Yes
17. **Do you feel pretty worthless the way you are?** Yes
18. Do you worry a lot about the past? Yes
19. Do you find life very exciting? No
20. Is it hard for you to start on new projects (plans)? Yes
21. **Do you feel full of energy?** No
22. **Do you feel that your situation is hopeless?** Yes
23. **Do you think most people are better off (in their lives) than you are?** Yes
24. Do you frequently get upset over little things? Yes
25. Do you frequently feel like crying? Yes
26. Do you have trouble concentrating? Yes
27. Do you enjoy getting up in the morning? No
28. Do you prefer to avoid social gatherings (get-togethers)? Yes
29. Is it easy for you to make decisions? No
30. Is your mind as clear as it used to be? No

Notes: (1) Answers refer to responses which score '1'; (2) bracketed phrases refer to alternative ways of expressing the questions; (3) questions in bold are for the 15-item version. Threshold for possible depression: >/=11 (GDS30); >/=5 (GDS15); >=2 (GDS4).

Dysthymia chiefly occurs in younger adults but may occur in later life in association with chronic ill-health. Where there is a clear onset of depressive symptoms within 1 month of a stressful life event without the criteria for a depressive episode being met, then an *adjustment disorder* may be diagnosed.

Epidemiology

In the United Kingdom, pervasive depression (a term denoting a depressive syndrome that a psychiatrist would regard as warranting intervention) is found between 8.6 and 14.1 per cent of elderly people living at home. The prevalence of a depressive episode is between 1 and 4 per cent of elderly people living at home.[4] The finding of a high rate of depressive symptoms but a much lower rate of depressive episodes is an epidemiological dilemma which is discussed in Chapter 4.5.4. It is likely that current classification

Table 8.5.4.5 Investigations for depression in later life

Investigation	First episode	Recurrence
Full blood count	Yes	Yes
Urea and electrolytes	Yes	Yes
Calcium	Yes	Yes
Thyroid function	Yes	If clinically indicated, or more than 12 months elapsed
B_{12}	Yes	If clinically indicated, or more than 12 months elapsed
Folate	Yes	If clinically indicated (for example recent poor diet)
Liver function	Yes	If indicated (for example suspected or known alcohol misuse)
Syphilitic serology	If clinically indicated (for example relevant neurological symptoms)	Only if clinically indicated
CT (brain)	If clinically indicated	If clinically indicated
EEG	If clinically indicated	If clinically indicated

systems overlook many of the late-life depressions found in community studies.

Depression in later life, whether major or 'minor', is associated with worsened medical morbidity, disability, and increased health utilization.[1] Co-morbidity from physical disorder or cognitive impairment is the main determinant of prevalence. Handicap, the disadvantage imposed by a physical impairment and attendant disability, is a further strong predictor of depression.[5] This matters because handicap is amenable to social intervention.

In residential care, nursing homes and medical wards the rates are between 20 and 40 per cent.

Aetiology

The risk factors for depression in later life are discussed in Chapter 4.5.5. A depressive episode usually arises from a combination of vulnerability factors along with a triggering (precipitating) adverse life event. Avoidant and dependent personality types are associated with late-life depression, and a lifelong lack of a capacity for intimacy is another risk factor.[6] Precipitating life events occur at a similar frequency to other age groups, although health-related events are more common among older people.[6]

The concept of vascular depression suggests new aetiological insights.[2] However, criticisms against vascular depression as a distinct subtype include the difficulty in establishing a temporal link between depression onset and vascular disease and that, if causal, vascular disease is likely to have been present well before old age. Furthermore, in studies of vascular depression the direction of causality is unclear since patients with vascular disease have a high rate of depression, and depression appears to worsen vascular disease, perhaps by direct effects on blood vessel endothelial function and indirectly through poor self-monitoring of health and poor adherence to medical drugs.

If confirmed, the vascular depression hypothesis could lead to antidepressant strategies aimed at improving the underlying vascular impairment as well as mood. In the meantime, a patient presenting late-onset depression should be thoroughly investigated for vascular disease as a potential aetiological contributory factor which should be optimally treated along with the depression.

Course and prognosis

Across all age groups depressive disorder is prone to persistence. Beekman *et al.*[7] followed 277 community-dwelling subjects, aged over 55 (most over 75), from a Dutch epidemiological survey. Using multiple assessments of mood over a 6-year period, they found almost half the sample was depressed for more than 60 per cent of the time. Twenty three per cent had true remissions, 12 per cent remissions with recurrence, a third a chronic-intermittent course; another third had chronic depression. Outcomes reported from the community and medical ward patients are worse than those of depressed patients under psychiatric care,[8] possibly linked to undertreatment in the non-specialist settings.

(a) Comparative outcome

Mitchell and Subramaniam[9] reviewed the literature between 1966 and July 2004, finding 24 publications which could be used to assess outcomes between different age groups. Overall the authors concluded that episodes of depression remitted in later life as well as in other times but with a greater risk of relapse. Two factors seemed to explain this: age of onset (recurrent depression from earlier life conferring a poorer prognosis) and medical comorbidity (with a worse prognosis linked to a later onset). Although these mechanisms differ, the high risk of relapse in late-life depression highlights the need for effective continuation and maintenance phases of treatment, regardless of age of onset.

Mortality

A number of studies show that depression is an independent risk factor for increased mortality,[1] not accounted for by suicide. Following a cohort of 652 depressed and non-depressed subjects over 3.5 years, Geerlings[10] found that duration, chronicity, and increasing symptoms from baseline were all linked to a higher risk of death, leading them to suggest that adequate treatment may reduce this effect. Physical illness, occult disease (e.g. a carcinoma), poor self-monitoring of health, inactivity, poor adherence to treatments, and effects on the hypothalamic-pituitary-adrenal axis or other endocrine systems are possible factors.

Factors predictive of outcome

Clinical features that have been shown to be associated with a poorer outcome, include a slower initial recovery, more severe initial depression, duration of illness for more than 2 years, three or more previous episodes, a previous history of dysthymia, psychotic symptoms, and cerebrovascular disease (including vascular depression). Other factors that may affect outcome adversely are chronic stress associated with a poor environment, crime, and poverty as well as a new physical illness, becoming a victim of crime, and poor perceived social support.

The practical message is that to improve the prognosis of depression one must treat episodes early and vigorously and attend to the patient's social supports, and milieu.

(a) Does depressive disorder predispose to later dementia?

There is growing evidence from epidemiological studies that depression is a risk factor for later cognitive impairment or dementia.[11] Why this might be so is not clear but it is known that chronic depression is associated with hippocampal atrophy in older patients,[12] and that depressed patients may adopt unhealthy lifestyles, which can aggravate the risk factors for vascular disease and later dementia.

Treatment

Multi-modal management (pharmacological, psychological, and social) within a multidisciplinary framework is as important in late-life as it is at other times of life. Attending to an elderly depressed person's physical health needs, physical environment, and social needs is essential. The goal is remission of all symptoms and not merely improvement, as residual symptoms increase the chance of chronicity. Ageing and frailty result in increased dependency and less ability to adapt in a flexible way to the kinds of adversity that maintain depression. To give a simple example, good chiropody aimed at optimizing mobility can have a major positive impact alongside medical intervention, but no one aspect of treatment should be prioritized over another. Another important principle is patient-centredness. This should include giving the patients as much choice as possible regarding their treatment. Many older depressed patients, if asked, would prefer a psychological approach to medical management and there is good evidence that psychological treatments work well in older adults.[13] Resource limitations are understood, but age alone should not determine the likelihood of receiving a psychological intervention, if preferred.

Collaborative care, whereby, a depression care manager (usually a nurse, psychologist, or social worker) coordinates the care and works closely with both primary care physician and psychiatrist, is an important model for improving outcomes. In the largest study to date, 'IMPACT' from the United States, involving 1801 depressed primary care patients (major depression, 17 per cent; dysthymia, 30 per cent; or both, 53 per cent), at 12 months the Number-Needed-to-Treat (NNT) was highly significant at four in those receiving the intervention.[14]

General principles of pharmacological management include: building a therapeutic partnership with the patient; explanation of how and when antidepressants work; addressing adherence through building therapeutic concordance; tailoring antidepressants drug to the patient; arranging appropriate follow-up.

Evidence of efficacy

(a) Antidepressants

Altered pharmacokinetics, different pharmacodynamics, a greater chance of polypharmacy and hence drug interactions and reduced compensatory mechanisms are all important factors which bear upon treatment response in late-life depression.[15] An important practical consequence is to be mindful of greater inter-individual variation in drug-handling in older patients. Patients worry about antidepressants being addictive, which they are not, and that depression means 'senility', which it does not. Psychoeducation is important and can improve adherence to medication recommendations. Recommended starting and therapeutic dosages are listed in Table 8.5.4.6. These are average doses. For some drugs, notably the tricyclics, there is a very wide therapeutic range and higher levels may be required, provided they are tolerated.

A Cochrane systematic review of Randomized Controlled Trials (RCT)[16] found efficacy for antidepressants over placebo in late-life major depression. However, the analysis could only find 17 suitable studies (two of SSRIs). The NNT averaged four, but was higher for SSRIs. In a further Cochrane systematic review of studies including patients aged over 55 (29 trials), there was no difference in efficacy between tricyclics and SSRIs, but tricyclics were associated with higher withdrawal rates due to side-effects. Patients receiving tricyclic-related antidepressants (Mianserin or Trazodone) had a similar withdrawal rate to SSRIs, leading the authors to conclude that tricyclic-related antidepressants may offer a viable alternative to SSRIs in older depressed patients. The analysis also investigated 'atypical' antidepressants but it was not possible to make recommendations because of low statistical power. Atypicals included the important antidepressants reboxetine, venlafaxine, and mirtazapine.[17]

More recent RCTs have suggested less positive results.[18] Trials involving older adults and with venlafaxine, fluoxetine, citalopram, and escitalopram showed these drugs to be no more effective than placebo. Sertraline and duloxetine were superior to placebo but remission rates, as opposed to response rates, were relatively low in all these studies. Trials which are of insufficient duration and the use of antidepressants for milder depressions, for which they are ineffective, are possible factors.

(b) Depression in special patient groups

A Cochrane systematic review of antidepressants for depression in dementia found 'weak' evidence for their effectiveness,[19] but there were few admissible trials. This does not mean

Table 8.5.4.6 Suggested starting and therapeutic doses for antidepressants in the United Kingdom

Drug	Average therapeutic doses[a]	Average starting doses
Tricyclics		
Amitriptyline	75–100	25
Clomipramine	75–100	10
Dosulepin (dothiepin)	75–150	25–50
Imipramine	75–100	10–25
Nortriptyline	75–100	10–30
Lofepramine	140–210	70–140
SNRIs		
Venlafaxine	150	37.5 bd
Duloxetine	60	30–60
SSRIs		
Fluoxetine	20	20
Fluvoxamine	100–200	50–100
Paroxetine	20	20
Sertraline	50–150	50
Citalopram	20–40	20
Escitalopram	10	5
Reversible monoamine oxidase inhibitor (RIMA)		
Moclobemide	150–600	150 bd
5-HT2 receptor blocker		
Trazodone	100–300	100
NASSA		
Mirtazapine	15–30	30
Others		
Mianserin	30–90	30

[a] See text.

antidepressants are ineffective in depression-related dementia but there is a high rate of spontaneous recovery of depression complicating dementia so that 'watchful waiting' is reasonable for mild-to-moderate cases.

There is little trial data for individual antidepressants in patients with common medical disorders, but in the previously mentioned IMPACT research, both physical function and pain were improved in participants who received active case management compared to usual care.[20,21]

Depression post-stroke is common. A high rate of spontaneous recovery occurs, especially in the first 6 weeks. Studies are underway to assess whether repetitive Transcranial Magnetic Stimulation (rTMS) may be helpful in post-stroke depression. TCAs and SSRIs in standard dosages are effective in post-stroke emotionalism.

(c) Choice of antidepressant

Tricyclics often cause postural hypotension, which may lead to unpleasant dizziness or dangerous falls. Secondary amine tricyclics are generally safer in this respect than tertiary drugs. Poor left ventricular function is a risk, and so are diuretics or antihypertensive medication. Delirium is more likely in medically ill patients.

Behavioural toxicity (affecting vigilance, reaction times, etc.) has been largely ignored in the elderly. Now that so many older people drive and pursue other activities demanding high levels of vigilance, this must be addressed. The *SSRIs* are safer in this respect than tricyclics, except for lofepramine which causes less impairment than the older tricyclics. *Mirtazepine* enhances noradrenergic and serotonergic function via antagonism at the pre-synaptic α_2 receptor. Differences in pharmacodynamics and pharmacokinetics are minimal with age. The side effect profile is similar to tricyclics; weight gain and sedation can be troublesome. *Duloxetine*, like venlafaxine is a dual-acting drug. The latter has been subject to cautions, regarding heart disease, at present in the United Kingdom, although recent restrictions have been lifted. Duloxetine has some RCT evidence in older depressed adults.[22] Although a special diet with *moclobemide* is not required, patients should be aware of drug interactions with painkillers and other antidepressants. Co-prescriptions of tricyclic and SSRIs should be avoided. A wash-out period of around 4–5 half-lives of the drug and any active metabolite is advised when transferring from a tricyclic or SSRI to moclobemide (but not from moclobemide to a tricyclic or SSRI).

(d) Failure to respond to initial treatment

If a patient has made minimal or no recovery after 4 weeks of treatment at optimal dose, then the chances of recovery are slim.[23] The antidepressant may be changed to one of another class but if the patient shows at least 25 per cent improvement and is on an improving trajectory, then augmentation with lithium or a psychological intervention should be considered (see below). Electroconvulsive Treatment (ECT) is safe and effective in older patients. It is recommended when drug treatment has failed, when the patient is in danger of inanition or is acutely suicidal and is probably the treatment of choice for psychotic depression.

(e) Continuation treatment

Most relapses occur in the first 12 months,[24] so that this is a reasonable time for continuation therapy. Patients must be educated about why they should continue to take medication even when feeling better. In psychotic depression anti-psychotic medication should be continued for 6 months and gradually withdrawn if the patient is well. Following ECT, medication should be continued to avoid relapse. Limited evidence suggests either continuing antidepressants at the acute treatment dose or using lithium.

Older people have been shown to benefit substantially from maintenance therapy,[25] even after a first episode.[24] Maintenance treatment is considered later.

(f) Resistant depression

Data in the elderly are sparse but the most important consideration is a rational stepped care approach. Before moving up the steps of treatment, the following should be addressed: is the diagnosis correct (for example has a psychotic depression been overlooked)? Is poor tolerance a reason for non-recovery? Does the patient take the tablets? Have psychosocial reinforcing factors (for example, family conflict) been addressed? The steps themselves include optimizing the dose of antidepressant (relevant mainly for older tricyclic antidepressants), changing from one class of antidepressant to another, augmentation with lithium or a psychological intervention and combining antidepressants (for example, a SSRI plus mirtazepine). Finally ECT should be considered as it remains the most effective antidepressant treatment. Using such an approach 80 per cent of patients in one study responded.[26]

(g) Psychological therapies

Cognitive behavioural therapy (CBT), Interpersonal Psychotherapy (IPT), and psychodynamic psychotherapy have been shown to work in older people,[13] including in group format. CBT and IPT along with family interventions are discussed elsewhere. Problem-solving Treatment (PST) addresses the here and now, focusing on current difficulties and setting future goals.

Psychological interventions may also be important in relapse prevention. Reynolds *et al.*[27] showed in a study of older patients that monthly IPT given in the continuation phase of treatment was more effective than routine care, with combined IPT and antidepressant therapy being the most effective strategy. However, the same group were unable to replicate this in a later study with a group of patients who were somewhat older.[25]

Anxiety management can be an effective adjunctive treatment for depressed patients, especially those recovering from depression but left with residual anxiety, low confidence, or phobic avoidance, any of which can undermine functional improvement. Techniques include progressive relaxation, either alone with a commercial tape, or in groups. Exercise and activity are important both to avoid depression and counter it. Behavioural activation is a technique which can overcome the withdrawal and apathy that so often exists in late-life depression. It works by helping the patient develop a schedule of activities, agreed with the patient, with or without a written diary to support implementation.

Work to support the family and main caregivers is also important.

Prevention

(a) Primary prevention

Many prevalent diseases of later life are associated both with depression as well as lifestyle factors: diet, exercise, and obesity. Cole and Dendukuri[28] carried out a meta-analysis of risk factors for late-life depression, finding five which were robustly linked to it. These were bereavement, sleep problems, disability, prior depression, and female gender. Some of these are amenable to a public health preventative approach.

Those most vulnerable to depression will often be in touch with a home care services. This is one area where education about detection could be usefully targeted. Another example is the staff of nursing homes where depression is highly prevalent. Postgraduate training of general practitioners is another way of improving detection via the 'filter' of primary care.

(b) Secondary prevention

Maintenance treatment with a tricyclic,[24] the SSRIs citalopram[29] and paroxetine[25] or a combining medication with a psychological treatment[27] are effective prevention strategies.

Expert guidelines[30] recommend a minimum of 12 months continuation treatment for a first episode, 24 months for a second, and at least 3 years for three or more episodes. Some clinicians recommend lifelong treatment with antidepressants following even a single episode of major depression on the grounds that a substantial later period morbidity might be reduced. This must be balanced against an increased risk of side effects as patients age.

(c) Tertiary prevention

Often the emphasis is on basic explanations and on simple instructions about how to manage problems such as frequent hypochondriacal complaints or apathy. Although respite care is usually associated with dementia, there is occasionally a case for it in those with chronic treatment-resistant depression, in order to allow the relative(s) a break.

Bipolar disorder

Practice guidelines for bipolar disorder are available from the internet. Two are: *British Association of Psychopharmacology* (2003)[31]—http://www.bap.org.uk/consensus/bipolar_disorder.html and the *National Institute for Clinical Excellence (NICE) (2006)*.[32] http://www.nice.org.uk/page.aspx?o=CG38.

Mania

Clinical features

Clinical descriptions of mania in late life often portray it as atypical. However, Broadhead and Jacoby[33] found few clinical differences between 35 manic patients over the age of 60 compared to 35 younger manic patients, aged below 40. The younger manic patients were more severely ill but there was no support for the often-held view that there is a greater depressive admixture in older patients.

Diagnosis and differential diagnosis

The main differential diagnosis of mania in late life lies between a late-onset manic episode and bipolar disorder. In later presentations of bipolar disorder the time between depression and first manic episode can be us much as 15 to 40 years or more. Given this long latency it is easy to overlook bipolar disorder unless a thorough history is taken.

Epidemiology

Although only about 10 per cent of new onset cases of bipolar disorder occurs after the age of 50 they account for proportionally greater morbidity. Changing demography makes it likely that there will be more cases of bipolar disorder in later life. Episodes can be misdiagnosed; for example a depressive mood swing presenting with withdrawal or a manic one with irritability.

Aetiology

The phenomenon of conversion to bipolarity after many years of unipolar depression has led to speculation that cerebral organic factors may play a part in the aetiology of late-onset mania. In support of this, cognitive function is significantly impaired in between a fifth and a third of elderly manics.[33,34] Furthermore studies[35] have shown a high rate of neurological disturbance, cerebral deep white matter lesions, and reduced heritability in late-life mania.

The term 'secondary mania' denotes manic illness which starts without a prior history of affective disorder in close temporal relationship to a physical illness or drug treatment and often in the absence of a family history of affective illness. A large number of conditions have been associated with secondary mania, including stroke, head injury, tumours, and non-specific lesions to the right side of the brain.

Course and prognosis

The prognosis for mania is similar to that for late-life depression; that is, there is an 80 to 90 per cent recovery in the acute phase but relapses and/or recurrences occur over time in about 50 per cent of cases.[35]

Treatment

As with younger patients, the mainstays of acute treatment are neuroleptics and mood stabilizers which include lithium and anticonvulsants, with ECT reserved for refractory cases. Increasingly atypical antipsychotics are used. These include olanzapine, risperidone, and quetiapine with aripiprazole as a possible new contender. Valproate preparations are the most widely used anticonvulsant in bipolar disorder.

Some general points to consider are: (1) a greater inter-individual variability in drug metabolism, which makes predicting the therapeutic dose difficult. Emergency rapid tranquillization with haloperidol 5 to 10 mg (often with 1 to 2 mg of lorazepam) can be used, but haloperidol has a long half-life and may lead to sudden immobility after a few days; (2) balancing risks caused by overactivity and exhaustion against an increased risk of falls in the elderly when using sedative tranquillizers; (3) an increased risk of confusion and delirium if anticholinergic drugs are given to counteract side effects; and (4) the higher risk of side effects and toxicity from lithium in older patients (including a risk even at what are considered therapeutic doses in younger patient).[35] The optimal treatment dose of lithium is not known. NICE recommends levels of 0.6 to 0.8 mmol/L for adults requiring maintenance lithium. Some old age psychiatrists use lower dosages but the evidence for low dose treatment in older patients is mixed.

The NICE Bipolar Guidance also covers the treatment of bipolar depression. The main message is that antidepressants, if used, should be combined with a mood stabilizer or an antipsychotic because of the risk of a manic switch.

Prevention

Given the high rate of relapse or recurrence, prophylaxis should be considered in all patients. There has been a steady shift away from lithium to valproate over recent years, although some argue this has occurred ahead of evidence.[36] Also, there is some evidence that lithium may reduce the risk of suicide in bipolar disorder as

well as being neuroprotective, possibly reducing the risk of dementia which some population studies have been shown to be raised in affective disorder.[31]

8.5.5 Stress-related, anxiety, and obsessional disorders in elderly people

James Lindesay

Stress-related, anxiety, and obsessional disorders in elderly people are common, distressing, costly to services, and potentially treatable. However, despite their clinical importance, many patients still go untreated, or are treated inappropriately. The specific conditions covered here are described in detail elsewhere; this chapter focuses on the differences and difficulties that are encountered when they occur in old age.

Classification

The ICD-10 and DSM-IV diagnostic classifications are described in Chapter 1.11. Although the term 'neurotic disorder' is not used in DSM-IV, it is retained in ICD-10 as a collective term for the disorders considered in this chapter. The extensive comorbidity between these conditions and their diagnostic instability over time are also apparent in elderly people, which supports the idea that they are better considered as aspects of a general neurotic syndrome than as discrete diagnostic categories.[1] This model is particularly applicable to elderly patients, whose illnesses are often the result of a long interaction between individual vulnerability, circumstances, and maladaptive responses to distress. Obsessive–compulsive disorder (OCD) is probably not part of a general neurotic syndrome. Although classified with the anxiety disorders in ICD-10 and DSM-IV, it has a number of features that suggest it is a distinct and stable condition with a different aetiology (see Chapter 4.8).

Clinical features

These disorders have psychological, somatic, and behavioural features. In elderly people, these symptoms and behaviours are similar to those seen in younger patients, but there are some important differences in how they manifest themselves or are perceived by others. Although most neurotic disorders in elderly patients are long standing, an important minority of cases have their onset in old age, and it is these that usually cause the greatest diagnostic difficulties.

Psychological symptoms

Symptoms of anxiety and depression occur to some extent in all of these disorders in late life. Depressive symptomatology in old age is described elsewhere (see Chapter 8.5.4). Regarding anxiety, the focus of the worries and fears of elderly people is on those issues that are of general concern in this age group (health, finances, crime). The phobias described by elderly people are similar to those seen in younger adults,[2] although some, such as the fear of falling, are more commonly seen in old age. Clinically significant anxieties and fears in elderly people are often dismissed as reasonable purely on grounds of age. In fact, it is physical frailty and the availability of social support that determine elderly people's perceptions of vulnerability and risk, and these rather than age should be considered when deciding whether or not concerns are reasonable.

The clinical features of OCD in old age are similar to those seen in younger patients. Obsessional symptoms rarely appear for the first time after the age of 50 years, and in such cases the possibility of an organic cause such as dementia or a space-occupying lesion should be investigated. They may also form part of a primary affective disorder.

Somatic symptoms

The somatic symptoms of anxiety are similar at all ages, but in elderly patients there is a greater likelihood of misdiagnosis and inappropriate investigation and treatment. This is particularly true of elderly patients experiencing panic attacks, who tend to be misdirected to cardiologists, neurologists, and gastroenterologists.

Behavioural disturbance

The psychological and somatic symptoms of anxiety have several adverse behavioural consequences, for example, phobic avoidance, the abuse of sedative drugs and alcohol, and the development of troublesome abnormal illness behaviours such as somatization and hypochondriasis. In elderly patients these behaviours are usually of long standing, but they can develop following the onset of anxiety or depression in old age. In cognitively impaired patients, disturbed behaviour may be the main presenting feature.

Diagnosis and differential diagnosis

In old age, these disorders usually present in primary care and the general hospital, and clinicians working in these settings need to be able to identify them, and to distinguish them from the other mental and physical disorders that they may accompany or mimic.

Depression

There is extensive comorbidity between neurotic disorders and depression, and depressive symptoms are an integral component of many neurotic disorders, particularly in old age. It is therefore important to assess to what extent depression forms part of the clinical picture, as this may require treatment in its own right. Depressive disorder that is comorbid with anxiety responds less well to antidepressant treatment, and there is a greater likelihood of relapse and recurrence.

Dementia

In the early stages, dementia may present with symptoms such as anxiety, and obsessionality. More commonly, anxiety and depression cause subjective cognitive impairment, which may be the presenting symptom. Dementia is associated with higher rates of anxiety, unrelated to severity of cognitive impairment. Patients with vascular dementia may be more vulnerable in this respect.

This anxiety may be associated with the implications of the diagnosis in those patients who retain insight, or a response to psychotic symptoms or misinterpretations of the external environment in those who are more severely affected. The caregivers of people with dementia are also vulnerable to developing depressive and anxiety disorders, particularly if they have a previous psychiatric history.

Delirium

Although delirium is a relatively quiet disorder in elderly patients (see Chapter 8.5.1), it may be associated with significant affective disturbances, often in response to frightening visual hallucinations and imagined assaults. Conversely, in vulnerable individuals, severe anxiety may be sufficient to precipitate delirium.

Paranoid states and schizophrenia

Patients suffering from these disorders may experience significant fear and anxiety in response to their psychotic experiences, but this rarely causes diagnostic difficulty. Unusual hypochondriacal ideas may sometimes be difficult to distinguish from monosymptomatic delusional disorders.

