4.15.2 Deliberate self-harm: epidemiology and risk factors

Ella Arensman and Ad J. F. M. Kerkhof

Introduction

Deliberate self-harm (DSH) refers to behaviour through which people deliberately inflict acute harm upon themselves, poison themselves, or try do so, with non-fatal outcome. These behaviours are somehow linked to, but do not result in, death. Common to these behaviours is that they occur in conditions of emotional turmoil. In former days these behaviours were often regarded as failed suicides. However, this view did not appear to be correct, and the great majority of patients in fact do not try to kill themselves. Therefore, the term deliberate self-harm was introduced to describe the behaviour without implying any specific motive.[1] But this too has some disadvantages because there is a temporal association between non-fatal and fatal suicidal behaviour; many people who die by suicide have engaged in DSH before. Thus, Kreitman *et al.*[2] introduced the concept of parasuicide to describe behaviour that, mostly without the intention to kill oneself, communicates a degree of suicidal intent. However, both terms, deliberate self-harm and parasuicide, are still somewhat confusing, because in practice they include people who really have the intent of killing themselves but survive the attempt. The difficulty of finding a good terminology for these behaviours is reflected in differences in research populations in empirical studies: some studies are limited to self-poisoning only (overdose), a few studies are restricted to self-injury (wrist cutting) only, some to self-poisoning and self-injury combined, and some studies include behaviours in which, due to last-moment intervention from others, there was no actual self-harm inflicted at all. In recent years the term self-harm is being used in the United Kingdom and North America since the adjective 'deliberate' is not favoured by patients, particularly those who repeatedly engage in acts of self-harm.[3]

In this chapter, we will use the term deliberate self-harm interchangeably with attempted suicide to refer to non-fatal suicidal behaviours in which there may have been an intention to die, however ambiguous this intention may have been, and irrespective of other intentions that may have been operating at the same time. It should be stressed that in deliberate self-harm many motives may play a role simultaneously, even contradictory motives such as the hope of being rescued and the wish to continue living. Intentions may vary from attention seeking or communication of despair, appeal for help, to a means for stress reduction. Common to these behaviours is that they are motivated by change: people want to bring about changes in their present situation through the actual or intended harm or unconsciousness inflicted upon the body. Deliberate self-harm may be defined as follows.[4]

> An act with non-fatal outcome, in which an individual deliberately initiates a non-habitual behaviour that, without intervention from others, will cause self-harm, or deliberately ingests a substance in excess of the prescribed or generally recognised therapeutic dosage, and which is aimed at realising changes which the subject desired via the actual or expected physical consequences.

This definition covers deliberate non-fatal suicidal behaviours. Not included are accidental cases of self-poisoning, accidental overdoses of opiates, or self-harmful acts by persons who do not anticipate the consequences of their actions. It does not include automutilation, which is an habitual, often obsessive act of inflicting (minor) self-harm, mostly without a conscious intent of changing the present situation, as with certain persons with learning disability.

Clinical features

Deliberate self-harm can have very different motivations, varying from an intention to die to a cry for help. These behaviours may be well prepared or carried out impulsively, and may have different physical consequences. The degree of lethality and the degree of medical seriousness of the consequences thus depend upon intention, preparation, knowledge and expectations of the method chosen, and sometimes upon coincidental factors such as intervention from others.

It is often difficult to assess the true intent of DSH. Because of fear for consequences, such as admission to a psychiatric hospital, or because of psychological defence mechanisms, people sometimes deny or conceal their intention to die. They also may exaggerate their intention to die in order to receive help. Sometimes people engage in potentially highly lethal self-harming behaviour without any wish to die, for example when they do not have adequate knowledge of the medication used. People who present at a general hospital with minor self-injury or minor self-poisoning may have had strong intentions to die but had insufficient knowledge of the lethality of the method. Therefore, one cannot always reliably infer what the precise meaning of the behaviour was, either from its overt characteristics or from the person's self-report. Among a large sample of adolescents aged 15 and 16 years, Rodham *et al.* found that adolescents who took an overdose more often expressed a wish to die compared to those who engaged in self-cutting.[5] Motives associated with self-cutting were self-punishment and interruption, i.e. trying to get relief from a terrible state of mind.

Epidemiology

In the 1960s and 1970s, there was a sharp increase in the number of people treated in hospitals in Europe, the United States and Australia because of intentional overdoses or self-injury. In the 1980s several studies showed a stabilization.[6,7] In the early 1990s these numbers increased further in some regions.[8,9] The absolute number of persons treated for deliberate self-harm in general hospitals, however, does not adequately reflect the size of the problem. These numbers should be calculated against the size and the characteristics of the population in the areas that are being served by the hospitals. Furthermore, in some countries DSH patients are treated by general practitioners when there is no need for hospital admission. In many instances emergency attendance for overdosing is not even registered. Except for Ireland, where a National Registry of Deliberate Self-Harm has been established,[10] there are no national registries that reliably monitor trends in DSH treated in general hospitals. Even though DSH is considered a major problem in the United States, clinical epidemiological research into DSH is uncommon.[11] Also, few epidemiological studies on DSH originate from other parts of the world.

Changes over time

In Edinburgh and Oxford, in the United Kingdom, there has been continuous monitoring of deliberate self-harm over a long period of time, where characteristics of persons engaging in DSH have been related to the corresponding population.[7,12,13] In these two cities trends in DSH rates have been documented reliably. After a period of stabilization in the 1980s a marked increase was observed. Between 1985 and 1995 the rates of DSH in Oxford increased by 62 per cent in males and 42 per cent in females. The increase in DSH has been most marked among young males. A similar trend has been observed in North Worcestershire where hospital referred cases of DSH were monitored over a period of 20 years (1981–2000).[14]

In Canada, the DSH rate was estimated to be around 304 per 100 000.[15] In the United States National Institute of Mental Health's Epidemiological Catchment Area study (1980–1985) it was found that 2.9 per cent of the respondents had engaged in DSH at some point of time.[16]

So far only one international multicentre study into deliberate self-harm has been conducted taking into consideration the methodological pitfalls outlined above. The World Health Organization (WHO) initiated a collaborative multicentre study in 16 regions in Europe using the same methodology, definition, and case-finding criteria.[9,17] The findings were related to the size and characteristics of the corresponding general population in order to investigate rates, trends, risk factors, and social indicators. Most of the epidemiological data presented here have been drawn from that study.[9,18]

Differences between countries and regions

There is widespread variation between countries with regard to rates of deliberate self-harm. Based on the latest available data for the years 1995–1999, overall, DSH rates (person-based) were highest in the United Kingdom (Oxford), Belgium (Ghent), Hungary (Pecs) and Finland (Helsinki), with female rates per 100 000 ranging from 83 in Padova (Italy) to 433 in Oxford. Male DSH rates per 100 000 ranged from 53 in Umea (Sweden) to 337 in Oxford.[9] Looking at trends over time, an average decrease for male DSH rates of 13 per cent was found comparing average person-based rates for 1989/1993 to the period 1995/1999, with the greatest reduction (70 per cent) in Innsbruck (Austria). For female DSH rates the average decrease in the same period was lower (4 per cent), with the greatest reduction (31 per cent) in Sor-Trondelag (Norway). In addition to medically referred cases of deliberate self-harm, community-based studies show that an even higher proportion of DSH appears to be 'hidden' from health care services.[19]

Differences between catchment areas in deliberate self-harm rates in the WHO/EURO study have been studied in relation to socio-economic characteristics of these areas.[9,20] No correlations were found with most of the social and economical factors supposedly related to DSH, such as population density, urban–rural distribution, proportion working in agriculture forestry or fishery, sex ratio, percentage aged 40 and over, number of people per household, percentage people living alone, percentage single parent families, per capita income, unemployment rate, life expectancy, mortality rate, infant mortality, crimes per year per 1000, and per capita alcohol consumption. Only two characteristics of the catchment areas seemed to be related to DSH rates: the percentage

of divorced people in the area and the percentage receiving social security. Family stability and the percentage of the population relying on welfare both seem to be related to the frequency of DSH, but the interpretation of these findings is difficult because one would expect the other related social indicators of societal cohesion to covary as well.

It is important, however, to realize that the characteristics mentioned above relate to regions or countries, and do not relate to individuals. At individual level, characteristics such as unemployment play an important role, but this does not mean that unemployment rates do explain high DSH rates in a region.[21,22] This relationship holds only for some regions and not for others, as is documented repeatedly.[23] The effect of exposure to risks factors may be due to contextual effects, which arise if individuals' risks of suicidal behaviour depends not only on their personal exposure to risk or protective factors, but also on how these are distributed in their social, cultural or economic environments.[24,25] In a small area study in South East London, Neeleman *et al.* found that the DSH rate of minority groups relative to the white group was low in some areas and high in other areas.

Cultural variation in DSH has been documented from India,[26] Sri Lanka,[27] and Pakistan,[28] and from ethnic groups within Western societies, such as the Inuit in Canada.[29] Neeleman *et al.*[30] studied ethnic differences in DSH in Camberwell, London, and found considerable differences between the DSH rates for white people and for British-born Indian females and African-Caribbeans.[30] Indian females had a particularly high rate, 7.8 times that of white females. Marriage problems seem to be related to DSH in Asian countries such as India, Pakistan, Sri Lanka, and China. Young married women may have serious difficulties after moving in with their husbands' extended families. Dowry problems and problems with in-laws are thought to be precipitants of attempted suicide among young married women. In Asian countries the methods used in DSH reflect differences in accessibility. Self-poisoning with organophosphate pesticides and other household poisons is prevalent. As in the Western world DSH appears to reflect feelings of hopelessness and helplessness in adverse living conditions with no prospect of improvement. Women tend to be more powerless to bring about changes in their living conditions. In Sri Lanka, the continuous warfare, poverty, and the lack of opportunities at home and abroad frustrates the young who are relatively well educated.[27]

Sex and age

In all but one centre (Helsinki) of the WHO Multicentre Study on Suicidal Behaviour the female DSH rates were higher than the male rates. Across the participating regions, on average, the rates for females were 1.5 times higher than those for men. DSH rates were consistently higher among those in the young age groups, with the highest person-based male DSH rates in the age group 25–34 years, whereas for females in most centres the highest rates were found in the age group 15–24 years.[9]

Sociodemographic characteristics

Single and divorced people were over-represented among people who engaged in DSH in the WHO/EURO study.[9,18] Nearly half of the males and 38 per cent of the females were never married. An interaction effect was found for age in that the proportion of single persons among those engaging in deliberate self-harm reduced with increasing age, whereas the proportion of divorced, separated, and widowed people increased with age. Among deliberate self-harm patients who were economically active, a high percentage was unemployed. Based on average DSH rates over the period 1995–1999, 26 per cent of the males and 14 per cent of the females were unemployed.[9]

These findings are consistent with outcomes of earlier research conducted in the United Kingdom, where socio-economic deprivation (low social class and unemployment) repeatedly appear as characteristics of the DSH populations.[22]

These findings indicate that DSH patients disproportionately have had low education, and have high levels of unemployment, poverty, and divorce. The findings may be partly related to underlying common causes, such as the presence of psychiatric disorders, but they also suggest the influence of sociological factors impacting on a relatively economically deprived group in society with a greater share of adversity.[24] Socio-economic deprivation is a well-established determinant of psychiatric morbidity and DSH.[32,33] In contrast with completed suicide, where the presence of psychiatric disorders is well documented (up to 95 per cent of suicides may have suffered from a psychiatric disorder), psychiatric disorders are much less frequent among those who deliberately harm themselves. Among those who engage in DSH for the first time in their lives, the prevalence of psychiatric disorders may be rather low; among repeaters, psychiatric morbidity is considerable.[34,35]

Methods

Methods used in deliberate self-harm are mostly 'non-violent'. In the WHO Multicentre Study, 65 per cent of males and 82 per cent of females took an overdose, based on average DSH rates for the period 1995–1999. Cutting, mostly wrist cutting, was employed in 16 per cent of male cases and 9 per cent of female cases. There are some differences between European countries in the use of particular methods. Based on the years 1995–1999, a relatively high percentage of self-cutting was found in Tallinn (Estonia, 50 per cent), Ljubljana (Slovenia, 30 per cent), and Innsbruck (Austria, 26 per cent). In Szeged (Hungary), 19 per cent of males and 15 per cent of females used poisoning with pesticides, herbicides, or other toxic agricultural chemicals, whereas in other regions this ranged from 0–3 per cent.[9] In Sor-Trondelag, Norway, higher percentages engaged in DSH by deliberate alcohol overdose (6 per cent of males and 5 per cent of females). In general, somewhat older men used the method of jumping or jumping in front of a moving object. In the Oxford studies between 1985 and 1995, 88 per cent of all episodes involved self-poisoning, 8 per cent involved self-injury, and 4 per cent involved both. There was an increase in the use of paracetamol from 31 per cent of poisoning cases in 1985 to 50 per cent in 1995.[6] There was also an increase in antidepressant overdoses and a decrease in overdoses of minor tranquillizers and sedatives. Comparing the early 1990s with the late 1990s, a slight increase was observed in overdose by medication.[9] For all regions the methods used in DSH acts did not covary significantly with age.

The differences in methods between countries may be related to differences in the accessibility of certain methods. Until 1998 paracetamol was available in large quantities in the United Kingdom, unlike other European countries.[36,37] The ingestion of

alcohol during or before the act sometimes can be considered to be a part of the actual method of DSH (when used to bring about unconsciousness, or to increase the risk of a fatal outcome), as part of the preparation (to lower the threshold for engaging in an act of DSH, because of disinhibition), or as a long-term risk factor. Hawton *et al.*[38,39] found that 22 to 26 per cent of DSH patients had consumed alcohol at the time of the act (males more frequent than females), and that 44 to 50 per cent had consumed alcohol during the 6 h before the DSH acts, this again being more common in males than in females. About 28 per cent of DSH patients in Oxford appeared to be substance misusers (alcohol and drugs).

General population self-report surveys

General population epidemiological surveys of adolescents indicate that DSH acts occur more frequently than suggested by hospital statistics.[40,41] A number of surveys have been conducted to estimate the prevalence of DSH. Most of these surveys concerned adolescents and were administered anonymously. Most questionnaire studies revealed that between 1 and 20 per cent of respondents had engaged in DSH at some point in time.[41–44] However, the methodology used in the various studies varies considerably and therefore limits comparison of the outcomes. In the study by Hawton *et al.*[41] a minority (12.6 per cent) of adolescents who had engaged in DSH had presented to hospital.

Lifetime prevalence

Based upon the rates from the WHO/EURO study the lifetime prevalence of deliberate self-harm should be around 3 per cent for females and 2 per cent for males, with some variations between countries and regions.[9] DSH acts that did not lead to medical treatment at a hospital or general practitioner's surgery are very difficult to study, because of the limited validity of self-report data. Based on two large community-based surveys, the lifetime prevalence of suicidal ideation varied from 2.6 to 25.4 per cent and for deliberate self-harm this varied from 0.4 to 4.2 per cent.[45,46]

Classification

As previously mentioned, there is a considerable variety of behaviours within the broad category of non-fatal suicidal behaviour. A review of classification studies[34] revealed three types of DSH patients: a 'mild' type, a 'severe' type, and a 'mixed' type in between.

The mild type of DSH encompasses mostly relatively non-violent methods followed by non-serious physical injury. Young age, living together, few precautions to prevent discovery, low level of suicidal preoccupation, low suicidal intent, interpersonal motivation are all characteristics associated with mild forms of attempted suicide/deliberate self-harm. The severe category consists mostly of relatively hard methods followed by serious physical consequences. Older age (over 40), many precautions to prevent discovery, high level of suicidal preoccupation, high suicidal intent, self-directed motivation, often relocated, previous attempted suicides, depression, drug dependence, a high degree of overall dysfunctioning, poor physical health, and previous psychiatric treatment are all characteristics associated with the concept of 'severe' deliberate self-harm. The risk of repetition is greater in the severe type. In between, in the mixed type of DSH, the DSH acts and patients involved show mixed characteristics, which makes this type harder to identify in medical practice.

In order to further refine the classification of deliberate self-harm, Arensman[47] included psychological and personal history variables and these characteristics were studied in relation to recurrent DSH in a follow-up period of 1 year. **The mild DSH type** was validated, approximately 40 per cent of the total sample, as being predominantly younger than 30 years of age, single, living alone or with parents, and having minor injuries because of the index attempt. The mean number of previous DSH acts was 3.7. The repetition rate in the follow-up period for this group was 27 per cent. In the older age group, two groups were distinguished: a moderate group and a group with an extremely high risk for non-fatal repetition were identified. The high-risk group, consisting of approximately 28 per cent of the total sample, suffered more physical injury as a consequence of their deliberate self-harm.

The high-risk group consisted predominantly of females in the age group 30 to 49 years who were divorced or separated, living alone, and who were economically inactive. Most of them had engaged in previous DSH acts (mean number: 5). They had histories of traumatic life events that mostly started early in life. The high-risk group showed the highest scores on depression, hopelessness and expression of state-anger, and two-thirds were diagnosed as having borderline personality disorder. In the follow-up at least 75 per cent engaged in repeated DSH.

The moderate group was characterized by low levels of physical injury following their DSH, they were predominantly aged at least 30 years and married, and scored intermediate on measures of depression, hopelessness, and anger. The mean number of previous attempts was 2.3, and 33 per cent made one or more repeated DSH acts in the follow-up. Surprisingly, this classification into three types of non-fatal suicidal behaviours did not correspond to the levels of reported suicide intent nor to the levels of the different motivations reported (to die, to appeal, to lose consciousness, revenge), underlining the difficulty of classifying DSH according to intentions. Rodham *et al.*[5] found evidence for different subgroups of DSH patients based on DSH methods and motives. For example, they identified a subgroup of female adolescents who engaged in self-cutting and who reported *self-punishment* as the primary motive, followed by *trying to get relief from a terrible state of mind*. Furthermore, *wish to die* as a motive was significantly more often reported by those who took an overdose compared with those who engaged in self-cutting.

Aetiology

The last psychological step towards deliberate self-harm is always set in conditions of emotional turmoil, an emotional crisis. Essential in crisis is the absence of any positive outlook towards the future. People completing suicide do not expect any improvement of their situation in the near or distant future. People who engage in deliberate self-harm indicate that their future is hopeless, but they still seem to have a faint hope, however ambiguous this may be, that the future might improve. In this way deliberate self-harm may be conceived as a self-invented form of crisis intervention. Studies into the cognitive functioning of DSH patients indeed show a global and stable form of negative anticipations and absence of positive anticipations towards the future, probably as a consequence of disturbances in their autobiographical memory, i.e. an

overgeneral memory.[48,49] Whenever these anticipations remain overgenerally negative after an act of DSH, it is likely that hopelessness will increase and that this behaviour will occur again.[50]

Precipitants

Difficulties or conflicts that may bring the person to believe that his or her future is without hope can trigger the psychological crisis resulting in deliberate self-harm. DSH is often precipitated by disharmony with key figures, work-related problems, financial difficulties, or physical illnesses. Long-standing relationship problems or feelings of loneliness are especially common. People who engage in DSH have a weak social support system,[48] and they report relational difficulties as major problems in life. They show deficits in interpersonal problem solving, and their future holds no promise. Their emotional status can best be described as a state of learned helplessness, a situation of a blocked escape, in which no solution exists for a perceived insurmountable adversity.[51] This leads to the question as to why these persons have developed such helpless attitudes.

Long-term vulnerability factors

The conflicts experienced by DSH patients in the days before an act of DSH are not different from the same conflicts they have experienced over and over again. Not only recent life events, but also the life events that occurred in their past are important.[47] Many DSH patients, males as well as females, have had traumatic childhood experiences, including physical and emotional neglect, broken homes, other unstable parental conditions, violence, sexual and physical abuse, incest, parents who had psychiatric treatment, who were alcoholics and/or addicted to opiates. Women who have been abused have a much greater probability of becoming a repeater later. In addition they often develop poor relationships, lack self-esteem, and experience overwhelming feelings of helplessness and hopelessness. Any trigger, for example an argument with a friend, may be sufficient to provoke suicidal ideation and behaviour.

DSH patients not only suffer from helplessness with regard to interpersonal conflicts, they also tend to be powerless in other domains of life. The DSH population disproportionately consists of unemployed persons, from low social classes, with low educational levels, economically deprived, divorced, disabled, addicted, incarcerated, and/or lonely. Many have received in- or outpatient psychiatric treatment. These findings are somewhat complicated by the fact that many of these vulnerability factors are strongly interrelated. Unemployment, addiction, and unstable partnership relations all may be caused by psychiatric diseases. For example, unemployment and DSH may both be a consequence of addiction. However, it is not fair to assume that most of the economic deprivation of suicidal patients is explained by their psychiatric condition. The considerable differences between nations in the prevalence of DSH support the importance of socio-economic conditions.

Course and prognosis

Repetition is one of the core characteristics of suicidal behaviour. Among those who die by suicide up to 40 per cent have a history of previous DSH acts.[52] Among DSH patients 'repeaters' are more common than 'first-evers'. Between 30 and 60 per cent of DSH patients engaged in previous acts, and between 15 and 25 per cent did so within the last year.[3,7,53,54]

Risk of suicide after deliberate self-harm

Prospectively, DSH patients have a high risk of dying by suicide. Between 10 and 15 per cent eventually die because of suicide.[11,53] The connection between DSH and suicide lies between 0.5 and 2 per cent after 1 year and above 5 per cent after 9 years.[11] Mortality by suicide is higher among DSH patients who have engaged in previous acts of DSH.[55,56] The risk of suicide after deliberate self-harm for males is nearly twice the female risk, the risk being particularly high in the first year.[57,58] Alcohol and drug abuse and related social deterioration are risk factors for subsequent suicide,[59] as are psychiatric diagnosis (affective disorders, schizophrenia, personality disorders), and a highly lethal non-impulsive index act of DSH. In a large European study focusing on young deliberate self-harm patients, positive correlations were found between rates of DSH and suicide for both males and females, with a statistically significant association among males aged 15–24.[60]

Repetition of deliberate self-harm

Risk of repeated DSH is highest during the first year after an act of DSH, and especially within the first 3 to 6 months.[55,57,61] In the WHO/EURO Multicentre Study on Suicidal Behaviour it was found that at least 54 per cent of DSH patients had engaged in a DSH act before, 30 per cent at least twice. Prospectively, 30 per cent of DSH patients made at least one repeated attempt in a 1-year follow-up.[62,63]

It is hoped for that knowledge of antecedents or risk factors may foster early identification of persons at risk, and improvement of treatment. Many studies have tried to identify risk factors or antecedents and some of these by now are well known. Sociodemographic risk factors associated with repetition are belonging to the age group of 25 to 49 years, being divorced, unemployed, and coming from low social class. Psychosocial characteristics of repeaters are substance abuse, depression, hopelessness, personality disorders, unstable living conditions/living alone, criminal records, previous psychiatric treatment, and a history of stressful traumatic life events, including broken homes and family violence, especially physical and mental maltreatment by partners. Prospectively, a history of previous attempts is one of the most powerful predictors of future non-fatal suicide attempts.[34,51,64,65]

Conclusions

Deliberate self-harm is a major problem in many contemporary societies. DSH seems to reflect the degree of powerlessness and hopelessness of young people with low education, low income, unemployment, and difficulties in coping with life stress. As such, non-fatal suicidal behaviour should be a major concern for politicians. There are substantial differences between communities in the prevalence of deliberate self-harm. This suggests that some communities better meet the needs of their underprivileged youngsters than others do, but we barely understand the differences between communities and nations. Preventive action therefore is difficult to design. There is a need for a better nationwide continuous registration of DSH and related socio-economic conditions. There is also a need for better mental health care management of DSH patients, and for experimental studies on the prevention of

repetition. Although we know that persons who engage in DSH are at high risk for future fatal and non-fatal suicidal behaviour, development of effective intervention, and prevention programmes is a key priority.

4.15.3 Biological aspects of suicidal behaviour

J. John Mann and Dianne Currier

Modelling suicidal behaviours

To understand the biological underpinnings of multi-determined behaviours such as suicide and attempted suicide it is necessary to situate them within an explanatory model that can elaborate the causal pathways and interrelations between biological, clinical, genetic, and environmental factors that all play a role in suicidal behaviour. Where possible, such a model should be clinically explanatory, incorporate biological correlates, be testable in both clinical and biological studies, and have some utility in identifying high-risk individuals.

We have proposed a stress–diathesis model of suicidal behaviour wherein exposure to a stressor precipitates a suicidal act in those with the diathesis, or propensity, for suicidal behaviour.[1] Stressors are generally state-dependent factors such as an episode of major depression or adverse life event. The diathesis, we have hypothesized, comprises trait characteristics such as impulsive aggression, and pessimism.[1] Uncovering the biological mechanisms relevant to the stress and the diathesis dimensions of suicidal behaviour will facilitate the identification of both enduring and proximal markers of risk, as well as potential targets for treatment.

One biological correlate of the diathesis for suicidal behaviour appears to be low serotonergic activity. Abnormal serotonergic function may be the result of numerous factors including genetics, early life experience, chronic medical illness, alcoholism or substance use disorder, many of which have been correlated with increased risk for suicidal behaviour. Moreover, serotonergic dysfunction may underlie recurrent mood disorders or behavioural traits that characterize the diathesis, such as aggression and impulsivity. In terms of stress response, the noradrenergic and HPA axis have been the focus of biological studies in suicidal behaviour. This chapter gives an overview of the major neurobiological findings in suicide and attempted suicide, as well as emerging findings from studies of genes related to those systems.

Serotonergic system

Serotonin is involved in brain development, behavioural regulation, modulation of sleep, mood, anxiety, cognition, and memory and is shown to be disturbed in various psychiatric disorders. Serotonergic function is under genetic control and, moreover, deficits in functioning have been shown to be enduring, marking it as a biological trait. The serotonergic system became a target for investigation in relation to suicide when, more than 30 years ago, Asberg and colleagues observed that depressed individuals who had either attempted suicide by violent means or subsequently died by suicide in the study follow-up period were more likely to have lower CSF 5-HIAA levels.[2] Since that time the function of the serotonergic system in suicide and attempted has been examined in many paradigms, and while not all studies agree, there is substantial consensus that individuals who die by suicide, or make serious non-fatal suicide attempts, exhibit a deficiency in CNS serotonin neurotransmission.

Evidence of hypofunction comes from *cerebrospinal fluid* and postmortem studies. 5-hydroxyindoleacetic acid (5-HIAA) is the major metabolite of serotonin and level of CSF 5-HIAA is a guide to serotonin activity in parts of the brain including the prefrontal cortex. There have been over 20 studies of CSF 5-HIAA and suicidal behaviour in mood disorders, and a meta-analysis of prospective studies of 5-HIAA found that in mood disorders lower CSF 5-HIAA increased the chance of death by suicide over fourfold over follow-up periods of 1–14 years.[3]

Multiple *postmortem studies* of suicide, report lower brainstem levels of 5-HIAA and serotonin (5-hydroxytryptamine, 5-HT) (see Mann *et al.* for a review[4]). These deficits in 5-HT or 5-HIAA are observable across diagnostic groups[5] and, despite early reports to the contrary, independent of suicide method. This abnormality appears to be largely specific to the brainstem, and multiple studies have reported no differences between suicides and controls in 5-HT level in other brain regions including the hippocampus, the occipital cortex, the frontal cortex, the temporal cortex, the caudate, the striatum, or the hypothalamus.[4] Serotonin neurone cell bodies are in the brainstem raphe nuclei, while their axons innervate most of the brain including the ventral prefrontal cortex. Morphological analysis of stained serotonin neurones in the brainstem of depressed suicides and non-suicides observed greater cell density in the dorsal raphe nucleus in the suicides[6] suggesting that reduction in serotonin activity is associated with dysfunctional neurones and not with fewer neurones.

Neuroendocrine challenge studies using fenfluramine provide further evidence of anomalous serotonergic function associated with suicidal behaviour. Fenfluramine is a serotonin-releasing drug and a reuptake inhibitor that may also directly stimulate postsynaptic 5-HT receptors. The release of serotonin by fenfluramine causes a measurable increase in serum prolactin levels that is an indirect index of central serotonergic responsiveness. In depressed patients, those with a history of suicide attempts have a more blunted prolactin response to fenfluramine challenge than non-attempters with some evidence that the effect is more strongly related to seriousness of past attempt.[7]

Studies of receptors suggest lower serotonergic transmission in the central nervous system may be accompanied by a compensatory upregulation of some serotonergic postsynaptic receptors such as the 5-HT_{1A} and 5-HT_{2A}, and a decrease in the number of serotonin reuptake sites.[4] There is a reported increase in the concentration of the postsynaptic 5-HT_{2A} receptors in the prefrontal cortex of suicides compared with non-suicides.[8] This increased binding is reflected in more protein and may be due to elevated gene expression in youth suicide.[9] Elevated 5-HT_{2A} binding has also been reported in the amygdala in depressed suicides. In depressed and non-depressed suicides there is evidence that 5-HT_{2A} receptors are upregulated in the dorsal prefrontal cortex but not the rostral prefrontal cortex.[8]

Platelet studies examine 5-HT_{2A} in living subjects with respect to non-fatal suicide attempt. 5-HT_{2A} receptors, serotonin reuptake sites, and serotonin second messenger systems are present in blood platelets, and changes in these platelet measurements may reflect similar changes in the CNS. Multiple studies have reported higher platelet 5-HT_{2A} receptor numbers in suicide attempters compared with non-attempters and healthy controls.[11]

Studies of second messengers indicate impaired 5-HT_{2A} receptor mediated signal transduction in the prefrontal cortex of suicides, [12] and in platelets 5-HT_{2A} receptor responsivity is significantly blunted in patients with major depression who have made high-lethality suicide attempts compared to depressed patients who have made low-lethality suicide attempts.[13] The implications of such a defect in signal transduction, if present in the brain, would be that although there may be greater density of 5-HT_{2A} receptors, the signal transduced by 5-HT_{2A} receptor activation may be blunted, which would compound deficient serotonergic input as seen in the lower levels of brainstem serotonin and/or 5-HIAA in suicide victims.

Some *postmortem studies* of the postsynaptic 5-HT_{1A} receptor report higher binding in prefrontal cortex and more rostral segments of raphe nuclei, and lower binding in more caudal raphe nuclei, hippocampus, prefrontal cortex, and temporal cortex.[7] Less 5-HT_{1A} autoreceptor gene expression is also reported in the dorsal raphe[14] and would favour higher serotonin neurone firing rates.

Postmortem studies of depressed suicides report fewer 5-HT transporters in prefrontal cortex, hypothalamus, occipital cortex, and brainstem.[15] Moreover, in suicides this deficit appears localized to the ventromedial prefrontal cortex, whereas depressed individuals who died of other causes had lower binding throughout the prefrontal cortex.[16]

The emerging picture from postmortem studies of greater 5-HT_{2A} receptor binding in the frontal cortex of depressed individuals who die by suicide, fewer brainstem 5-HT_{1A} autoreceptors, and fewer serotonin transporters in the cortex, as well as findings of greater tryptophan hydroxylase (the rate-limiting step in serotonin synthesis) immunoreactivity in serotonin nuclei in the brainstem[17] all point to homeostatic changes designed to increase deficient serotonergic transmission evidenced by low 5-HIAA in CSF and

brain, low 5-HT and 5-HIAA in brainstem, and blunted prolactin response to fenfluramine challenge.

Serotonergic dysfunction and suicide endophenotypes. Increased aggression has been associated with suicide and more highly lethal suicide attempts and impulsivity has shown a stronger relationship to non-fatal suicide attempts.[18] Impulsive aggressive traits are potentially part of the diathesis for suicidal behaviour.[1] Reduced activity of the serotonin system has been implicated in impulsive violence and aggression in studies in a variety of paradigms including: Low CSF 5-HIAA in individuals with a lifetime history of aggressive behaviour with personality and other psychiatric disorders;[19, 20] a blunted prolactin response to serotonin-releasing agent fenfluramine in personality disorder patients,[21, 22] and; greater platelet 5-HT_{2A} binding correlated with aggressive behaviour in personality and other psychiatric disorder patients.[23, 24] In a postmortem study of aggression, suicidal behaviour, and serotonergic function a positive relationship between lifetime history of aggression scores and 5-HT_{2A} binding in several regions of prefrontal cortex of individuals who had died by suicide was found.[25]

Positron emission tomography (PET) studies have shown a deficient response to serotonergic challenge in the orbitofrontal cortex, medial frontal, and cingulate regions in individuals with impulsive aggression compared to controls[26, 27] and lower serotonin transporter binding in the anterior cingulate cortex in impulsive aggressive individuals compared to healthy controls.[28] The prefrontal cortex is important in the inhibitory control of behaviour, including impulsive and aggressive behaviour.[29] Thus aggressive/impulsive traits, related to serotonergic dysfunction, are potentially an aspect of the diathesis for suicidal behaviour, whereby aggressive/suicidal behaviours is manifested in response to stressful circumstances or powerful emotions. This tendency might be conceived of as a diminution in natural inhibitory circuits, or as a volatile cognitive decision style.

Noradrenergic system

Within the stress–diathesis model of suicidal behaviour, it is the confluence of stressful events with the diathesis that is thought to precipitate a suicidal act. Thus, investigating the functioning of stress response systems in suicidal individuals is important for elucidating neurobiological concomitants of suicidal behaviour and identifying targets for preventative intervention. The noradrenergic system and the HPA axis are two key stress response systems.