Physical illness

There is an important association between physical illness and neurotic disorders in old age. As a life event, an episode of physical illness may be the cause of neurotic disorder, particularly if it is severe or has sinister implications. For example, mild anxiety symptoms are common following myocardial infarction in old age, and vulnerable individuals may develop a disabling 'cardiac neurosis' focused on their somatic anxiety symptoms. Most cases of agoraphobia that develop after the age of 65 years are not induced by panic but arise following an alarming experience of physical ill health.[1] Follow-up studies of stroke survivors show that conditions such as agoraphobia and generalized anxiety are common, tend to become chronic in a significant proportion of cases, and are associated with poor functional recovery.[3] Chronic disabilities that limit mobility and independence, such as arthritis, balance disorders, and sensory impairments, increase the patient's sense of personal vulnerability and are also associated with elevated rates of anxiety and secondary avoidance.

Neurotic disorders can also cause physical illness by direct or indirect effects on the body. In elderly people, this may come about as the result of many years of harmful anxiety-driven behaviours such as smoking and alcohol abuse.

In terms of differential diagnosis, there is also the problem that a wide range of physical disorders may present with neurotic symptoms, and vice versa. In particular, a number of important cardiovascular, respiratory, and endocrine disorders may present with anxiety or depression and little else in old age.[4] Anxiety symptoms may also be caused by prescribed drugs such as oral hypoglycaemics and corticosteroids, or by excessive intake of caffeine and preparations containing sympathomimetics. In view of this, the clinical assessment should always include a drug history and a physical examination. A physical cause for neurotic symptoms should be considered if there is no past psychiatric history and no life event or other circumstances to account for their onset.

Epidemiology

While neurotic disorders are relatively uncommon in clinical populations, there are significant prevalence rates in community samples, indicating that they do not pass easily through the filters on the pathway to care. Surveys using different diagnostic criteria produce different rates of disorder, which makes comparisons difficult. However, some general findings include a female preponderance for most disorders, and a fall in prevalence and incidence rates with age. Most elderly people with neurotic disorders developed them before their fifties, but elderly cases of phobic disorder, panic, and OCD tend to be of later onset.[5,6]

Aetiology

The acquisition and subsequent loss or elaboration of the symptoms of anxiety and depression are determined by the patient's premorbid vulnerability, the particular factors that precipitate the episode of illness (destabilization), and the measures taken by the patient or the doctor to control it (restitution).[7]

Biological factors

Most of the evidence that biological factors play a role in the development of neurotic disorders derives from studies in younger subjects (see Chapters 4.7.1–4.7.3). These studies indicate that genetic factors contribute significantly to premorbid vulnerability, but the role that they play in old age is not known. Neuroimaging studies of elderly depressed patients provide only limited information about neurotic disorders, suggesting that patients with milder forms of depression and higher anxiety scores are more likely than severely depressed patients to have normal CT scans. It has been suggested that some anxiety disorders following stroke may be related to lesion location.[8]

Psychosocial factors

(a) Social adversity

This may have its effect through higher rates of physical illness and exposure to adverse life events, or by inculcating a sense of poor self-esteem. However, the impact of adversity on self-esteem in old age is not clear, since a hard life may in fact equip one to cope better with the difficulties of old age.

(b) Life events

Adverse life events have an important role in determining the onset of depressive and anxiety disorders (see Chapters 4.5.5.1 and 4.7.1–4.7.3). It is the meaning of the event to the individual that is important; loss events lead to depression and threatening events to anxiety. Some types of life events (physical illness, bereavement, retirement, institutionalization) are more common in old age, and are associated with psychiatric morbidity in vulnerable individuals.

Extreme trauma and catastrophe are well known to have adverse psychological consequences, and post-traumatic stress disorder (PTSD) is a recognized diagnosis in ICD-10 and DSM-IV (see Chapter 4.6.2). It is clear from studies of elderly survivors of traumatic experiences such as war and the holocaust that PTSD is often a persistent disorder, and that its onset or recurrence may be precipitated by events many years after the original traumatic

experience. PTSD may also develop following trauma in late life, and as in younger subjects it tends to persist.

(c) Early experience

Early parental loss and childhood physical and sexual abuse are associated with the development of mental disorder in adult life, an effect that persists into old age.[1]

(d) Relationships

There is evidence that both the quantity and quality of social relationships are important determinants of psychological well-being in old age, and that factors such as smaller social networks are associated with anxiety disorders.[9]

Course and prognosis

The limited evidence suggests that neurotic disorders in elderly people tend to become chronic and that older age of onset is a predictor of poor outcome, particularly in men.[10] The pattern of symptoms may change over time.[11] Elderly patients with anxiety disorders have an excess mortality.

Treatment

Evidence

There is little high-quality evidence available about the effects of treatments for these disorders in elderly patients. Cognitive behaviour therapy (CBT) is of proven benefit in younger adults (see Chapter 6.3.2.1), and there is some evidence that it is also effective in later life.[12] There have been surprisingly few trials of anxiolytic drugs in elderly patients, but there is evidence that antidepressant drugs such as SSRIs and venlafaxine are effective in the treatment of generalized anxiety. In the absence of good evidence for a particular treatment, patient preference, and choice are important considerations.

Management

Since most patients are seen in primary care and general medical settings, this is where the focus of management should be. The role of specialist old age psychiatry services should be to provide any advice and support that is necessary, which may include assuming responsibility for the most complex cases. Wherever the patient is seen and treated, the following should need consideration from the outset (see also Chapter 8.6):

- a thorough assessment and accurate diagnosis as the basis for the management plan
- the full range of physical and psychological treatment options, including patient education, lifestyle advice, bibliotherapy, and supportive counselling
- clear goals for the treatment plan, agreed if possible with the patient
- an adequate trial of treatment
- the likely duration of treatment
- frequency of review
- any possible adverse consequences, such as dependency, adverse side effects, risk of self-harm.

(a) Psychological treatments

For the most part, the goals and techniques of CBT are the same for elderly patients as they are for younger adults (see Chapter 6.3.2.1). However, these may require some adaptation to accommodate sensory impairments, physical illness and disability, and cognitive dysfunction.[13] The need to tailor treatment to the individual may limit the value of CBT in a group setting, although this has to be set against the benefits of shared experience and peer support. Group treatment is probably more straightforward with task-centred activities such as anxiety management.

The use of formal psychodynamic approaches to management is currently limited by economic constraints, and the lack of evidence regarding their effectiveness. However, health professionals should have some knowledge of the psychodynamics that underlie the concerns of elderly patients, and the mental defences that they use. They also need to be aware of their own preconceptions and cognitive distortions regarding the experience of old age, the psychological sophistication of elderly people, and their capacity for growth and change.

(b) Physical treatments

Chapter 8.6 describes the general principles of drug treatment in old age. None of the drugs used to treat anxiety in elderly people is entirely without problems, so they should be prescribed with care.[14] Benzodiazepines are the most commonly used drugs, but they are often prescribed inappropriately. Elderly patients are particularly sensitive to their adverse effects, and drug accumulation may lead to delirium, incontinence, and falls. Compounds with short half-lives and no active metabolites, such as oxazepam, are least problematic, although patients may develop withdrawal symptoms if they are discontinued, or taken erratically. Long-term benzodiazepine use should be avoided where possible, although it may be necessary in a few patients unresponsive to other forms of treatment.

Antidepressant drugs are now the first choice in generalized anxiety and panic, particularly if depressive symptoms are prominent. The use of antidepressants in elderly patients is discussed in Chapter 8.5.4. SSRIs also have a specific effect in OCD. Neuroleptics have only a limited role in the management of anxiety, given their potentially disabling extrapyramidal side effects. However, a short course of low-dose treatment with a drug such as haloperidol or zuclopenthixol may be considered in those unable to tolerate benzodiazepines. Alternatively, sedative antihistamine drugs such as hydroxyzine may be useful. β-blockers are used in younger adults to control the sympathetic somatic anxiety symptoms, but contraindications such as chronic obstructive airways disease, sinus bradycardia, and heart failure limit their use in elderly patients. Buspirone is an azapirone anxiolytic that is well tolerated by elderly patients, but it takes about 2 weeks to become effective, so is not useful for the management of acute episodes. It is indicated for severe chronic generalized anxiety and in patients where there is risk of dependence or abuse.

Prevention

The possibilities for primary prevention are limited at present. However, in view of the association with physical illness, there may be an opportunity to intervene and prevent the development of chronic neurotic disability following strokes, heart attacks, and

falls. It remains to be seen if the improved management of these disorders earlier in life will result in lower rates of chronicity and recurrence as cohorts age.

8.5.6 Personality disorders in the elderly

Suzanne Holroyd

Introduction

The study of personality disorder (PD) in late life presents conceptual, diagnostic, and methodological difficulties. By definition, PD is considered a group of personality traits that relatively persistent through adulthood. However, the concept of PD persisting throughout the lifespan contradicts widespread clinical belief that they become less severe with ageing. For example, DSM-IV[1] notes that 'some types of personality disorders . . . tend to become less evident or remit with age'.

There are difficulties in studying PD in the elderly. One is the instability of the definition of PD over time, making it difficult to relate earlier studies to those using current definitions of PD. In addition, diagnostic criteria are subject to criticism when applied to the elderly, in that they may be 'age-biased'.[2,3] Finally, the methodology used to diagnose PD has been highly variable and difficult to interpret between studies.

A major issue is whether personality is fully developed by early adulthood and then remains unchanged, or whether personality continues to develop and change throughout life. The work of McCrae and Costa[4] demonstrated that personality characteristics are relatively stable within individuals over a 30-year period with correlations ranging from 0.7 to 0.8. However, this also demonstrates that complete stability is not there and suggests certain aspects of the personality may still develop and change with ageing. This suggests that PD may also change over the lifespan.

Another issue is whether underlying traits that persist throughout the lifespan can rise to the level of a PD depending on the environment. For example, traits that may be personality disordered in young adult life, such as extreme dependency, may be an appropriate and adaptive trait for an older individual with multiple physical disabilities.[5] Conversely, an individual may have a trait of extreme independence that may be adaptive in earlier life but which leads to distress and maladaptive functioning in a setting requiring dependence, such as a nursing home. Thus it is possible to have a PD diagnosed for the first time in late life, which goes against the very definition of lifelong PD.

Clinical features

Clinical features of PD and details of their classification are reviewed in Chapters 4.12.2 and 4.12.3. However, there is difficulty in simply relating these criteria, which were developed for younger individuals, to the elderly. Typical diagnostic behaviours that clinicians associate with PD in younger adults may present as different behaviours in the elderly. This may lead clinicians to overlook personality traits and disorders in older individuals. For example, a criterion of antisocial personality disorder is the repeated failure to sustain consistent work, behaviour not applicable to the older retired individual. Yet it is possible that the personality trait of irresponsibility, which led to the loss of jobs earlier in life continues, now appearing as a behaviour such as medicine non-compliance. Some authors have thus argued that the clinical

features for some PD are age-biased since certain behaviours are less likely to occur in elderly persons despite the persistence of personality traits.[2,3]

Diagnosis of personality disorders

Diagnostic criteria for PD are discussed in Chapter 4.12.3. Because features of PD may change with ageing, diagnosis can be difficult. Overlap with Axis I diagnoses such as depression or dementia make the diagnosis even more challenging. For example, depressed elderly people have symptoms normally associated with PD as they may be more dependent, avoidant, resistant, negative, and somatic.[6] In addition, depressed elderly people may view their lives negatively and overestimate personality psychopathology.[7,8]

Clinicians may be reticent to give a personality diagnosis to an individual with multiple medical problems to which maladaptive behaviours may be attributed even if a lifelong history of personality pathology is established.[8] They may also be concerned about the validity of historical information needed to make a PD diagnosis. Therefore, in making a diagnosis of PD, a clinician should take a thorough history from as many reliable outside informants as possible. If the patient is in a state of acute distress with a current Axis I diagnosis such as depression, it is best to defer diagnosis of the PD until the illness is in remission. Otherwise, it is especially important to ask outside informants to think back to when the individual was a younger person, as current symptoms can colour the perception of lifelong personality traits. Asking for specific examples of history such as, details of relationships and job history, legal history, and the like, will be more helpful than just general descriptions of personality.

If behavioural difficulties and personality problems are found to be recent, the clinician needs to search carefully for a superimposed medical condition, or a psychiatric condition such as depression. Clinicians should carefully screen for illnesses such as dementia, stroke, or other neurological disease, or a systemic medical illness. Those with frontal lobe dementia, Alzheimer's disease, or vascular dementia may have personality changes early in their life course.[9–11]

Epidemiology and aetiology

The prevalence of PD in the elderly varies as to the methodology used and the population studied. It should be noted that no assessment instrument for PD in the elderly has been validated.

Community studies

Community studies have been the most useful to date. A community study,[12] using the Epidemiologic Catchment Area (**ECA**) data, had 841 subjects examined by psychiatrists using the semi-structured Standardized Psychiatric Examination with DSM-III criteria. Comparing those over the age of 55 with those under 55, older individuals were found significantly less likely to have a PD (6.6 to 10.5 per cent) as compared with younger individuals. This finding was almost entirely due to a three-fold higher prevalence of cluster B PD in those under the age of 55, especially antisocial and histrionic PD. Interestingly, in this study none of the older individuals were found to have cluster A PD. Table 8.5.6.1 summarizes the findings of this large community study. The strengths of this study were that it was a community rather than a clinical sample, and subjects were evaluated by psychiatrists using a structured questionnaire. Limitations of this study were those inherent to the study of PD in late life, in that older subjects may have been inaccurate in recalling maladaptive behaviours, outside informants were not used, and lack of non-validated instruments for diagnosing PD in the elderly.

Table 8.5.6.1 Weighted prevalence (%) of DSM-III personality disorders in a large community study

	Age < 55 years	Age > 55 years
Cluster A	0.1	0.0
Paranoid	0.0	0.0
Schizoid	0.1	0.0
Schizotypal	0.1	0.0
Cluster B	6.8	2.2*
Antisocial	2.7	0.1*
Borderline	0.8	0.0
Histrionic	4.3	2.2*
Narcissistic	0.0	0.0
Cluster C	3.8	4.3
Avoidant	0.0	0.0
Dependent	0.2	0.1
Obsessive–compulsive	3.6	3.3
Passive-aggressive	0.0	1.0
Any personality disorder	10.5	6.6*

Reproduced from B.J. Cohen *et al.* (1994). Personality disorders in later life. A community study. *British Journal of Psychiatry*, **165**, 493–9, copyright 1994, The Royal College of Psychiatrists.

A community study of 43 093 persons, examining alcohol and related conditions across the life span, confirmed that those over 65 years had significantly lower rates of all studied PD including avoidant, obsessive–compulsive, paranoid, schizoid, histrionic, and antisocial, using DSM-IV criteria.[13]

A community survey study of DSM-III PD traits using the Personality Diagnostic Questionnaire revealed that 'dramatic' and 'anxious' personality traits declined up to 60 years of age with a slight increase thereafter, but that 'odd' or 'eccentric' traits showed no change with age.[14]

Psychiatric populations

In addition to community samples, specific clinical samples have been examined. Limitations of these studies are the possibility of over diagnosis of PD due to symptoms of Axis I diagnoses.

A retrospective study of 2322 psychiatric inpatients with major depression found the prevalence of PD to be 11.2 per cent in those over the age of 65 as compared with 17.2 per cent for those under 65.[15]

Psychiatric inpatient studies suffer from the limitation of diagnosing PD in the face of an acute psychiatric illness requiring hospitalization, making them likely to overdiagnose. Such studies are of very limited value.[16,17]

Unfortunately, outpatient studies have similar limitations when examining those with concurrent Axis I diagnoses. A study of 36 psychiatric outpatients, including those with bipolar disorder, delusional disorder, and schizophrenia, revealed that 58 per cent had a diagnosis of personality disorder.[18] Arguably, diagnosing

personality disorder in the face of these disorders is likely to be difficult and result in an overestimation.

Prevalence summary

A meta-analysis of 11 articles published from 1980 to 1994 of personality disorders based on DSM-III or DSM-IIIR criteria revealed an approximately 10 per cent prevalence of personality disorders in those aged 50 and over.[19] In comparing these studies it was noted that the method of diagnosis affected the prevalence of personality disorder. In conclusion, the authors felt that there was a definite need for well-designed studies using statistically robust samples to assess the true prevalence of personality disorders in late life.

Taking the best studies together—the ECA community study and the meta-analysis—the prevalence of personality disorder in the elderly, as currently defined, ranges from 7 to 10 per cent, with a decrease in prevalence of cluster B diagnoses.

Course and prognosis

Longitudinal community studies of PD have not been performed. With longitudinal data lacking, only cross-sectional studies are available. However, cross-sectional studies have a variety of limitations, including the possibility of a cohort effect explaining changes in prevalence in late life.

Antisocial personality disorder has been the best studied. The ECA study revealed that antisocial personality disorder declined from a 1-month prevalence of 0.9 per cent for individuals between 25 and 44 years of age to 0 per cent for those over the age of 65. When considering men only, the rate fell from 1.5 per cent in those aged 22 to 44 to 0.1 per cent in those over 65.[20] Supporting this is a study revealing the decline in lifetime prevalence in antisocial personality disorder from between 2.1 and 3.3 per cent to between 0.2 and 0.8 per cent in those aged 65 and older.[21] In addition, antisocial traits, as measured by the Minnesota Multiphasic Personality Index, reveal a decline with ageing.[22] However, a forensic centre study revealed while antisocial PD declined after the age of 27, one-third remained criminally active throughout their lives.[23]

Several hypotheses exist to explain this apparent decline in antisocial personality disorder with ageing. Personality may continue to mature and develop. Early death due to high-risk behaviour or a change in antisocial behaviours to other symptoms including hyperchondriasis, depression, or alcoholism may occur.[23] Also, behaviours such as criminality may decrease in older individuals, but antisocial personality traits remain and are simply more difficult to measure using current diagnostic criteria. Also, decrease in impulsive and aggressive behaviours may correlate with full myelination of frontal, temporal, and parietal cortices that does not occur until 30 or 40 years of age.[24] Changes in brain neurochemistry with ageing, including serotonin and dopamine, may also result in decreased impulsiveness or aggressiveness.[12] Decreased testosterone levels in men with ageing may contribute to a decline in these traits.[25]

Other Cluster B disorders may decline with ageing. The ECA study previously reviewed found a decline in antisocial and histrionic disorder.[23] Another community study supported a decline in histrionic PD with ageing.[26] Interestingly, the pattern of decline varied with gender, with rates remaining constant in women but declining in men. Similarly, a diagnosis of borderline PD is rare in elderly individuals, with only two case reports in the literature.[5] There is conflicting data regarding a decline in cluster A or C diagnoses. A large community study revealed lower rates of both Cluster A and C diagnoses in the elderly.[13] However, a study of schizotypal PD revealed all cases began before 40 years of age and continued lifelong.[27]

Some work has been done on the interaction of PD with Axis I diagnoses. Studies of depressed elderly patients suggest PD is associated with earlier age of depression onset, chronicity, and severity of dysthymia[28,29] however depression may exacerbate or conceal personality traits, thus making firm conclusions of PD in such individuals difficult. In the ECA study, certain Axis I diagnoses were found to be more common with a PD diagnosis. For example, all cases of obsessive–compulsive disorder in older individuals occurred concurrent with a PD.[12] Both generalized anxiety disorder and substance use disorders were more common in the presence of a PD. There were no differences in the prevalence of schizophrenia and major depression in those with or without a PD. The findings need to be confirmed since the group of elderly with PD was small.

A recent interesting study has revealed any PD (DSM-IV criteria) is associated with increased risk of stroke and ischemic heart disease, adding to the possible morbidity of these disorders.[30] However, such results should be viewed with caution as no screening was done to rule out depression or other associated factors that are prevalent in this population and may have led to over diagnosis of PD.

Treatment and management

Given the relative lack of data regarding PD in the elderly, it is not surprising there is a corresponding lack of information regarding treatment and management. In general, clinicians should have a low threshold for suspecting concurrent psychiatric diagnosis, as major depression, anxiety, substance use disorders or dementia may mimic or exacerbate a personality disorder.[5] Physical and medical problems should be thoroughly evaluated and treated to minimize any associated complaints.

Social and family supports should be explored and maximized. Firm and consistent limits must be set by the clinician for both patients and their families in regard to inappropriate behaviour.[5] Clinicians should also try to determine why the disordered behaviour is occurring at a particular time. For example, placement in a nursing home may be stressful to an individual who has had difficulty forming relationships and is now dependent on a group of caregivers. Psychotherapy with the goal of focusing on current life stresses, the individual's vulnerabilities, and adaptive strategies can help the patient adjust to the current circumstance.[5]

Psychotherapeutic treatments used for personality disorders in younger individuals may be tried although little data exists on their effectiveness for elderly. A study of Dialectical Behavior Therapy (DBT) used in combination with medication to treat elderly depressives with personality disorders revealed better results than just medication. The study is limited in that such results are common in other studies using any psychotherapy with medication versus medication alone and does not support a specific usefulness of DBT in elderly personality disorder. However, the study is the first to use DBT in an older population and shows it is tolerable in this age group.

If possible, psychiatric medication should be avoided unless there is a specific diagnosed condition. This will minimize the possibility

of side effects in elderly individuals and avoid dependency and control issues.[5] This is important as elderly individuals with abnormal personality traits have been found to be at higher risk of receiving psychotropic medication.[31]

Possibilities for prevention

There are no data available for preventing the development of a PD in late life. Clearly, more information is needed on the longitudinal course of diagnosed PD in late life so that information regarding treatment and prevention may be realized.

Further information

At the time of writing, there are no books or reports that give an overview of personality disorder in the elderly. Further information about specific aspects of the subject can be obtained from the relevant references in the text.

8.5.7 Suicide and deliberate self-harm in elderly people

Robin Jacoby

Introduction

Although in some countries suicide rates in young males have risen dramatically in the last decade or so, suicide in old age is important because rates in older people, especially those over 74, are still proportionately higher in most countries of the world where reasonably reliable statistics can be obtained.[1] For example, in 2004 in Lithuania where suicide incidence is currently the highest, the

overall rate in males per 100 000 total population was 70.1, but in men over 74 the rate was 80.2. In the United States, where suicide is neither especially common nor rare, in 2002 the overall rate for males per 100 000 total population was 17.9, but 40.7 in men over 74. Rates for older women are nearly always much lower than for their male counterparts.

A second reason for the importance of suicide in old age is that the proportion of older people in the population is rising worldwide. Indeed, the increase in developing countries is likely to be even greater than in developed countries. Although rates vary from year to year and birth cohort to cohort, it is highly likely that unless suicide prevention becomes a great deal more effective than at present, more and more older people will kill themselves in the coming years.

As with younger people, completed suicide in old age may be seen as part of a continuum from suicidal thinking through deliberate self-harm (which does not lead to death), to completed suicide. An added component within this continuum for older people is that of 'indirect self-destructive behaviour', such as refusal to eat and drink or 'turning one's face to the wall' which is clearly intended to hasten death. Finally, although this section does not deal with euthanasia and related issues, assisted suicide in people with terminal illness such Alzheimer's disease and cancer may also be seen as part of the suicide continuum.

Suicidal thinking in community-dwelling elderly people

A number of studies have explored this issue. Fleeting thoughts of suicide or the idea that life is not worth living occur in up to about 15 per cent of community-dwelling older people,[2] but serious consideration of suicide is very much less.[3] It is those older people with mental disorders, mostly depressive, who show a higher frequency of thoughts that life is not worth living and harbour ideas of committing suicide. It seems logical to suppose, therefore, that depressed elders should be the target of suicide prevention strategies.

Indirect self-destructive behaviour

Unlike the young, some elderly people have the possibility open to them of behaving passively in such a way as to hasten death. This may happen either by refusing medical treatment essential to maintain life, or simply by declining to eat and drink—'turning one's face to the wall'. As regards the latter, many people, especially non-medical, believe that this is reasonable behaviour akin to so-called 'rational suicide', and court rulings have sanctioned it. There is no doubt that there are several cases in which a person's right to refuse treatment or nutrition, for example during the terminal phase of cancer, should and would be respected. However, it has been argued that many of such cases suffer from undiagnosed but treatable depressive illnesses. Some support for this point of view was provided by a questionnaire study of more than 1000 residential and nursing home administrators in the United States.[4] Cognitive impairment, loss events, refusing medication, food, and drink, loneliness, feeling rejected by families are all risk factors for indirect suicidal behaviour in residential homes.[5] It is wise, therefore, that no one should be permitted to turn his or her face to the wall before assessment for the presence of a treatable depressive disorder.

Deliberate self-harm

Incidence

It is less possible to make a clear distinction between deliberate self-harm (DSH) and completed suicide in older than younger people. DSH at all ages has been quite extensively studied, but for obvious reasons mainly in hospital samples, and it is possible that several cases are undetected in the community. Broadly speaking the incidence curve for DSH is highest for the young and declines with age, whereas that for completed suicide rises with age. By the same token suicidal intent behind acts of DSH in older people is significantly greater than in younger adults.[6] In clinical practice it is therefore wise to consider deliberate self-harm in those over 75 as failed suicide.

Sex

As with completed suicide, rates for DSH differ quite widely from country to country. As with younger attempters, females outnumber males at a raw number ratio of approximately 3:2, but the *proportionate* gender ratio is approximately unity because fewer males survive into old age. Contrast this with completed suicide where men clearly outnumber women.

Methods

Deliberate drug overdose is the favoured method for DSH at all ages in Western countries; in some others, corrosive poisons or detergents are used. The most common types of drug for overdose are benzodiazepines, analgesics, and antidepressants. After drugs, self-cutting is the next most frequent method.

Psychiatric diagnosis

Older people are more likely to be assigned a psychiatric diagnosis after DSH, about half suffering from major depressive disorder, up to about a third from alcohol abuse, and under 10 per cent from other disorders.[7] Only about 10 per cent have no psychiatric diagnosis at all. Alcohol abuse together with depressive disorder augments the risk of DSH in older people. The status of cerebral organic disorder is uncertain because selection bias in reported case series reduces comparability. However, mild cognitive impairment and a co-morbid depressive disorder have been considered risk factors, and should be borne in mind by the clinician, if only on common-sense grounds. Personality factors have been implicated in DSH in older people, but research data are too poor and too few to make reliable statements on the subject.