The majority of norepinephrine neurones in the brain are located in the brainstem locus coeruleus. Postmortem studies of suicides have documented fewer noradrenergic neurones in the locus coeruleus.[30] There are also indications of cortical noradrenergic overactivity including lower alpha and high-affinity $beta_1$-adrenergic receptor binding,[31] and lower β-adrenoceptor density and $alpha_2$–adrenergic binding in the prefrontal cortex in individuals who died by suicide.[23] There is some, but not unanimous, evidence from prospective studies of lower levels of CSF 3-methoxy-4-hydroxphenylglycol (MHPG), a metabolite of noradrenaline, in future suicides,[33] although not in those making non-fatal suicide attempts.[34]

Fewer noradrenergic neurones observed in depressed suicides may indicate a lower functional reserve of the noradrenergic system, which if accompanied by an exaggerated stress response with greater release of noradrenaline may result in norepinephrine depletion leading to depression and hopelessness, both of which are contributory factors to suicidal behaviour.

Noradrenergic and HPA axis responses to stress in adulthood appears to be greater in those reporting an abusive experience in childhood.[35] Such individuals are potentially at greater risk in adulthood for major depression and suicidal behaviour. Childhood abuse may be associated with increased risk for depression and suicidal behaviour because of a dysfunctional stress response both via the noradrenergic system and the HPA axis, and secondary effects of norepinephrine depletion and elevated cortisol levels. There is interaction between the noradrenergic system and the stress response activity of the HPA axis with reciprocal neural connections between corticotropin-releasing hormone neurones in the hypothalamic paraventricular nucleus and noradrenergic neurones in human brainstem and the locus coeruleus.[36]

The hypothalamic-pituitary-adrenal (HPA) axis

The hypothalamic-pituitary-adrenal axis is a major stress response system. Major depression is associated with hyperactivity of the HPA axis,[37] and suicidal patients in diagnostically heterogeneous populations exhibit HPA axis abnormalities, most commonly failure to suppress cortisol normally after dexamethasone.[33] We found most future suicides were dexamethasone suppression test (DST) non-suppressors.[33] In mood disorders, DST non-suppressors had a 4.5-fold greater risk of dying by suicide compared with suppressors.[3] Moreover, non-suppression may be characteristic of more serious attempts that result in greater medical damage[38, 39] or the use of violent method in the suicide attempt.[40] In other indices of HPA axis function suicide attempters had attenuated plasma cortisol responses to fenfluramine although that may indicate less serotonin release and not an HPA abnormality,[41, 42] and lower CSF corticotropin-releasing hormone (CRH) compared to non-attempters,[43] though not all studies agree.

Larger pituitary and larger adrenal gland volumes are reported in depressed suicides,[44, 45] and fewer CRH-binding sites in the prefrontal cortex of depressed suicide victims which may mean receptor downregulation due to elevated CRF release.[46]

As with the noradrenergic system, early life adversity appears to have lasting effects on stress response in the HPA axis in adulthood. Abnormalities in HPA axis function have been implicated in poor response to antidepressant treatment, and greater likelihood of relapse in major depression, both of which increase the risk for suicidal acts.[33] Increased anxiety and agitation are another potential pathway whereby abnormal stress response, in both the noradrenergic and HPA axis, contributes to risk for suicidal behaviour.

Other biologic systems

Abnormality in the dopaminergic system has been reported in depressive disorders,[47] however studies of dopaminergic function and suicidal behaviour are relatively few and inconclusive.[48] Low dihydroxyphenylacetic acid levels, indicative of reduced dopamine turnover, in the caudate, putamen, and nucleus accumbens are reported in depressed suicides,[49] although the same group of investigators found no difference in number or affinity of the dopamine

transporters.[50] Accordingly, it is unlikely that the reduced dopamine turnover initially observed in depressed suicides is a result of decreased dopaminergic innervation of those regions. Prospective studies disagree as to whether CSF HVA predicts suicidal behaviour.[51–53]

There is a well-documented relationship between thyroid dysfunction and depression[54] and some studies link thyroid function and suicide. Abnormal thyroid-stimulating hormone (TSH) response to thyrotropin-releasing hormone (TRH) has been observed in individuals who died by suicide in a follow-up study. [55] Abnormal TSH response to challenge tests has also been associated with poor response to antidepressant treatment and a higher relapse rate, which may increase risk for suicidal behaviour.[56]

Neurotrophins are involved in brain development and growth, neuronal functioning, and synaptic plasticity. Lower protein levels and gene expression of brain-derived neurotrophic factor (BDNF) in the prefrontal cortex and hippocampus,[57,58] and less mRNA of nerve growth factor, neurotrophin 3 and neurotrophin 4/5 in the hippocampus[59] are reported postmortem in suicides. Lower plasma BDNF has been reported in MDD suicide attempters compared to MDD non-attempters and healthy controls.[60]

Suicide is more common in groups with very low cholesterol levels or after cholesterol lowering by diet (see[61] for a review). This relationship between cholesterol and suicide may be mediated by serotonergic function, as studies of non-human primates on a low-fat diet found lower serotonergic activity and increased aggressive behaviours.[62] Long chain polyunsaturated fatty acids, particularly omega-3, may also be a mediating factor in the relationship between low cholesterol and increased risk for depression and suicide.[63] Lower docosahexaenoic acid percentage of total plasma polyunsaturated fatty acids and a higher omega-6/omega-3 ratio predicted depressed individuals who made a suicide attempt during a 2-year follow-up,[64] and lower eicosapentaenoic acid is found in red blood cells of suicide attempters compared to controls.[65]

Neurobiology, genetics, and suicidal behaviour

Family, twin, and adoption studies support a genetic contribution to suicidal behaviour independent of psychiatric disorder (see Brent and Mann for a review),[66] and genetic studies have sought to determine the responsible genes for suicide and suicide attempt though linkage and SNP association studies. Candidate genes for most studies were selected based on evidence from neurobiological studies in suicide, as a result of which the serotonergic system has been most extensively investigated. A tri-allelic polymorphism in the serotonin transporter promotor has two alleles with lower transcriptional activity and fewer transporters. In varied psychiatric populations, despite some negative findings, the S, or more common lower-expressing allele, has been associated with suicide and with suicide attempts, particularly violent or high-lethality attempts.[67] Functional MRI studies find greater amygdala activation in individuals with the SS genotype when they are exposed to negative stimuli such as angry or fearful faces, negative words, or aversive pictures (see Brown and Hariri 2006 for a review).[68] The amygdala is densely innervated by serotonergic neurones and 5-HT receptors are abundant, and plays a central role in emotional regulation and memory. Excessive responses to emotionally negative events such as abuse, may be over-encoded and contribute to stress-sensitivity in adulthood and thereby to major depression after stress and even suicidal behaviour.

Other genetic studies of the serotonergic system including the 5-HT_{1A}, 5-HT_{2A}, 5-HT_{1B} and other serotonin receptors have largely reported negative results, although there have been some positive findings for the 5-HT_{2A} 102C allele and attempted suicide or suicidal ideation.[67] For tryptophan hydroxylase (TPH1 and TPH2 are two forms of TPH with TPH1 only expressed in the brain during development), associations are reported with suicide and suicide attempt and TPH1 SNPs, however multiple negative findings have also been reported,[67] while haplotype and SNP studies suggest the involvement of the TPH2 gene in suicide and suicide attempt, however again not all studies agree.[67] Monoamine oxidase (MAO-A) plays a key role in metabolism of amines. Low MAO activity results in elevated levels of serotonin, norepinephrine, and dopamine in the brain. The MAO-A gene has functional variable number tandem repeat however no association has been found between this uVNTR and suicidal behaviour, although there is some indication that it may be related to aggression[67] and it is linked to the impact of adversity in childhood on adult antisocial behaviour and trait impulsiveness.[69,70]

Genetic studies in dopaminergic system, noradrenergic system, BDNF, and GABA are few and generally negative,[67] although there are reports of positive association of the catechol-*O*-methyltransferase (COMT), a major catecholamine-catabolic enzyme, gene in Finnish and Caucasian suicide attempters[71] and in Japanese suicides.[72] Inconsistent findings in genetic studies of suicidal behaviour may be due to the complexity of the suicide phenotype, gene–gene interactions, the presence of multiple psychiatric disorders, population racial differences, possible epigenetic effects, and the influence of gene/environment interactions. Nonetheless, new microarray technologies that test expression of thousands of genes simultaneously allowing better gene coverage, and haplotype mapping approaches offer promise for future investigation. Other options include examining more basic endophenotypes such as mood regulation and decision-making.

Genes and environment

Early life stress in conjunction with genetic vulnerability can have enduring effects into adulthood and affect psychopathology and the functioning of biological systems including the serotonergic and stress-response systems (see Mann and Currier 2006).[73] For example monkeys exposed to maternal deprivation in infancy and having the 5-HTTLPR lower expressing S allele in the serotonin transporter gene manifest a lowering of CSF 5-HIAA that persists into adulthood.[74] In 6-month-old macaque monkeys exposed to social stress, those with the S allele had a higher ACTH response, an HPA axis hormone related to stress response, compared with those without that allele and to S allele animals who were maternally reared.[75] Thus the low-expressing S allele not only increased vulnerability to stress in development, but early life stress may further interact with genotype to lower serotonergic function and to increase sensitivity to stressful events later in life, both of which are risk factors for suicidal behaviour.

In human studies, individuals who had experienced childhood maltreatment, those with the low-expressing S allele were at risk for

suicidal ideation and suicide attempt,[76] and those with a lower expressing variant of the MAO-A gene were more likely to manifest antisocial behaviour and more impulsivity as adults.[69, 70]

Future directions

There is much still to be learned about the biologic aetiology of suicidal behaviour and the pathways and mechanisms through which biologic dysfunction is involved in suicidal acts. New techniques for imaging the brain, identification of basic intermediate phenotypes and denser gene markers will contribute to elucidating the biological factors and mechanisms involved in suicide and attempted suicide, and identifying potential targets for prevention.

4.15.4 Treatment of suicide attempters and prevention of suicide and attempted suicide

Keith Hawton and Tatiana Taylor

Introduction

In considering the treatment and prevention of suicidal behaviour account should be taken of recent trends in suicide and attempted suicide, particularly in individual countries. These have been reviewed in other chapters in this section. The term 'attempted suicide' is used in this chapter and includes any act of non-fatal self-poisoning or self-injury, irrespective of motive or intention.

Suicide prevention has been incorporated within the World Health Organization Health for All strategy[1] and has received substantial support from the United Nations.[2] Furthermore, in recent years several countries have developed national suicide prevention programmes. Increased suicide rates in young people have probably acted as a stimulus behind this trend. However, suicide rates in most countries remain higher in older populations and prevention programmes must include this increasingly larger sector of society.

Treatment of suicide attempters

Suicide attempts occur for a wide range of reasons. In many cases the primary aim is not death but some other outcome, such as demonstrating distress to other people, seeking a change in other people's behaviour or temporary escape.[3] This means that a broad range of treatments are required since the needs of individual patients will vary widely (Table 4.15.4.1).

Factors relevant to treatment needs in suicide attempts

(a) Repetition of attempts and risk of suicide

Repetition of attempts is common, with 15 to 25 per cent repeating suicidal acts within a year, and is associated with a greater risk of eventual suicide.[4] The frequency of suicide following attempted suicide varies from country to country,[5] depending on the overall characteristics of the patient population and the rate of suicide in the general population. Prevention of repetition of suicidal behaviour and especially of suicide is a major aim in treating suicide attempters.

(b) Psychiatric and personality disorders

A range of psychiatric disorders are found in suicide attempters.[6] Depression and alcohol abuse are particularly common. In addition, substantial proportions of patients have personality disorders. While treatment directed at the underlying causes of such disorders, where possible, will be important in managing attempted suicide patients, often the disorders themselves will require specific treatment.

(c) Life events and difficulties

Certain problems are particularly common in suicide attempters, including difficulties in interpersonal relationships, especially with partners and with other family members, employment problems, particularly in males, and financial difficulties. Life events, especially disruption in a relationship with a partner, frequently precede suicidal acts.[7]

(d) Poor problem-solving skills

Many suicide attempters have difficulties in problem-solving, particularly in dealing with difficulties in interpersonal relationships.[8] These difficulties are more marked in suicide attempters than in patients with psychiatric disorders who have not carried out a suicidal act.

Table 4.15.4.1 Factors relevant to treatment needs in suicide attempters

Risk of repetition of attempts
Risk of suicide
Psychiatric disorder (especially depression and substance abuse)
Personality disorders
Life events and difficulties
Poor problem-solving skills
Impulsivity and aggression
Hopelessness
Low self-esteem
Motivational problems and poor compliance with treatment

(e) Impulsivity and aggression

There is a strong link between suicidal behaviour and both impulsivity and aggression. There is also accumulating evidence that hypofunction of brain serotonergic systems is linked to aggression (and possibly impulsivity) and also to suicidal behaviour[9] (see Chapter 4.15.3). It is unclear whether this represents a state phenomenon associated with psychiatric disturbance or a trait phenomenon, but current evidence points towards the latter.

(f) Hopelessness and low self-esteem

Hopelessness, or pessimism about the future, which has been shown to be a key factor linking depression with suicidal acts, is an important predictor of repetition of suicidal behaviour, and a risk factor for eventual suicide.[10] Low self-esteem is another important characteristic associated with suicidal behaviour. There is likely to be a link between low self-esteem and a tendency to experience hopelessness when faced by adverse circumstances.

(g) Motivational problems and poor compliance with treatment

Management of suicide attempters is complicated by the fact that some patients appear to be poorly motivated to engage in aftercare. This is also likely to affect compliance with treatments. The style of organization of general hospital psychiatric services (including continuity of care) and the attitudes of clinical staff may be important factors determining whether patients engage in aftercare.

General overview of treatments

Treatments for suicide attempters include both psychosocial and pharmacological approaches. While these are considered separately below, in some patients both will be appropriate. This might be the case, for example, if a patient suffers from depression with biological features in the setting of employment and financial difficulties, when treatment with an antidepressant might be combined with problem-solving therapy.

Psychosocial treatments

A range of psychosocial therapies have been evaluated in suicide attempters in randomized controlled clinical trials. The efficacy of these approaches has been examined in a systematic review of the worldwide literature.[11] The findings from this review and some further studies are summarized below.

(a) Problem-solving

Meta-analysis of the results of trials that have been conducted so far to evaluate the effectiveness of brief problem-solving therapy (see Chapter 6.3.1) compared with treatment as usual indicates a trend towards reduction of repetition of self-harm episodes, but the total numbers of subjects and trials have precluded a definitive result. However, evidence of other positive outcomes, such as reduced levels of depression and hopelessness and improvement in problems, has been convincingly demonstrated in these studies.[12] This approach is useful, either used alone or in the context of other treatment. It is reasonably easily taught and can be used by clinicians from different professional backgrounds.

(b) Psychotherapy

Cognitive behaviour therapy, combined with care management has recently been shown to be effective in reducing frequency of suicide attempts and in producing other positive outcomes.[13] A brief psychological intervention combined with provision of a treatment manual seems to be less effective in the treatment of patients with repeated attempts.[14]

Two trials have been conducted in which an intensive form of psychological treatment known as dialectical behaviour therapy was evaluated.[15,16] Female patients with borderline personality disorders who had a history of repeated self-harm were offered a year of individual and group cognitive behavioural therapy aimed at addressing the patients' problems of motivation and strengthening their behavioural skills, particularly in relation to interpersonal difficulties. Compared with routine care this approach seems to result in a reduction in repetition of self-harm as well as a number of other positive outcomes. Further evaluation of this approach is required to determine if it is effective in male patients and in adolescents, and whether it can be delivered in an abbreviated form. While it is a labour-intensive approach, it appears to be helpful for what is a particularly difficult group of patients.

(c) Outreach

Several trials have been conducted to assess the impact of community outreach, either for all patients or for those that have not attended treatment sessions. Some of these studies have included relatively intensive treatment programmes. Overall these studies indicate that some form of outreach may improve outcome in terms of reducing repetition of attempted suicide. In one study, nurse home visits to encourage non-attending participants to attend outpatient appointments resulted in a significantly greater number of appointments attended as compared to the control group and there was a near significant reduction in the rate of repetition of suicide attempts during the year after study entry.[17] In other studies, telephone contact,[18] and contacting patients regularly by post[19] have also produced promising results. Outreach combined with specific treatment may be useful, perhaps reserved for those who are poorly compliant with aftercare.

(d) Provision of emergency cards

In the United Kingdom there has recently been interest in providing suicide attempters with cards which indicate how they might get emergency help at times of crisis. Two initial, relatively small, studies of this approach, one involving adults and the other young adolescents, produced encouraging results but a larger evaluation did not show the cards to be effective.[20] Provision of emergency cards requires there to be a 24 h service to deal with emergency calls. They might be thought helpful in a minority of cases, but there needs to be careful selection of patients who are offered this facility because of risk of it possibly being abused.

Pharmacological treatments

There have been relatively few treatment trials evaluating the effectiveness of pharmacological agents in suicide attempters. This perhaps reflects the problems of compliance with therapy, which were noted earlier, and risk of overdose.

(a) Antidepressants

A trial in the Netherlands in which paroxetine was compared with placebo in patients who were all repeaters of self-harm but who did not suffer from current depressive disorder showed apparent benefits for a subgroup of patients who received paroxetine, namely

those who had a history of between one and four episodes of self-harm. Patients with a history of five or more episodes did not seem to benefit.[21] The findings of this study are clearly of interest (although *post hoc* subgroup analyses of this kind must be treated with caution). Recently there has been much attention to the risk of antidepressants increasing suicidal ideation and acts in adolescents.[22] Also, it has become clear that there is increased risk with all types of antidepressants during the initial period of treatment.[23] These findings have highlighted the need to be cautious in the use of antidepressants, to provide early follow-up after initiating therapy, and to consider combining antidepressant treatment with other therapies, especially for adolescents (in whom only fluoxetine is currently recommended for the treatment of depression).

(b) Neuroleptics

A trial in which the depot neuroleptic flupenthixol was administered monthly in a dose of 20 mg for 6 months to repeaters of self-harm and compared with placebo in similar patients appeared to show that the active drug was effective in reducing the recurrence of self-harm.[24] While this type of study requires replication, perhaps using one of the atypical oral neuroleptics in patients who frequently repeat self-harm may be worth trying.

(c) Lithium

A systematic review of trials of lithium therapy versus a range of other drugs and placebo in patients with affective disorders has shown convincing evidence that lithium may prevent suicide.[25] It is not known if it may be anti-suicidal in other groups of patients.

Management in clinical practice

Before a treatment plan can be formulated a careful assessment must be carried out. In conducting the assessment the clinician needs to try and establish good rapport with the patient and be sensitive to the patient's preferences. The key factors that should be covered during the assessment are listed in Table 4.15.4.2. For the purpose of formulating a management plan it is particularly useful to draw up a problem list which summarizes the patient's current difficulties. This should be done in active collaboration with the patient as far as possible. Qualitative studies have shown that patients appreciate clinicians and other staff keeping them well informed of their mental and physical status and including them in decision-making in regard to their care.[26]

(a) Assessment

During the assessment it is crucial to estimate the risk of suicide or another non-fatal attempt. However, accurate assessment is far from easy. Risk factors for suicide following attempted suicide are shown in Table 4.15.4.3. Because suicide is uncommon, the predictive value of the items is limited. One predictor of suicide risk is the degree of suicidal intent involved in the current attempt (see Table 4.15.4.4). Clinicians should consider the use of the valuable Beck Suicide Intent scale.[27] Factors known to be associated with risk of a further attempt are listed in Table 4.15.4.5. It should be noted that while individuals who score positive on several of these factors will have considerably increased risk of repetition, a substantial proportion of those who repeat will not show these characteristics, i.e. the predictive value of scales to predict repetition is modest.

Table 4.15.4.2 The assessment of attempted-suicide patients

Factors that should be covered
Life events that preceded the attempt
Motives for the act, including suicidal intent and other reasons
Problems faced by the patient
Psychiatric disorder
Personality traits and disorder
Alcohol and drug misuse
Family and personal history
Current circumstances
Social (e.g. extent of social relationships)
Domestic (e.g. living alone or with others)
Occupation (e.g. whether employed)
Psychiatric history, including previous suicide attempts
Assessments that should be made
Risk of a further attempt
Risk of suicide
Coping resources and supports
What treatment is appropriate to the patient's needs
Motivation of patient (and significant others where appropriate, to engage in treatment)

Table 4.15.4.3 Factors associated with risk of suicide after attempted suicide

Older age
Male gender
Unemployed or retired
Separated, divorced or widowed
Living alone
Poor physical health
Psychiatric disorder (particularly depression, alcoholism, schizophrenia, and 'sociopathic' personality disorder)
High suicidal intent in current episode
Violent method involved in current attempt (e.g. attempted hanging, shooting, jumping)
Leaving a note
Previous attempt(s) (including repetitive self-injury)

Table 4.15.4.4 Factors that suggest high suicidal intent

Act carried out in isolation
Act timed so that intervention unlikely
Precautions taken to avoid discovery
Preparations made in anticipation of death (e.g. making will, organizing insurance)
Preparations made for the act (e.g. purchasing means, saving up tablets)
Communicating intent to others beforehand
Extensive premeditation
Leaving a note
Note alerting potential helpers after the act
Subsequent admission of suicidal intent

Table 4.15.4.5 Factors associated with risk of repetition of attempted suicide

Previous attempt(s)
Depression
Personality disorder
Alcohol or drug abuse
Previous psychiatric treatment
Unemployment
Lower socio-economic status
Criminal record
History of violence
Age 25–54 years
Single, divorced, or separated

(b) Treatment

The treatment plan should be drawn up on the basis of the patient's needs and risks. Inpatient psychiatric treatment will usually be indicated for patients with severe psychiatric disorders, especially where immediate risk of suicide appears to be high.

(i) Psychiatric disorders

Major psychiatric disorders should be treated in the usual way, but with particular care about use of medication which might be toxic in overdose. Specific treatment should be provided for alcohol and drug abuse; indeed, a suicide attempt is sometimes the first occasion that abuse may come to clinical attention.

(ii) Community therapy

Most patients can be managed in the community. Brief psychological therapy, with a focus on problem-solving will be appropriate for those patients who have clear problems, such as in interpersonal relationships, employment, or social adjustment. Some form of outreach (e.g. home visiting, telephone contact) may be helpful to increase the proportion of patients who engage in treatment, but is not necessary for most patients. Outreach may be essential in the treatment of patients in remote rural areas in developing countries.

If possible there should be continuity of therapy in terms of the same person who saw the patient in hospital after their attempt providing aftercare as this is likely to result in better compliance with therapy. Longer term cognitive behavioural therapy or dynamic psychotherapy may be required for patients whose attempts are related to traumas, such as sexual abuse, or to personality disorder. People who are repeaters of suicide attempts may also require more intensive treatment, especially those who frequently repeat. If resources permit, the use of a programme based on dialectical behaviour therapy, possibly using a group format for at least part of treatment, might be considered.

(iii) Adolescents

Family therapy may be required for young adolescents, and also for patients with difficulties in relation to children. Group therapy may be helpful for adolescents who are repeaters of self-harm.[28]

Prevention of suicide and attempted suicide

A widely diverse group of individuals are at risk of suicidal behaviour and it occurs in relation to a wide range of problems and situations. For example, suicide may occur in the context of long-term difficulties extending back to childhood, acute severe life events or, and perhaps most importantly, acute or long-term and relapsing mental illness. Because of this the range of potential prevention strategies is also considerable.

Suicide prevention programmes have been established in many countries. This is to be welcomed, not only because of the potential benefits in terms of suicide prevention, but also because of the likely benefits for the broader population of individuals with mental health problems. When considering prevention strategies, it is important to be aware of and sensitive towards issues relating to culture and ethnicity. For example, while suicide rates are generally relatively low in young females in the United Kingdom, this is not the case in young Asian females of the Hindu faith, in which rates appear to be relatively high and greater than those of their male peers.[29] The issues surrounding such deaths are often related to cultural clashes regarding values and expectations between young Asian females and their parents.

While ethical issues in relation to suicide prevention are not dealt with in detail in this chapter, they are none the less highly important.[30] Opinions will vary, for example, about whether suicide should always be prevented. This particularly relates to suicides occurring in the context of terminal and/or painful physical illnesses, and relapsing and debilitating mental illnesses. The ethics of suicide prevention overlap those of assisted suicide and euthanasia. Psychiatrists are increasingly likely to be drawn into debate and controversy about the ethical aspects of these issues, particularly in relation to severe and chronic mental illness, and mental health aspects of assisted suicide and euthanasia in people with severe physical illnesses.

General principles of prevention

Broadly there are two approaches to suicide prevention.[31,32] As described by Rose[33] in the context of prevention of health problems in general, one can distinguish between population approaches, which aim to decrease risk in the population as a whole, and high-risk group strategies, in which specific groups that are at increased risk are targeted. High-risk group strategies often appear more attractive and realistic. However, risk factors for many disorders are widely spread in the population and so the high-risk strategy tends to exclude a large number of people at moderate risk and is often ineffective in reducing the burden of a disease at the population level. Conversely, population strategies may appear more difficult to achieve but are more likely to be effective in reducing population levels of disease (see also Chapter 7.4). The main population and high-risk group strategies in the prevention of suicide and attempted suicide which are considered here are shown in Table 4.15.4.6.

It is unclear if national suicide prevention programmes are effective, although evidence of effectiveness for specific components of such strategies is emerging.[34] The most impressive programme, developed in Finland, was based on information from a detailed national study of all suicides in 1 year and includes a wide range of elements.[35] A decline in the Finnish suicide rate has been attributed to the programme.[36] In England a national suicide prevention strategy with a suicide target was introduced in 2002.[37] Strategies have also been introduced in Scotland[38] and Ireland.[39] While prevention strategies are difficult to evaluate[40] there are indications that programmes for prevention of suicide on a national scale may be effective.

Table 4.15.4.6 Examples of strategies for prevention of suicide and attempted suicide

Population strategies
Reducing availability of means for suicide
Educating primary care physicians
Influencing media portrayal of suicide
Educating the public about mental illness and its treatment
Educational approaches in schools
Befriending agencies and telephone helplines
Addressing the economic factors associated with suicidal behaviour
High-risk strategies
Prevention of suicide in:
Patients with psychiatric disorders
The elderly
Suicide attempters
High-risk occupational groups
Prisoners

Population strategies

(a) Reducing availability of means for suicide

This is the most widely discussed population strategy.[41] It is based on evidence that if the availability and/or danger of a popular method for suicide changes then this tends to have an impact on suicide rates. The general principles of prevention through reducing availability of means are, first, that many suicidal acts occur impulsively and therefore if a dangerous means is available this is more likely to result in death and, secondly, that the eventual suicide rate in survivors of serious attempts is remarkably low. Also the common adage that if people are intent on committing suicide they will find a means is not necessarily correct (see below).

(i) Coal gas

The most cited evidence for the effectiveness of this approach is the reduction in suicides in the United Kingdom which occurred in the 1960s and early 1970s when toxic coal gas supplies were gradually replaced with non-toxic North Sea gas.[42] Prior to this time coal gas poisoning through people placing their head in a gas oven was the most common method of suicide in the United Kingdom. As North Sea gas was gradually introduced the suicide rate dropped steadily, eventually being reduced by approximately a third. It is estimated that as many as 6000 deaths may have been prevented by this change. The effect also illustrates the point that when one method of suicide is no longer available people do not automatically turn to another, or if they do it may be to one that is less likely to cause death. Thus, it was some years before the suicide rate rose again, this being related to an increase in deaths from poisoning with carbon monoxide from car exhausts. Another factor that may have been relevant to the decline in suicides was the reduction in prescribing of barbiturates, these being replaced by far less toxic benzodiazepines.

(ii) Carbon monoxide

Suicide by carbon monoxide poisoning from car exhausts has become less common because cars are now fitted with catalytic converters. This has resulted in a decline in suicide rates in countries where this method of suicide had become more common, particularly in young males.[43]

(iii) Firearms

The widespread availability of guns in certain countries, particularly the United States, has been proposed as an important reason for their relatively high suicide rates. Guns are used in more than half of all suicides in the United States and their use for suicide correlates with the holding of gun licences in households.[44] Some controversy surrounds the question of whether restricting availability of guns leads to a reduction in suicide rates, but the weight of evidence seems to indicate that it does.[45]

(iv) Antidepressants

Given the very strong link between suicide and depression, and the risk of death from overdose of some of the older antidepressants, there has been much debate about whether more extensive use of newer, less toxic antidepressants would prevent suicides. This is not a simple question, as some patients respond better to the older tricyclic antidepressants. Another consideration concerns the cost of the newer antidepressants compared with the older varieties. Also it is very important to remember that most people who are taking antidepressants do not kill themselves with their antidepressants but use other methods. This and the probable selective prescribing of SSRIs to people judged to be at risk may account for the finding that suicide rates were higher in patients taking fluoxetine than patients taking other and in some cases more toxic antidepressants.[46] Nevertheless, common sense dictates that patients known to be at risk, and especially those with a history of suicidal behaviour, should be prescribed the less toxic preparations.

(v) Analgesics

In the United Kingdom and some other countries there has been particular concern about deaths from self-poisoning with paracetamol. Due to evidence that countries which have fewer tablets per pack seem to have a lower rate of mortality from paracetamol self-poisoning and because overdoses of paracetamol are often taken impulsively and involve household supplies, legislation was introduced in the United Kingdom in 1998 to reduce in the number of tablets of paracetamol (and aspirin) available per pack. This resulted in fewer overdoses, decreased cases of hepatotoxicity due to paracetamol toxicity, and a reduced number of deaths from both paracetamol and aspirin.[47]

(vi) Safety measures

Much attention has been paid to improving safety at popular sites for suicide. This includes erecting suicide barriers on bridges, multi-storey car parks, and other sites. If environmental changes are made such that a popular suicide site becomes safer, this does not mean that people at risk automatically move to using another site. For example, erection of barriers on the Clifton Suspension Bridge in Bristol, a popular site for suicide, has resulted in far fewer deaths by jumping.[48]

Clinicians involved in the development of suicide prevention strategies should look very carefully for local patterns which might provide clues about potentially effective measures for reducing access to methods. This could include, for example, ensuring that psychiatric inpatient units are free of hooks, pipes, and other objects or structures from which patients could hang themselves, and that all bed rails are collapsible (compulsory in the United Kingdom), secure fencing of railway lines or waterways close to psychiatric hospitals, and making local popular sites for suicide safer (e.g. suicide barriers on bridges). In addition, attention should

be paid to common dangerous methods of self-poisoning. Specific strategies may be required depending on local patterns. For example, the high rates of suicide in rural areas of developing countries due to self-poisoning with pesticides might be reversed with safe-storage programmes.

(b) Education of primary care physicians

Much of the attention regarding improved detection of individuals at risk has concerned the detection and management of depression in general practice. This was stimulated by findings that showed many people who died by suicide or who attempted suicide had seen their general practitioners shortly before these acts. Evidence that an intensive educational programme for general practitioners might be effective in influencing suicide rates comes from a study conducted on the Swedish island of Gotland.[49] In the year following this programme the suicide rate dropped significantly, prescribing of antidepressants by general practitioners increased, referrals to psychiatry, especially for depression, decreased, the amount of time lost from work for depression decreased, as did psychiatric admissions. Unfortunately this effect was fairly short-lived in that suicide rates rose again in subsequent years, which the authors attributed to some of the general practitioners having left the island. They also suggested that such programmes need to be repeated.[50] It is also important to note that the suicide rate only declined in females. The evidence in this study was based on relatively small numbers, at least with reference to suicide, although the effects on the management and outcome of depression were perhaps more impressive.

While the Gotland study has generated a lot of debate about suicide prevention in primary care, detection of people most at risk in general practice is extremely difficult because a large number of patients share risk factors and because suicide is a rare event. The most pragmatic view is that effective detection and treatment of depression (and other psychiatric disorders) in primary care are extremely important aims in their own rights and that they might also have benefits in terms of preventing some suicides.

Psychiatrists involved in designing suicide prevention strategies might ensure that there are effective local educational programmes for clinicians in primary care and other settings regarding detection and treatment of people with mental disorders.

(c) Influencing media portrayal of suicidal behaviour

Dramatic reporting and portrayal of suicidal behaviour by the media can facilitate suicidal acts in other people. This has been shown in a wide range of studies of both newspaper and television reporting of suicides and fictional presentations of suicidal behaviours in films and television dramas. The impact of media presentations appears to be greatest where the method used in the suicidal act is described in detail, where details of the deceased and/or the site of the act is provided, and for deaths by suicide of celebrities. The largest impact of media influence is on young people, although there is also influence on older people.[51]

In each country, consideration should be paid to the development of consensus statements about media policies in relation to reporting and portrayal of suicide,[52] which could be produced by joint working parties including representatives of the press, clinical and voluntary agencies, and experts in the field of suicidal behaviour. More difficult is the potentially valuable task of encouraging a policy whereby the media can be used to portray effective coping strategies for people in distress. Such a strategy will need to encompass local cultural factors. Psychiatrists and other professionals developing suicide prevention strategies might examine the practices of their local media with regard to reporting of suicides and, if necessary, hold meetings with media producers to explain the dangers of dramatic and extensive reporting, and also to explore how the media might help in prevention.

Concern is growing about influences on suicidal behaviour through the internet, especially web sites providing instructions on methods of suicide and chat rooms whereby individuals can instruct. Some sites seem to be intended to promote suicide, such as those which initiate meetings between suicidal individuals. Attempts can be made to regulate such sites, but this impossible for sites from other countries. Also, internet providers can be encouraged to ensure that sites offering positive help appear before less desirable sites.

(d) Education of the public about mental illness and its treatment

In view of the very strong link between suicide and mental illness, effective treatment of psychiatric disorders must be a central theme in suicide prevention. However, detection of people with disorders will depend on the awareness that they and those around them have regarding the signs and symptoms of disorder, and their willingness to seek appropriate help.[53] These important stages in receiving effective help will depend on the general public's attitudes towards mental illness and knowledge of its nature and the feasibility of treatment. In several countries, programmes to encourage education of the public about psychiatric disorders (especially depression) and to tackle stigmatization of those who are ill have been established. At this stage, evidence is lacking as to whether or not they have been successful. Psychiatrists and their colleagues might consider similar campaigns where these are not already in place, although the method of delivery of messages (e.g. media presentations, leaflets, workshops, articles) will clearly depend on local factors.