Risk factors

Risk factors for deliberate self-harm in elderly people include: physical illness; widowhood and divorce or separation from a cohabitee; social isolation and loneliness (not the same thing); or simply living alone.[6,7] Unresolved grief, usually after death of a spouse, is a commonly found risk factor. The threat of transfer to a nursing home is, unsurprisingly, a precipitant of deliberate self-harm, although once an elderly patient is transferred to institutional care the risk of an overdose or some other attempt at suicide is reduced, probably because of lower access to the means and higher supervision. Surprisingly perhaps, terminal illness is not commonly found in older patients who attempt suicide but

fail, although hitherto undiagnosed but treatable physical disorders are sometimes revealed.

In keeping with the fact that more older suicide attempters are assigned a psychiatric diagnosis than younger ones is the fact that about 50 to 90 per cent, depending on the case series, undergo some form of psychiatric treatment as a result of the act of deliberate self-harm. Although fewer older people commit DSH than younger ones (about 5 per cent compared with 12 per cent) the risk of subsequent completed suicide is higher, compared with people of all ages (about 7 per cent compared with 3 per cent). Individual risk factors for later successful suicide include being male, having a prior psychiatric history, divorce, and current treatment for a persistent depressive illness.[6,8]

Completed suicide

Rates

The point has already been made in the opening paragraph of this chapter that suicide rates are still highest in the oldest old in most countries. Men outnumber women by about three or four to one in most countries; the exception being rural China.[1] However, suicide rates in the old have in fact been declining in many industrialized countries over the past 25 years, whilst those in young males have been rising—a reminder of the maxim that rates in all groups can and do vary over time and between countries, so that general conclusions about suicide should always take context into account. The reasons for incidence variations are discussed elsewhere, but socio-economic conditions and access to means play their part with the old as well as younger suicide victims.

Suicide at all ages is associated with divorce, widowhood, and single marital status. Widowers are more likely to kill themselves than widows, which has relevance for old age psychiatry, since in the overall population there are more old widowers than young ones.

Methods

Methods of suicide chosen by older people depend to a great extent on availability. In the United States, firearms are used by the majority of older men who kill themselves.[9] Shooting is also commonly chosen in Australia and Finland. In the United Kingdom, which has more stringent firearms control, drug overdose, especially in women and frequently with combination analgesics, hanging (especially in men), suffocation, or jumping from tall structures are preferred methods.[10] In Japan hanging, in Hong Kong jumping from one of the many very high buildings, and in Sri Lanka organophosphate poisoning are the commonest means in use.

Planning

Suicide in older persons is marked by careful planning and about half of the victims leave a note to indicate why or to confirm that they have killed themselves.[10] Suicide pacts are generally rare, but half of those that do occur involve people over 65. A previous history of a suicide attempt (DSH) is found in about a third of those older people who kill themselves.

Psychiatric diagnosis

Studies, including case-control, in the United States, Scandinavia, and the United Kingdom have found that 70 per cent of older suicide victims suffer from a mental illness, most commonly a major depressive disorder at the time they die.[11–14] Chronic symptoms of depression and a first depressive illness in later life are associated with a greater risk of suicide. Untreated or inadequately treated depressive illness is also found more commonly in elderly suicides. By contrast with younger suicide victims, alcohol and drug abuse rates are lower in elderly people, although co-morbid depression and alcohol abuse do occur more frequently than by chance. Schizophrenia or schizophrenia-like disorders are found less commonly in older than younger suicides. Similarly, cerebral organic impairment or dementia are infrequent and even absent from some series of cases. There has been more recent interest in the role of personality in suicide in older people. In various studies obsessional or anankastic traits which researchers have called 'low openness to experience' have been shown to predispose to suicide.[14,15]

Co-morbid physical illness

Co-morbid physical illness is, on common-sense grounds alone, likely to be a risk factor for suicide in older people and this has been confirmed in a number of studies.[16–18] Also, older people are much more likely to have visited their primary care doctor in the month prior to killing themselves than are younger suicide victims, and furthermore more likely to complain of physical than mental symptoms. Nevertheless, suicide to bring about the premature ending of a terminal illness or the avoidance of pain, although found to be a factor in studies of a variety of specific diseases, is not as common as one might imagine.

Social risk factors

Social risk factors for suicide in old age have been found to include: isolation and poor social integration; lack of a person to confide in; and concerns over dependence or a move from home to residential care.[13,18–20] Bereavement by itself is no more of a risk factor in older than the younger suicides, but a grief reaction prolonged for more than a year has been found to increase the risk.

Risk assessment

The study of suicide at any age is primarily for the purpose of prevention. In older people this means that, episodes of deliberate self-harm need to be considered as serious, even and perhaps especially when they do not appear to be so. A quantitatively small overdose of a relatively less lethal drug is frequently no indication of the seriousness of suicidal intent. Primary care doctors should be aware of the suicide risk in those attending with physical disorders, especially where the patient's complaints seem to be out of proportion to the actual evidence of disease. Nor is the identification of a physical illness a reason to relax vigilance over suicide risk. Dismissal of an older person's wish to die as 'rational' is probably wrong in the great majority of cases, but in any case should never be done before a thorough assessment of the mental state concentrating in particular on depressive disorder. Anxiety is frequently so prominently a presenting symptom of depressive disorder in elderly people, that other manifestations, such as suicidal thinking, may be overlooked. Whilst elderly people respond well to antidepressant medication, many live alone. Thus, a prescription for perhaps a month of treatment might be an enhancement of suicide risk. It is therefore prudent either to arrange close supervision or administration of medication by a carer rather than the patient

themselves, or for no more than a week's supply to be dispensed at a time. Pharmacists may be willing to assist in this by providing proprietary boxes with compartments for each dose.

8.5.8 Sex in old age

John Kellett and Catherine Oppenheimer

Introduction

A Darwinian sees man as devoted to reproducing himself. The decline of fertility with age makes one question the biological purpose of sexuality in the senium. Is it simply the remains of a once useful behaviour, a vestigial characteristic? The fact remains that sexual interest and sexual activity, both as sources of enjoyment and as important components of pair bonding, continue among men and women even into extreme old age. However, as Alex Comfort memorably remarked, 'old people give up sex for the same reasons that they give up cycling—general infirmity, fear of looking ridiculous, no bicycle'.[1] Or, more soberly: the common obstacles to the continued enjoyment of sex in old age are illness, attitudes, and demography.

Surveys of sexuality in old age

A comprehensive discussion of surveys in this field can be found in Bouman.[2] These vary widely in their focus, setting, methods, and target age groups. The details are of great interest but only the main themes and a few illustrative examples can be described here.

Methodology

As with all surveys, one has to consider what factors influenced the selection (and self-selection) of the responders. In general, participants in these studies tend to be better educated and more liberal in their attitudes than their contemporaries; and important groups, such as people with chronic illness, may be under (or over) represented, depending on the setting of the survey.

Cross-sectional and longitudinal studies

Attempts to assess the effects of ageing on sexuality by surveying different age-groups at a single point in time are vulnerable to *cohort effects*—the sexual experience of those brought up before the Second World War is different from that of people whose childhood was in the 1950s, and need have nothing to do with age. Longitudinal studies are demanding and costly, but they reveal the effects of ageing more clearly, and they also allow individual patterns, stable over time, to be identified. For example, the series

of studies conducted at Duke University showed that although the *prevalence* of sexual interest and activity in both men and women decreases with age, *individual* patterns of sexuality tend to be stable until some event (such as illness or loss of a partner) disrupts the pattern.[3]

Sexual interest and sexual pleasure

There is more to sex than actual intercourse, especially in old age. A consistent finding is that in both sexes interest in sex is more resistant to ageing than is sexual activity, even when non-coital activity is included. For example, in a cross-sectional study of volunteer respondents aged 80 or over, living in a residential home in the United States,[4] 88 per cent of the men and 71 per cent of the women enjoyed daydreams and fantasies about sex, 82 per cent of the men and 61 per cent of the women engaged in touching and caressing, while 63 per cent of the men and 30 per cent of the women had sexual intercourse 'at least sometimes'. Janus and Janus[5] surveyed 2765 subjects in the United States by questionnaire, supplemented by 125 interviews. They found less reduction of activity in the older groups than had been found in earlier surveys, probably because they did not confine the question to coitus. In every age group men thought that they were more active than 3 years previously, but women, particularly those over 50, noted a decline. Unlike earlier studies foreplay was discussed, and the authors concluded that older men gain greater pleasure and experience more intimacy and warmth after coitus than younger men.

Obstacles to continued sexual activity

The commonest reasons given by people for a decline in their accustomed level of sexual activity were illness, and the loss of their partner.[3] Interestingly, women (but not men) also gave illness of their partner as a reason. This may reflect the traditional male role in initiating sexual activity, and also perhaps the fact that husbands tend to be older (therefore more at risk of illness) than their wives. For example, in a Swedish community study of 85-year olds,[6] participation in sexual intercourse was reported by 10 per cent of married women but only 1 per cent of the unmarried women, and by 22 per cent of married men compared to 13 per cent of the unmarried men. The rates for sexual interest (as opposed to activity) were higher: 46 and 37 per cent for married and unmarried men respectively; 24 and 15 per cent for married and unmarried women.

Attitudes to sexuality

Attitudes towards sexuality in old age—as revealed in responses to systematically varied vignettes—have become generally more positive over the last half-century, among both younger and older people.[2,7] Probably this is true also of professional attitudes, and where this matters most is among the staff caring for older people in institutional settings. The evidence suggests that care staff who are older, better educated and have had vocational training, and who have more experience of caring, are likely to be more open to the sexual needs of their residents. However as Bouman[2] points out, the same cannot be said of health policies and strategy. Government guidance on the care of older people has ignored their sexuality, and in most official surveys and policies on sexual issues, people aged 60 or more are excluded from consideration.

Demography

With increasing life-expectancy many marriages continue well into the 9th decade of one or both partners. Divorce has now overtaken death as the main cause for the ending of a marriage, though this does not necessarily mean increasing numbers of people left single in old age. Many older people experience second or third marriages (or cohabitations), and the age gap between the partners in these new relationships tends to be larger than that between partners still in their first marriage. The complex effects on family structure of these different social trends are analysed by Harper.[8] She shows that married older people have higher levels of health, social participation, and life satisfaction than those not married, and they live longer; while divorced men (compared to women, and to widowers) are the most disadvantaged in those respects. To this we can add (based on the survey data mentioned above) that in old age married people also enjoy greater opportunities than the unmarried for sexual expression.

Sexual orientation

Much less is known and written about the sexual lives of older people who are not heterosexual in their orientation. Despite the prevailing trend in Western societies towards valuing diversity, most older homosexual people in their earlier lives will have feared—or faced—stigma, discrimination, even the threat of criminal procedure, and may still face such discrimination. Further discussion of this important group of people can be found in Bouman.[2]

Sexuality and dementia

The effect of dementia on sexual interest and activity is unpredictable. Most often it is associated with a decline in interest, but sometimes (probably in less than 10 per cent of cases) a person with dementia may become more sexually demanding, or may lose the ability to judge when the expression of sexual interest is unwanted or out of place.[2,9] The effect of the patient's dementia on the spouse is also difficult to predict. In some couples the physical relationship continues as an important expression of their affection, support, and concern for each other. More commonly, sexual activity declines. For example, Wright[10] followed a group of couples in which one partner had dementia, alongside a control group of couples without dementia. Only 27 per cent of the afflicted couples continued sexual contact over the 5 years after diagnosis, compared to 82 per cent of the control couples.

Patients with dementia who have altered sexual behaviour, or who can no longer make reliable judgments about potentially sexual social situations, become vulnerable to misunderstanding, exploitation, or censure. In marriages the impact of these changes is often borne alone by the spouse, who also keeps them hidden from others. But people with dementia who live alone or who go into institutional care (even if only temporarily, into hospital perhaps) are not so protected, and clinical staff may be asked to intervene—to control behaviour that has offended or is harmful to others, or to reduce risk to a vulnerable patient. It may be crucial to establish whether such a patient is making an autonomous choice (for example, to engage in sexual contact with a fellow resident) or whether their failure of understanding is being exploited; and Lichtenberg and Strzepek[11] describe a helpfully structured approach to this question.

Normal sexual function in old age

The normal human sexual response cycle and the physiology of sexual intercourse are described in Chapter 4.11.1 in this textbook. These descriptions hold true for sexually active older people, although age does bring some relatively minor physical changes (see Table 8.5.8.1, based on data from Masters and Johnson[12])—changes experienced by some but not necessarily by all. The most noticeable of these are probably the much longer refractory period in older men (the interval which follows ejaculation before renewed erection is possible), and the oestrogen-dependent changes in vaginal tissue and lubrication in older women. However, according to the self-reports of older sexually active people, the capacity for sexual pleasure and the quality of orgasms are not at all affected by age.

Sexual dysfunction in old age

The range of sexual dysfunctions is discussed in detail in Chapter 4.11.2 in this textbook. In old age, as mentioned earlier, physical illnesses and their treatments assume increasing importance in curtailing the normal sexual activity and interest of an established couple. Likewise, with ageing, the balance between psychological and physical factors in the causation of a sexual problem, tips towards the physical. An example of this is erectile dysfunction, where a notable increase in research into the physiology of penile erection has led to a number of effective physical treatments, especially relevant to erectile problems associated with illnesses common in old age (such as diabetes and vascular disorders).[13,14] However, a clearer understanding of the physical components of a problem does not diminish the importance of psychological factors. Myocardial infarction, probably accompanied by hypertension and atherosclerosis, provides a good example. After the infarction the couple may misperceive the breathlessness of orgasm as cardiac distress, and they may need encouragement to resume sexual relations which may reduce the risk of further infarction.[15] Even a hospital admission interrupts the couple's sexual routine which may then be difficult to resume.

Some of the most common physical causes of sexual dysfunction are listed in Tables 8.5.8.2, 8.5.8.3, and 8.5.8.4.

Table 8.5.8.1 Physical changes of ageing

	Male	Female
Retained	Nil	Nipple erection Clitoral tumescence and retraction
Reduced	Penile and nipple erection Testicle elevation Power of ejaculation Rectal contractions	Vaginal lubrication and expansion Uterine elevation Bartholin gland secretion Orgasmic contractions
Lost	Flush Scrotal swelling Re-erection Ejaculatory inevitability Prostate contractions	Breast engorgement Flush Swelling of labia majora
Other	Refractory period >24 h	

Table 8.5.8.2 Medical factors affecting sexual function

Drugs reducing sexual drive	Drugs reducing testosterone	Drugs blocking physical arousal
Dopamine antagonists	Digoxin	Thiazide diuretics
Major tranquillizers	Cimetrdine	Some β-blockers
Metaclopamide	Cyproterone	
5-HT_2 agonists–SSRIs except nefazodone, trazodone, fluvoxamine	Finasteride	
Benzodiazepines	Oestrogens Progesterone	

Treatment of sexual problems in old age

The treatment of sexual dysfunction is founded on a comprehensive understanding of the problem. It begins with listening. Perhaps this is a statement of the obvious—except that the emotional power of sexuality makes it hard for patients and their partners to speak about sex, and for others to listen properly. Sexual histories are rarely taken as a routine part of the assessment of older people,[2] and even when patients disclose a sexual problem, their doctor may shrink from embarking on an exploration of the difficulty. Yet there is good evidence that opening up communication about a sexual problem—not only between clinician and patient but also (helped by the clinician) between sexual partners—forms a large part of successful treatment, and sometimes may be all that is needed. Even patients attending a specialized clinic may be satisfied by receiving assessment and information, without necessarily wanting active treatment.[13]

Sexual problems come to the notice of many different medical and surgical specialties (gynaecology, urology, genitourinary medicine, diabetology, endocrinology) who have expertise in the physical treatments now available, and sometimes also in the psychological and relationship components of the dysfunctions that they treat. In other cases the psychiatrist may be helping the couple to work with a physical treatment that one of them is receiving, and to make the most of the improvements in sexual function that it offers.

Behavioural treatment for sexual dysfunction, first described by Hunter,[16] was developed by Masters and Johnson.[17] Their *Sensate focus exercise* (see Chapter 4.11.2) is a simple behavioural technique that can be very effective in helping couples in whom sexual intercourse has become (for whatever reason) difficult, painful, or disappointing, and who have then retreated from all pleasurable physical contact with each other. In this technique attention is removed from intercourse (in fact intercourse is forbidden), and instead the focus is put on renewing the partners' pleasure in mutual touch and caressing for its own sake.

Table 8.5.8.3 Surgical procedures affecting sexual function

Transurethral prostatectomy leads to retrograde ejaculation
Pararectal surgery damages nervi erigentes
Indwelling catheters and pessaries
Mutilation affecting body image
Surgery to genitalia

Table 8.5.8.4 Diseases affecting sexual function

Diabetes
Myxoedema, pituitary tumours
Neurofibromatosis, paralysis, myotonia dystrophica, autonomic neuropathy
Peyronie's disease
Malignancy and infections of genitalia and prostate, vaginal fistulas
Liver failure leading to higher oestrogens
Arthritis
Hypertension, vascular diseases, myocardial infarction
Respiratory distress
Depression, schizophrenia, cortical dementias

There is little scope for pharmacological treatment of most sexual difficulties arising in old age, other than erectile dysfunction.[13,14] Hormonal treatments are no longer thought to be helpful except where deficiencies have been clearly demonstrated. The commonest hormonal treatment in old age is probably the use of oestrogen (topically) in dyspareunia. Treatment of hypersexuality and sexual aggression in the context of dementia is difficult: pharmacological methods have been reviewed by Series and Degano.[18]

Conclusion

Ageing brings increasing diversity. This certainly applies to sexual behaviour. Those who work in the field of old age psychiatry can help their patients by understanding this diversity, making it safe and acceptable for patients to talk about whatever sexual concerns they have, and helping them in the acquisition of all the information they need. Sex in old age is not the frightening imperative of the teenager, but it can still contribute greatly to the quality of life.

8.6

Special features of psychiatric treatment for the elderly

Catherine Oppenheimer

Introduction

Three themes underlie the topics in this chapter.

Old age is a time of multiple problems

Physical, psychological, and social problems often occur together, linked by chance or causality in the life of the old person. Very rarely can one problem be dealt with in isolation, and many different sources of expertise may be engaged with a single individual. Therefore good coordination between different agents is essential in old age psychiatry, both for the individual patient and in the overall planning of services.

Clear boundaries between 'normality' and 'disease' are rare in old age

Many of the pathologies characteristic of old age are gradual in onset and degenerative in nature, and more due to failures in processes of repair than to an 'external foe', so the distinction between disease and health is often quantitative rather than qualitative. 'Normality' becomes a social construct with fluid borderlines, containing the overlapping (but not identical) concepts of 'statistically common' and 'functionally intact'. Thus the popular perception of normal old age includes the 'statistically common' facts of dependence and failing function, whereas 'intactness' (excellent health and vigorous social participation) is seen as remarkable rather than the norm. But the boundaries of 'old age' are also socially constructed—in developed countries good health at the age of 65 would nowadays be regarded as a normal middle-aged experience, whereas superb health at 95 would still be something noteworthy.

Since some degree of physical dependence, forgetfulness, and vulnerability to social exclusion is expected in old age, meeting those needs is also regarded as a 'normal' demand on families and community agencies such as social services, rather than the responsibility of health care providers. As the severity of the needs increases, however, so also does the perceived role of health professionals, both as direct service providers and in support of other agencies.

Lack of competence is common in old age

Because of the high prevalence of cognitive impairment in old age (especially among the 'older old'), questions frequently arise as to the competence of patients to make decisions. Older people who cannot manage decisions alone may come to depend increasingly on others for help; or, resisting dependence, they become vulnerable through neglect of themselves or through the injudicious decisions they make. When an incompetent person is cared for by a spouse or family member, the danger of self-neglect or of ill-considered decisions is lessened, but instead, there are the risks of faulty decisions by the caregiver (whether through ignorance or malice), and also risks to the health of the caregiver from the burden of dependence by the incompetent person. Legal mechanisms, differing from one country to another, exist to safeguard the interests of incompetent people.

These three themes will be developed further, and with them the following special topics:

1 multiple problems: including sleep disorders in old age, medication in old age psychiatry, and psychological treatments in old age psychiatry;

2 blurred boundaries of normality: including the role of specialist services and support between agencies;

3 incapacity and dependence: including balancing the needs of patients and caregivers, abuse of older people, ethical issues, and medico-legal arrangements for safeguarding decisions.

Multiple problems

Sleep disorders in old age

Useful reviews of this topic may be found in Anconi-Israel and Ayalon,[1] Sivertsen and Nordhus,[2] and Mosimann and Boeve.[3] More detailed general discussion of sleep and its disorders will be found in Chapters 4.14.1–4.14.4 of this textbook.

(a) Normal changes with age

With age, the architecture of sleep changes—in fact, most of the change occurs before the age of 60. Sleep is divided into shorter periods interspersed with wakefulness or brief arousals, there is a decrease in total sleep time and in sleep efficiency (the ratio of time asleep to time in bed), and there is less stage 4 (deep) and more stage 1 and 2 (shallow) sleep, without an increase in the proportion of rapid-eye-movement (REM) sleep. This change in sleep architecture is conventionally associated with changes in circadian rhythms with age, such as decreased amplitude and phase length of these rhythms (but see Monk[4] for a critical review).

Many people adapt to these changes, but others find the altered pattern distressing. Thus the borderline between normal and problematic sleep is blurred, because subjective assessments of sleep quality are not necessarily matched by objective measures (such as polysomnography); consequently the definition of 'insomnia' hinges not only on features of night-time sleep, but on impaired functioning in the daytime.

(b) Comorbidity

The majority of healthy older people have no complaints about their sleep, but there is a strong association between poor sleep and other health problems, and sleep problems make a material contribution to the impaired quality of life suffered by people with comorbid illness. In a study of patients in primary care,[5] a positive answer to even one question about sleep ('do you feel excessively sleepy during the day?') predicted the quality of life related to physical or mental health problems. Attention to improving sleep in these patients can improve their well-being, but too often the sleep problem is missed in the general assessment of the patient. Impaired sleep can have serious consequences: it is associated with symptoms of anxiety and depression, an increased risk of falls, and diminished memory and cognitive functioning.[1]

(c) Causes of disordered sleep

These include the following:

1 **Environmental causes**: e.g. a strange bed, noise, cold or heat, or loss of a familiar bed companion (e.g. through bereavement).

2 **Physical causes**: sleep can be broken by pain, stiffness (e.g. Parkinson's disease or arthritis), limb movement (restless legs syndrome, periodic movements of sleep), breathlessness (cardiac failure or sleep apnoea), the need to urinate (prostatic disease or urinary tract infection), eating too close to bedtime, or dehydration (e.g. voluntary restriction of fluids to prevent nocturia).

3 **Medication**: alcohol, especially if taken to relieve anxiety or to assist sleep (since the rapid metabolism of alcohol leads to rebound anxiety and wakefulness), and antidepressants such as selective serotonin reuptake inhibitors (**SSRIs**) can cause wakefulness or nightmares. Information on the numerous other medications which may impair sleep can be found in Anconi-Israel and Ayalon.[1]

4 **Psychological causes**: for example, anxiety, depression, hypomania, and paranoid illness. Often a sleep problem is triggered initially by a physical cause, but is then maintained by the patient's anxiety about wakefulness.

5 **Sleep in dementia**: changes in sleep rhythm in dementia are similar to those of normal old age, but often more severe: daytime drowsiness or napping, difficulty in falling asleep at night, decreases in slow wave sleep and in rapid-eye-movement sleep. However, another common cause of sleep impairment is the use of benzodiazepines or major tranquillizers to treat behaviour disturbances: the patient may end up drugged in the day and wakeful at night. A partial remedy may be to create an overriding diurnal rhythm (e.g. by attendance at day care or a programme of physical activity in the day), together with the minimal use of medication at night. Patients in institutional care are particularly likely to be deprived of the normal cues for circadian rhythms: quiet and darkness at night, bright daylight in the morning, and physical activity in the day. On the other hand sleep time may be strikingly increased in dementia, especially in vascular dementia where it may be part of the apathy that is common in that disease.

(d) The parasomnias

The parasomnias that are common in old age are obstructive sleep apnoea (or sleep-disordered breathing); restless legs syndrome and periodic limb movements in sleep; and REM sleep behaviour disorder (RBD). They may range in severity from troublesome to severely disabling, and accurate recognition is important for all of them, because of the consequences both to the patients and to their bed partners if their diagnosis and treatment are missed. Further details can be found in the sources mentioned above,[1,3] but RBD warrants some further discussion here. This disorder is defined as an 'intermittent loss of the muscle atonia normally present during REM sleep, and episodes of elaborate motor activity associated with dream mentation'.[6] Typically, in the early hours the patient (usually male) shouts, thrashes around, and may attack his bed partner, without waking, and without any recollection of the episode when he does wake later. The importance of this condition lies in the fact that it is very distressing, and possibly dangerous, for the bed partner; it can often be treated effectively (with clonazepam); and it is strongly associated with the development (sometimes after a very long latent period, of a decade or more) of neurodegenerative disease—especially Lewy body dementia, Parkinson's disease, or multisystem atrophy—the alpha-synucleopathies.[6,7]

(e) Management of sleep disorders

(i) Psychological methods

These are now the methods of choice with insomnia in older adults.[2,8] Trials comparing psychological with pharmacological treatment, and with a combination of the two, show equivalent effects in the short-term, but a longer-term advantage to the psychological methods. More importantly, it has also been shown that in secondary insomnia ('insomnia occurring when a psychiatric condition, a medical condition, a non-insomnia sleep disorder, or a medication appears to precipitate and then appears to maintain insomnia') it is not necessary to wait until the primary condition has been resolved: the insomnia can usually be effectively treated in its own right, and even if it is not completely cured, valuable improvements can be achieved.[8] Likewise, psychological methods can be used to help in withdrawing medication in hypnotic dependent insomnia.[9]

The methods used have generally been 'multicomponent behavioural treatments'. The components include:

- Relaxation training
- Stimulus control (requiring the patient to leave the bedroom if they are not sleeping)
- Sleep restriction and sleep compression (using a fixed time for getting up, progressively shortening the time in bed until it matches the time asleep)
- Cognitive restructuring (modifying the pre-sleep thinking patterns, which in insomnia usually include negative thoughts about the effects of sleep loss, and the use of worry and self-blame as an attempted strategy for controlling thoughts[10])
- Sleep hygiene education (advice on the effects of tea, coffee, exercise, etc on sleep)

Such treatment packages need not be dependent on sources of specialist expertise: Sivertsen and Nordhus[2] discuss the feasibility of treating insomnia psychologically within primary care.