(e) Educational approaches in schools

There have been three broad approaches in trying to prevent suicide through school-based programmes.[54] The first of these includes teaching about the facts of suicide. Worrying evidence from the United States that such a programme appeared to lead to a small increase in pupils' ratings of the acceptability of suicide as an option compared with the ratings of pupils who did not receive the programme suggests that this is not a wise approach.

Suicidal behaviour in young people often appears to be related to depression, anxiety, low self-esteem, difficulties during upbringing (e.g. abuse, deprivation), life events (especially break-up of relationships, family problems, and bullying), and poor problem-solving skills.[54] Also, troubled and suicidal young people most often seek help from their peers. A second school-based strategy has been the development of educational programmes in schools about recognition of psychological distress in individuals and their peers, problem-solving, and peer support. Given the early age at which suicidal behaviour begins, such programmes should probably be targeted at extremely young school children, with later sessions for adolescents.

A third approach is to screen adolescents with questionnaires to detect children and adolescents at risk of psychiatric disorder and

possible suicidal behaviour. Pupils that are so detected will then need referral to an appropriate agency for further assessment and possible treatment. While there is some evidence to support such an approach it is not without drawbacks. (Suicide in children and adolescents is considered further in Chapter 9.2.10).

For psychiatrists and others involved in developing local prevention strategies it is important to recognize that school-based approaches to prevention represents is a highly sensitive area and one where the most effective (and least risky) approach is at present unclear. Another important aspect of suicidal behaviour in school pupils is the management of the aftermath of suicides and its impact on other pupils and how to tackle outbreaks of self-harm.[54]

(f) Befriending agencies and telephone helplines

A very important component of suicide prevention policy in many countries is the support provided by largely volunteer staffed befriending agencies and especially telephone helplines. The best known of these is Samaritans. A key principle on which such services are based is that people in distress and at risk of suicide will benefit from being able to discuss their problems with someone entirely confidentially. Recently, more assertive outreach programmes, in which volunteers meet up with distressed individuals such as in prisons and in remote areas, have been added to the traditional telephone service. In the United Kingdom and elsewhere counselling by e-mail and text messaging is being used extensively.

The effectiveness of these approaches is largely unknown. Conducting controlled trials to examine their efficacy is very difficult. Naturalistic studies have produced conflicting evidence about the effectiveness of the Samaritans in the United Kingdom.[55,56] An examination of changes in suicide rates in areas with and without crisis intervention services in the United States suggested that suicide rates in young white females may have been reduced in areas where such services were developed.[57] Given the large numbers of contacts made with Samaritans in the United Kingdom (nearly 5 million in 2005), it appears that the service is valued by people in distress.

Volunteer-run telephone helplines and similar services may benefit greatly from the support and advice of local clinicians, who should regard them as a potentially valuable element in a local suicide prevention strategy.

Addressing the economic factors associated with suicidal behaviour

The association between suicidal behaviour and unemployment and poverty suggests that in order for suicide rates to change markedly these important socio-economic factors must be modified. The big increase in suicide rates during the economic depression of the late 1920s and early 1930s and the statistical association between suicide risk and unemployment would support this. Clearly such factors are increasingly a reflection of the global economic situation, but the strategies of individual governments, particularly in relation to the employment prospects for young people, may be influential. The main role of psychiatrists may be in highlighting these factors. The considerable evidence that changes in the economic environment can exert a powerful influence on suicide rates indicates that governments with serious intentions to reduce suicide rates should address these issues.[32]

Strategies for high-risk groups

There are a wide range of possible prevention strategies which can be targeted at high-risk groups. Here are some of the more important examples of such groups and relevant strategies will be discussed.

(a) Patients with psychiatric disorders

(i) Risk identification

One approach to preventing suicide in people with known psychiatric disorders is to try and use recognized risk factors for suicide in each disorder to identify high-risk patients. The main psychiatric disorders in series of people who have died by suicide are depression (approximately two-thirds), severe alcohol abuse (approximately 15 per cent), and schizophrenia (5–10 per cent).[58] The main suicide risk factors identified in these three disorders include, for example, previous attempts, family history of suicidal behaviour, and living alone. Comorbidity of disorders (e.g. depression and alcohol abuse) and of personality and psychiatric disorders increases risk.

One difficulty in using a risk-identification approach, however, is that the risk factors identified from studies of groups of individuals who have died from suicide are often misleading when applied to individual patients. Also when applying such factors a relatively large number of individuals will appear to be at risk when they may not in fact be so. In clinical practice it is important to be aware of patients who, because of their individual characteristics, are at long-term high risk. Clinicians must also be aware of acute situations which may temporarily increase the risk in patients, be they ones at long-term risk or not.

The most pragmatic approach, therefore, is to ensure that proven effective treatments for patients with these conditions are available and also to be particularly cautious at times of obvious high risk. There are particular periods of risk of suicide for patients with psychiatric disorders. One of these is during the first few weeks after discharge from psychiatric hospital.[59] This emphasizes the necessity for continuity of care at this critical time. Other risk times may be following the break-up of a relationship or other significant loss, during periods of marked hopelessness, shortly after discharge from hospital, and following recent suicidal behaviour by another patient or someone else close to the individual.

(ii) Preventative strategies

Prevention of suicide in patients with psychiatric disorders must be a major element in any suicide prevention strategy.[60] Important strategies in preventing suicide in patients with affective disorders include active treatment of individual episodes of illness, psychological therapy to improve compliance with treatment and assisting individuals to manage their disorder, use of lithium and other mood stabilizers for patients with recurrent bipolar disorders, and use of long-term antidepressants in patients with frequent relapses of depressive disorders. Risk is often greatest during the early stages of a disorder.[53]

The risk factors in schizophrenia indicate that risk tends to be highest between episodes of acute illness when patients may have insight and feel hopeless about their circumstances and prospects. Risk is related more to affective symptoms than core features of the disorders.[61] Continuity of care is likely to be a particularly important factor in preventing suicides in such patients at risk, with care

being continued energetically during periods of remission. Community psychiatric nurses have a very important role with such patients. The use of the newer atypical neuroleptics may also be beneficial.[62]

Direct treatment of abuse is likely to be the best preventive strategy for patients with substance abuse disorders, with care taken to manage episodes of depression. The particularly high risk in the weeks following a break-up of a relationship for patients with severe alcohol abuse[63] again points to the need for continuity of support in the community.

The prevention of suicide in patients with comorbid disorders, especially the combination of depression with alcohol abuse and/or personality disorder, is a challenging task, particularly as compliance with treatment is often less good than in patients with single disorders. Effective prevention is likely to depend on close integration of care between different statutory care agencies.

Another important element in prevention in this population is education in suicide risk assessment and management procedures for clinical staff at all levels of seniority. These should be incorporated in educational programmes for risk assessment in general.

(b) Elderly people

In planning suicide prevention in the elderly population, account must be taken of the relative immobility of many older people. In a region of Italy, introduction of a telephone service to provide support and access to emergency help for elderly persons at risk has been associated with an encouraging decline in elderly suicides in the area.[64] This might serve as a model for other countries.

(c) Suicide attempters

In view of the clear association between non-fatal suicidal behaviour and subsequent suicide, establishment of adequate services for suicide attempters, including the provision of careful assessments of patients in the general hospital and offering treatments for which at least some indicators of benefit are available (see above), is an important element in any national suicide prevention strategy. There is good evidence that well-trained, non-medical psychiatric staff can effectively carry out assessments and arrange aftercare. Models for ideal services exist, such as those published by the National Institute for Clinical Excellence[65] in the United Kingdom.

(d) High-risk occupational groups

Certain occupational groups are known to be at relatively high risk of suicide. In the United Kingdom these include farmers, veterinary surgeons, dental practitioners, medical practitioners, pharmacists, and female nurses. It is interesting to note that all these groups have relatively easy access to dangerous methods for suicide. Since prevention through detection of those most at risk encounters the usual difficulties of prevention of relatively rare behaviour using rather crude risk factors, it is probably more important to have general strategies for improving care in individual groups. In doctors, for example, there are some particular difficulties about confidentiality and therefore providing easy means of doctors getting confidential help is important. In farmers, improving the knowledge and attitudes of farming communities towards psychiatric disorder, and removing access to firearms at times of risk, are likely to be important.

(e) Prisoners

There are relatively high suicide rates in prisoners,[66] especially young males held on remand. While one aspect of prevention is through ensuring that prisons and police cells are safe in terms of absence of structures from which inmates can hang themselves, there are a range of other potentially useful and humane strategies. These include careful assessments of new inmates using risk-assessment procedures, training of staff with regard to both assessment skills and attitudes towards mental health problems and suicide prevention, in-reach programmes by befriending organizations such as the Samaritans, and ready access to psychiatric and psychological services. Clinicians involved in local suicide prevention programmes should include prisons in their considerations.

Culture-related specific psychiatric syndromes

Wen-Shing Tseng

The concept of culture-related specific (psychiatric) syndromes

In certain ways, all psychiatric disorders are more or less influenced by cultural factors, in addition to biological and psychological factors, for their occurrence and manifestation. 'Major' psychiatric disorders (such as schizophrenia or bipolar disorders) are more determined by biological factors and relatively less by psychological and cultural factors, but 'minor' psychiatric disorders (such as anxiety disorders, conversion disorders, or adjustment disorders) are more subject to psychological causes as well as cultural factors. In addition to this, there are groups of psychiatric disorders that are heavily related to and influenced by cultural factors, and therefore addressed as culture-related specific psychiatric syndromes.

Culture-related specific psychiatric syndromes, also called culture-bound syndromes[1] or culture-specific disorders,[2] refer to mental conditions or psychiatric syndromes whose occurrence or manifestations are closely related to cultural factors and thus warrant understanding and management primarily from a cultural perspective. Because the presentation is usually unique, with special clinical manifestations, the disorder is called a culture-related specific psychiatric syndrome.[3] From a phenomenological point of view, such a condition is not easily categorized according to existing psychiatric classifications, which are based on clinical experiences of commonly observed psychiatric disorders in western societies, without adequate orientation towards less frequently encountered psychiatric conditions and diverse cultures worldwide.

Around the turn of the twentieth century, during a period of colonization by western societies, western ministers, physicians, and others visited faraway countries, where they encountered behaviours and unique psychiatric conditions that they had never experienced at home. Most of these conditions were known to the local people by folk names, such as *latah*, *amok*, *koro*, *susto*, and so on, and were described by westerners as exotic, rare, uncommon, extraordinary mental disorders, mental illnesses peculiar to certain cultures, or culture-bound syndromes. The latter term implies that such syndromes are bound to a particular cultural region.[4]

Recently, however, cultural psychiatrists have realized that such psychiatric manifestations are not necessarily confined to particular ethnic-cultural groups. For instance, epidemic occurrences of *koro* (penis-shrinking panic) occur among Thai or Indian people, not only among the Southern Chinese as originally claimed; and sporadic occurrences of *amok* attacks (mass, indiscriminate homicidal acts) are observed in the Philippines, Thailand, Papua New Guinea, and in epidemic proportions in many places in South Asia,[5] in addition to Malaysia where it was believed to most commonly occur. Terrifying examples of *amok* have recently occurred with frequency on school campuses and in workplaces in the United States.

Therefore, the term culture-bound does not seem to apply, and it has been suggested that culture-related specific psychiatric syndrome would be more accurate to describe a syndrome that is closely **related** to certain *cultural traits* or *cultural features* rather than **bound** specifically to any one *cultural system* or *cultural region*.[4] Accordingly, the definition has been modified to a collection of signs and symptoms that are restricted to a limited number of cultures, primarily by reason of certain of their psychosocial features,[6] even though it is recognized that every psychopathology is influenced by culture to a certain degree.

Subgrouping of culture-related specific syndromes

In order to organize and categorize the various culture-related syndromes, several different subgroup systems have been proposed by different scholars in the past, such as by cardinal symptoms or by 'taxon' (according to a common factor). However, instead of focusing on the clinical manifestation descriptively, it will be more meaningful to subgroup the syndromes according to how they might be affected by cultural factors.

It has been recognized that there are different ways culture contributes to psychopathology. Namely: *pathogenetic effect* (culture has causative effect), *pathoselective effect* (culture selects the nature and type of psychopathology), *pathoplastic effect* (culture contributes to the manifestation of psychopathology), *pathoelaborating effect* (culture elaborates and reinforces certain types of manifestations), *pathofacilitating effect* (culture contributes to the frequent occurrence of particular psychopathologies), or *pathoreactive effect* (culture determines the reaction to psychopathology). Furthermore, culture impacts differently on different types of psychopathology.

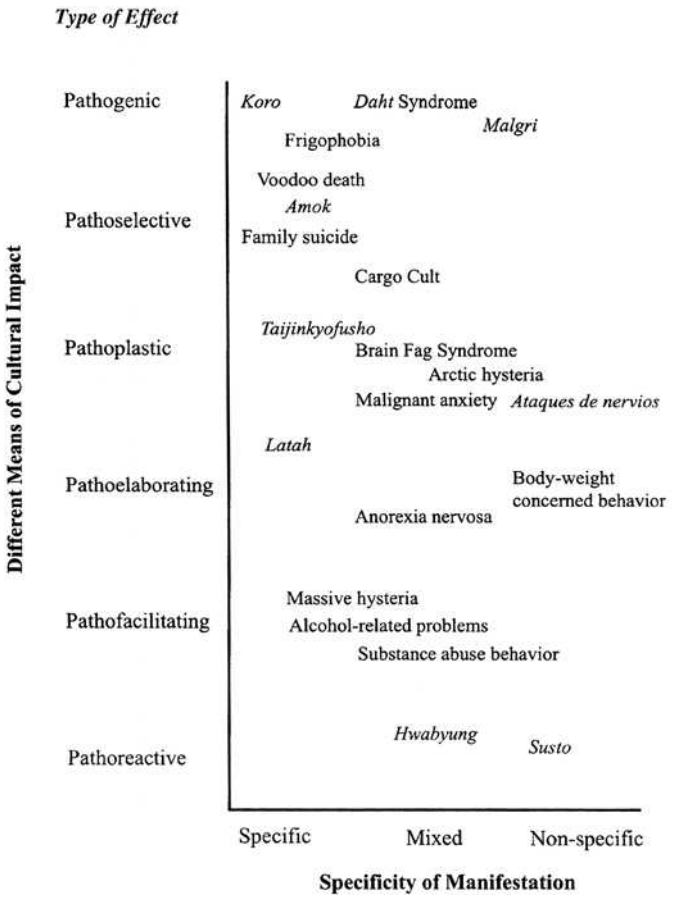

Fig. 4.16.1 Position of culture-related syndromes according to two parameters (This article was published in Handbook of Cultural Psychiatry, Tsend, W.S., copyright Elsevier (2001).)

If the psychopathology is divided into that which is more biologically determined (such as organic mental disorders or major psychiatric disorders), psychologically determined (such as minor psychiatric disorders), or socio-culturally determined (such as culture-related specific syndromes or epidemic mental disorders), it can be said that a pathoreactive effect is observed for all types of psychiatric disorders while a psychogenetic effect is observed mainly for those psychiatric disorders which are more socio-culturally determined, such as culture-related specific syndromes or epidemic mental disorders.

Academically identified culture-related specific syndromes can be compared according to two parameters, namely, the different means of cultural impact and the specificity of the manifestation. It will be useful to determine the basic ways culture contributes to the psychopathology, namely: pathogenic, pathoselective, pathoplastic, pathoelaborating, pathofacilitating, or pathoreactive effects; and to what extent the manifested syndrome is: specific, mixed, or non-specific (Fig. 4.16.1). For example, the primary cultural contribution to *koro* is a pathogenic effect with specific manifestation; to *latah* a pathoelaborating effect with specific manifestation; and to *susto* a pathoreactive effect with non-specific manifestation.

Culture-related beliefs as causes of the occurrence (pathogenetic effects)

(a) Koro (genital-retraction anxiety disorder)

(i) Definition

Koro is a Malay term which means the head of a turtle, symbolizing the male sexual organ which can 'shrink'. Clinically *koro* refers to the psychiatric condition in which the patient is morbidly concerned that his penis is shrinking excessively and subsequently dangerous consequences (such as death) might occur. The manifested symptoms may vary from simple excessive concern to obsessive/hypochondriac concern, intense anxiety, or a panic condition related to the shrinking of the penis. Clinically, this is usually a benign (non-psychotic) condition that occurs in individual, as a sporadic case, but occasionally it may grow to epidemic proportions, so that several hundreds or a thousand people may develop this disorder in a panic manner within a limited time of several weeks or several months. The majority of cases are young males who fear that their penises are shrinking. However, the organ concerned may be any protruding part of the body, such as the nose or ear (particularly when patients are prepuberty children) or the nipples or labia (in females).

Sporadic occurrences of female *koro* cases have never been reported. However, in *koro* epidemics, a small portion of the victims may be female.[7,8] In those cases, the female patients demonstrate slightly different clinical pictures, mainly focusing on the retraction of the nipples and some on the labia. The clinical condition is characterized by a more or less hysterical panic, associated with multiple somatic symptoms, a bewitched feeling, or the misinterpretation or accusation by others of being bewitched.

(ii) Geographic and ethnic group distribution

Cultural psychiatrists originally considered *koro* to be a culture-bound disorder related only to the Chinese. Most Chinese investigators have taken the view that the disorder is related to the Chinese cultural belief in *suoyang*, literally means shrinkage of yang organ due to excess loss of Yang (male) element. It has been speculated further that the occurrence of *koro* among people in South Asian countries, such as Malaysia and Indonesia, was the result of Chinese migrants. However, this cultural-diffusion view is doubted now, since *koro* epidemics have been reported in Thailand and India as well, involving non-Chinese victims.

As a result of the dissemination of knowledge about *koro* as a culture-bound syndrome, there is increased literature reporting so-called *koro* cases from various ethnic groups around the world, such as from the United Kingdom, Canada, and Israel. However, it was pointed out that among the cases reported, all suffered primarily from many psychiatric conditions: affective disorders, schizophrenia and anxiety disorders, drug abuse, or organic brain disorders. Therefore, they were referred as having *koro*-like symptoms, not exactly the same as the *koro* syndrome. It is necessary for clinicians to recognize that *koro* is referred to on different levels as: a symptom, a syndrome, or an epidemic disorder.

(iii) Epidemic of koro

Koro attack may occur occasionally as endemic or epidemic, involving many victims. Epidemic *koro* has been observed in several areas: Guangdong area of China, Singapore, Thailand, and India. As an epidemic, it is manifested as a panic state rather than an anxiety or obsessive state. The epidemic *koro* has tended to occur when there

was socio-political stress within the epidemic areas, and an outburst of *koro* by a group of people may be interpreted as a way to deal with the social stress that they encountered.

(iv) Diagnostic issue

Clinicians habitually try to fit pathologies into certain diagnostic categories. Because the patient, based on his misinterpretation, is morbidly preoccupied with the idea that certain ill-effects may occur due to the excessive retraction of his genital organ, the condition may, in a broad sense, be classified as a hypochondriacal disorder as defined in DSM-IV. The condition is also similar to a body dysmorphic disorder, as the patient is preoccupied with a culturally induced, imagined defect in his physical condition. If the focus is on how the patient reacts emotionally, how he responds to the culture-genic stress, with fear, anxiety, or a panic state, anxiety disorder may be considered. However, when we try to categorize culture-related specific syndromes according to the existing nosologically oriented classification system, their meaning and purpose are lost.

(v) Therapy

As for therapy of sporadic individual cases, assurance may be provided or medical knowledge offered in the form of educational counselling to eliminate the patient's concern about impending death. This supportive therapy may work in many cases, but, for someone who firmly believes the *koro* concept, it may not. In general, a young, unmarried male, who lacks adequate psychosexual knowledge and experience, will respond favourably to therapy. If necessary, it is desirable to work on issues such as the patient's self-image, self-confidence, or his masculinity.

(b) Dhat syndrome (semen-loss anxiety)

Very closely related to the genital-retraction anxiety disorder (*koro*) is the semen-loss or semen-leaking anxiety disorder, or spermatorrhea, also known by its Indian folk name, *dhat* syndrome. The *dhat* syndrome refers to the clinical condition in which the patient is morbidly preoccupied with the excessive loss of semen from an improper form of leaking, such as nocturnal emissions, masturbation, or urination. The underlying anxiety is based on the cultural belief that excessive semen loss will result in illness. Therefore, it is a pathogenically induced psychological disorder.[9,10] The medical term spermatorrhea is a misnomer, as there is no actual problem of sperm leakage from a urological point of view.

From a clinical point of view, the patients are predominantly young males who present vague, multiple somatic symptoms such as fatigue, weakness, anxiety, loss of appetite, and feelings of guilt (about having indulged in sexual acts such as masturbation or having sex with prostitutes). Some also complain of sexual dysfunction (impotence or premature ejaculation). The chief complaint is often that the urine is opaque, which is attributed to the presence of semen. The patient attributes the passing of semen in the urine to his excessive indulgence in masturbation or other socially defined sexual improprieties.[11] The syndrome is also widespread in Nepal, Sri Lanka (where it is referred to as *prameha* disease), Bangladesh, and Pakistan.

(c) Sorcery fear and voodoo death (magic-fear-induced death)

The peculiar phenomenon of voodoo death refers to the sudden occurrence of death associated with taboo-breaking or curse fear. It is based on the belief in witchcraft, the putative power to bring about misfortune, disability, and even death through spiritual mechanisms.[12] A severe fear reaction may result from such beliefs, which may actually end in death. From a psychosomatic point of view, it would be psychogenically induced death. From a cultural psychiatric perspective, it is another example of culture-induced morbid fear reaction.

Medically it has been recognized that sudden death was related to psychological stress occurring during experiences of acute grief, the threat of the loss of a close person, personal danger, or other stressful situations. It has been speculated that the cause of death was possibly from natural causes; the possible use of poisons due to sorcery or witchcraft; excessive fear reaction; or death from dehydration or existing physical illness due to old age.

Culture-patterned specific coping reactions (pathoselective effect)

(a) Amok (indiscriminate mass homicide attacks)

(i) The nature of the behaviour

Amok is a Malay term that means to engage furiously in battle. Clinically *amok* refer to an acute outburst of unrestrained violence associated with (indiscriminate) homicidal attacks, preceded by a period of brooding and ending with exhaustion and amnesia.[13] *Amok* homicides are distinct from other murders: the killer chooses an extremely destructive weapon, a crowded location, and insanely and indiscriminately kills a large number of people.[14]

There has been much speculation as to why *amok* behaviour tends to occur in Malay society. One explanation is its connection to the religious background of the people. Muslims are not permitted to commit suicide, which is considered a most heinous act in the Mohammedan religion. In the past, aggressive-homicidal behaviour influenced by infectious diseases has been considered, along with malaria, dengue, neurosyphilis, epilepsy, and so on, as biological in some cases. From a psychological point of view, an extraordinary sensitivity to hurt and the tendency to blame others for one's own difficulties are considered possible causes for the phenomenon. Loss of social standing, by way of insult, loss of employment, or financial loss, has been posited as a precipitating event for *amok*.

(ii) Amok behaviour in other areas

The outburst of aggressive (mass) homicidal behaviour is not necessarily confined to one cultural area, but can potentially be observed elsewhere, such as the territory of Papua and New Guinea, or many areas in South Asia, such as Thailand, the Philippines, Lao, and Indonesia.[5] It has challenged the previous view that *amok* occurs endemically within a particular society. It has been indicated that *amok* could happen in a fashion by communicability and through transmission from one population to another.[5] During the past decade in the United States, there have been increasing episodes of massive (and aimless) killing of people in neighbourhoods, workplaces, and of teachers/students in schools by deadly military weapons. These are American versions of *amok* attacks.

(b) Family suicide

When adults encounter severe difficulties (such as financial debt or a disgraceful event), there are many ways to deal with such problems. As one of the ways to cope with the difficult situation, Japanese parents, may decide to commit suicide together with their young children. This stress-coping method is based on the cultural

belief that it would be disgraceful to live after a shameful thing had happened, and that the shame would be relieved by ending one's life. This is coupled with the belief that the children, if left as orphans (after parents' committing husband–wife double suicide), would be mistreated by others. 'Blood is thicker than water' is the common saying reflecting the emphasis of blood-related family tie. Therefore, it would be better for them to die with their parents. This unique way of solving problems was often observed in Japan in the past. It is declining now but still observed some times.

(c) Cargo-cult syndromes (millenniary delusions)

Numerous social and behaviour scientists have noted that, historically, there have been occurrences of crisis cults in many different countries. The Taiping (Great Peace) Rebellion in China, Kikuyu maumau in Kenya, and the Ghost Dance of the Plains Indians of North America are some examples. Central to all these cultures are marked feelings of inferiority, conflict, and anxiety among the member-participants after being exposed to other, superior cultures and an attempt to renovate their self-images. Underlying these non-logical, magic-religious endeavours is a strong wish for resolution of their social, economic, and political problems and for a new and better way of life, such as that of the invading, superior cultures.

One kind of crisis cult is the cargo cult that has repeatedly arisen in Melanesia over the past century as a means of obtaining the manufactured articles possessed by European invaders.[15] Cargo is a neo-Melanesian or pidgin word that designates all of the manufactured goods, including canned foods and weapons, possessed by the Europeans, which are greatly desired by the indigenous people. Without knowing how the cargo was manufactured in the home countries of Europe, based on their own folk beliefs, the local people thought that it was given to the white people by their powerful ancestors through the performance of proper rituals. Accordingly, the local people tried to perform the white people's rituals, in the hopes that their ancestors would send them a lot of cargo and their lives would eventually be full of wealth. This behaviour might be individual, or it might involve a group of followers that gave up their normal lives to perform religious rituals, waiting for the arrival of the cargo, not only for several months, but for many years. They would become collectively deluded and led by a cult leader. As a culture-related specific syndrome, it may be understood that culture contributed to the stress that was encountered and also shaped the unique, pathological pattern of coping with it, a combination of pathogenic and pathoselective effects.

Culture-shaped variations of psychopathology (pathoplastic effect)

This category includes a group of disorders that manifests a clinical picture that is considerably different from the ordinal symptomatology of identified disorders described in current psychiatric classifications (of Euro-American origin). It is considered that the uniqueness of the symptomatology may be culturally attributed, i.e. due to cultural pathoplastic effects. Culture affects not only the content of symptoms, but, even more, the total clinical picture by the absence, addition, or variation of symptoms, resulting in considerable change in the manifestations of variations or subtypes of universally recognized psychiatric disorders.

(a) Anthropophobia (interpersonal relation phobia)

(i) Definition and nature of the disorder

Anthropophobia is the English translation for the Japanese term *taijin-kyofu-shio*. In Japanese, *taijin* means interpersonal, *kyofu* means phobic, and *shio* means syndrome or disorder. Therefore, *taijin-kyofu-shio* literally means the disorder with fear of interpersonal relation.[16] *Taijinkyofushio* is said to be prevalent among Japanese and is considered a culture-related psychiatric disorder. According to the clinical study, the onset of illness was as early mostly between 15 and 25 years, more prevalent among males than female. The cardinal symptoms manifested by the patients are: fear of one's bodily odours, fear of flushing, fear of showing odd attitudes towards others, fear of eye contact with others, concern about others' attitudes towards oneself, and fear of body dysmorphia.

(ii) Dynamic interpretation and culture formulation

The characteristic of *taijinkyofushio* is that the fear is induced in the presence of classmates, colleagues, or friends, those who are neither particularly close (such as family members) nor totally strange (such as people in the street). In other words, subjects are concerned with how to relate to people of intermediate familiarity. It is towards these people that a person must exercise delicate social etiquette. This is different from social phobia described in western societies, where patients have fear of socializing with strangers.

Culturally it has been explained that Japan is a situation-oriented society, very much concerned with how others see one's behaviour. It is considered that the act of staring at the person to whom one is talking is quite extraordinary and considered to be rude. Thus, there are cultural characteristics that cause Japanese to be hypersensitive about looking at and being looked at.

Taijinkyofushio is a psychological disorder of the adolescent. It is closely related to the problems associated with psychological development in the area of socialization. The Japanese child is raised in an atmosphere of indulgence and trust. However, when this protected child enters the wider world of junior high school, he or she faces multiple tasks: coping with conflict between biological needs and social restrictions, personal identity problems, and an increasing need for acceptance and love by others in social settings. This intensifies a feeling of unworthiness, making him or her more concerned about others' sensibilities and reactions.

(b) Brain fag syndrome

This syndrome was described originally as a very common minor psychiatric disorder occurring among the students of Southern Nigeria. Clinically, it is characterized by subjective complaints of intellectual impairment, (visual) sensory impairment, and somatic complaints, mostly of pain or a burning sensation in the head and neck. The student-patients often used the term brain fag to complain that they were no longer able to read, grasp what they were reading, or recall what they had just read, basically stressing their difficulty in mental function. Therefore, the term brain fag syndrome was suggested for this distinct clinical mental condition.[17]

In Nigeria, education was often a family affair, in which one of the brighter children was supported financially by family members; the educated member in turn was expected to be responsible for other family members when the need arose. Because of this family aspect of education, the student was burdened by the responsibility of maintaining the family's prestige. Thus, his or her academic

success or failure was associated with great stress. Therefore, it can be said that this syndrome is adjustment disorder with somatic feature and its symptomatology is shaped by culture.

(c) Arctic hysteria (pibloktoq)

Arctic (or polar) hysteria, also known by the local name *pibloktoq*, refers to a unique hysterical attack observed among the polar Eskimo people living in Arctic areas. The clinical condition is characterized by the sudden onset of loss or disturbance of consciousness. During the attack, as the patient may show various abnormal behaviours, such as tearing off his or her clothing, glossolalia, fleeing (nude or clothed), rolling in the snow, throwing anything handy around, performing mimetic acts, convulsion, or other bizarre behaviour. This emotional outburst occurs predominantly in women, but occasionally among men.[18]

No specific precipitating causes are noted. It has been speculated that the reaction is a manifestation of the basic Eskimo personality. Because the reaction is prevalent in winter, it is also thought that it may be related to increased threats of starvation or higher accident rates. Generally, it is suspected that the disorder is due to some basic, underlying anxiety, triggered by severe, culturally typical stresses: fear of certain impending situations, fear of loss, or fear of losing emotional support, including the sense of being on safe, solid, familiar ground.

(d) Malignant anxiety

A special, intensified form of anxiety disorder, termed as malignant anxiety, was reported to occur in Africa.[19] The condition was characterized by intense anxiety, extreme irritability, restlessness, and intense fear, and, therefore, named it malignant anxiety. It was referred to as frenzied anxiety as well. Often, the patient claimed that there was a change in his sense of self and reality, but there was no sign of personality deterioration or disintegration and no latent or overt psychotic symptoms. However, patients often suffered from intense feelings of anger that led to homicidal behaviour. The condition usually occurred in sporadic cases, but occasionally as an endemic. The disorder was thought to be situation related, associated with problems of adaptation to new and stressful life situations. Very often the patients were culturally marginal persons, who were in the process of renouncing their age-old cultures, but had failed to assimilate the new.

Culturally elaborated unique behaviour (pathoelaborating effect)

(a) Latah (startle-induced dissociative reaction)

(i) Defining the condition

Latah is a Malay word referring to the condition in which a person, after being startled by external stimuli, such as being tickled, suddenly experiences an altered consciousness and falls into a transient, dissociated state, exhibiting unusual behaviour (such as echolalia, echopraxia, or command automatism), including explosive verbal outbursts, usually of erotic words that are not ordinarily acceptable.[20] Beside Malaysia, the phenomenon has been observed in other places around the world and has been given various folk names: in Burma (where it is called *yaun*), Indonesia, Thailand (*bah-tsche*), the Philippines (*mali-mali*), indigenous tribes in Siberia, Russia (*myriachit*), and among the Ainu in Japan (who call it *imu*).

The *latah* reaction is found predominantly among women, although men may occasionally be involved. It was found that *latah* tends to run in families. In the past, it was primarily young women who were involved in *latah*. Most of the subjects found now are beyond middle age. Most cases are found in rural areas. Some develop *latah* reactions insidiously, without any precipitating events, whereas others symptoms occur after they endure psychologically stressful events. The loss of a significant person usually occurs shortly before the first experience of *latah* reaction. Once the reaction is experienced, it becomes habitual, and, thereafter, any sudden stimulation may provoke it. Hearing a sudden noise or being suddenly touched or poked by others may cause *latah*. Throwing a rope or other snake-like object in front of the person or simply shouting snake! will sufficiently startle the person to start a *latah* reaction.

The condition may last for several minutes or several hours if the person is continuously provoked. After the dissociative reaction is over, the subject usually claims amnesia and is puzzled about what had happened. Often, the subject is very apologetic and embarrassed for the (socially) inappropriate things he or she may have said (sexually coloured, dirty words) or done (such as touching men) during the attack.

(ii) Aetiological speculations

Anthropologists have tried to understand the *latah* condition from a cultural point of view. It has been pointed out that the *latah* reaction is remarkably congruent with the cultural themes emphasized, but in a paradoxical way. It is a peculiarly appropriate means of communicating marginality to others. The *latah* subjects are engaging in a performance, a role, and theatre, a culture-specific idiom expressing marginality while simultaneously reaffirming normative boundaries. The traditional polygamous Malay extended family structure is male dominated. Within this cultural system, *latah* is socially accepted as a female attention-seeking response, one of the few permissible overt, excitable, aggressive, and/or sexual demonstrations. In other words, *latah* is a culturally sanctioned emotional outlet for females. It is also a culturally elaborated unique behaviour.[21]

Cultural influence of prevalent occurrence of disorders (pathofacilitating effects)

This category includes several conditions that are commonly known as psychiatric disorders. There is nothing particular about them in terms of clinical manifestation (thus, they are not *specific* or *unique* disorders). However, their prevalence is influenced strongly enough by cultural factors that they may be viewed as heavily culture-related syndromes, rather than merely *ordinary* psychiatric disorders. Among this group of disorders, massive hysteria, group suicide, alcohol-related problems, or substance abuse are some of the examples.