(ii) Treatment of sleep problems in dementia

When cognitive impairment makes psychological treatment difficult, pharmacological treatment may be necessary. Benzodiazepines (probably temazepam for preference) must be used very cautiously; they are dangerous in ambulant patients, though less so for a patient who is no longer mobile. Sedating antidepressants (e.g. trazodone) can be used instead. An atypical antipsychotic may be appropriate if there is severe anxiety and suspiciousness (sometimes of delusional intensity) of the carer at night.

The sleep problems of the carer of a patient with dementia also need to be taken very seriously. The carer may benefit from the psychological measures outlined above, and can institute some of the measures (such as sleep hygiene) on behalf of the patient. Insomnia in a caregiver, caused by the wakefulness of the person cared for, can lead to rapid breakdown of the support system. If the patient's sleep problem cannot be resolved then it is essential to give the carer the opportunity for uninterrupted sleep at times, through arranging residential respite care, a night-sitter, or some other form of relief.

The use of medication in old age psychiatry

Specific uses of medication for the various psychiatric disorders occurring in old age are dealt with in the relevant chapters. Here, three general principles will be discussed:

- medication as an experimental trial
- stopping medication
- compliance and concordance.

(a) Medication as an experimental trial

Starting medication for any condition ought to be treated as the test of a hypothesis. There should be a plan, shared with the patient, setting out the following:

1 how long the trial will last before a decision is made that the treatment is unsuccessful and should be ended;

2 which target symptoms will be monitored, and what records should be kept (by the patient or caregiver);

3 when progress will be reviewed;

4 what side-effects might be developing and which of these should alert the patient to stopping the drug and contacting the doctor;

5 what will follow if the trial succeeds;

6 what will be tried instead if the trial fails.

This watchful approach to medication is particularly important for people with dementia. Often the patient's confusion, lack of insight, and communication difficulties mean that a tentative diagnosis has to be based on scanty information. For example, disturbed behaviour in a patient in a nursing home may be due to depression, but the patient cannot describe the depressive symptoms. Clues to the diagnosis may come from the care staff (e.g. 'She never jokes with us now'), and an empirical trial of an antidepressant may result in a resolution of the symptoms. However, the trial must be set up carefully and medication not thoughtlessly continued for months without review, merely because no one has asked whether it is helpful or not.

(b) Stopping medication

The decision to withdraw medication can be as valuable and informative as the decision to start it, and documentation of the reasons for the decision is equally important (though often neglected). In delirium, medication may be contributing to the problem, particularly where a cocktail of medications has been built up over time—improvement after withdrawal of a drug gives valuable guidance for a future episode. Also, patients reaching the terminal stages of dementia should have their medication gradually decreased, to test whether it is still needed: drugs prescribed at an earlier stage to control behavioural syndromes are rarely, if ever, required for the entire course of the disease.

However, there are also reasons for being cautious about stopping medication. Some drugs have important withdrawal effects (e.g. paroxetine and benzodiazepines). Medication that has been used prophylactically may seem to be unnecessary while the patient is well, but when the drug is withdrawn the need for it is revealed. For example, a patient can remain well for years on an antidepressant following a severe depressive episode, or on a low dose of antipsychotic after a schizophrenic illness—until well-intentioned withdrawal of the drug, however carefully monitored, precipitates the return of the illness.

(c) Compliance and concordance

The word 'compliance' appears to imply that patients must be obedient in following instructions; but nowadays patients are seen more as partners in their own treatment, for which the word 'concordance' (when the partnership is successful) is more apt. The same principle of partnership in treatment decisions applies to older people, wherever possible. However, in addition to willingness to participate there needs to be the ability to do so, which in older people is often impaired by physical causes (such as arthritic hands which cannot open child-proof packaging, or poor vision which misreads instructions), and by psychological causes, especially memory loss and temporal disorientation. Therefore patients will often need help in maintaining their concordance with treatment, through suitable packaging and memory aids (such as calendar boxes), or through supervision or administration of the tablets by others. Families may take a long time to notice that their parent or grandparent, who has taken medication reliably for years, has started to miss or duplicate doses.

It is important to understand the feelings of a caregiver who takes responsibility for the medication prescribed for a patient with dementia, especially where it is being used to control behaviour. Anything prescribed on an 'as-needed' basis should be very carefully explained. The caregiver may be afraid of provoking the difficult behaviour by offering the medication, or conversely of overdosing her relative into stupor, or she may feel guilty about meeting her *own* needs by giving drugs to another. Such feelings make it hard for a caregiver to judge objectively when discretionary medication should be used.

Psychological treatments in old age

Many older people prefer a 'talking treatment' to medication, and there is increasing evidence of the success of psychological interventions with cognitively intact older people.[11] Brief focused interventions are particularly suitable.

However, even mild cognitive impairment, too slight to amount to dementia but enough to interfere with grasp and retention, may hamper psychological treatment. For example, such a patient being treated psychologically for anxiety may try hard to cooperate with her therapist, only to be made more anxious as she fails to remember the instructions, or to put them into practice, and so the sense of failure she feels elsewhere in her life is reinforced.

The principles of supportive psychotherapy and problem-solving are always relevant, both on their own or in conjunction with medication: providing 'unconditional positive regard' for the patient; accepting a degree of dependence by the patient, while limiting its consequences; setting appropriate expectations so that the patient is not unnecessarily exposed to a sense of failure; openly facing realities that cannot be altered (such as loss, disability, and death); helping to think through practical problems as they arise.

Family and systems therapy[12] has a particular role in old age psychiatry, because it explicitly recognizes the patient in his or her social context. Although family therapy requires special training, the principles of a family approach can be adopted by all those working with older people.

When patients are cognitively impaired, psychological approaches generally focus more on the interaction between the patient and the caregivers, who can be helped to understand the patient and the reasons for her behaviour, as well as their own actions and the reciprocal effects that these have on her. For example, reminiscence therapy helps professionals to respond to patients as 'whole people' with individual lives, as well as helping patients to reconnect with their former identities, and to recover some of the confidence they took for granted in the past.

Therapies based on music, dance, drama, art, and sensory stimulation are also important in old age.[13] They can help patients, individually or in groups, to express feelings and thoughts, bypassing the impairments of verbal skills which come with dementia.

The blurred boundaries of 'normality'

We consider two examples of the way in which 'normality' is not clearly defined in old age.

First, social expectations allow for increasing dependency in the old, and many people have personalities better suited for protective relationships than for solitude and independence. People who have struggled with anxiety and loneliness in middle age can experience the onset of physical dependence as a kind of relief: now they can allow themselves to be looked after. What was a dysfunctional personality structure in earlier life becomes adaptive in old age. In contrast, the person who has always jealously guarded his or her personal boundaries will find the adjustment to disability very hard. Determined refusal to accept necessary help converts a 'normal' preference for independence into a problem for others.

The second example concerns the idea of death. For a younger person to say that they were waiting for death would prompt a psychiatrist to look for evidence of a depressive illness. In old age this way of thinking may be found in someone with no disorder of mood, with the ability to enjoy life, and with a rational appreciation of life's inevitable limits. But even in old age, to see nothing valuable in one's future might be a sign of depression.

The role of specialist services and cooperation between agencies

This topic is dealt with more fully in the succeeding chapter (see Chapter 8.7).

The difficulty in separating the normal from the pathological, and in deciding when specialist intervention is required, is reflected at a structural level in shaping the responsibilities of the different bodies involved in the welfare of older people. Help required by older people can range from the simplest of neighbourly assistance to the full resources of specialist hospital care. As people live longer, despite some morbidity, the demand for care increases. The response to this demand is shaped by many different factors: market forces, public concern, private enterprise, voluntary or charitable groups which spring up to fill perceived gaps, and governments acting to remedy abuse or to limit demand on state-funded services. The divisions of responsibility are arbitrary, and people fall between services as often as within them. Systems change. For example, in the United Kingdom older people with permanent disability (especially dementia) used to be cared for in state-funded hospitals, but this care has now become the responsibility of independent-sector nursing homes, with means-tested financial support from the social security system.

The scope of specialist services for older people extends beyond the treatment of established illness. They have a role in the prevention and early detection of illness, in supporting and educating other service providers and in collaborating with other agencies in strategic planning. This span of interest can be represented as a pyramid (Fig. 8.6.1). The peak of the pyramid represents those requiring the scarcest and most intensive specialist services, and the base represents the population at large. In the middle are the people who need day care, support at home, social support, and help in primary care.

Between a population base of, say 20 000 older people and an inpatient provision of, say 10 beds lies the range of people to whom psychiatric services can offer significant help without assuming total responsibility for care. It is essential that the different agencies interact effectively and overlap their care, rather than leaving patients to negotiate their way from one island of provision to another.

Key components of such a 'mixed economy of care' should include:

1 A system for prompt and accurate assessment of people's needs which leads to offers of appropriate help, including reassessment. Assessment for specialist psychiatric care should be both 'generic' (using the skills that all disciplines share) and specific (using the particular skills of medicine, nursing, occupational therapy, etc.).

2 A clear understanding by staff working in the various agencies of what their tasks will be, and good training that will allow them to carry these out with confidence and satisfaction. When non-specialist care breaks down, it is usually because the carer do not expect to have to deal with the problem which faces them.

3 Systems ensuring that people are not obliged to make frequent and abrupt transfers between one setting and another as their disabilities increase. Assessment must therefore include prediction of future need; and each provider should offer a degree of

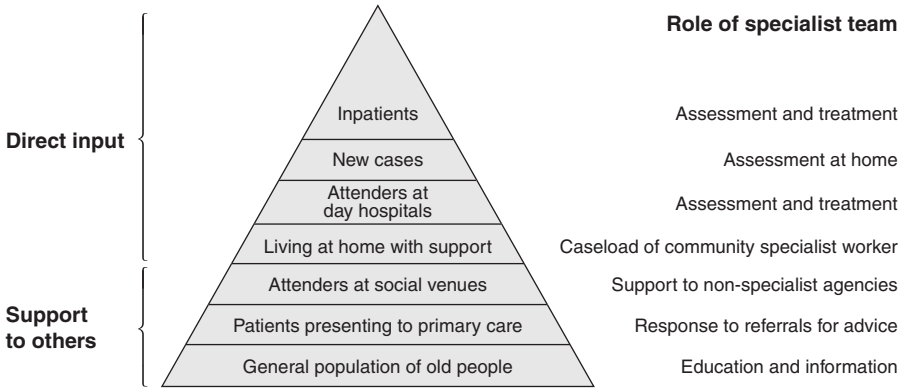

Fig. 8.6.1 The span of old age psychiatry services.

flexibility, to encompass people who will soon need what they provide, and others whose needs are greater than the norm. For some people, a change of setting as their condition progresses—for example, from a sheltered flat to care in a nursing home—will be inevitable, so care systems must have ways of making transitions as smooth as possible.

Loss of capacity and dependence on help

Mutual helpfulness is an accepted part of marital and family relationships. Family members often adapt unquestioningly to an older person's increasing dependence until the emotional pressures, or the adjustments they have to make in their day to day lives, become severe.

The 'needs of caregivers' are part of the currency of discussion amongst service providers. But people in everyday life do not necessarily perceive themselves that way: they think of themselves as simply participating in a normal aspect of family life. Younger people who have duties to their work, partner, and children—duties which conflict with the needs of their parents—may be readier to seek professional help than are the ageing spouses of a failing partner. Spouses often view caring as an intrinsic part of their lifelong relationship, and may resent offers from outside as an intrusion upon their privacy.

On the other hand, relationships can have malign as well as protective aspects, and sometimes the dependent partner in a caring relationship suffers more disadvantages than benefits. In extreme cases, abuse can occur.

Abuse of older people

This is much better understood now than a few decades ago, although systematic study is difficult because of the varieties of abuse or exploitation that arise, the ambivalent relationships that surround them, and the concealment often practised by abusers and victims alike.[14] Abuse can occur in any circumstances, any class, and any relationship, from blood ties and friendships to professional and commercial relations. Nevertheless pointers to risk have been identified (Table 8.6.1).

Typically, the victim is disabled, often but not always with a dementing illness, perhaps with impaired communication, and is unrewarding to look after. Typically, the abuser is also impaired in some way, isolated from support (often by refusal rather than the absence of offers of help), and may abuse alcohol. There may have been a long history of ambivalence or of mutual aggression between abuser and victim, or the victim's illness may have reversed a power relationship that previously operated (damagingly) in the opposite direction. The intention of the abuser is sometimes clearly to do harm. In other cases the abusive behaviour seems to be an impulsive response to emotional pressures which the abusers are poorly equipped to deal with because they do not understand them properly, do not know how to share the burden with others, or are overwhelmed by the patient's need for care. The abuse may range from a single assault by a caregiver, who is immediately horrified by what he or she has done, to systematic cold-blooded persecution. Abuse may be physical, emotional, psychological, sexual, or financial.[15]

Where harm to a vulnerable person is suspected, there is an obligation to report it to the appropriate authority—in the United Kingdom, the local social services. Sometimes they in turn will involve the police and a criminal prosecution may follow. But frequently the problem can be dealt with in other ways, such as arranging a different form of care for the vulnerable person. The emphasis will be on reducing and managing risk, and on enhancing

Table 8.6.1 Some risk factors for abuse in old age

Victim	Abuser	Relationship
Female	Family member in caregiver role	Previous relationship – not close, ambivalent, mutually abusive
Aged over 75	Psychiatric history	Role reversal
Physically dependent	History of abuse as a child	Power reversal
Cognitively impaired	Substance misuse	Lack of problem-solving skills in the relationship
Socially isolated (lacking external support)	Financial dependence on victim	Forced proximity
Sensory impairment	Dependence for housing on victim	Mutual dependence
Incontinence	Overburdened by caregiver role	
Abusive or unrewarding to caregiver	Unsupported, or rejecting support	
Ready to adopt sick role

the quality of life of the person concerned. Difficult ethical issues arise when an elderly couple both suffer from dementia and one of them (often the husband) insists on continuing to care alone for his wife, unaware of the loss of his competence to do so. For a time, professional staff will try to support both partners in their wish to remain together at home, and to mitigate the effects of the inadequate care by the husband. But at some point the professional duty may need to shift from supporting, to taking over legal responsibility for the neglected person—though the displacement of the caregiving spouse in this way is distressing for everyone concerned.

Ethical problems in old age psychiatry

The same classical principles of bioethics (beneficence, non-maleficence, autonomy, and confidentiality)[16] apply in old age psychiatry as in other age groups, but with differences in emphasis.[17] Since older people can rarely be considered in isolation, ethical principles have to be applied with the whole system in mind, and professionals often have ethical obligations to more than one person at a time.

(a) Values

In old age, as in youth, we should seek to produce benefit and not harm—but identifying which of these is which may be more difficult in old age. Death is usually thought of as harm, but sometimes may be regarded as a blessing. Therefore it is essential to understand what the patient, rather than the professional, sees as beneficent, and the patient's right to name the value that they set on something must be respected. Some older people would prefer their assets to go to their descendants rather than being spent on their own care at the end of their lives—but the state sets limits to such self-denial.

(b) Ambivalence

Impairments of thinking and communication can complicate ethically observant professional practice. People of all ages may have ambivalent feelings, or say things which seem belied by their actions, but this is particularly common among older people with cognitive impairment. Perhaps memory failure causes decisions to be swayed by feelings of the moment, so that decisions are not consistently maintained; and cognitive difficulty in marshalling complex information means that weighing alternative possible outcomes to a decision is much harder.

An illustration may make this clearer.

Case study: A woman with early cognitive impairment lives alone in the house where she brought up her children. She loves her house and garden, and tells her daughters that she never wants to live anywhere else, and she is convinced that she needs no help from them. At night, however, she becomes anxious and confused, and telephones her daughters, asking them why they 'haven't come home yet' and begging them not to abandon her.

Does the night or the day reveal her 'true wishes' better? Which should guide the decisions of her family, and of the professionals whose help they seek? Possibly, her considered daytime thoughts and her anxious actions at night are tapping different areas of her experience—the daytime communication reflects her aspirations and her lifetime self-perception, while her telephoning at night reflects the immediacy of her feelings and needs. Our duty is to give weight to both kinds of communication, helping the patient herself to understand what they mean, and to offer her the real-life opportunity (rather than theoretical discussion) of testing out the options she needs to consider.

(c) Giving information and safeguarding information

Ethical obligations here include truth telling, giving information to patients about themselves, and protecting patients' information from others.

'Loss of insight' is a feature of dementia, but good insight is also dependent on sound information. A person who is making significant errors, or beginning to fail in self-care, should not be left in ignorance of what is happening to them. In fact, public knowledge nowadays about Alzheimer's disease is so much greater that sufferers often recognize the early signs themselves. They are entitled to an open discussion with their doctors, in which full information is put before them. (Relatives often shy away from such open disclosure, although when asked in surveys what they would wish for themselves, they tend to say that they would rather be told).

When it comes to disclosing information about a patient to the people involved in his or her care, the arguments are different. It is generally accepted that better care must depend on the best information, and it is normal for information to be shared between members of a clinical team, where the members share also in the duty of confidentiality to their patient. But in old age it is harder to know where to set these boundaries—both as regards information that should be protected, and as regards recognition of who is a team member. For example, senior staff in some residential homes, strictly preserving confidentiality, may not share information about the residents with the untrained care staff. However, if they know nothing about a resident's former life, caregivers will tend to respond to her as 'a bundle of needs' rather than as a real person; and if she cannot tell her own story, others must do it for her. This is much better recognized now than it used to be, and homes may ask families to construct a diary or album of a resident's life, with photographs, mementos, and recollections by different relatives. The diary also acts as a memory prompt and trigger for enjoyable conversations between resident and caregiver, and it creates a domain of shared information about individuals within the institution.

(d) Autonomy

Healthy people strongly value the freedom to make their own decisions, to pursue their own aims, and to determine the course of their own lives. The onset of a physical illness may constrain this freedom, but people should still have as much influence as possible over decisions about their illness and its consequences.

Psychiatric disorder is different, because it may affect the powers by which that freedom is exercised, and may lead to decisions which would never have been made in health. From this comes the need, universally recognized although taking different legal forms in different countries, to set external controls over the decisions of people when they are mentally ill. Such legal controls are typically based on acute functional illness as the paradigm case. This gives them an 'all or nothing' character, envisaging hospital treatment of an illness capable of being relieved, so allowing patients to resume their autonomy when they recover their health.

This legal model is not really suited to cognitive impairment and its effect on decision-making in old age. The illness will not get better,

and patients are unlikely to give (as they might with an acute illness) later 'retrospective informed consent' to the treatment. The emphasis therefore has to be much more on **minimal necessary interference**—on setting up protective frameworks, in which as much autonomy as possible can be exercised; on supporting patients at home or in homely settings, rather than bringing them into a hospital where no effective treatment can be given; and on gathering the information (both from patients and from those who know them best) which will enable professional decisions to reflect the wishes that the patient would have expressed, had they been able to do so.

Looking after cognitively impaired patients requires us to try constantly to maximize the opportunity for autonomous decisions, while also being very clear when a patient lacks the capacity to engage with a more complex issue. At such times, the responsibility for the decision must be openly and seriously taken by others. Trying to circumvent the problem by concealment and persuasion is a greater affront to autonomy than is an honest explanation to the patient of the reasons why a decision has been taken out of his hands.

Medico-legal issues

'Doctors and lawyers have common responsibilities to ensure the protection of people who are incapable of deciding matters for themselves, and to promote the choice of those who can and should regulate their own lives. The careful assessment of whether individuals have or lack capacity is essential to protect their rights'.[18]

The legal framework in England and Wales for both financial and welfare decision-making where capacity is in doubt has been transformed by the Mental Capacity Act 2005, which came into force in April 2007. Some general principles of the Act are worth discussing here: more detail can be found in Lush.[19]

'Capacity' is a legal rather than a medical concept (see Chapter 11.1). Every adult is presumed to have full capacity, and a loss of capacity must be proved in relation to the particular decision being made: capacity is 'decision-specific'. For example, a person may *have* the capacity to choose another person to act for her in the management of her affairs, while *lacking* the capacity to manage those affairs herself. Although the final decision on capacity is made by the courts, they look to doctors to advise on whether a mental disorder has affected the individual's ability to make a particular decision or to carry out a specific task.

(a) Assessing capacity

The Act states that a person lacks capacity if ' . . . he is unable to make a decision for himself . . . because of an impairment of, or disturbance in, the functioning of the mind or brain'. Such a person lacks capacity in relation to a particular decision if he cannot:

- understand the information about the decision
- retain the information
- use or weigh the information in the process of making the decision
- communicate the decision

The information that he must understand should include the consequences of deciding one way or another, and of making no decision. The information must be retained only for long enough to allow a decision to be made, therefore memory loss does not automatically remove capacity. The focus of this test of capacity is on the *process* of decision-making: the Act explicitly states that 'a person is not to be treated as unable to make a decision merely because he makes an unwise decision'.

(b) Acting on behalf of a person who lacks capacity

Anyone acting on behalf of an incapacitated person must do so in the 'best interests' of that person. The action or decision in question should be delayed if there is a chance that the person may regain capacity; every effort should be made to enable them to participate in the decision-making process; the decision-maker should take into account the person's past and present wishes, beliefs, values, and feelings, especially any that had been written down when they had the capacity; the views of families, carers and anyone else interested in their welfare should be sought; and the least restrictive method for achieving the intended purpose should be chosen. The obligation to act in a person's best interests, and the protection from legal liability if they do so without negligence, extends to anyone carrying out acts of treatment and care, such as physical assistance, doing shopping, giving medical treatment, or nursing care.

(c) Lasting power of attorney

A person with capacity can choose to appoint someone to act on their behalf (their 'attorney'). The power to act continues to be valid even after the 'donor' loses capacity, provided that the document giving the power has been registered with the Public Guardian (a newly created statutory office, replacing the former Court of Protection). The donor can give authority to his attorney to take both financial decisions *and* decisions relating to his health and welfare, provided that he is shown to lack the capacity to make those decisions himself at the relevant time. The attorney has the duty to act in accordance with the principles of the Mental Capacity Act 2005 and the guidance of its Code of Practice, and must act in the best interests of the donor.

(d) Advance decisions to refuse treatment

The Mental Capacity Act 2005 also provides a framework and safeguards for a person who wishes to decide in advance what treatments should be withheld if they lose capacity in future. Advance decisions to refuse life-sustaining treatment have to be explicit, in writing, signed, and witnessed.

(e) Driving

A common problem concerns the ability of older patients with early cognitive impairment to drive safely.[20] Scores on simple cognitive tests (e.g. the Mini-Mental State Examination) are very poorly correlated with driving ability, except where there is severe and obvious impairment. No quick objective test of driving skills has yet been devised. A worried but competent patient can often be reassured by booking an hour with a driving instructor. Loss of the freedom to drive represents such a loss of independence and enjoyment, and such a blow to self-esteem, that advice to give up driving may be strenuously resisted. On the other hand, families and professionals are conscious of potential risks to the public even if the patient denies these risks. Legally, the position in England and Wales is straightforward: individuals have a duty to notify the Driving and Vehicle Licensing Authority (**DVLA**) if they have an illness which might impair their ability to drive. A doctor must tell the patient who has such an illness that they are under an

obligation to inform the DVLA; if it seems that this advice has been ignored, the doctor has an obligation to inform the DVLA himself—the duty of confidentiality is overruled by that requirement. Thereafter, the DVLA will arrange for the patient to receive an independent medical examination, and it is the DVLA which decides whether the driving licence should be withdrawn. If the patient fails to attend the medical examination (whether through forgetfulness or lack of insight), the licence is automatically withdrawn.

The planning and organization of services for older adults

Pamela S. Melding

Introduction

When does an individual become an older adult? When they show signs of ageing? When they retire from work? When their health becomes frail? When they feel old? When society says they are old? Any of these indicators could define an 'older person' anywhere between 40 and 90 plus years! However, it was for statistical simplicity that many jurisdictions chose the chronological age of 65 to mark the change in status from mature adulthood to 'older person', mainly to establish an age for expected retirement and entitlement to certain benefits, including access to geriatric health services. When this arbitrary discriminator was instituted in the mid-twentieth century, 70 years was a good lifespan for most people. However, over the past 50 years, life expectancy steadily increased and is currently advancing at 6 weeks per annum, boosting the overall number of adults over 65 years and, particularly the over 80 years cohort.[1] Increasing life expectancy, due to improved health care and lowering birth rates, is causing worldwide 'population ageing'. This phenomenon will affect all health and mental health services in future years.

Already, health care resource and cost implications of population ageing for health services are enormous. Older adults occupy about two-thirds of general hospital medical, surgical, and orthopaedic beds; they are the greatest users of primary care and prescription medicines. Internationally, late-life illness takes up a considerable proportion of government or insurance funded health care budgets. As an example of the enormous costs involved, in 2003/2004, the United Kingdom's NHS spent around 43 per cent (£16.471 billion) of its hospital and community health services budget on people over the age of 65, and the cost of community and residential care for older people was 44 per cent (£7.38 billion) of all social welfare budgets.[2] These figures will rise dramatically over the next decades.

Mental Health Services have been slow to anticipate that population ageing will also increase the need for psychiatric services for older people. In many areas of the world, services are scarce, sporadic, or sub-standard. Even in developed nations, there is considerable variation in availability from one area to another. In the past decade, practically all OECD countries have promoted policies of de-institutionalization and community-based care for the elderly, in response to rising cost pressures associated with population ageing, plus a requirement to improve satisfaction for increasingly knowledgeable and assertive consumers, by providing better quality in all health services for older adults, including mental health.[3]

The need for services for older adults

Epidemiology

Whilst most people aspire to longevity, it can be a mixed blessing. Living longer increases risk of developing chronic degenerative diseases of body and brain, which can precipitate mental illness, possibly for the first time in life. Psychiatry services for older adults see a full range of new and chronic psychiatric disorders. However, the commonest new threats to mental health in late life are affective disorders and dementia.[4] Healthy, community-dwelling older adults are generally resilient, with a prevalence of major depressive illness of about 3 per cent, but studies of people in residential care find significant depressive symptoms in 14–42 per cent,[5] and in populations over 80 years, about 40 per cent.[6] Depression occurs in 15 to 40 per cent of medical inpatients[7] and in approximately 35.9 per cent of patients in geriatric rehabilitation units.[8] Among the many aetiological contributors to mental health problems in late life, physical illness and poor health are major risk factors, particularly for depression,[9] the risk increasing with disability.[10] Co-morbid physical disorders can mask depression or impede management with psychotropic medications. Although, pure anxiety disorders reduce in late life to about 1 per cent in community-dwelling older adults, anxiety co-morbid with other psychiatric disorders, particularly depression, is more common at approximately 4 per cent. Older people with anxiety disorders are high users of health care resources and may initially present with physical symptoms.[11] Affective disorders are often multi-dimensional, their treatment complicated, and frequently, they need joint management with geriatric colleagues.