Cultural interpretation of certain mental conditions (pathoreactive effect)

(a) Ataques de nervios (attack of nerves)

The folk name, *ataques de nervios*, literally meaning attack of nerves, refers to a stress-induced, culturally shaped unique emotional reaction with mixed anxiety-hysterical features.[22] This is an illness category used frequently by Hispanic people.

Initially observed among Puerto Rican army recruits, it was also labelled Puerto Rican syndrome. This condition typically occurs at funerals, in accidents, or in family conflicts, and calls forth family or other social supports. Commonly experienced symptoms include shaking, palpitations, a sense of heat rising to the head, and numbness, symptoms resembling a panic attack. The individual may shout, swear, and strike out at others, and finally fall to the ground, manifesting convulsion-like movements.

Based on clinical study, it has been reported that most of the patients (about 80 per cent) were female. From a clinical, diagnostic point of view, according to DSM-III-R criteria, the condition belongs to many subtypes of disorders, including panic disorder, recurrent major depression, generalized anxiety disorder, non-specific anxiety disorder, and others. Because the clinical picture is of a mixed, rather than a specific, nature, it may be interpreted simply as a folk label for an emotional reaction based on psychoreactive effect. It may be understood as an acute episode of social and psychological distress related to upsetting or frightening events in the family sphere. Focusing on symptoms alone misses what is most salient and meaningful about illness categories.

(b) Hwabyung (fire sickness)

Hwa-byung in the Korean language literally means fire (*hwa*) sickness (*byung*). Based on a traditional Chinese medical concept that is still prevalent in Korea, that an imbalance among the five elements within the body (metal, wood, water, fire, and earth) may cause physical disorders, laypeople in Korea use the folk term fire sickness to describe ill conditions. This is a folk idiom of distress characterized by a wide range of somatic and emotional symptoms. About three-fourths of the patients that complained of *hwabyung* were women, who linked their conditions to anger provoked by domestic problems, such as their husbands' extramarital affairs and strained in-law relationships. Culturally, it has been explained that male chauvinism has always been dominant in Korean society, and women tend to suffer from their vulnerable status. When a housewife is mistreated by her husband or is having troubles with her in-laws, she has to suppress her emotional reactions so that there will be no disturbance in the stability of the family. As a woman, she is taught to accept defeat, bear frustration, and suppress her hatred. As a result, accumulated resentment (*hahn* in Korean) becomes a major issue for some women. This is the core dynamic for understanding *hwabyung*.[23]

Cultural factors may indirectly contribute to the occurrence of particular psychological problems that are encountered by Korean women, but through pathoreactive effect, emotional reaction was labelled by laymen as an indication of fire sickness (*hwabyung*).

(c) Susto (soul loss)

Susto is a Spanish word that literally means fright. The term is widely used by people in Latin America to refer to the condition of loss of soul.[24] It is based on the folk belief that every individual possesses a soul, but, through certain experiences, such as being frightened or startled, a person's soul may depart from the body. As a result, the soul-lost person will manifest certain morbid mental conditions and illness behaviour. The remedy for such a condition is to recapture the soul through certain rituals. The concept of loss of soul as a cause for sickness is prevalent around the world, and that terms similar, or equivalent, to *susto* are found widely distributed across many different cultural groups, such as *el miedo* (fright) in Bolivia, *lanti* in the Philippines, or *mogo laya* in Papua New Guinea.

It should be pointed out that, although the cause is attributed to spiritual-psychological reasons relating mostly to a frightening experience or misfortune, from a clinical point of view, the manifested syndrome is quite heterogeneous, without a commonly shared syndrome. The victim may manifest loss of appetite, sleep disturbance, reduced strength, absentmindedness, headache, dizziness, or other somatic symptoms, as well as emotional symptoms of depression, anxiety, or irritability. Therefore, strictly speaking, it is not a culture-related specific syndrome derived from psychogenic or psychoplastic effects. It is culture-related *only* in the sense that the morbid condition is interpreted after the fact according to folk concepts of aetiology and certain ways of regaining the lost soul, such as rituals, are offered. Therefore, the role of culture is interpretation of and reaction to the illness.

Final comments

Diagnosis and classification issues

Associated with the increased awareness of the impact of culture on psychiatric classifications, there is controversy regarding how to deal with culture-related specific syndromes from a diagnostic point of view.[12] Some clinicians feel strongly that various known culture-bound syndromes (such as *koro* or *hwabyung*) should be officially recognized and included in the present classification system.

However, it needs to be pointed out that the present DSM classification system is based on the descriptive approach, categorizing psychiatric disorders by certain sets of manifested symptomatology. If we try to fit culture-related specific syndromes into the categories of the existing classification system or try to create new categories of disorders, they will be classified as NOS (not otherwise specified) or, at best, as variations of presently recognized disorders. Most importantly, by squeezing the culture-related specific syndromes into the descriptive-oriented classification system, we will lose the unique meaning of the syndromes from a cultural perspective.[25]

Culture-related specific syndromes in western societies

Another point that must be made is that, by definition, culture-related specific syndromes should be able to be discovered everywhere, as every society, no matter East or West, has its own culture. However, the trend has been to consider that most culture-related specific syndromes (such as *koro*, *amok*, or *dhat* syndromes) occur in non-western societies. This is because they were considered peculiar phenomena observed in areas previously colonized by western people and they simply did not fit the classification system developed for Euro-American populations. This trend is now changing. There is an increased interest in recognizing syndromes in our own western cultures that are heavily culture-related.[26] Several psychiatric disorders have been suggested by various scholars for consideration as western culture-related syndromes. These include: anorexia nervosa, obesity, drug-induced dissociated states, and multiple personality, disorders that are seldom observed or concerned in non-western societies. Because these conditions are already recognized in the existing western nosological system, they are, in a sense, not viewed as specific syndromes. However,

they can be viewed as culture-related psychiatric conditions that are influenced by the pathoelaborative, pathofacilitative, or pathoplastic effects of western culture.

Clinical implications for general psychiatry

Even though the encounter of culture-related specific psychiatric disorder in our daily psychiatric practice is relatively rare, the purpose of examining such specific syndromes has its significant purpose and implications. Through such unique examples, it helps us to appreciate the cultural attribution to the stress formation, reaction pattern, symptom manifestation, occurrence of frequency of disorders, and reaction to the disorders. It also concerns how to work on therapy for the disorder by complying patient's cultural background.

Preface to the second edition

This new edition, like the first, aims to present a comprehensive account of clinical psychiatry with reference to its scientific basis and to the ill person's perspective. As in the first edition, the authors are drawn from many countries, including the UK, the USA, 12 countries in continental Europe, and Australasia. The favourable reception of the first edition has led us to invite many of the original authors to revise their chapters for this second edition but 50 chapters are the work of new authors, many concerned with subjects that appeared in the first edition, while others are completely new. The forensic psychiatry section has the most new chapters, followed by the section on psychology as a scientific basis of psychiatry.

The overall plan of the book resembles that of the first edition (see preface to the 1st edition, reprinted on pages vii and viii). One important feature is that information about treatment appears in more than one place. The commonly used physical and psychological treatments are described in Section 6. Their use in the treatment of any particular disorder is considered in the chapter concerned with that disorder and the account is in two parts. The first part is a review of evidence about the effects of each of the treatments when used for that disorder. The second part, called Management, combines evidence from clinical trials with accumulated clinical experience to produce practical advice about the day to day care of people with the disorder.

Although much information can now be obtained from internet searches, textbooks are still needed to provide the comprehensive account of established knowledge into which new information can be fitted and against which recent findings can be evaluated. As well as seeking to provide an authoritative account of essential knowledge, each chapter in the new edition includes a brief list of sources of further information, including where appropriate, regularly updated web sites.

An essential component of good practice is the need to be aware of patients' perspectives, to respect their wishes, and to work with them, and often their families, as partners. The book opens with an important chapter on the experience of being a patient, and there are chapters on stigma, ethics, and the developing topic of values-based practice.

We are grateful to the following who advised us about parts of the book; Professor John Bancroft (Psychosexual Disorders), Professor Tom Burns (Social and Community Psychiatry), Professor William Fraser (Intellectual Disability), Professor Keith Hawton (Suicide and Deliberate Self Harm), Professor Susan Iversen (Psychology), Professor Robin Jacoby (Old Age Psychiatry), Professor Paul Mullen (Forensic Psychiatry), Sir Michael Rutter (Child and Adolescent Psychiatry), and Professor Gregory Stores (Sleep Disorders).

Preface to the first edition

Three themes can be discerned in contemporary psychiatry: the growing unity of the subject, the pace of scientific advance, and the growth of practice in the community. We have sought to reflect these themes in the *New Oxford Textbook of Psychiatry* and to present the state of psychiatry at the start of the new millennium. The book is written for psychiatrists engaged in continuous education and recertification; the previous, shorter, *Oxford Textbook of Psychiatry* remains available for psychiatrists in training. The book is intended to be suitable also as a work of reference for psychiatrists of all levels of experience, and for other professionals whose work involves them in the problems of psychiatry.

The growing unity of psychiatry

The growing unity in psychiatry is evident in several ways. Biological and psychosocial approaches have been largely reconciled with a general recognition that genetic and environmental factors interact, and that psychological processes are based in and can influence neurobiological mechanisms. At the same time, the common ground between the different psychodynamic theories has been recognized, and is widely accepted as more valuable than the differences between them.

The practice of psychiatry is increasingly similar in different countries, with the remaining variations related more to differences between national systems of health care and the resources available to clinicians, than to differences in the aims of the psychiatrists working in these countries. This unity of approach is reflected in this book whose authors practise in many different countries and yet present a common approach. In this respect this textbook differs importantly from others which present the views of authors drawn predominantly from a single country or region.

Greater agreement about diagnosis and nosology has led to a better understanding of how different treatment approaches are effective in different disorders. The relative specificity of psychopharmacological treatments is being matched increasingly by the specificity of some of the recently developed psychological treatments, so that psychological treatment should no longer be applied without reference to diagnosis, as was sometimes done in the past.

The pace of scientific advance

Advances in genetics and in the neurosciences have already increased knowledge of the basic mechanisms of the brain and are beginning to uncover the neurobiological mechanisms involved in psychiatric disorder. Striking progress has been achieved in the understanding of Alzheimer's disease, for example, and there are indications that similar progress will follow in uncovering the causes of mood disorder, schizophrenia, and autism. Knowledge of genetics and the neurosciences is so extensive and the pace of change is so rapid that it is difficult to present a complete account within the limited space available in a textbook of clinical psychiatry. We have selected aspects of these sciences that seem, to us and the authors, to have contributed significantly to psychiatry or to be likely to do so before long.

Psychological and social sciences and epidemiology are essential methods of investigation in psychiatry. Although the pace of advance in these sciences may not be as great as in the neurosciences, the findings generally have a more direct relation to clinical phenomena. Moreover, the mechanisms by which psychological and social factors interact with genetic, biochemical, and structural ones will continue to be important however great the progress in these other sciences. Among the advances in the psychological and social sciences that are relevant to clinical phenomena, we have included accounts of memory, psychological development, research on life events, and the effects of culture. Epidemiological studies continue to be crucial for defining psychiatric disorders, following their course, and identifying their causes.

Psychiatry in the community

In most countries, psychiatry is now practised in the community rather than in institutions, and where this change has yet be completed, it is generally recognized that it should take place. The change has done much more than transfer the locus of care; it has converted patients from passive recipients of care to active participants with individual needs and preferences. Psychiatrists are now involved in the planning, provision, and evaluation of services for whole communities, which may include members of ethnic minorities, homeless people, and refugees. Responsibility for a community has underlined the importance of the prevention as well as the treatment of mental disorder and of the role of agencies other than health services in both. Care in the community has also drawn attention to the many people with psychiatric disorder who are treated in primary care, and has led to new ways of working between psychiatrists and physicians. At the same time, psychiatrists have

worked more in general hospitals, helping patients with both medical and psychiatric problems. Others have provided care for offenders.

The organization of the book

In most ways, the organization of this book is along conventional lines. However, some matters require explanation.

Part 1 contains a variety of diverse topics brought together under the general heading of the subject matter and approach to psychiatry. Phenomenology, assessment, classification, and ethical problems are included, together with the role of the psychiatrist as educator and as manager. Public health aspects of psychiatry are considered together with public attitudes to psychiatry and to psychiatric patients. Part 1 ends with a chapter on the links between science and practice. It begins with a topic that is central to good practice—the understanding of the experience of becoming a psychiatric patient.

Part 2 is concerned with the scientific foundations of psychiatry grouped under the headings neurosciences, genetics, psychological sciences, social sciences, and epidemiology. The chapters contain general information about these sciences; findings specific to a particular disorder are described in the chapter on that disorder. Brain imaging techniques are discussed here because they link basic sciences with clinical research. As explained above, the chapters are selective and, in some, readers who wish to study the subjects in greater detail will find suggestions for further reading.

Part 3 is concerned with dynamic approaches to psychiatry. The principal schools of thought are presented as alternative ways of understanding the influence of life experience on personality and on responses to stressful events and to illness. Some reference is made to dynamic psychotherapy in these accounts, but the main account of these treatments is in Part 6. This arrangement separates the chapters on the practice of dynamic psychotherapy from those on psychodynamic theory, but we consider that this disadvantage is outweighed by the benefit of considering together the commonly used forms of psychotherapy.

Part 4 is long, with chapters on the clinical syndromes of adult psychiatry, with the exception of somatoform disorders which appear in Part 5, Psychiatry and Medicine. This latter contains more than a traditional account of psychosomatic medicine. It also includes a review of psychiatric disorders that may cause medical symptoms unexplained by physical pathology, the medical, surgical, gynaecological, and obstetric conditions most often associated with psychiatric disorder, health psychology, and the treatment of psychiatric disorder in medically ill patients.

Information about treatment appears in more than one part of the book. Part 6 contains descriptions of the physical and psychological treatments in common use in psychiatry. Dynamic psychotherapy and psychoanalysis are described alongside counselling and cognitive behavioural techniques. This part of the book contains general descriptions of the treatments; their use for a particular disorder is considered in the chapter on that disorder. In the latter, the account is generally in two parts: a review of evidence about the efficacy of the treatment, followed by advice on management in which available evidence is supplemented, where necessary, with clinical experience. Treatment methods designed specially for children and adolescents, for people with mental retardation (learning disability), and for patients within the forensic services are considered in Parts 9, 10, and 11 respectively.

Social psychiatry and service provision are described in Part 7. Public policy issues, as well as the planning, delivery, and evaluation of services, are discussed here. Psychiatry in primary care is an important topic in this part of the book. There are chapters on the special problems of members of ethnic minorities, homeless people, and refugees, and the effects of culture on the provision and uptake of services.

Child and adolescent psychiatry, old age psychiatry, and mental retardation are described in Parts 8, 9, and 10. These accounts are less detailed than might be found in textbooks intended for specialists working exclusively in the relevant subspecialty. Rather, they are written for readers experienced in another branch of psychiatry who wish to improve their knowledge of the special subject. We are aware of the controversy surrounding our choice of the title of Part 10. We have selected the term 'mental retardation' because it is used in both ICD-10 and DSM-IV. In some countries this term has been replaced by another that is thought to be less stigmatizing and more acceptable to patients and families. For example, in the United Kingdom the preferred term is 'learning disability'. While we sympathize with the aims of those who adopt this and other alternative terms, the book is intended for an international readership and it seems best to use the term chosen by the World Health Organization as most generally understood. Thus the term mental retardation is used unless there is a special reason to use another.

In Part 11, Forensic Psychiatry, it has been especially difficult to present a general account of the subject that is not tied to practice in a single country. This is because systems of law differ between countries and the practice of forensic psychiatry has to conform with the local legal system. Although many of the examples in this part of the book may at first seem restricted in their relevance because they are described in the context of English law, we hope that readers will be able to transfer the principles described in these chapters to the legal tradition in which they work.

Finally, readers should note that the history of psychiatry is presented in more than one part of the book. The history of psychiatry as a medical specialty is described in Part 1. The history of ideas about the various psychiatric disorders appears, where relevant, in the chapters on these disorders, where they can be considered in relation to present-day concepts. The history of ideas about aetiology is considered in Part 2, which covers the scientific basis of psychiatric aetiology, while the historical development of dynamic psychiatry is described in Part 3.

Michael Gelder
Juan López-Ibor
Nancy Andreasen

Acknowledgements from the first edition

We are grateful to the many colleagues who have advised us about certain parts of the book.

The following helped us to plan specialized parts of the book: Dr Jeremy Holmes (Section 3, Psychodynamic Contributions to Psychiatry); Professor Richard Mayou (Section 5, Psychiatry and Medicine); Professor Robin Jacoby (Section 8, Psychiatry of Old Age); Sir Michael Rutter (Section 9, Child and Adolescent Psychiatry); Professor William Fraser (Section 10, Intellectual Disablity); Professor Robert Bluglass (Section 11, Forensic Psychiatry).