Dementia affects 5–7 per cent of people at 65 and 20 per cent of those over age 80 years. By 2040, the number of people with the disorder will double in the developed countries of Europe and North America.[12] Older adults with dementia are an exemplar of consumers who require multi-disciplinary management. While geriatricians manage the majority of patients, those who exhibit behavioural and psychological symptoms of dementia (BPSD), approximately one-third, do best with additional specialist psychiatric

expertise and management.[13] People with dementia can live for many years as their disorder progresses, requiring increasing levels of support from family, social workers, nurses, residential care providers, and other community health care workers in addition to psychiatry services.

Why are specialist services required?

As indicated above, mentally or physically frail older adults have complex needs and frequently require a broad, multi-disciplinary approach in several domains, (a domain being a broad area of specialist services i.e. mental health, geriatrics, primary care, social services, etc.). This can be difficult to achieve if provision is by disjointed services. In many places in the world, lack of specialist services requires generic mental health services to treat older adults with dementia, depression, or other mental illnesses but this practice risks medical needs being unnoticed, or unappreciated. Frail older adults can find the experience of inpatient care in units with younger psychotic patients frightening and unacceptable. There are also different perspectives for working-age and geriatric psychiatry. Many working-age services promote a recovery model whereas care of older adults focuses on maintaining function, improving quality of life and paying more attention to the spiritual, environmental, and social influences on mental health. In addition, there is greater need to involve the social and family network of mentally frail elderly people than there is for working-age adults. For older adults, specialist services, with close collaboration with geriatricians and other geriatric providers, are preferred for optimal management.

Principles of good service delivery for older adults

Optimal service delivery starts by establishing the principles that services wish to adopt. These should govern the ethos of service delivery. For the World Health Organization (WHO), the mnemonic CARITAS (Latin for Compassion) summarizes a global consensus on specific values required for good service delivery for psychiatry of old age.[14] These principles, championed over many years by many international pioneers of mental health services for older adults, assert that optimal services are:

- **Comprehensive**

  They take all aspects of the patient's physical, psychological, and social needs and wishes into account i.e. are *patient-centred*.

- **Accessible**

  They minimize the geographical, cultural, financial, political, and linguistic obstacles to obtaining care.

- **Responsive**

  They act promptly and appropriately to a wide variety of patient needs.

- **Individualized**

  They focus on each person in her/his family and community context aiming, wherever possible, to maintain and support the person within her/his home environment.

- **Transdisciplinary**

  They optimize the contributions of people with a range of personal and professional skills and facilitate collaboration with voluntary and other agencies.

- **Accountable**

  They accept responsibility for assuring the quality of the service delivered, monitoring this in partnership with patients and their families. They are ethically and culturally sensitive.

- **Systemic**

  They work flexibly with all available services to ensure continuity of care.

Summarizing, good services provide *patient-centred* care with *easy access to a comprehensive range of services* delivered by *multi-disciplinary personnel* working in a *collaborative, responsive, respectful, and accountable* way.

Patient-centred care

The UK National Frameworks for Older People[15] and most OECD health administrations promote patient-centered care as a major means of improving quality of services and consumer satisfaction. Whilst most health professionals believe that they already practice patient-centred care, many patients would not agree. Predominantly, health systems for older people, particularly hospital-based, are far from patient-centered, being mostly organized around clinician or administrative requirements rather than patient needs. Patients encounter rigid appointment times, lack of evening or night services, inflexible boundaries between departments, inconvenient visiting hours, limited or expensive parking, and silo'd funding streams. Access or contact processes are obscure or difficult, information is inadequate, multiple assessments take place, and poor coordination between providers leads to treatment omissions or errors. Notably, older adults and their caregivers consider having multiple referrals to different specialists or providers and frequently repeating the same history to be a waste of time and resources.[16]

Consumer appraisals of their experience of services often result in common themes. Many experience poor communication—provider to patient, provider to caregiver, and provider to provider. Another common topic is lack of flexibility in developing management plans capable of involving several domains and dimensions of care (a dimension is a subset of a specialist domain, i.e. depression, dementia, continence, or mobility). As many elderly people have difficulties with mobility, or live far from services, transportation is another major issue.

In contrast, patient-centered services emphasize smoothing the progress of the patient 'journey' through the health system, eliminating duplication, matching care plans to patient needs, and generally making a demanding experience easier for the patient and their family. Unsurprisingly, the concept is appealing to patients and families. Increasingly, consumers, and their advocates, want to contribute to service planning, delivery, and evaluation.[17] So, what do older people want from their health care providers? Older people value their independence and being involved in the decision-making for their own care plans. Most want to remain in their own homes for as long as possible, but if that is detrimental for them, they want the right to relinquish decision-making, in various degrees, to other parties such as family members or their clinicians. They expect providers to treat them as an individual, to preserve their dignity, and to elicit and respect their preferences. Above all, they wish to be appropriately informed.[18] These desires are appropriate to all health care delivery for older adults, not just mental health. As most of us hope to grow old, we can empathize

with these wishes. Perhaps we need to remember that in planning and organizing services for older adults, we are potentially designing them for ourselves. The quality of care required is what we would be happy with, if we ever become clients.

Comprehensive and integrated services

Patient-centered care is more achievable with comprehensive or integrated services. The terms comprehensive and integrated are not interchangeable. A comprehensive service is one with a full range of inpatient and community services available within the same domain. An integrated service is one with a single point of entry capable of providing care plans that incorporate interventions and support in multiple domains and specific dimensions of care. Integrated services are characterized by a single point of entry, case management, geriatric, psychogeriatric and social assessments, and have multi-disciplinary teams.[3] They should have a seamless joining together of the various components of service, encompassing 'systemness' without diminishing component part identities.[19] Integration of different organizations is much easier if there are common administrative processes and financial systems. However, many mental health organizations have reporting and funding structures separate from other older adults' services (e.g. The Mental Health Trusts in the United Kingdom). Quasi-integration can be achieved by building effective *functional* links with a wide variety of health care professionals outside mental health e.g. primary care, geriatrics, acute medical and surgical care, social care, community health care, and non-clinical resources. For these collaborations to work, it is essential that bureaucratic processes enable easy transfer of funding and information across different entities and do not thwart clinicians' efforts to implement care plans for patients.

Integrated services are potentially more efficient as they should reduce duplication of assessments or investigations and service gaps. Currently, the majority of well-established services for older adults provide comprehensive rather than integrated services,[20] the latter being more ideology than practice, although this might be slowly changing. Research indicates that integrated care can delay institutionalization, reduce costs, and has benefits in consumer satisfaction[3] but is insufficient, as yet, to demonstrate that integrated services are more effective in achieving better health outcomes.

(a) The place of the common geriatric assessment (CGA)

An important tool for assisting integration is the common geriatric assessment (CGA). Different disciplines all have their own styles and foci for assessment but, despite individual differences, it is useful to have some common information for all teams and multidisciplinary groups, regardless of who takes the main responsibility for the patient.[21] Advocacy for the comprehensive geriatric assessment (CGA) covering all the main domains and dimensions of physical illness, mental health, disability, and social assessment, is increasing internationally, notwithstanding a lack of research on their effectiveness in improving health outcomes. They aim to save a patient from multiple repetitions of the same information.[16] To be useful, CGAs require personnel to work across professional and agency barriers, which can have benefits in creating relationships with allied colleagues, essential for developing integrated services. There needs to be agreement amongst the providers as to the applicability of the information required, agreed processes by which the CGA generates onward referral to the appropriate domains of care and procedures for updating and review. In some jurisdictions, (e.g. United Kingdom) CGAs or single assessment processes (SAPs) are mandatory for all older adults' services, in others, i.e. New Zealand and Australia, they are being trialed with a view to future obligatory use. SAPs and CGAs vary in their comprehensiveness and can aim at different levels, e.g. screening, proactive assessment, primary care, or secondary care services. They provide useful background information common to a range of providers but are not a substitute for specialized clinical assessment.

(b) The 'core business' of mental health services for older adults

Irrespective of whether a mental health service for older adults is part of a comprehensive or integrated system, their 'core *business*' is the:

- Diagnosis and management of new cases of mental illness arising in late life, often associated with the ageing process.
- Treatment of mental illness complicating physical illness and disability.
- Management of older adults with long-term mental illness complicated by ageing.
- Education and support for caregivers of older adults with mental illness.

Most psychiatry for older adults is about the management of chronic illness and care, rather than cure, is usually the main priority. An adaptation of the 5As model for patient-centred chronic illness management[22] is useful to describe the 'core *tasks*' of patient-centered psychiatry of old age. They are:

- Assessment of multiple care needs
- Advice on diagnosis and options for management
- Agreement with patient and caregiver on a care plan
- Assistance with implementation of care plan
- Assertive follow-up when needed

The 'core areas of *expertise*' for specialist services for older adults are the:

- Treatment of affective and psychotic disorders in late life
- Assessment of neurocognitive disorders and the management of the behavioural and psychological symptoms of dementia (BPSD)
- Rehabilitation of long-standing, chronic psychiatric disorders in patients whose disorder is complicated by physical illness or ageing
- Management of delirium in medically ill or complicating dementia
- Liaison with families, caregivers, and community providers

Core components of psychogeriatric service delivery

The evidence base for the 'core components'

Working with mentally ill older adults involves a variety of locations i.e. the patient's own residence, medical and surgical wards in a general hospital, psychiatry inpatient facilities, residential care facilities, outpatient clinics, outreach clinics, geriatric rehabilitation

units, or day hospitals. Several models of services for older adults have evolved over the past 30 or 40 years, shaping a degree of accord amongst clinicians on what are 'core components'. The evidence for these has been systematically reviewed by Draper and Low.[23] (See Table 8.7.1.)

Community old age psychiatry services

The lynchpin of geriatric psychiatry services is the community-based assessment and case management team. The community team model originated from the closure of the mental hospitals and the move into community-care in the 1980–90s. Their focus is domiciliary assessment and management. This offers the clinician opportunities to observe patients in their own environment, and promotes optimal cognitive functioning by decreasing stress for the individual. Home assessment avoids the sometimes-perceived stigma of attending a psychiatric clinic and eliminates transportation difficulties, as well as allowing ready access to family members or other caregivers. Treatment for most patients can take place at their residence (own home or nursing home), reducing reliance on inpatient or residential care. The model has proven to be efficient and highly acceptable to consumers and caregivers.

A typical multi-disciplinary team consists of at least one psychiatrist, psychiatric nurses, clinical psychologists, social workers, occupational, and other therapists plus support and administration staff. A psychiatrist traditionally leads a multi-disciplinary team but not necessarily so. As a whole, the team should be able to address the biopsychosocial, therapeutic, and psychoeducational requirements of a wide range of disorders and intervention settings. Team members case-manage depending upon their own special skills and expertise. Working collaboratively, with appropriate training, good supervision, and well-designed protocols and communication systems enhances the multi-disciplinary team. Some of the most effective teams are 'interdisciplinary' who develop flexible working patterns characterized by a non-hierarchical structure, and shared decision-making. They facilitate lateral communication between team members, and free exchange of ideas to develop optimal treatment and support management plans as a group. The evidence for community-delivered specialized multi- or interdisciplinary psychogeriatric assessment and management teams is strong and indicates consistently better outcomes than 'usual care' of primary care or generic mental health management.

Inpatient units

Inpatient units vary from the specialized older person's assessment, treatment, and rehabilitation (ATR) unit, similar to their geriatric counterparts, to dedicated beds in geriatric wards, or donated beds in working-age mental health units. Preferably, a specialized inpatient unit is purpose built or has the functionality to separate patients with functional and organic disorders, as each group has different clinical features, nursing needs, disabilities, and requirements for care plans. The evidence for specialized inpatient psychogeriatric units is positive but as there have been few random controlled trials (RCTs), it is less robust than the evidence for

Table 8.7.1 Level of evidence and study qualities for areas of service delivery

Area	No. of studies reviewed	No. of controlled trials	Quality range,* range (low) 0–1 (high)	Mean rating of quality	Level of evidence of effectiveness
Psychogeriatric day hospitals	10	0	0.43–0.82	0.57	Level IV (particularly depression)
Community old age psychiatry services	24	7	0.79–0.94	0.87	Level I for multi-disciplinary psychogeriatric teams, level IV for adult psychiatry teams
Integrated hospital and community-care	4	2	0.71–0.82	0.76	Level II for psychogeriatric services post-discharge care, no evidence for geriatric medical services (level I)
Primary care collaborations	3	2	0.89–0.94	0.92	Level II
Older people in general adult psychiatric wards	6	0	0.51–0.67	0.59	Level IV
Acute psychogeriatric wards	23	0	0.43–0.78	0.61	Level III-2
Hospital medical services	6	2	0.82–0.90	0.89	Level II for prevention of delirium without dementia, no evidence for other mental health outcomes (level 1)
Combined psychogeriatric and medical wards	3	0	0.52–0.53	0.52	Level IV
Hospital-based CL psychogeriatric service delivery	7	3	0.62–0.90	0.79	Level II effectiveness for reducing costs and length of stay
Long-term psychogeriatric care	11	0	0.58–0.71	0.66	Level III-2
Psychogeriatric outreach to long-term care	8	6	0.73–0.95	0.84	Level II for liaison style outreach services, Level III-2 for consultation style
Overall	108	25	0.62–0.95**	0.85**	

*If ≥2 controlled trials in service area, quality range reported for RCTs only, otherwise reported for all studies. **overall mean and range reported for controlled trials only.

community teams. Nevertheless, what evidence exists points to specialized psychogeriatric units having better outcomes for psychogeriatric patients than working-age mental health, or geriatric medical units.[23] Scientific evaluation of combined psychogeriatric and geriatric medical wards is inadequate but expert clinical opinion considers them useful in the management of co-morbid medical and psychiatric illness.

Consultation and liaison

Hospital-based consultation and liaison (CL) services are important components because of the high number of mental disorders in the physically ill, general hospital populations. However, while the evidence is relatively good for CL outcomes such as hospital stays and costs, it is only modestly positive for mental health outcomes.[24] Notwithstanding, in recent years, older adults' CL services have outreached from the general hospital to provider organizations in the community. The evidence for these liaison services, usually provided by community teams to psychogeriatric long-term care facilities and voluntary organizations, is relatively good.[23]

Day Hospitals

Day Hospitals, originally attached to the old psychiatric institutions, have mostly devolved into community facilities and many United Kingdom psychiatrists of old age consider them indispensable.[25] Specialist day hospitals provide care for people with moderate and severe needs, including people with functional mental illnesses such as depression, anxiety, and schizophrenia, who may need specific support with daily activities and people with moderate to severe dementia. The Day Hospital allows hospital level treatment while allowing patients to remain living in their own residence. The evidence for their effectiveness, while positive, is sparse. As they are less common, they are not as revered in other parts of the world as much as they are in the United Kingdom. Day Hospitals need to be differentiated from Day Centres, managed by the voluntary or welfare sectors, which usefully provide social activities to keep the patient involved with their community and much needed respite for caregivers.

Residential care

An elderly person unable to support themselves in their own home needing daytime or 24 h supervision requires a resident caregiver or residential care facility. A community may have a range of residential care facilities managed by a variety of agencies such as local authorities, voluntary organizations, for-profit or not-for-profit religious and welfare organizations in the independent sector. These non-government organizations (NGOs) provide care homes for older adults who need support because of physical or mental frailty but not to the extent of requiring hospital level care. Many of the residents have some cognitive impairment and, unsurprisingly, a relatively high number of patients have complicating depression and/or psychosis. Residential care homes vary markedly in their ability to support older adults with mental health problems. Evidence from The Netherlands[26] and Australia[27] indicates that mental health enhanced care in the form of regular psychogeriatric team liaison to these residential facilities has beneficial outcomes for patients for example less inpatient stays, less psychotropic medication, and improvement in depression and psychosis.

Long-term care

Progressive de-institutionalization since the 1980s saw the transfer of many long-stay, public sector beds, for patients with dementia or intractable mental illness, to community-based nursing homes or hospitals. These facilities were generally smaller, more home-like and provided additional activities for the residents than traditional long-term care did. The change required many old age psychiatry services to collaborate with independent sector stakeholders and evolve outreach and liaison models of care with the new long-term residential care facilities. This paradigm shift for service delivery was beneficial for patient outcomes.[23]

Disturbed behaviour resulting from dementia (BPSD) can be severe enough for patients to need Specialized Care Units (SCUs). Examples are in Italy, France (CANTOUs), Tasmania (ADARDS unit), and London (Domus units). Such units have a small number of beds, well-trained staff with high staff to patient ratios and access to ongoing specialized psychogeriatric team care. When compared with traditional psychogeriatric ward patients, unsurprisingly, those in a specialized care unit, show improvements in cognition, self-cares, activity participation, and behaviour. The key elements to success appear to be training staff to anticipate and recognize mental health problems and close liaison with specialist mental health teams.

Respite care

The community-care model relies on family, rather than professionals to attend to most of the needs of a mentally frail, elderly person. This is demanding, difficult work for caregivers who usually have other responsibilities of family, home, and jobs. The main focus of respite care is to give lay caregivers a break from caring every few weeks, so they may continue to provide care and thus delay the need for permanent nursing home care as long as possible. Respite can be in the patient's own home, by providing a 'live-in' professional caregiver, or in hospital or a residential care facility for a week or two, every couple of months, allowing the family caregiver to take a holiday. Whilst seeming an admirable concept, the effectiveness of respite care is doubtful and there is little evidence that it has a significant effect on caregivers' burden, psychiatric status or physical health, or on patients' cognition, function, physical health, or rate of institutionalization.[28] Respite care, even when available, may be poorly utilized. Caregiver barriers to using respite care include guilt, financial reasons, cultural attitudes, and fear of stigma. Access barriers include unavailability, lack of publicity about services, long waiting lists, and poor identification of at-risk caregivers. Patient barriers include severe problem behaviours, immobility, incontinence, wandering, and inability to communicate.[29]

Primary care collaborations

Despite older adults forming the majority of patients seen by general practitioners (GPs), they detect and treat less than half the number of older adults with mental disorders.[30] Short consultation times, with a concentration on physical symptoms, with few patients presenting explicitly with mental health complaints, plus a reluctance of older adults, especially men, to express psychological distress to their GP, leads to under-recognition of mental disorders in older adults. Depression may be erroneously attributed to loneliness or ageing and early dementia overlooked. Primary care practitioners also make fewer decisions to treat or refer patients

to specialist services and often preferred to monitor, or defer decisions.[31]

Mere cooperation between mental health services and primary care seems insufficient to improve matters. Collaborations such as mental health enhanced primary care looks more promising. Education of primary care nurses in recognition of mental disorders and use of screening instruments might be useful to improve identification of mental disorders.[31] Even better is the idea of 'embedding' nurses, who have the skills necessary to identify health problems and coordinate care for older adults, into primary care practices. One experimental scheme in New Zealand, 'The Coordinators of Services for the Elderly' (COSE project) works within a primary care small group of practices to coordinate care of the practices' elderly patients across health, mental health, community, and accident services. An RCT of the COSE project over usual care significantly demonstrated that patients in the COSE arm were less likely to be hospitalized, their residential care was delayed and morbidity reduced.[32]

The primary care physician is crucial to patient care from start to finish, not only in identifying people who are at risk but also for any post hospital discharge care as the majority of patients seen by specialist services eventually return to primary care for ongoing management, in conjunction with their family caregivers. Even if patients or their caregivers can self-refer to secondary services, it is important not to bypass the general practitioner, who has awareness of the patient's overall health care and context.

Special components of services

Memory clinics

The substantial growth in numbers of memory clinics, over the past 10–15 years, was stimulated by the licensing of cholinesterase inhibitor drugs for Alzheimer's disease.[33] Memory clinics offer a range of services from assessment of cognition to specialized treatment of memory problems. Dedicated memory services can improve diagnostic expertise and lessen stigma for the patient. Usefully, they often focus on education of patients and caregivers as well as monitoring medications. However, the concept of a 'memory clinic' flies in the face of the trend towards community-based services and integration with local services. Furthermore, the intervention base is often very narrow. Very few studies provide any evidence of increased mental health gain over other psychogeriatric services, but there is some evidence that the attention, communication, and counselling offered increases consumer satisfaction.[34]

Older adults with intellectual handicap

People with intellectual handicap are also living longer and they are at particular risk for developing dementia. Over 55 per cent of people with Down's syndrome between the ages of 60–70 have Alzheimer type dementia, which often begins to emerge in midlife rather than old age. Consequently, the intellectually handicapped older person has complex care needs that require dementia, mental health, and learning disability services to work together assiduously.[2]

Older prisoners

An often forgotten group is ageing prisoners, who are also increasing in number. Older prisoners have increased risk for depression and other mental health problems. Long-serving older prisoners may develop dementia and require the special challenge of care delivery whilst incarcerated. Specialist services for older prisoners are scarce and, if available, usually provided by visiting community assessment and treatment services in conjunction with local forensic psychiatry services.

Younger people with dementia

Early onset dementia is fortunately rare but when it occurs, it is devastating. The patients usually have family responsibilities with young children, jobs, and financial commitments. Early onset dementia usually has a more accelerated course and genetically related family members may be concerned for themselves or their offspring. Diagnosis is often delayed for younger people so considerable distress and problems have usually built up before they reach services. Their management needs may also be different as they are usually physically fitter and they may require more structured activities than their older counterparts do, but need similar levels of supervision. Appropriate services for younger people who develop dementia are often scarce and the patients may fall into an under-resourced gap between working-age and older adults' services.

Academic units

Although there has been a growth in the number of geriatric psychiatry academic units and positions worldwide, they are still under-represented in universities worldwide. They are important providers of under and postgraduate teaching and research.

Planning to commissioning

Commissioning is 'the process of specifying, securing, and monitoring services to meet the needs of a population at a strategic level'.[2] Proposed services require a 'business case' with the place of an intended service clearly demonstrated in the overall schemata of health provision for a population. Demonstration of the need for services and projections of likely demand is necessary and the chief scientific tools available to identify these are epidemiology, demography, and utilization studies.

Epidemiology predicts the likely problems in a population and demography the characteristics of the population that could increase risk. The older the population, the more likely it will have a high prevalence of dementia requiring services. An important demographic to consider when planning services is the socio-economic status of a population. Low socio-economic status increases the likelihood of poor physical health, poor functionality and deprivation causes stress, leading to poverty of control over one's life, low self-esteem, anxiety, insecurity, and depression.[35] Also important is the number of immigrant residents. Ethnic elders are more likely to have earlier social disadvantage compounding in later life into a multiple jeopardy of social disadvantage, poorer physical health, and mental health problems.[36]

Whilst epidemiological studies may predict potential need, and demographics highlight areas of possible risk, not all people with problems will demand services. Demand or utilization is considerably less than the potential need as predicted from the demographical and epidemiological data. International research consistently shows similar demand patterns. About half of identified patients obtain treatment from a health care provider. Only 10–16 per cent reaches specialist mental health services, and

primary care treats about 30–40 per cent. For older adults utilization is even less than for working-age adults.[37] Stigma can have a detrimental effect on willingness to access services[38] as may cultural barriers.[36] For individuals, utilization of mental health services is more likely if the disorder is severe, is adversely affecting the family or social network, or the patient is female.

Services are usually commissioned based on expected demand rather than predicted need. Demand often increases, outstripping supply once services are available and information about them permeates into the community. Resource review on a regular basis as demand rises is necessary.

Commissioning new or revised services involves stocktaking of available resources for older adults. Often these are inequitable, with urban areas enjoying a range of services that rural areas lack. Despite unique individualities of different countries of the world, some characteristics tend to be true of all rural communities. They tend to be older and poorer than urban populations with a higher percentage of females.[39] Stoical older adults living in rural areas have a high tolerance of distress and are often reluctant to seek help from mental health services.[40] Consequently, rural populations are even more vulnerable for late-life mental health disorders, yet outreach services are usually infrequent, and primary care limited. Some countries with very large rural areas, for example United States, Canada, Africa, Australia, and New Zealand commission novel methods of outreach, such as flying doctor services.

Ideally, service planning should be in conjunction with key stakeholders, that is consumers, other geriatric services and providers, including NGOs. For optimal patient-centred mental health care for older adults to be effective, individual specialist hospital services need to work with general practitioners and other community providers. Attention to administrative pathways and funding structures that promote collaboration between providers is important. Commissioning strategies that propose integration of existing services need to recognize that, whilst the end result *may* be beneficial to patients, the process *will* cause enormous upheaval and distress among the workforce involved, particularly if there is decommissioning or amalgamation of duplicate services.

Service development is contingent on there being a skilled, educated workforce. A development plan needs to consider the specialist disciplines required, based on expected case mix and work loads, staff availability, recruitment and retention, morale, job satisfaction, and very importantly, training issues. Clinical services have important roles in teaching and training ongoing professional development and in clinical evaluation, and systems research. These tasks can also be important means of cross-fertilization, dissemination of ideas between related services, teams, and disciplines. Involvement of different disciplines in undergraduate or postgraduate teaching programmes including psychiatry trainees can be useful for disseminating a broader perspective to prospective health professionals intending to work with older adults.

A vital aspect of commissioning is monitoring, that is, the methods of service review and evaluation. This is important for continuing quality initiatives and research but also to provide evidence for review and future commissioning of even better services.

Conclusion

Worldwide, population ageing is driving the development of mental health services for older adults. Finite resources, burgeoning costs, expanding therapeutic repertoires, and increasing consumer interest in involvement in health care is challenging health organizations to develop effective, efficient, and economic patient-centred services for older adults. Fundamentally, the quality of services is dependent on health personnel working with their patients and other providers, towards shared aims of improving health outcomes and quality of life. Clinicians' adaptability, flexibility, responsiveness, availability for patients, and willingness to collaborate are the keys to success in developing future services for older adults.

9.1.1 Developmental psychopathology and classification in childhood and adolescence

Stephen Scott

Introduction

Classification schemes of psychiatric disorders in childhood and adolescence have to take into account three particular features. Firstly, the individual is continually changing and growing. Sound knowledge is therefore required of the normal range of development and its limits. For example, some fears may be normal in a 5-year-old but abnormal in an 8-year-old. Once identified, it is helpful to decide if abnormalities are due to *delay in* or *deviance from* the usual pattern of development. The implications of each differ, and should be classified differently. Secondly, the majority of childhood mental health problems arise from an excess of behaviours exhibited by many young people, such as aggression or dieting. They are seldom due to qualitatively distinct phenomena of the kind more often seen in adult conditions, such as hearing voices or hanging oneself. Consequently choosing a cut-off point to make a categorical entity from a dimensional construct is more often used in child psychiatry. This is inevitably an arbitrary process (albeit informed by empirical criteria), which may lead to loss of information, and may be held to be labelling the child unnecessarily. That dimensions can be interchanged with categories does not necessarily mean they are unhelpful—after all, day and night are useful terms yet the boundary between them is continuous and arbitrary. Psychiatrists in particular may be criticized for 'medicalizing' a child's difficulties by talking about disorders or diagnoses, whereas other professionals and parents may prefer to see them as understandable variations in child development, and prefer to call them 'emotional and behavioural difficulties'. However, diagnoses are a quick way to convey a lot of information that dimensions may not. Thus to only say a child is at an extreme of an antisocial behaviour dimension does not necessarily convey the association with specific reading retardation and ADHD, which could be (and often are) consequently missed.

Thirdly, children's difficulties nearly always arise in the context of relationships within the family. More often than in adulthood, some or all, of the problem may appear to be the result of the functioning of the family, rather than in the individual child who may merely be reacting to the situation. For example, a child who is disobedient and shouts in class may simply be behaving the way his parents do at home. A classification system will be stronger if it can take family functioning into account—it will have a greater chance of capturing clinically important causal and therapeutic considerations.

A valid and useful classification system will need to take into account these features and be based on a thorough understanding of normal development and how it can go wrong, rather than merely include static descriptions of presumed pathological states. The term of *developmental psychopathology* was coined in the early 1980s to denote the scientific study of how abnormalities can be understood in terms of processes underpinning human development.[1,2] There are now journals and books incorporating the term into their titles.[3,4] Many disciplines are relevant, from embryology and genetics to social learning theory and criminology. Developmental psychopathology, besides studying the impact of pathogenic influences on pathways through life, such as the way the

monoamine oxidase-A (MAOA) genotype interacts with an abusive upbringing to cause conduct disorder,[5] or how specific reading retardation leads to low self-esteem, also investigates protective mechanisms, such as the ameliorating effect of high IQ on the propensity to juvenile offending, or the beneficial effect of a trusting and caring relationship with an adult on the impact of childhood abuse. This chapter aims to show how findings from developmental psychopathology have informed current classification systems, and what challenges remain.

General issues

Change over time

Because mental processes and behaviour change as a child develops, it is not always clear whether the same diagnoses should be applied across the age range. Thus a highly aggressive toddler may throw himself screaming onto the floor in daily tantrums, whereas a highly aggressive teenager may assault old ladies and rob them. Do they suffer from the same disorder? ICD 10 holds that they do—both meet criteria for conduct disorder, which is defined in terms of antisocial behaviour that is excessive for the individual's age, and that violates societal norms and the rights of others. DSM IV-R on the other hand has two separate diagnoses, oppositional-defiant disorder for the younger case, and conduct disorder for the older. However, as both diagnoses have similar correlates and there is a strong continuity from one to the other, the validity of the division is questionable. Yet current adult psychiatric schemes have no diagnosis at all to apply to antisocial behaviour, unless it is part of a personality disorder.

The extent to which adult criteria should be applied to children requires good empirical data. In the case of obsessive–compulsive disorder, the phenomenology is remarkably similar in childhood, so there is no problem. However, for depression the picture is rather different. Currently, ICD 10 and DSM IV-R have few emotional disorder categories specific to childhood, and they are mostly subtypes of anxiety. Mood disorders are diagnosed according to adult criteria, with the consequence that surveys of depression find prevalence rates close to zero under 8 years of age. Yet there are miserable children who cry frequently, say they are unhappy, look sad, and are withdrawn.[6] However, they usually sleep and eat reasonably well, and their mood fluctuates during the day, with spells when they sometimes appear more cheerful. Should they not be allowed a diagnosis? ICD 9 had a category for 'disturbance of emotions specific to childhood and adolescence, with misery and unhappiness', and such children suffer impairment.[7] Follow-up studies of prepubertal children referred with this picture showed a moderately increased risk of adult type depression later on, whereas adolescents with depressive symptoms had a higher risk of adult depression.[8] Genetic studies show that symptoms of depression in prepubertal children are predominantly due to environmental influences, whereas after puberty genetic influences become more important.[9] Finally, tricyclics are not effective in childhood but are effective in adults. This example shows that misery in younger children has some phenomenological features and external correlates in common with adult depression but also several differences, so the current approach which makes a comprehensive yet parsimonious classification system for all ages loses validity.

In contrast, there is continuing reluctance to diagnose personality disorders in childhood. This may be because they are often seen as a life sentence of a noxious, untreatable condition, in distinction to the general hope that there is opportunity for 'growing out of' conditions in childhood, or treatment for them. However, with perhaps the most destructive personality type, dissocial, there is growing evidence that the combination of antisocial behaviour and callous-unemotional traits is well established by the age of seven. Moreover, this combination of childhood characteristics has a far higher heritability than antisocial behaviour without callous-unemotional traits.[10]

Validity

Categories need to be distinct not only in terms of the phenomena used to define them, but, crucially, also in terms of external criteria. Even if categories can be reliably distinguished, if external criteria are the same, then one is likely to be dealing with two variants of the same condition. An analogy would be the difference between black and white cats.

Typical validating criteria in child psychiatry derived from developmental psychopathology are:

1 *Epidemiological data*, such as age of onset and sex ratio. Forty years ago 'childhood psychosis' was a unitary classification, but work showing the clear difference in age of onset helped validate the distinction between autism and schizophrenia, which seldom co-occur. Disruptive disorders occur four times more commonly in boys, whereas emotional disorders are commoner in girls.

2 *Long-term course*. Most childhood disorders show reasonable *homotypic continuity*, that is they stay the same. Some show *heterotypic continuity*, so that for example, some cases of childhood hyperactivity end up as antisocial adults. This does not necessarily invalidate the category, but requires explanation.

3 *Genetic findings*. If individuals with distinct categorical diagnoses have relatives with different disorders, this helps validate the distinction. This has confirmed the validity of several diagnostic categories, but not all. For example, it has not held for the many specific subtypes of anxiety disorder in ICD 10, whose validity is questionable. Genetic studies can also clarify the scope of symptom clusters. For example, family studies of autism have revealed a broader phenotype in relatives of probands,[11] so that new disorders may need to be considered, which encompass only one of the original three constituent domains of classical autism, namely social relatedness, communication problems, and repetitive and stereotyped behaviours.

   The hunt is now on for specific genes associated with particular psychiatric disorders. Thus dopamine receptor and transporter genes are reliably associated with Attention Deficit Hyperactivity Disorder,[12] but unless (i) the gene always leads to the disorder and (ii) all cases of the disorder are caused by the gene, particular genotypes are unlikely to be used to validate diagnostic categories.

4 *Psychosocial risk factors*. The association between institutional upbringing with many changes of carer and reactive attachment disorder is so strong that it has been made a requirement for diagnosis in ICD 10. Conduct disorders are strongly associated with discords at home, whereas autistic disorders are not. However, most psychosocial risk factors are less specific in their associations, and so are only modestly helpful as validating criteria.

5 *Neuropsychological tests*. The hyperkinetic syndrome is clearly distinguishable from conduct disorder on tests of attention such

as the continuous performance task. Recently, there has been considerable progress in showing that one of the core deficits in autism is failure on 'theory of mind' tests of ability, to see another person's point of view, which non-autistic children, with comparable levels of intellectual disability, can do.

6 *Medical investigations*. There have been many failed attempts in this field, including biochemical markers of adolescent depression and endocrine markers of aggression. However, the advent of functional neuroimaging is allowing exciting relatively non-invasive pictures of children's brains to be built up, and reliable findings are beginning to emerge, for example in ADHD.[13] In future these may well be helpful validators for classification.

Reliability

This is a prerequisite for validity, and most categories have reasonable inter-rater and test–retest values, once investigators are trained up. Where there are many overlapping categories, as in current definitions of the many varieties of anxiety disorders, or personality disorders, inter-rater reliability falls.[14]

Effect of informant and instrument

Traditionally information is obtained from parents and the child, and is then combined by the clinician on a case-by-case basis. However, the need for consistent diagnostic rules that is imposed by a 'menu-driven' approach can prove difficult, since the weight given to a particular informant may best vary according to condition. Thus, if a parent says a child has symptoms of conduct disorder but the child denies it, the parent is more likely to be right and the child may be covering up or ashamed. However, if the parent says the child is not depressed but the mental state examination of the child reveals otherwise, it is the parent who may be ignorant of their child's true state. Such difficulties reduce the validity of interviews which use invariant combination rules. Further, in genetic studies, the heritability of a condition may vary greatly according to which informant is believed. Thus in the Virginia Twin study, conduct disorder was 69 per cent heritable according to the information derived from the mother interview, 36 per cent using information from the child, and only 27 per cent using information from the father.[15] Studies such as these underline the need for clinically sensitive ways of combining information, and the use of multi-informant, multi-method ascertainment of information. Statistical techniques such as latent variable analysis may help reduce measurement error, but may build in unwarranted assumptions which distort the raw data.

Structured interviews, which accept the respondent's reply, do not require lengthy training or clinically informed investigators, and so are popular in epidemiological surveys. However, the quality of information differs little from that obtained by questionnaire,[16] and often has a high false-positive and false-negative rate in comparison to semi-structured interviews. Direct observation, although expensive, often provides the most reliable and valid information for assessment of disruptive disorders.

Comorbidity

There are many artefactual reasons for comorbidity appearing high, such as Berkson's bias[17] in clinical samples (where not all cases get referred, the chance of referral will be related to the *combined* likelihood of referral for each condition separately), or overlapping criteria, or artificial subdivision of syndromes. However, even after taking these possible sources of error into account, comorbidity is marked for child psychiatric disorders. In a meta-analysis of community samples,[18] the odds ratio for anxiety with either Attention Deficit Hyperactivity Disorder (ADHD) or conduct disorder is 3, for anxiety and depression 8, and ADHD and conduct disorder 10. Rates are even higher in clinical samples. True comorbidity may arise through several mechanisms:[19] (i) shared risk factors (e.g. early deprivation may lead to oppositional-defiant disorder and an attachment disorder), (ii) overlap between risk factors (thus a depressed mother may pass on a genetic liability to depression in her son and provide inconsistent discipline which predisposes him to conduct disorder), (iii) one disorder creating an increased risk for the other (e.g. conduct disorder leading on to drug dependency), or (iv) the comorbid pattern constitutes a meaningful syndrome (e.g. depressive conduct disorder, described below under combined categories).

Some classification schemes

A simple scheme with three main groups of disorders

A simple but well researched, valid way of grouping child disorders 'lumps' them into three groups, which are helpful to hold in mind when considering specific diagnoses:

Emotional disorders including anxiety, depression, phobias, somatization, and obsessive–compulsive disorder; **disruptive disorders** including conduct disorder and hyperactivity; and **developmental disorders** including intellectual disability, the autistic spectrum, language and reading delays, and enuresis and encopresis.

Comorbidity within each grouping is very common, but only occurs across groups in a minority of cases. External criteria validating the differences between these groups are given in Table 9.1.1.1.

Table 9.1.1.1 Validating criteria for main diagnostic groupings

	Emotional disorders	Disruptive disorders	Developmental disorders
Age of onset	over 8	under 8	under 3
Sex ratio	commoner in girls after puberty	commoner in boys	commoner in boys
Family size	normal	large	normal
Family history	anxiety and depression increased	criminality increased	related disorders may be increased
Socio-economic status	normal	lower	normal
IQ	normal	lower range of normal	normal or low, sometimes very low
Specific delays	absent	present in a third	common
Neurological signs	absent	uncommon	common
Cause	mixed, sometimes mainly genetic	mixed, sometimes mainly environmental	often mainly genetic

Current schemes: ICD 10 and DSM IV-R

The DSM IV-R and ICD 10 committees worked closely together and strove to have names and criteria that are as close as possible. However, there are some general differences.

(a) 'Picture-fitting' versus 'menu-driven' approaches

Firstly, as in adulthood, ICD 10 has one set of 'clinical descriptions and diagnostic guidelines' and a separate set of 'diagnostic criteria for research'. The former comprises general descriptions of disorders requiring a qualitative matching of case characteristics with the scheme, a 'picture-fitting' approach which is similar to the way clinicians practise. The latter comprises lists of symptoms with explicit criteria detailing the number and permutation required for diagnosis, a 'menu-driven' approach. DSM IV-R has only the latter. It has advantages in increased reliability, but is relatively cumbersome so that many clinicians do not bother to apply the criteria rigorously. Even for the simpler DSM III criteria, a study found that whilst trained researchers achieved kappa values of 0.83, 0.80, and 0.74 for attention deficit disorder, conduct disorder, and emotional disorder, the comparable figures for United States clinicians in regular practice were 0.30, 0.27, and 0.27, which are seriously low.[20]

A further disadvantage of the 'menu-driven' approach arises in cases where although the clinician believes a diagnosis is present because of the severity of symptoms, their number is insufficient to meet criteria. For example, consider the following youth: he repeatedly mugs old ladies, sets fires frequently, often argues, is often spiteful or vindictive, has unusually severe tantrums, and has no friends or job because of his behaviour. According to ICD 10 research diagnostic criteria (or DSM IV-R criteria) he has no diagnosis, as he has two but not three symptoms of conduct disorder, and three but not four symptoms of oppositional-defiant disorder. However, according to ICD 10 'diagnostic guidelines' he easily meets the requirements for conduct disorder since 'any category, if marked, is sufficient'.

(b) Multiple diagnoses

A second difference between ICD 10 and DSM IV-R is in multiple diagnoses. ICD 10 encourages the selection of one diagnosis that closest fits the picture, assuming that differences are due to a variation upon the typical theme. DSM IV-R (and the closely linked ICD 10 research criteria) encourage selection of as many diagnoses as criteria are met. Problems arise with this approach when symptoms are common to two disorders, for example irritability contributes to affective disorders and to conduct disorders, so double coding is more likely. Since comorbidity is very common in clinical practice, multiple coding is frequent using a 'menu-driven' approach so that it begins to approach a dimensional system and to lose the advantages of categorization.

The pros and cons of each approach will vary according to whether extra information is conveyed by the second diagnosis. Where there is good evidence of the validity of common comorbid conditions, ICD 10 has combined categories. Thus the external validating characteristics of 'depressive conduct disorder' are similar to those of pure conduct disorder, with no increase of affective disorders in individuals, nor in their relatives, followed up to adulthood. Double coding would convey erroneous information about the depressive aspect. 'Hyperkinetic conduct disorder', on the other hand, is characterized by more severe neuropsychological deficits than occur in either condition alone, and by worse psychosocial outcome in adulthood. Double coding would not convey the poor prognosis.

(c) Multiaxial framework

The ICD 10 has a multiaxial framework for psychiatric disorders in childhood and adolescence[21] which will be described here. DSM IV-R uses a somewhat different multiaxial framework, which is applicable for disorders arising at all ages. It will not be described here except as a contrast to ICD 10. Each axis except the last (psychosocial impairment) is coded independently of the apparent causal contribution to the psychiatric syndrome. This avoids tricky decisions about causality and allows conditions to be recognized and clinical needs addressed.

(i) Axis one: clinical psychiatric syndromes

Criteria for particular diagnoses are described in the relevant chapters of this text.

(ii) Axis two: specific disorders of development

These include speech and language, reading, spelling, and motor development. In DSM IV-R they are included in Axis one. However, having a separate axis helps to ensure that they are not overlooked. This can easily happen, for example, in children with conduct disorder, where the antisocial behaviour tends to command attention, while in fact one-third of the children also have specific reading retardation (dyslexia), which if untreated worsens the prognosis.[22] It very desirable to administer standardized psychometric tests in order to characterize specific disorders of development.

(iii) Axis three: intellectual level

The categories are no intellectual disability (IQ 70 or over), mild intellectual disability (50–69), moderate intellectual disability (IQ 35–49), severe intellectual disability (IQ 20–34), and profound intellectual disability (IQ under 20). In DSM IV-R personality disorders are also included on the axis.

Subtyping intellectual disability gives a good example of substantial differences which arise when categories are imposed on top of a dimensional construct. If all children with an IQ below 50 are taken together (often together also called severe), and compared with those having an IQ of 50–70 (mild), major differences emerge on independent validating criteria, as shown in Table 9.1.1.2.

From the table it will be seen that there are major differences between the categories on fronts as varied as brain pathology and life expectancy. There is no particular psychiatric pattern arising in children with intellectual disability, rather the incidence of all disorders is raised, so that in those with IQ under 50, fully one half have a psychiatric disorder.[23]

(iv) Axis four: associated medical conditions

All medical conditions should be coded. A few have specific associations with psychiatric disorders, for example tuberous sclerosis predisposes to autism, Cornelia de Lange syndrome to self-injury; Down syndrome on the other hand protects against autism but often leads to presenile dementia. Even where there is no specific disorder, congenital syndromes are often characterized by a particular pattern of behaviour. The study of these *behavioural phenotypes* is a discipline in its own right.

(v) Axis five: associated abnormal psychosocial conditions

These include a range of pyschosocial hazards, from abnormal intrafamilial relationships such as physical or sexual abuse, to mental disorders in other family members, distorted intrafamilial communication patterns, abnormal upbringing, e.g. in an institution,

Table 9.1.1.2 Characteristics of children with severe versus mild intellectual disability

	Severe retardation	Mild retardation
Definition	IQ under 50	IQ 50–70
Social functioning	Invariably marked impairment	Many have minor or no impairment
Cause	Organic pathology in majority	Usually no organic cause evident
Family history	Parents and siblings usually of normal intelligence	Parents and siblings often at lower levels of intelligence
Background	Fairly equal distribution across SES levels Neglect at home unlikely	Much commoner at lower SES levels Neglect at home more likely
Appearance	Dysmorphic features often evident	Normal appearance
Medical complications	Physical handicap common (e.g. cerebral palsy) Major health problems frequent Life expectancy shortened Fertility low	Physical handicap uncommon Health in normal range Life expectancy normal Fertility little impaired
Psychiatric complications	Severe and pervasive disorders such as hyperactivity, autism, and self-injury especially common Presentation of disorders often altered, mental state may be difficult to determine	Disorders similar in type to those found in children without MR, but occur more frequently Form of disorders and mental state examination similar to children without retardation

acute life events, and chronic interpersonal stress arising from difficulties at school. Each is coded dimensionally on a three point scale. As the number of psychosocial adversities goes up, the rate of psychiatric disorders increases.[24] Conduct disorder is particularly associated with poor immediate psychosocial environments. As with other axes, abnormalities are coded irrespective of apparent cause. This is particularly relevant since while perhaps 20 years ago the mechanism was thought to be directly environmental, in the last 10 years good evidence has been collected to show that some environmental characteristics of the home are genetically mediated.[25] For example, the association between lack of books in the home and poor child reading is partly mediated through parents with lower IQ buying fewer books.

(vi) Axis six: global social functioning

Here a judgement is made on a nine point dimensional scale ranging from superior social functioning to profound and pervasive social disability. Unlike other axes, ratings of disability are not independent, but have to be judged as due to a psychiatric or developmental disorder on axes one to three. Thus impairment arising from adverse circumstances cannot be coded—it must arise from intraindividual factors. This rule therefore excludes recognition of psychosocial interventions which aid functioning, from reduction of parental Expressed Emotion to changing schools. DSM IV-R studies often use the Children's Global Assessment scale,[26] an adaptation of the Global Assessment of Functioning (GAF) used in adults. An advantage of the CGAS is that it is rated without impairment having to be caused by psychiatric disorder. A disadvantage is that psychiatric symptoms, rather than impairment alone, contribute to the rating.

(d) Should impairment of social function be part of psychiatric diagnosis?

In general, ICD 10 and DSM IV-R do not require impairment of social functioning to be present in order to make a diagnosis. There are exceptions, thus in DSM IV-R, oppositional-defiant disorder *does* require impairment. With many qualitatively distinct adult disorders, having no impairment criterion makes sense, so that a person experiencing the delusions and hallucinations characteristic of schizophrenia, but able to go to work and form relationships while on neuroleptics still has schizophrenia. But should a child who says he is afraid of dogs and crosses to the other side of the pavement on seeing one, but otherwise functions well, be deemed to suffer from a phobia? If impairment criteria are not applied, very high rates of disorder are obtained in epidemiological surveys. This lacks credibility with the general public, who may then dismiss all psychiatric problems in children, and is unrealistic for clinicians and health planners, who would not see most of the identified individuals as cases needing treatment. For example, a large epidemiological survey[27] found that using DSM III criteria, 50 per cent of children and adolescents had a diagnosis. However, when an impairment criterion was added, the figure came down to 18 per cent. This would appear to be a much more realistic figure. However, it could be argued that social impairment is too constraining, and for example would exclude an adolescent who is fairly depressed but able to function. The term *impact* can be used to include subjective distress as well as impairment, and is gaining in popularity among many child psychiatrists.[28]

Falling through the cracks: children with social impairment but no diagnosis

Diagnostic systems have to be practically useful above all. If they are overinclusive, the risk is that there are too many categories, which have poor reliability and high overlap. If on the other hand they are too exclusive, the risk is that there will be many individuals suffering from problems which are not encompassed by the scheme. In one thorough survey, 9.4 per cent had no diagnosis but significant impairment.[29] Across a variety of 'caseness' measures, the individuals were as disturbed as those with a diagnosis. Many of the difficulties were around relationships with parents and siblings, and arguably, such children who have symptoms associated with psychosocial impairment should be regarded as suffering from a psychiatric disorder.

Conclusion

Classification of child psychiatric conditions has advanced enormously in the last 20 years. There is a much stronger empirical basis to support current schemes, which are grounded in the many scientific disciplines that contribute to developmental psychopathology. Nonetheless there are considerable obstacles to overcome if DSM V and ICD 11 are to be major steps forward.

9.1.2 Epidemiology of psychiatric disorder in childhood and adolescence

E. Jane Costello and Adrian Angold

Epidemiology is the study of patterns of disease in human populations.[1] Patterns are non-random distributions, and patterns of disease distribution occur in both time and space. Whenever we observe a non-random distribution, we have the opportunity to identify causal factors that influence who gets a disease and who does not. For example, we observe that depression rises rapidly after puberty in girls, but not to the same extent in boys.[2] This non-random distribution in time suggests that there may be something about puberty in girls that is causally related to depression.[3] An example of disease distribution in space can be seen in the Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) study of five sites in the United States and Puerto Rico.[4] Although the prevalence of psychiatric disorders was fairly similar across sites, the likelihood that a psychiatric diagnosis was accompanied by significant functional impairment was much higher in children at the mainland sites than in Puerto Rico. This offers the opportunity to study between-site differences that might result in differences in the level of impairment caused by psychiatric disorders. The task of epidemiology is to understand these observed patterns in time and space, and to use this understanding as a basis for the prevention and control of disease.

Epidemiological medicine has both similarities to and differences from clinical medicine. Like clinical medicine, epidemiology is an action-oriented discipline, whose goal is intervention to prevent and control disease. Scientific knowledge about the cause and course of disease is another common goal. Epidemiology also reflects clinical medicine in using two methods of attack on disease: *tactical* methods, concerned with the practical and administrative problems of disease control at the day-to-day level, and *strategic* methods, concerned with finding out what causes disease so that new weapons of prevention and control can be engineered.[5,6] Thus, for example, in their tactical or public health role epidemiologists can be found reporting on the prevalence of adolescent drug abuse, the social burden (including cost) that drug abuse creates, and the best ways to control its spread, while others working at the strategic level might be exploring the science underlying environmental constraints on gene expression.

Epidemiology diverges from clinical medicine to the extent that it concentrates on understanding and controlling disease processes in the context of the *population at risk*, whereas the primary focus of clinical medicine is the *individual* patient. This does not mean that epidemiology is not concerned with the individual; on the contrary, it is very much concerned with understanding the individual's illness and the causes of that illness. The difference lies in the frame of reference. Put crudely, clinical medicine asks: 'What is wrong with this person *and how should I treat him or her*?' Epidemiology asks: 'What is wrong with this person and *what is it about him or her that has resulted in this illness*?' Why is this child depressed, but not her brother? If her mother is also depressed, is the child's depression a cause, a consequence, or an unrelated, chance co-occurrence? Such questions immediately set the individual child within a frame of reference of other children, or other family members, or other people of the same sex or race or social class.

Sampling, or selecting the population within which to count cases, is of central importance in epidemiology. Counting cases is an important first step towards measuring the social burden caused by a disease, and the effectiveness of prevention. For most diseases, however, simply counting the number of individuals presenting for treatment will produce estimates that are seriously biased by referral practices, ability to pay, and other factors. This is a big problem in child psychiatry because parents, teachers, and pediatricians all serve as 'gatekeepers' to treatment.[7] Community-based data are needed to measure the extent of need, and the unmet need, for prevention or treatment. Methods for assessing psychiatric disorders in the general population are discussed in another chapter. However, it is worth noting that methods for assessing disorder, whether they take the form of interviews, questionnaires, or neuropsychiatric tests, can only be as good as the taxonomy they are designed to operationalize. Current instruments mainly use scoring algorithms that turn the responses into diagnoses based on the DSM-IV or ICD-10 taxonomies. If these taxonomies do not mirror the 'reality' of psychiatric disorder then the results of using interviews or questionnaires based on them will in turn be faulty.

Estimating the burden of child and adolescent psychiatric disorders

In a world of scarce health care resources, it is important to understand the size of the burden to the community caused by these disorders. Burden, in terms of numbers affected, impact on the individual, and cost to the community, is a crucial factor in the battle for resources for treatment and prevention.

Attempts to reduce the burden of mental illness must, of necessity, pay attention to the early years. It is becoming increasingly clear that most psychiatric disorders have their onset before adulthood, and that many should be regarded as chronic or relapsing disorders. For example, the National Comorbidity Survey Replication, a representative population sample of over 9000 adults aged 18 and over in the United States,[8] found that, of the 46.4 per cent of all participants reporting one or more psychiatric disorders during there lifetime, half reported onset by age 12, and three-quarters by age 24.[9] Since we can expect a lot of forgetting of early episodes by older participants,[10] it is likely that onset in childhood is even more common than this.

If the burden of mental illness begins to be felt in childhood, it is important to know the extent of the problem so that we can begin to plan for treatment and prevention. Unfortunately, the data on which to build such estimates are very sparse. We have to rely on a national prevalence study of psychiatric disorders in the United Kingdom, and another of a large area of Brazil, together with a few national or large community surveys using symptoms scales, and a handful of diagnosis-based studies in smaller community samples, some of them longitudinal. Questionnaire-based surveys are not very useful for measuring prevalence, because they tend to define 'caseness' in terms of a certain percentage of the sample with high scores; a method that predefines prevalence.

In the past decade the United Kingdom has carried out a national prevalence study,[11,12] conducted by the Office for National Statistics, with funding from the Department of Education and other agencies. The primary purpose was to produce prevalence estimates of conduct, emotional, and hyperkinetic disorders, as well as pervasive developmental disorder, eating disorders, and tic disorders, using both ICD-10 and DSM-IV criteria. The second aim was 'to determine the *impact* or *burden* of children's mental health. *Impact* covers the consequences for the child; *burden* reflects the consequences for others'.[13] (p. 185). Third, the study measured service use. A stratified random sampling plan for England, Scotland, and Wales produced a sample of 10 438 children aged 5 to 15. Parent and child were interviewed using the Development and Well-Being Assessment (DAWBA),[14] a computer-assisted lay interview that uses a 'best-estimate' approach to diagnosis, in which responses recorded by lay interviewers are evaluated by clinicians. The first interview wave, conducted in 1999,[13] was followed by a questionnaire mailed 18 months later to all 'cases' with a diagnosis at Time 1, and a one-in-three random sample of non-cases. A second interview of all those completing questionnaires at Time 2, and all others who were cases at Time 1, was completed in 2002.[15] By weighting the responses to account for the various selection factors and for non-response, Meltzer and colleagues developed estimates of prevalence (i.e. the presence of a disorder at the Time 1 interview), of incidence (new cases between the two interviews), and of persistence.

The UK study found that almost one child in 10 (9.5 per cent) aged 5 to 15 had a psychiatric disorder based on the ICD-10 classification system. Prevalence was higher in adolescents (11.2 per cent at 11 to 15) than in children (8.2 per cent at 5 to 15), and in boys (11.4 per cent than girls 7.6 per cent). Conduct disorders were the most common (5.3 per cent), followed by anxiety disorders (3.8 per cent). Depression was rare in both sexes and all age groups

(0.9 per cent over all), as were hyperkinetic disorders (1.4 per cent). Seven per cent of previously unaffected children developed a psychiatric disorder in the 3 years between the interviews. Four per cent developed a new emotional disorder (anxiety and/or depression), and 5 per cent a behavioural and/or hyperkinetic disorder. More girls developed emotional disorders, and more boys developed behavioural disorders. Persistence, measured as the presence of the same diagnosis the years apart, was higher for behavioural disorders (43 per cent) than for emotional disorders (about one in four).

Factors affecting prevalence estimates

It is not a simple matter to compare the British prevalence rates with those from other countries, because there are few large studies, and the age ranges do not overlap. A study of youth age 7 to 14 in south-eastern Brazil, which used the same diagnostic interview but the DSM-IV taxonomy, found an overall prevalence of 12.7 per cent. Although prevalence estimates were slightly different from those reported by the UK study, the relative ordering was the same. Behavioural disorders were again the most common (7 per cent), followed by anxiety disorders (5.2 per cent) and ADHD (1.8 per cent). Once again, depression was rare (1.0 per cent). Other studies from around the world[16] usually generate prevalence rates of around 20 per cent. This puts the British and Brazilian studies at the low end of the range. However, there are many factors other than the 'true' rate of psychiatric disorder (if there is any such thing) that affect a published prevalence rate. The most important of these are:

1 *The time frame of the diagnostic measure*. Questions can be asked about symptoms occurring 'now', 'in the past month', 'in the past 3, 6, or 12 months', or 'ever'. Clearly, if recall is accurate the latter questions will elicit more symptoms than the former. Unfortunately, recall is not always accurate. Prevalence rates are higher from interviews with longer time frames, but not as much higher as would be consistent with accurate recall. For example, The National Comorbidity Study Replication, based on a nationally representative sample of adults in the United States, found that the lifetime prevalence of any disorder was 46.4 per cent, while the 12-month prevalence was 26.2 per cent. This means that 26.2 per cent /46.4 per cent = 56.5 per cent of all cases across the lifespan were present in the past 12 months. This could be explained in several ways: (i) there was an epidemic of psychiatric disorders in the 12 months before the survey; (ii) over half of all psychiatric diseases are chronic; once they occur they remain active for the rest of life; (iii) many early episodes are forgotten, and people report the onset of the most recent episode as the first occurrence of the disorder. In the absence of any evidence for (i), some combination of (ii) and (iii) seems the most likely explanation. We have evidence that the reliability with which children and adults recall the first occurrence of a symptom falls dramatically after 3 months,[17] and recommend concentrating on symptoms occurring in the past 3 months if a fairly reliable estimate is sought.

   In general, when comparing prevalence rates from different reports it is important to bear in mind the time frame. In a comparison of reported rates of child and adolescent depression published since the 1970s, we found that the time frame of the interview accounted for most of the variance, compared with taxonomy (DSM-III, DSM-IIIR, DSM-IV, ICD-9, ICD-10), diagnostic interview, or birth cohort.[2]

2 *The number and nature of the informants*. For several decades now clinicians and epidemiologists alike have recommended collecting information about a child from a range of informants: the parents, siblings, teachers, and peers, as well as the child. Most diagnostic instruments, whether questionnaires or interviews, exist in forms for diverse informants, with scoring algorithms that allow a diagnosis to be made on the basis of one informant or more. In the latter case, most follow the rule that clinicians generally observe, of counting a symptom as present if reported by any informant, rather than expecting agreement among informants, which rarely occurs.[18] Rates of psychiatric disorder will vary with the number of informants, and also depending on which informants report on which diagnoses. For example, across repeated assessments of 1420 children and adolescents, only 26 per cent of those with a diagnosis from the child interview also had one from the parent interview, and only 22 per cent of those with a diagnosis based on the parent interview had one from the child interview. This was statistically a highly significant level of agreement (OR 5.4, 95 per cent; CI 3.6, 7.9; $p < .0001$), but nevertheless only 13.5 per cent of cases were reported by both informants. Readers of epidemiological studies need to decide for themselves how much the number and type of informant matters in judging the accuracy of a prevalence estimate of a specific disorder. For example, parents often do not know much about their children's drug use, while young children themselves generally have little insight into their own hyperactivity, and teachers seldom notice children's depression. Prevalence rates based solely on these informants would be likely to be quite low.

3 *The age and sex of the subjects*. The prevalence rates of different disorders vary markedly by age, sex, and age-by-sex across childhood and adolescence. For example, a meta-analysis of 26 studies of child and adolescent depression[2] estimated the prevalence of adolescent depression (5.6 per cent) as twice that of childhood depression (2.9 per cent), and that of adolescent girls (5.9 per cent) as significantly higher than that of adolescent boys (4.6 per cent). Figure 9.1.2.1 shows prevalence rates of any psychiatric disorder (dotted lines) from a representative population sample of 1420 youth assessed regularly between ages 9 and 21. It is clear that prevalence, even when measured over time in the same subjects, varies markedly with age. This is because some of the common disorders of childhood, such as functional enuresis and encopresis, ADHD, and separation anxiety, diminish as children grow up, but then later on the problems of adolescence and young adulthood, such as drug abuse and depression, take their place. Between about 11 and 14, when the disorders of childhood have faded and those of adulthood not yet appeared, relatively few children have disorders. Prevalence rates will also differ depending on the distribution of males and females in the sample. Boys are significantly more likely to have developmental disorders, enuresis and encopresis, and ADHD in the early years, and drug abuse in the later years. Although girls are more vulnerable to depression after puberty,[19] this does not have a large effect on the overall prevalence of psychiatric disorder.

4 *The inclusion of measures of functional impairment*. Most DSM-IV and ICD-10 diagnoses require that to be clinically significant, symptoms must have a harmful effect on patients' ability to

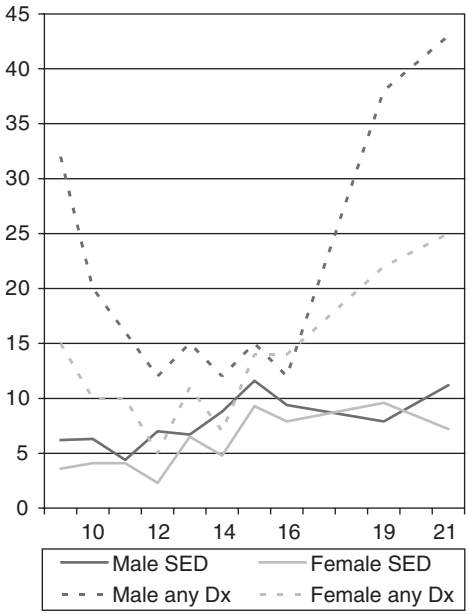

Fig. 9.1.2.1 (solid lines) shows the effect of applying a functioning criterion to diagnoses. It has the effect of flattening the U-shaped curve and revealing a doubling of psychiatric disorder with age, from around 5 per cent at age 9–10 to 10 per cent at age 21. This gradual increase is seen in both boys and girls.

function in their normal environments.[20] There is a wide range of measures of functional impairment,[20] and many diagnostic interviews employ measures of impairment as part of their diagnostic algorithms.

The inclusion or exclusion of a measure of impairment can make a dramatic difference to prevalence estimates. For example, version 2.3 of the Diagnostic Schedule for Children, a widely used interview for youth and parents, uses two measures of impairment. First, if a symptom is reported further questions are asked about whether it affects the child's functioning. Second, the interviewer scores the child on the Global Assessment Scale,[21] which rates the child's overall level of function from 0 to 100. Table 9.1.2.1 shows the impact on the prevalence of any anxiety disorder of including or excluding either or both of these measures of impairment, using data from a multi-site epidemiological study.[21] When no measure of impairment was used almost 40 per cent of subjects received an anxiety diagnosis. With both criteria applied at their most rigourous level, the prevalence of anxiety was cut to 3.2 per cent.

Future directions in the epidemiology of child and adolescent psychiatric disorders

Up to this point, the role of epidemiology has been mainly a descriptive one, addressing the basic questions: how many? who? where? when? However, child psychiatry is changing, and epidemiology will change as well. The goal is now to understand how risk exposure and vulnerability change over the life course, and how the requirements of 'normal' development shape the types of psychopathology that emerge if these requirements are not met. The term 'developmental epidemiology', first coined by Kellam in the 1970s,[22] is useful to describe what epidemiology is doing these days.

In this section we describe some rapidly growing research areas that will contribute to the next generation of studies, and will contribute to the shift from 'child psychiatric epidemiology' to 'developmental epidemiology'. We discuss the future under five headings: longitudinal research, genetic epidemiology, life course epidemiology, intergenerational epidemiology, and prevention science.

Longitudinal research

Although there have been many longitudinal developmental studies, some of them beginning at birth (or even before), longitudinal studies of psychiatric disorders had to await the development of appropriate technology; specifically, data collection methods that validly and reliably translated the psychiatric taxonomy into instruments that could be used repeatedly with the same subjects. Several of these have become available in the past 20 years.[23]

There are now several research groups that have used their longitudinal data to look at continuities and discontinuities in mental illness from childhood into adolescence and beyond. Some of the longitudinal studies have followed their subjects into adulthood.[16] These are beginning to show indications of continuity of disorder across childhood and adolescence,[24] and between temperamental characteristics in early childhood and the onset of psychiatric disorders in late adolescence and young adulthood.[25]

Genetic epidemiology

There have been two revolutions in genetic epidemiology in the past two decades that will have a tremendous impact on psychiatry in the next decade.

(a) Psychiatric–behavioural genetics

The first revolution occurred when the methods of psychiatric epidemiology were applied to behavioural genetics. Psychiatric interviews

Table 9.1.2.1 Effect of different rules for defining impairment on the per cent prevalence of any anxiety disorder (parent or child interview) using the DISC 2.3

	Diagnosis without diagnosis-specific impairment criteria				Diagnosis with diagnosis-specific impairment criteria			
	Criteria only	CGAS <= 70 (mild)	CGAS <= 60 (moderate)	CGAS <= 50 (severe)	Criteria only	CGAS <= 70 (mild)	CGAS <= 60 (moderate)	CGAS <= 50 (severe)
Any anxiety diagnosis	39.5	18.5	9.6	4.3	20.5	13.0	7.2	3.2

(Reproduced from D. Shaffer *et al.* The NIMH diagnostic interview schedule for children version 2.3 (DISC 2.3): description, acceptability, prevalence rates, and performance in the MECA study, *Journal of the American Academy of Child and Adolescent Psychiatry*, **35**, 865–77, copyright 1996, American Acadamy of Child and Adolescent Psychiatry, Lippincott Willams & Wilkins.)

DISC = Diagnostic Interview Schedule for Children. CGAS = Children's Global Assessment Scale.

like those described earlier were used in studies with genetically informative designs, such as twin, adoption, family, and migrant studies. For the first time, researchers examined categorical disorders such as depression, in ways that approximate clinical diagnosis. Furthermore, behavioural geneticists began to take seriously, issues of sampling, so that they could talk about the contribution of genes to disease in the population as a whole, rather than in highly selected families or groups. There have also been some longitudinal studies looking at how genes can have different effects at different developmental stages.[26]

(b) Molecular genetics

The second genetic revolution occurred when it became feasible to apply the methods of molecular genetics to epidemiologic samples. This development opens up the opportunity to use not only twin or adoption studies but a wide range of singleton samples to test theories about candidate genes for specific symptoms. Even more exciting is the new opportunity to use the treasure house of data from longitudinal studies to test for gene–environment interactions. Such studies can answer questions about which genes interact with which environmental factors, and at what developmental stage.[27,28]

Life course epidemiology

Life course epidemiology is the study of long-term effects on chronic disease risk, of physical and social exposures, during gestation, childhood, adolescence, young adulthood, and later adult life. It includes studies of the biological, behavioural, and psychosocial pathways that operate across an individual's life course, as well as across generations, to influence the development of chronic diseases.[29]

Life course epidemiology has developed a special concern with 'the "embodiment" of social phenomena into the biological'[30] encapsulated in the concept of 'health inequalities'. This concern arose historically from work showing that mortality from many diseases is spread unequally across the population and that these differences in risk can be linked to social inequalities that often go back to infancy or even to the parental generation. This body of work has had enormous significance for international thinking about social policy and is having a direct effect on the allocation of public resources in the United Kingdom and elsewhere.

Intergenerational epidemiology

A life course approach to epidemiology intertwines biological and social transmission of risk across generations, recognizing that geographical and secular characteristics may be unique to one cohort of individuals.[31,32]

Experiences of the previous generation can operate at many different levels of generality. They may be specific to the mother–child dyad (e.g. the effect of drug use during pregnancy), or may affect everyone living in a certain neighborhood (e.g. poverty, or exposure to an environmental toxin). All mothers and children maybe affected by a particular event, such as a period of famine or disease, or children may be affected by their mother's developmental stage (e.g. children of teen mothers or elderly mothers). Models for intergenerational research have recently appeared[33] and statistical methods have become more tractable.

Prevention science

Prevention science uses theory about the causes of disease to generate interventions, which when tested provide information not only about the effectiveness of the intervention, but also about the aetiology of the disease. Epidemiology traditionally divides prevention into thee categories, depending on the mean level of risk in the population of concern. Programmes available to all, like clean water, car seat belts, and parental leave programmes, are examples of *primary* or *universal* prevention. For example, the 'Just Say No' drug abstinence programme was introduced as a primary prevention for all children in school, designed to stop drug use before it began. Unfortunately, the results were neutral if not negative.[34] On the other hand, primary prevention with both children[35] and *families*[36] can be both effective, and suggest aetiologic pathways that could be explored in further research.

Secondary intervention *programmes* are based on high-risk children, schools, or communities. Many of them are both theory-driven and scientifically sound. A good example of a secondary intervention that yields insights for epidemiology is the 'Fast Track' programme for aggressive children in grade school. This was based on clearly articulated theory about cognitive difficulties that could interact with environmental risk to produce aggressive behaviour in socially ambiguous situations.[37] Hostile attributional bias was indeed found to be a partial mediator of the effect of the intervention on reductions in aggressive behaviour.

Once children have developed clinically defined psychiatric disorders, interventions tend at present to focus on clinical treatment rather than tertiary *prevention*. Tertiary prevention programmes are rare. One example of proven effectiveness is Multisystemic Therapy.[38] Given the early onset of most psychiatric disorders, this is clearly a vitally important area for future work.

Conclusions

This chapter has covered a lot of ground; from the first stirrings of understanding about childhood psychiatric disorders to the possibility of using molecular genetics to identify gene–environment interactions that can generate psychiatric disorder. There are fuzzy boundaries between epidemiology and developmental psychopathology, life course epidemiology, genetic epidemiology, services research, and clinical psychiatry. It will be important to keep these boundaries pervious, to share a common language where possible, and to learn and use one another's methods.

9.1.3 Assessment in child and adolescent psychiatry

Jeff Bostic and Andrés Martin

The goals of assessment of a child/adolescent are to (1) detect psychopathology and its impacts on the child's functioning in family, school, and peer domains, (2) allow appropriate intervention targets to be identified and prioritized; and (3) identify relevant variables, including family or school factors that may influence treatment adherence.

Distinctive aspects of the psychiatric assessment in children

1 Parents (or other adults) ordinarily initiate and pursue the evaluation of the child for diverse reasons. Adult expectations for the child sometimes exceed the child's abilities, or the adult's own parenting or teaching style may be a poor fit with this child. Some adults may seek treatment to alter the child to remedy this poor fit.

2 Children may not be receptive to changing their behaviour. Children may attribute problems to others and be unable to accept their contribution to an identified problem. The psychiatric assessment of children requires attention to what the child wishes would change.

3 Young children may not trust unfamiliar adults (including clinicians), and adolescents may perceive the clinician as another adult imposing expectations or judgements. Multiple informants[1] are often needed to identify the child's functioning in school, home, and peer domains, to identify the child's areas of strength on which the clinician can build, and to identify others (peers or adults) able to introduce or reinforce more adaptive skills or behaviours.

4 Most DSM-IV-TR diagnoses were defined amongst adult samples.[2] Efforts to consider where a particular child fits on the depressed mood, anxiety, and aggression axes, for example, requires attention to developmental differences in symptom expression.

5 The ability of the clinician to forge alliances with the child, the parent, and outside entities is essential. A breach in any of these relationships can impede treatment. Parental permission should be obtained to contact and collaborate with relevant parties.

Content of the clinical interview

Reason for referral

Who initiated this referral, their motivations, and what changes they seek is vital. Expectations of various parties may collide and must be reconciled for effective treatments to be implemented. For example, the school may seek changes in parental discipline, while parents may expect the evaluation to yield additional school services.

History of problem(s)

Parents often experience intense pain while recounting the deterioration or anguish of their child. Clinicians should provide parents an opportunity to describe the evolution of the problem, attending to the context in which symptoms emerged and occur, changes in frequency and intensity of symptoms, and their current progression. The clinician should inquire directly about the *functions* of problem behaviours, including secondary gains (e.g. tantrums diminish chore requirements, etc.). The clinician should clarify whether symptoms are specific to one functional domain or whether they pervade multiple areas of the child's functioning at home, school, and with peers.

Past problems

Significant past symptoms impairing the child should be identified. It is especially important to understand whether symptoms have been persistent since early childhood, are intermittent, or represent deterioration from a previously better level of functioning.

Comorbid problems

Clinicians should inquire about disorders often seen in tandem. For example, bipolar disorder in children is often associated with previous attention deficit hyperactivity disorder.[3] Screening instruments (such as those selectively available free of cost at websites such as www.schoolpsychiatry.org) can be useful to provide comprehensive information about less conspicuous symptoms.

Substance use history

Clinicians should inquire about the child's exposure to and use of tobacco, alcohol, and illicit substances. Children may perceive that substances alleviate their distress (e.g. anxiety, depression) and 'self-medicate.' Clarifying impacts of substances on symptoms may yield intervention points attractive to the child.

Previous treatment(s)

Chronological assessment of past treatments may reveal strategies adaptable to the current problem. Past treatment history may suggest treatment modalities (in)tolerable to this patient (and family). Medication trials, counselling, hospitalizations, or alternative treatments should be explored.

Developmental history

Parents may vary in their recollection of their child's attainment of developmental milestones. Review of earlier videotapes of the child may improve the reliability and completeness of reports regarding the sequence of the child's growth.

The child's development regulating *sleep, eating,* and *toileting* should be investigated. Attained skills may suddenly be lost, sometimes signalling the importance of emotional events at particular times. Eating behaviour has become complicated as both hunger and obesity increase risks of psychopathology.[4,5]

Psychomotor development includes standing, walking, running, throwing, hopping, and playing sports or musical instruments. How the child fares at sports may clarify psychomotor skills. Fine motor and gross motor skills may not be congruent.

Cognitive development refers to the child's acquisition of thinking skills. Specific inquiry concerning speech development, reading, writing, and math skill progression may reveal global or specific difficulties.

Interpersonal development refers to how the child interacts with others, particularly family members and other children and adults.

Stability of relationships, numbers of friends, types of activities shared, and expectations of peers often reveal sources of difficulty or maladaptive patterns.

Emotional development and *temperament* reveal the child's capacity to recognize his or her own mood state and to self-soothe or regulate negative affect. Prevailing moods can be described by parents, who may also detail past suicidality, irritability, specific fears and anxieties, and conditions associated with the child's happiness and pleasure.

The child's *moral development* indicates whether conscience or moral values are too lax, too harsh, overly focused on particular areas, or uneven and out of proportion to daily events. The child's ability to recognize impacts of decisions on others, and to acknowledge and correct mistakes provides clarity about the child's strengths and limitations. The child's religious and cultural/ethical views and practices also shape this area, and may guide treatment interventions.

Trauma may impact or even arrest development. Investigation of actual events (such as documented abuse), but also of events perceived traumatic by the child and family may shed important light on the child's behaviours and patterns of relating to others. Events surrounding the trauma, disclosures to others, and reactions of adults are also important for the clinician to recognize and address.

Harmful behaviour, towards self or others, may reveal important developmental progressions that warrant intervention. Head-banging may reveal sensory disturbances, thoughts or comments about death may reveal suicidality, and self-harmful acts such as self-mutilation or cutting may reveal primitive coping mechanisms.[6] Harmful acts towards animals or people may indicate needs for monitoring while other diagnostic or treatment interventions occur.

Family history

Few psychiatric disorders appear transmitted exclusively genetically. Many parents fear that their other child may be destined to suffer psychopathology when a family member manifests a disorder, so clarification of contributions to expression of disorders can reduce unwarranted fear, guilt, and distress. Please refer to Chapter 6.3.8 for more information on assessment of family functioning.

Divorce, separation, and single-parent family circumstances may stress all family members. Even when parents part amicably, children may attempt to reunite family members. Children may exhibit symptoms even years after separations as they enter different developmental phases.[7]

Adoption may be a positive event for the child, and adoption warrant tactful attention by the clinician, including age at adoption of the child and biological parents, the involvement with biological parents, the child's understanding of the adoption, and how the adoption is discussed at home.

Medical history

Pregnancy complications, birth difficulties, hospital stays, and medical illnesses requiring treatments (e.g. asthma, diabetes) should be investigated, as they increase the child's risk for psychopathology.[8] Inquiry into emergency room visits or surgeries can shed light on the child's fears, or parental over/underprotectiveness. Allergies should be ascertained, as well as responses or side effects to medications, including naturopathic or homeopathic agents.

Child strengths/weaknesses

Interests, hobbies, and talents of the child should be obtained from the child and parents. Parents may have aspirations the child does not share, or the child may have fantasies beyond apparent abilities. In most cases, though, the child will have some identifiable interests or abilities that serve as potential points of connection with peers and adults (including clinicians).

The child's media diet

Children are exposed to television, music, videos, electronic games, cell phones, e-mail and instant messaging, personal digital assistants, etc. It is important to clarify which media the child uses, how much time each day is spent with these various media, and what consequences these media have on the child (e.g. in response to watching action TV show the child becomes more violent versus has developed interest in Asian food through watching cooking programmes).[9] The degree of parental awareness and appropriate limit-setting regarding TV, video games, and instant messaging may warrant intervention.

Mental status examination (MSE)

The MSE must be adjusted for children (see Fig. 9.1.3.1). The MSE includes a clinical description of the child's appearance, mood, sensorium, intelligence, and thought content and process. Much of the MSE takes place implicitly as the clinician interacts and observes the child during the child and family interviews.

Structure of the clinical interview

Preparatory phase of the child interview

Unlike regular pediatric check-ups, the psychiatric evaluation usually occurs because of prominent symptoms often perceived as embarrassing by the parents or the child. A phone call before the interview by the clinician or staff can clarify the structure of the interview, the collaboration anticipated to devise solutions, and the opportunity for parents to provide any confidential information to the clinician.

The parent interview

The parent interview can be complicated by parental ambivalence about having a child evaluated by a psychiatrist, fears of loss of control or criticism, or parental shame or embarrassment about perceived parenting faults. The clinician should remain sensitive throughout the interview to parent vulnerabilities. Techniques to help parents overcome such obstacles during the interview are summarized in Fig. 9.1.3.2.

The developmentally sensitive clinical interview of the child

The interview process and wording of questions must be tailored to fit with the child's understanding.[10] The child may not understand terms necessary to answer questions accurately. The child may also provide misleading answers to shield other family members, to protect against acknowledging some perceived failing, or to address circumstances if the child fears it might entail placement out of the home. Please refer to Chapter 9.1.1 for more specific information for obtaining reliable information during the child interview.

Category	Components	What to Assess
Appearance	Physical Appearance	Gender; ethnicity; age (actual and apparent); cleanliness and grooming, hair/clothing style, presence of physical anomalies, indicators of self-care and parental attentiveness
	Manner of Relating to Clinician and Parents	Ease of separation from parent, guardedness, defiance, eagerness to please, flirtatiousness
	Activity Level	Psychomotor retarded to agitated, sustained or episodic, goal-oriented or erratic; coordination, unusual postures or motor patterns (e.g., tics, stereotypies, compulsions, catatonia, akathisia, dystonia, tremors)
	Speech	Fluency (including stuttering, cluttering, speech impediments), rate, volume, prosody
Mood	Current Affect	Predominant emotion and range (constricted to labile) during the interview, and appropriateness to content (e.g., giggles while talks about sibling's illness); intensity; lability
	Persisting Mood	Predominant emotion over days/weeks; whether current affect unusual or consistent with mood; whether mood reactive to situations or same across range of situations
	Coping Mechanisms and Regulation of Affect	How child manages conflict or distress, age-appropriateness of responses to and dependency on parents; sexual interests, impulses, aggression; control or modulation of urges (finding alternative or socially appropriate means of satisfying urges); how deals with frustration or when anxious
Sensorium	Orientation	Self (name), place (town, State), time (awareness of morning, day of week, month, year varies by age), situation (why at this appointment)
Intellect/ Cognition	Attention	Need for repeating, how long sustained on activity, degree to which child shifts from activity to activity, distractibility (to outside noises, etc.)
	Memory	Immediate (repeat numbers, names back), short-term (recall 3 objects at 2 and 5 minutes), long-term (recall events of past week)
	Intelligence; Fund of Knowledge	Age-appropriate recognition of letters, vocabulary, reading, counting, computational skills; age-appropriate knowledge of geography, history, culture (celebrities, sports, movies, etc.); concrete to abstract thinking, ability to classify and categorize
	Judgment	Best assessed after rapport established, as initially minimization or denial more common); what would do if found stamped envelope next to mailbox, fire started in theater, say if saw man with big feet
	Insight	Ability to see alternative explanations, others' points of view; locus of control (internal v. external); defense mechanisms
Thought	Process: *Coherence*	Logical, goal-directed, circumstantial or tangential (consider age-appropriateness), looseness of associations, word salad (incoherent, clanging, neologisms)
	Process: *Speed*	Mutism, poverty of thought (long latency, thought blocking), poverty of content (perseveration), racing thoughts, flight of ideas
	Perceptions	Altered bodily experiences (depersonalization, derealization), misperception of stimulus (illusion), no stimulus (hallucination: auditory [psychosis > PTSD > organic causes], visual [substance use, delirium], olfactory (neurological, seizure disorder] gustatory [from medicine side effects])
	Content	Obsessions (ego-dystonic), delusions (ego-syntonic), thoughts of harm to self or others (magical thinking, or fears at night often age appropriate)

Fig. 9.1.3.1 The mental status examination in children.

1 Forming a clinical alliance with parents
- (a) Facilitating Narrative History
  Open-ended questions allow parents control, and can be followed with narrow questions to fill in needed details. Using the parent's own words can help parents feel heard.
- (b) Finding Common Themes/Patterns
  Inquiry into problems or conflicts the child has with other adults, peers, or unfamiliar others may illuminate patterns of the child's behavior that play out in a variety of settings, decreasing parents' anxiety that they alone provoke the child's problem.
- (c) Finding Good Intentions Gone Awry
  Parents may feel ashamed of past parenting efforts done in desperation.
  Acknowledging the parent's good intention leading to a misguided effort can diminish self-reproach. For example, a parent's harsh response often belies a fear about the child's future behavior, so identifying the fear and then examining alternative responses can be productive).
- (d) Partnering with Parents (Clinician as "partner" in decision-making process)
  Clinicians increasingly serve as partners, outlining several appropriate treatments, risks, and side effects, and helping parents to choose and invest in preferred treatments. If parents propose treatments the clinician regards as unhealthy or unproven, the clinician can identify potential risks of such treatments to minimize risks to the child.
- (e) Clarifying Expectations of the Evaluation
  Parents sometimes have unrealistic fantasies about what the evaluation will accomplish. Inquiring early about what the parent hopes will be accomplished by this evaluation can reveal such expectations and fantasies, which the clinician can realistically address. For example, parents may believe the evaluation can definitively prove the child had been abused by someone. At the other extreme, parents may fear that the clinician will tell them that their child will never be normal, will require institutionalization, or ultimately harm others.

2 Eliciting Sensitive Information
- (a) Providing the Parent Opportunities to Convey Sensitive Information
  Apprising parents of times and methods to convey information can provide appropriate mechanisms for sharing of information.
- (b) Revisiting Sensitive Information at Safer Points
  If parents resist disclosing information, the clinician should not force answers (as they are more likely to be inaccurate or incomplete), but rather proceed to less distressing information.
- (c) Explaining the Purpose of Sensitive Information
  Some parents may need to understand the underlying reasons for inquiring about personal information. For example, the clinician may need to explain the need to inquire about relatives to clarify genetic contributions to the child's difficulties.
- (d) Describing How Sensitive Information Will Be Reported
  Parents are sometimes fearful that details of embarrassing past parental personal problems may be included in reports to be seen by others. Parents may fear that marital conflict information might be used to alter custody arrangements, or symptoms in a report that could jeopardize their child's future educational or occupational pursuits. Clarifying that general information will be provided ("history of substance abuse on maternal side") rather than specifics and that parents will be able to review reports whose release they authorize can diminish resistance to sharing sensitive information.

3 Handling Discrepant Reports
- (a) Contextualizing Points of View
  Differences between observers' descriptions of a child's behavior have several potential sources. For example, teachers sometimes report very different presentations than parents. Examining what precipitates the child's problem, and how it expresses itself in different environments may allow clinicians to borrow effective strategies across environments without "blaming" adults.
- (b) Aligning Different Perspectives
  When parents or adults exhibit conflict during the psychiatric evaluation, the clinician may continue to refocus adults to the child's needs. For example, the clinician may encourage "middle ground" approaches to increase consistency between environments.

Fig. 9.1.3.2 Parent interview techniques.

The child's understanding of the psychiatric interview

The child and parent are usually seen together at the beginning of the child psychiatric interview to put the child at ease. Once comfortable, the child usually can tolerate the parents leaving the room. Transitional objects (books, electronic devices from home) may ease these transitions. Inquiring about what the child believes parents, teachers, or other adults want to be different as a result of this interview often elucidates what the child recognizes about others' perspectives, and also facilitates the child projecting thoughts or fantasies about this evaluation.

Adolescents sometimes fear parents will skew the interview by telling their 'version' first to get the clinician to side against the adolescent.[11] Meeting briefly with the parent and adolescent to clarify objectives, and then meeting with the adolescent alone at length may enhance an alliance with an adolescent. During this initial segment the clinician can clarify the plan to meet alone with parents after meeting with the adolescent to review birth history, developmental milestones, and family.

Adolescents may resist answering questions or participating. Clinicians can identify the adolescent's priorities and side with those that are reasonable, or identify what the adolescent needs to do to satisfy parents so that the adolescent no longer needs to see a psychiatrist. Clinicians may also decrease resistance by inquiring first about the adolescent's interests, strengths, musical preferences,

rather than focusing on their 'problems,' as adolescents are developmentally struggling with their identity, and may resist fitting into the 'psychiatric patient' category.

Developmentally sensitive techniques for the psychiatric interview

Four categories of techniques are commonly employed in these interviews. *Engagement* techniques are often required to put the child at ease so that the child will provide accurate clinical information. *Projective* techniques allow the child to reveal underlying themes or issues which cannot be verbalized directly. *Direct questioning* techniques clarify particular points needed to distinguish disorders, contributions to the child's problems, and intervention options. *Interactive* techniques clarify how the child relates to, as well as accepts or integrates input from, others.

Techniques to engage the child

Child psychiatrists often provide toys or objects for patients in the waiting room and office. Toy figures, puppets, and 'relationship-oriented' toys may ease the child into the interview. Generic toy figures are usually preferable, since they are more likely to evoke the child's specific themes and concerns rather than 'scripts' based on TV shows or movies. Tasks framed as 'games' or active (e.g. drawing a house or family) often help the child transition into the psychiatric interview. By allowing the child to direct the content, the interviewer can follow the sequence of the child's concerns, note themes that emerge, and observe the points at which a child avoids or shifts to a new topic.

With *adolescents*, efforts to indicate familiarity with contemporary adolescent tastes (music, movies, terms, etc.) can be perceived ingenuine by the adolescent. Instead, clinicians may inquire about current interests, musical preferences, and current adolescent values from a curious, 'help me understand it' perspective, rather than from one of 'trying to be hip.' Manipulable items (squeeze balls, modelling clay, finger cuffs, cards, etc.) may allow adolescents a socially acceptable option for keeping their hands busy so that the interview feels less like an interrogation.

Projective techniques

Projective techniques may help the child express concerns indirectly, so that anxiety about significant fears, telling family secrets, or betraying loyalties is minimized. Common projective techniques include having the child draw a picture of him- or herself or family doing something. For pictures of the child, body details including sizes of appendages or body parts and articulation (fingers, toes), relative size of the figure to the page, and frequent erasures can all reveal underlying issues of anxiety, perceived agency to address difficulties, or needs to control the environment. Depictions of the self as non-human, grotesque, imbued with super powers, or of the opposite gender may provide clues about the child's self-image and underlying wishes. The relative size and placement or omission of family members in a family drawing may illuminate the child's feelings about family relationships. Aggressive or sexual themes may be revealed in drawings.

Verbal projective techniques can similarly yield important information. Asking what animal or character (TV/movie star, cartoon, superhero) the child would most like to be, or whom the child would take along to a deserted island, or asking what the child would do with three magic wishes often allow underlying issues to emerge. Wishes may reveal basic needs, such as food or a safe place to live, or longings for parents to reunite or for the return of a departed friend. Wishes sometimes reveal specific desires, such as 'not to have tics anymore,' or 'never to get teased.' Very general or altruistic wishes, such as 'world peace' or 'to live in a big house with lots of money' warrant further exploration, such as 'Are there particular fights you would especially like to stop?' or 'Who else would live there?' and 'What would you do first with lots of money?'

Projective techniques may help *adolescents* to reveal and share emotionally significant concerns with the clinician. Inquiries into favourite, or most disliked, movies, television characters, political or historical figures, musicians or artists, or sports figures, all allow elaboration of the teenager's ideas in displacement. Adolescents less distrustful of the clinician may readily speak about their own social longings or anxieties regarding friends at school. Adolescent resistances are often revealed by reluctance to divulge names of friends, or even questions about why the clinician needs to know this information. If resistance is detected, questions about what the adolescent most admires about a character, or what the adolescent imagines this character would do in given situations may reveal the adolescent's perceptions. Asking the adolescent about the different cliques or groups at school and his or her relationship to them provides useful information about the teen's self-image. Similarly, questions about what the adolescent sees as fair or would most like to change about school or the world often reveals underlying concerns and issues.

Direct questioning

Direct questioning can specify symptoms or events, clarify how the child sees the world and functions within it, and follow-up on material from other parts of the evaluation. Asking the child to describe friends ('Tell me about your best friend.'), siblings, or parents, is preferable to 'Do you get along with your brother?' Open-ended questions such as 'What sorts of things make you mad/afraid/happy?' and 'What do you daydream about?' are similarly preferable to 'Do you get mad?' or 'Do you ever daydream?'

Anchoring direct questions to major events may help children provide more accurate answers. For example, 'Did that happen before or after your birthday?' or 'How has that (problem) been since school ended?' improve respondent accuracy.

Substance abuse, sexuality, and risky behaviours are often assessed through direct questions. The clinician can use simple questions, such as 'Substance use?' that allow significant latitude, and then focus in further, contingent on the child's responses. For example, the clinician may hear 'No, I don't do any of that anymore,' which could then be followed by 'What led to that decision?' and then proceed back to when and what substances were used. Similarly, sexuality can be assessed by gentle direct questions that do not prematurely close off response options, such as 'Have you had romantic feelings towards another? How did that go?' (rather than 'Have you had a boyfriend yet?'). Adolescents may fear the interviewer will be disapproving, so questions like 'romantic feelings towards anyone' are preferable to 'are there any girls you like?'[12] Finally, direct inquiries into risky behaviours (stealing, vandalism, assaults, gambling, etc.) often require general questions such as 'Have you done anything that you now look back on and think was dangerous?' before proceeding to specific questions (e.g. 'Have you ever stolen anything? Have you ever been beaten up?

Beat up someone else?'). Suicidal risk behaviours may be minimized or trivialized, so additional questions to examine fantasies about impacts of the suicide on family and friends or value contradictions may be needed to clarify suicidality risks.[13]

Interactive techniques

Throughout, the clinician observes how the child relates to another person and what feelings or reactions this child elicits. How the child reacts to a new person, sustains interactions, and terminates the interview often reveal patterns important in the child's larger social life. The clinician can evaluate more complex social interactions during transitions ('It's time to put these toys up in the box.') and during games. Short games (tic tac toe) are useful since the clinician can quickly detect the child's response to winning, tying, and losing.

Adolescents employ more complex patterns, often specific to a subgroup to which they now belong, so clarifying what clothing symbols represent, meanings of confusing terms, and values espoused by subgroups can clarify how the adolescent relates to others. The clinician should observe provocative comments, often used to titrate space between the clinician and the adolescent, or to reject others first.

Concluding the interview

Ending collaboratively increases the likelihood that the child will feel positive about subsequent encounters with clinicians, including treatment. Questions such as 'Are there other things that would be important for me to know about what you're like or how things have been for you?' or 'What else have I not asked about that is important?' facilitate this process.

The child may be curious about what the clinician will say and to whom. The interview is one piece of a larger evaluation, so the clinician may need to clarify that other testing, conversations with others, or additional meetings may be needed. Discussing findings (including treatment recommendations) with parents is usually advisable since parents may disagree with the clinician's conclusions or resist suggested interventions (e.g. medication, school placement, etc.).

Confidentiality is one of the most challenging issues surrounding child psychiatric interviews, especially with adolescents. Describing to the adolescent what will be told to specific others is helpful, as well as what information will not be revealed (e.g. specific details about substance abuse or sexual behaviours). Parents and the child should be told explicitly that confidentiality does *not* extend to situations that pose a clear danger to the child or others. In cases where dangerous content emerges (e.g. the child describes obtaining bullets to frighten a peer), the clinician should clarify with the child *how* they will tell appropriate others, preferably together.

Neuropsychological testing

Patients may have subtle or complicated difficulties processing certain types of information. Consultation with a pediatric neuropsychologist may clarify appropriate tests to address persisting diagnostic questions. Clinicians should recognize that young patients may not be 'interested' in testing tasks, so scores should be interpreted cautiously, with input from the person who did the testing, when the clinician discusses findings with families.

Laboratory evaluation in the child psychiatric evaluation

Few definitive clinical tests identify specific child psychiatric disorders. Laboratory testing remains useful when symptoms and physical findings suggest a particular disorder. Collaboration with the primary pediatric care provider may guide decisions about possible further medical consultations (e.g. audiometric, genetic, neurological, speech, etc.) or diagnostic tests (e.g. blood tests, neuroimaging, sleep studies).

Testing in specific childhood disorders

Laboratory testing yields findings that alter the working diagnosis in approximately 1 per cent of cases, and the yield for laboratory abnormalities, without the presence of other supportive physical findings, remains less than 5 per cent.[14] Laboratory tests commonly considered are summarized in Table 9.1.3.1. Specialized technologies, such as positron emission tomography (PET), single photon emission computerized tomography (SPECT), functional

Table 9.1.3.1 Laboratory tests to consider in childhood psychiatric disorders

Lab test	Disorder					
	MR/PDD	Mood	Psychosis	OCD tics	Substance abuse	Eating disorders
Chromosomal testing	X		X			
Wood's (UV) lamp	X					
Monospot		X				
Thyroid		X	X			X
Lyme titre		X				
CBC	X	X	X		X	X
Serum chemistry	X	X	X		X	X
Lead level	X					
Throat culture antistreptolysin O antibody (ASO), antideoxyribonuclease B titres				X		
Urine drug screen		X	X		X	
Cerebrospinal fluid analysis		X	X			
Neuroimaging			X			
EEG	X					

MRI (fMRI), and brain electrical activity mapping (BEAM) remain attractive research tools at this time in child psychiatry.

9.1.4 Prevention of mental disorder in childhood and other public health issues

Rhoshel Lenroot

Introduction

Over the last two decades advances in psychiatric classification systems and screening tools have allowed the global and national burden of mental disorder to be described with the first large-scale epidemiologic studies. The World Health Organization's *World Health Report 2001* estimated that over 450 million individuals suffer from mental disorders, and that psychiatric disorders ranked as 5 of the top 10 causes of disability in the global population.[1] Studies specifically of psychiatric disorders in children report that between 3 per cent and 18 per cent of children have a clinically significant psychiatric disorder, a number far exceeding those with access to treatment.[2] A recent study which included data on age of onset found that 50 per cent of psychiatric disorders had their onset by age 14, and 75 per cent by age 24.[3] Treatment on this scale is unlikely to ever be feasible, even if available methods were more effective and less risky than those currently available. Preventing mental health disorders from occurring is an alternative to decrease the extent of this public health problem. However, if a key characteristic of prevention is acting prior to onset of a disorder, the early age of onset for most mental disorders indicates intervention must occur during long before adulthood.

Neuroscience has contributed evidence that longitudinal trajectories of brain development are affected by a combination of genetic and environmental factors. Neuroimaging studies have shown dynamic changes in brain structure and function continuing through childhood and adolescence, and geneticists have found that gene expression is highly dependent on environmental conditions. These findings imply that the brain is still highly plastic during childhood and adolescence. This may confer greater vulnerability to long-term effects of insults from trauma, substance abuse, or other adverse influences than in adulthood, but also the potential for lifelong beneficial effects from early positive interventions.

Growing interest in the possibilities afforded by research into prevention in children's mental health stimulated a series of large-scale reports and initiatives beginning in the early 1990s.[4–7] Advances in epidemiology, developmental psychopathology, and prevention science have converged to provide a framework to guide and evaluate prevention programmes. This chapter will discuss basic principles of public health and preventive medicine with application to mental health disorders in children and adolescents.

Public health and prevention: history and basic concepts

The goal of public health is the prevention of disease and promotion of health in communities. The World Health Organization has defined *health* as 'a state of physical, mental and social well-being and not merely the absence of disease or infirmity',[8] and *mental health* as 'a state of well-being in which the individual realizes his or

her own abilities, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to his or her community'.[1] Public health differs from clinical medicine in that it addresses health-related matters on the level of populations rather than individuals. Public health activities include assessment of the health status and risk factors within a community through epidemiology, and population-focused interventions such as supporting the practice of preventive medicine, health education and behavioural modifications, creating and enforcing measures to maintain a healthy environment, and working to increase support for public health initiatives within the political sphere. In countries without universal access to health care public health offices may also act as providers of medical treatment for individuals without other means of access.[9]

Communities have acted to support the health of their members throughout history.[10] Common concerns for most societies have included control of epidemics, public sanitation, and promotion of personal hygiene, although the forms of public health interventions have varied depending on societal values, conceptions of the causes of ill health, and available resources. The health risks posed by the large-scale urban poverty and overcrowding associated with the industrial revolution helped to stimulate the growth of modern public health organizations, whose concerns eventually broadened to include issues such as workplace safety and regulation of the production of foods and medicines. Public health interventions changed to reflect advances in the understanding of disease processes, for example moving from general notions of the value of sanitation to focusing on specific infectious agents. Measures such as widespread vaccination and regulation of sanitary conditions have been so effective in developed countries that the focus of public health in these areas has shifted to chronic disorders such as heart disease and hypertension. Although emotional and behavioural issues have always been a concern of communities, systematic intervention to prevent mental disorders has lagged behind other disorders, in large part because of the lack of consensus regarding the nature of these problems or even how to classify them. A key factor in the advances in public mental health of the past several decades has been progress in epidemiology of mental health disorders.[9]

Epidemiology in public mental health

Incidence and prevalence

Epidemiology provides information about the *incidence* of a condition, meaning the number of new cases, which arise during a certain period of time, and its *prevalence*, meaning how many individuals have the condition during a certain period. The goal of prevention is to decrease a condition's incidence, i.e. prevent new cases from occurring, while successful treatment results in the decrease of the prevalence. Mental health disorders have presented challenges to epidemiology on several levels. In order to determine how many cases of a certain condition exist within the population, it is necessary to know how to define a case, but this is far from straightforward in the realm of mental health. Classification of medical disorders tends to evolve from symptom-based to mechanism-based as the links between a specific pathophysiology and the observed signs and symptoms are established. The lack of knowledge about the mechanisms producing cognitive and behavioural symptoms means that classification of mental disorders still relies upon descriptions of constellations of symptoms. *The International Classification of Disease version 10*(*ICD-10*),[11] and its United States counterpart *the Diagnostic and Statistical Manual TR-IV* (*DSM-TR-IV*),[12] are the results of iterative attempts by experts in the field to create meaningful classifications of psychiatric disorders based upon such observations in conjunction with applicable considerations of length and severity of illness, age of onset, and risk factors. This work has provided the standardized terminology that made possible the first large-scale epidemiologic descriptions of mental disorders. However, problematic issues pertinent to epidemiology remain, including questions regarding the relative merits of categorical versus dimensional classification systems; how to interpret the high rate of comorbidities for several disorders; and how best to account for individuals who have subthreshold symptoms, including how to determine the starting point of a disorder. It is not uncommon for individuals who have come to meet criteria for a mental health disorder such as schizophrenia or depression to have had a preceding period of subthreshold 'prodromal' symptoms, but healthy individuals also have occasional subthreshold symptoms that resolve without intervention. Unfortunately this differentiation often cannot be determined except retrospectively, despite the fact that there may be different implications for epidemiologic and preventive efforts.

The question of how symptoms change over time gains additional relevance when attempting to describe the epidemiology of mental health disorders in children and adolescents. As described in more detail elsewhere in this volume,[13] the science of developmental epidemiology has arisen as a response to the recognition that mental disorders may manifest in different ways over the lifespan, and that certain types of symptoms at one age may indicate that an individual is at high risk for developing a different disorder at a later stage of maturation. Risk factors may also have differing impact depending on an individual's developmental stage. Function may appear impaired if children are developing slowly in comparison with their peers, and it must be decided when this is normal variation and when it should be considered pathological. An additional layer of complexity in epidemiology in paediatric populations is the incorporation of information from additional informants such as parents and/or teachers, and determining how to evaluate the relationship of symptoms to particular contexts.

Risk factors

Epidemiology is also used to assess for the presence of risk factors. *Fixed risk factors* are those that cannot be altered, such as genotype. *Malleable risk factors* are susceptible to intervention, such as exposure to lead-based paint or domestic violence. *Causative risk factors* are those with known relationships to a particular outcome, and are of particular interest to prevention because they represent potential points of intervention. *Protective factors* instead decrease the risk of an adverse outcome. *Resilience* is a term used to describe an individual's ability to do well despite exposure to a typically high-risk situation.

Effective intervention to decrease risk factors or increase protective factors requires determining how these factors relate to each other and to the targeted health issues. The ultimate goal is a chain of causative steps leading from risk factor to outcome, but epidemiological data itself may provide sufficient guidance for action. One of the most famous examples of this was John Snow's identification of tainted drinking water from a particular well as the root

of a cholera epidemic in London, which he did based solely on epidemiological observations. Removal of the pump handle stopped the epidemic and proved that exposure was a causative risk, decades before the bacteria itself was identified. We are currently in a similar situation to Snow in regards to connecting risk factors to mechanisms for many mental health disorders, with the additional complication that mental health disorders are typically associated with combinations of a large number of individually modest potential risk factors.

Risk factors can be classified in terms of how they relate to each other and to the specified outcome,[14] and thus what type of intervention if any is appropriate. *Mediating* risk factors are those which explain how or why another factor affects the outcome; for example, the phenylketonuria enzyme *mediates* the effects of the phenylketonuria gene on IQ.[14] Although all causal factors are mediators, the reverse is not true, and experimental conditions are generally necessary to demonstrate that a particular mediator plays a causal role. A *moderating* risk factor instead specifies under what conditions or for whom another risk factor will affect outcome. Moderating risk factors describe populations that have differing responses to a given exposure, and may also represent potential sites of intervention to prevent an adverse outcome by reducing vulnerability or increasing resilience. A *proxy* risk factor, also called a *pseudocorrelation*, is one that itself does not strongly predict outcome but is highly correlated to a risk factor that does. *Overlapping* risk factors are those that arise from the same underlying construct and are observed to equally predict outcome, be highly correlated with each other and not stand in a specific temporal relationship; these can often be combined into a single factor. *Independent* risk factors conversely are unrelated to each other; they both predict outcome but without correlation or temporal precedence.

Theoretical models in prevention

The identification of risk factors and their interpretation evolves together with theoretical models for the causes and treatments of health problems. The fundamental model used throughout public health and epidemiology is that of *host-agent-environment*, in which the *host* is the person affected or at risk, the *agent* is the direct cause of disease, and the *environment* includes external factors which affects the host's vulnerability to the agent and the vector by which the agent reaches the host. While this model was first developed for infectious disease, it has been expanded to include other types of chronic non-infectious disorders.[10] Examples of pathogenic agents in the latter case include nutrition, chemicals, and genes; host factors include age, sex, and lifestyle; while social or economic issues are among those potentially affecting the environment. Another dimension that has gained increased attention in psychopathology is the actual transaction between the individual and environment—for example, the features of the way a child and parent interact. Intervening to remove risk factors from multiple domains simultaneously can potentially provide the most effective outcome.

Incorporating development into this model adds many challenges. The fields of developmental science and developmental psychopathology arose to create as a framework for the integration of information from developmental epidemiology, neuroscience, genetics, psychology, psychiatry, sociology, and other disciplines in order to better understand the complex interplay of factors affecting the health of an individual throughout their lifespan.[15] Major contributions from work in this area have been establishing the importance of interactions between genes and environment in determining the trajectory of development, rather than attributing mental health outcome to being due entirely to one factor or the other, and the dialectical nature of the relationship between the developing individual and their environment. The recognition of the importance of context in development has led to an elaboration of the different overlapping systems, or *ecologies*[16] that a child resides within and which present unique risks and opportunities for intervention.

Risk factors may be generalized, such as malnutrition and poverty, or more disease-specific, such as exposure to a particular toxin. Many risk factors will tend to occur together, and often risk factors have a non-linear relationship to outcomes; i.e. one or two may not significantly affect outcome, while as the number goes above a certain level risk increases sharply for a number of disorders. An additional complexity in developmental psychopathology is the presence of multicausality and multifinality. Multiple risks or disease processes may produce similar behavioural phenomena, while specific risk factors may be associated with a wide range of clinical presentations. Tracing causal paths and determining what are the factors that are mediating and moderating the relationships between risks and outcomes depends upon the ability to follow the impact of specific interventions over time.

The prevention research cycle and evidence-based prevention