The following helped us to plan certain sections within Section 4, General Psychiatry: Professor Alwyn Lishman (delirium, dementia, amnestic syndrome, and other cognitive disorders); Professor Griffith Edwards (alcohol use disorders); Dr Philip Robson (other substance use disorders); Professor Guy Goodwin (mood disorders); Professor John Bancroft (sexuality, gender identity, and their disorders); Professor Gregory Stores (sleep–wake disorders); Professor Keith Hawton (suicide and attempted suicide). In Section 6, Professor Philip Cowen advised about somatic treatments, Dr Jeremy Holmes about psychodynamic treatments, and Professor David Clark about cognitive behavioural therapy. Dr Max Marshall provided helpful advice about forensic issues for Section 7. We also thank the many other colleagues whose helpful suggestions about specific problems aided the planning of the book.

Finally, we record our special gratitude to the authors and to the staff of Oxford University Press.

Psychiatry and Medicine

This page intentionally left blank

5.1

Mind–body dualism, psychiatry, and medicine

Michael Sharpe and Jane Walker

Introduction

Patients usually attend doctors because they are concerned about symptoms. When these symptoms are associated with persistent distress or disability we refer to the patient as having an illness. When assessing the patient's illness the doctor aims to make a diagnosis, on the basis of which management can be planned and prognosis made. The diagnoses available to doctors are conventionally defined as either 'medical' or 'psychiatric'. This division of illness into two types is such an accepted feature of current medical practice that we tend to take it for granted. But is it really the best way to think about patients' illnesses and to plan their care?

In order to answer this question we will examine what is meant by 'medical' and 'psychiatric' diagnoses and the assumptions underpinning this division. The disadvantages of this dualistic approach will be considered and solutions proposed.

Diagnosis

Medical diagnosis

A medical diagnosis is a label for a condition that is: (a) conventionally treated by medical doctors and (b) listed in the classifications of medical conditions such as ICD-10. Most medical diagnoses are based on identifiable bodily pathology (abnormal structure and/or function). Therefore, to make a medical diagnosis (such as cancer) doctors will seek specific bodily symptoms before confirming the presence of bodily pathology with physical signs and biological investigations (such as X-rays).

Psychiatric diagnosis

Similarly a psychiatric diagnosis is a label for a condition that is: (a) conventionally treated by psychiatrists and (b) defined in the psychiatric diagnostic classifications of ICD and DSM. Psychiatric diagnoses are not based not on bodily pathology. They are however associated with the idea of 'psychopathology', that is proposed abnormalities of the mind. Unlike bodily pathology these abnormalities of the mind cannot be objectively identified and have to be inferred from the patient's mental symptoms and their behaviour. Investigations play little or no role in diagnosis. Psychiatric diagnoses are therefore defined on the basis of symptoms and syndromes.

When is an illness psychiatric?

Why are some illnesses regarded as 'mental' or 'psychiatric' as opposed to 'medical'? Examination of the criteria for diagnoses listed as psychiatric reveals that readily observable factors common to most 'psychiatric' illnesses are:

- an absence of known bodily pathology
- an abnormal mental state as inferred by the patient's report
- a presentation with disturbed behaviour

Mind–body dualism

The underlying assumption of this dichotomous view is that it is both valid and useful to divide human illnesses into those of the body and those of the mind.[1] This idea of mind–body dualism is commonly attributed to the writings of the philosopher Descartes. So-called Cartesian dualism has exerted a profound influence on Western medical thinking and still shapes our thinking, training, and service provision.

However, dualism is at best an oversimplification and at worst a source of serious theoretical and practical problems. It may be argued that there is no such thing as a purely 'bodily' or purely 'mental' illness and that all illnesses have mental and bodily aspects.[2] Furthermore, the assumption that bodily symptoms indicate bodily pathology and that mental symptoms indicate psychopathology gives rise to specific problems: (a) when bodily symptoms occur without bodily pathology and (b) when mental symptoms occur together with bodily pathology (see Table 5.1.1).

Bodily symptoms with no bodily pathology: somatization

When patients present with bodily symptoms and bodily pathology is confirmed they are given a medical diagnosis. When patients have bodily symptoms but there is no evidence of bodily pathology the terms 'somatization' or 'somatoform disorder' are used to describe their illness. It is unclear, however, whether these illnesses are properly regarded as 'psychiatric' or as 'medical' as they do not clearly fulfil criteria for either. One solution to this dilemma is to allocate these illnesses to psychiatry. The assumption is made that their somatic symptoms are really explained by psychopathology. The absence of mental symptoms, from which psychopathology

Table 5.1.1 Diagnoses symptoms and bodily pathology

Symptoms	Bodily pathology	Diagnosis
Bodily symptoms	Present Absent	Medical diagnosis Somatization
Mental symptoms	Present Absent	Comorbidity Psychiatric diagnosis

can be inferred, is explained by the idea that the psychopathology is hidden and 'converted' into bodily symptoms by a process called 'somatization' (literally making the mental somatic). Clearly these are questionable assumptions.[3]

A second solution is to assume that the patients really do have bodily pathology in some form (even though is it unknown) and to give them a medical diagnosis of a so-called 'functional disorder' such as fibromyalgia.[4] As with somatization this approach is based on questionable assumptions.

A third, and all too common solution, is for the patient to be rejected as 'not really ill' by both psychiatry and medicine. They then end up in a no-man's land between specialities. The inadequacy of all three solutions has been particularly well illustrated by the controversy and conflict surrounding the condition called Chronic Fatigue Syndrome (CFS) or Myalgic Encephalomyelitis (ME).[5]

Mental symptoms and bodily pathology: comorbidity

When a patient has both bodily pathology and mental symptoms they are given both a medical diagnosis (based on the bodily pathology) and a psychiatric diagnosis (based on presumed psychopathology). This idea of 'comorbidity' gives rise to both theoretical and practical problems, however.

The theoretical problem concerns the psychiatric diagnosis. To make this diagnosis the doctor must identify symptoms, which are considered to be evidence of psychopathology. However, some symptoms may be considered as evidence of both psychopathology and bodily pathology. For example, a patient has mental symptoms of low mood and worthlessness, and a medical diagnosis of cancer, based on bodily pathology. Should the patient's weight loss be counted toward a psychiatric diagnosis of depression or regarded as a symptom of his cancer? There is no generally agreed answer to this conundrum (although a variety of ways of addressing it have been proposed[6]), probably because it is a manifestation of the fundamentally flawed dualistic assumption.

The main practical problem that results from making two diagnoses is a failure to adequately treat the patient. Depressive disorder comorbid with a chronic medical condition is a major cause of morbidity. However, the patient's need for psychiatric treatment often goes unmet[7] because the patient is considered to have two illnesses, each requiring diagnosis and treatment by a different speciality and the treatment of the medical condition takes precedence.

Solutions to dualism

Theoretical solutions

New scientific knowledge, such as the demonstration of a bodily (neural) basis to many 'mental' symptoms is increasingly rendering crude dualistic thinking theoretically untenable.[8] Mind and brain are coming to be regarded as two sides of the same coin—the mind/brain. This paradigm shift implies that 'psychiatric' illnesses are no more distinct from 'medical conditions' than the nervous system is separate from the rest of the body. Hence, there is a need for psychiatry to become less 'brain-less' and for medicine to become less 'mind-less'.[9] According to this new way of thinking, all symptoms, whether previously regarded as 'bodily' or 'mental' are in fact products of the mind/brain's integration of bodily, psychological, and social information. Therefore to speak of 'medical' and 'psychiatric' symptoms makes no sense. Symptoms are just symptoms.

If this paradigm shift is to be fully translated into clinical practice a new unified classification system is needed that would be used by both medicine and psychiatry. One way of achieving this might be to create a multi-axial system as is currently used by DSM-IV. However, rather than using separate axes for psychiatric and medical diagnoses, separate axes would be used for symptoms (not distinguishing between medical and psychiatric) and bodily pathology.[10] Other axes could be added to ensure that other important information is included. An example is shown in Table 5.1.2.

Practical solutions

For the present we must accept that dualism continues to shape our every day thinking, practice, and service organization. It is important therefore, that the psychiatrist is aware of the practical problems that result and is equipped with ways of addressing them. In this regard the psychiatrist is especially well placed to make a major contribution to the care of all patients by ensuring that biological, psychological, and social aspects of illness are considered in every case. This so-called 'biopsychosocial' formulation was first proposed by Engel.[11] A further enhancement of this formulation is to divide the aetiological factors into those that predisposed the patient to the illness, those that precipitated or triggered it, and those that are perpetuating it. The last group of causes is a target for treatment and the first two for prevention. A useful diagram that lists factors to consider in a biopsychosocial formulation is shown in Table 5.1.3.

Service solutions

Finally, the consequence of the professional and organizational separation of medicine and psychiatry has been a major obstacle to the integrated care of patients, especially those with comorbidity and somatoform disorders. One service solution has been the establishment of so-called liaison (linking) psychiatry services to general hospital inpatient units. Another is the increasing integration of psychological management into chronic illness management programmes.[12] However truly integrated care remains the exception rather than the rule.

Table 5.1.2 A proposed multi-axial diagnostic system for use by both psychiatry and medicine

Axis 1	Symptoms or syndrome, e.g. chronic fatigue or depression
Axis 2	Bodily pathology, e.g. cancer
Axis 3	Biological factors, e.g. autonomic arousal
Axis 4	Psychological factors, e.g. beliefs
Axis 5	Social and situational factors, e.g. bereavement

Table 5.1.3 A biopsychosocial formulation

Main factors	Subfactors	Predisposing	Precipitating	Perpetuating
Biological	Disease physiology			
Psychological	Cognition mood behaviour			
Social	Interpersonal social and occupational health care system			

Conclusion

It has been taken for granted that it is appropriate and desirable to separate patients' illnesses into medical and psychiatric types. Such an approach has had advantages in allowing specialization of training and service planning but has also created obstacles to effective patient care. It is important that practising psychiatrists are aware of these obstacles and ways of overcoming them. It also seems increasingly likely that in time better understanding of neuroscience will make dualism increasingly theoretically untenable and that a better understanding of chronic illness management will make it practically redundant. Only then will psychiatry become fully reintegrated with the rest of medicine.

5.2

Somatoform disorders and other causes of medically unexplained symptoms

Contents

5.2.1 Somatoform disorders and functional symptoms

Richard Mayou

Non-specific symptoms that are not explained by organic pathology are extremely frequent in the general population[1] and in all medical settings. Most are transient, but a substantial minority is persistent, disabling, and often associated with frequent consultation. They are likely, especially when there are multiple unexplained symptoms, to be associated with psychiatric disorder (see Chapter 5.2.3). They are widely regarded as difficult to treat but only a very small proportion is seen by psychiatrists and psychologists.

This chapter covers general issues relating to functional symptoms and syndromes and their psychiatric associations. The following chapters provide more detail about the more specific forms of somatoform disorder and about functional syndromes (pain, chronic fatigue).

Terminology of functional symptoms

The terminology is unsatisfactory.[2] These symptoms are often referred to as 'medically unexplained symptoms'. This usage has the advantage of describing the clinical problem without assumptions of aetiology, but it is unsatisfactory in that it wrongly implies that there is no medical explanation. Other generally used terms include somatization, somatoform symptoms, and functional overlay. It is perhaps most satisfactory to refer to functional symptoms and functional syndromes.

This chapter is concerned with functional symptoms whether or not they are associated with psychiatric disorder.

Aetiology

A traditional Western dualist view of aetiology as being either physical or psychological, continues to influence clinical practice and current psychiatric classifications (see Chapter 5.1). In western countries, this view has resulted in great problems in psychiatric and lay understanding, in taxonomy, and in the treatment of 'unexplained' symptoms. It has also caused bewilderment in cultures that do not share this dualist approach.

An increasingly widely held alternative view, for which there is compelling evidence, is that functional symptoms result from the interaction of physiological, pathological, and psychosocial variables.[2] A primary bodily sensation or concern (Table 5.2.1.1) is then attributed or interpreted as being of sinister significance with resulting subjective symptoms, disability, and behavioural and emotional consequences. For example, awareness of normal heart rate increase due to excitement or anxiety can result in, on the one hand, panic and, on the other, worry about heart disease, restriction of daily activities, and repeated consultation to seek investigation

Table 5.2.1.1 Causes of bodily sensations

Major pathology
Minor pathology
Physiological processes, for example:
Sinus tachycardia and benign minor arrhythmias
Effects of fatigue
Hangover
Effects of overeating
Effects of prolonged inactivity
Autonomic effects of anxiety
Lack of sleep

and reassurance. The role of these factors may vary over time during the course of any individual clinical problem.

There is considerable evidence on the ways in which psychological processes affect the interpretation of physical symptoms, whatever the underlying (major or minor) pathology or physiological processes. Cognitive-behavioural formulations emphasize the central significance of health anxiety and suggest that feedback of the physiological, cognitive, affective, and behavioural consequences of this anxiety can reinforce the physical symptoms as well as their effects on everyday life.

The process of interpretation of a bodily sensation or fear is affected by several sets of factors:

- the individual's medical experience and beliefs
- social circumstances (Table 5.2.1.2)
- personality and mental state

Once symptoms have developed they may be maintained by behavioural and psychological factors and also by the reactions of others. As with other forms of anxiety, neurobiological mechanisms may perpetuate and complicate the initial presentation.

Simple reassurance is often ineffective especially in those who, by reason of personality, are inclined to worry about their health. Misconceptions are frequently reinforced and maintained by the lack of any medical explanation for worrying symptoms or by ambiguous or contradictory advice.

The association with psychiatric disorder

The majority of functional symptoms in general populations are short lived and not associated with psychiatric disorder. There is now considerable evidence both from smaller local studies and international collaborative research that the more severe and disabling functional symptoms are associated with anxiety and depressive disorder, and that this relationship is strongest for those who have the greatest number of 'unexplained' symptoms. This is so for all ethnic groups and cultures studied.[1] There are also associations with the somatoform disorders as described below.

Table 5.2.1.2 Illness experience, which may affect the interpretation of bodily sensations and concern

Childhood illness
Family illness and consultation in childhood
Childhood consultation and school absence
Physical illness in adult life
Experience and satisfaction with medical consultation
Illness in family and friends
Publicity in television, newspapers, etc.
Knowledge of illness and its treatment

Classification of unexplained symptoms

The classification of persistent and disabling functional symptoms has taken two parallel approaches.

(a) Medical descriptive syndromes

These are very numerous, clinical patterns and terms overlap and some include assumptions about aetiology. There are cultural differences in the definition and naming. There is little evidence for the validity of separate syndromes. Lay pressure groups have increasingly claimed specific syndromes, such as alleged sensitivity to dental amalgam and many 'food allergies', which are more likely to be due to their own predicaments and the apparent lack of success of conventional medicine.[3] A small number of syndromes have now received operational diagnostic criteria which have proved valuable in clinical understanding and in planning treatment, for example the criteria for chronic fatigue (Chapter 5.2.7).

(b) Psychiatric classification

This covers both well established categories, such as anxiety and depressive disorders, and the new concept, first introduced in DSM-III, of somatoform disorder.

(i) Somatoform disorder

Somatoform disorders (Table 5.2.1.3) were seen as speculative and provisional in DSM-III. The defining feature was '*physical symptoms suggesting a physical disorder for which there are no demonstrable organic findings on known physiological mechanisms, and for which there is strong evidence, or a strong presumption, that the symptoms are linked to psychological factors or conflicts*'.

The original DSM-III classification was relatively narrow but subsequent revisions of DSM and ICD-10 have incorporated non-specific categories which have turned out to be much more prevalent in all settings.

Table 5.2.1.3 Categories of somatoform disorders in ICD-10 and DSM-IV

ICD-10	DSM-IV
Somatization disorder	Somatization disorder
Undifferentiated somatoform disorder	Undifferentiated somatoform disorder
Hypochondriacal disorder	Hypochondriasis
Somatoform autonomic dysfunction	—
Persistent pain disorder	Pain disorder associated with psychological factors (and a general medical condition)
Other somatoform disorders	Somatoform disorders not otherwise specified
—	Body dysmorphic disorder
—	Conversion disorders
Neurasthenia	—

It is important to recall that somatoform disorder remains a provisional grouping for statistical purposes rather than a grouping of categories that satisfy the normal requirements of disease entities. It nevertheless indicates a substantial clinical problem associated with considerable use of health care provisions.[3]

(ii) Factitious disorder

DSM-III also introduced another new category of 'factitious disorder' for self-inflicted physical problems. These are described in Chapter 5.2.9 and should be distinguished from deliberate falsification for external gain—*malingering*. It must be remembered that patients with factitious disorder may also suffer from unexplained symptoms attributable to somatoform or other psychiatric disorders and, indeed, not uncommonly also report symptoms of undoubted physical illness.

Somatoform disorders in DSM and ICD

There are substantial differences between the use of subcategories in DSM and ICD.[4] Neurasthenia is included in ICD-10 but is not used in any section of DSM-IV; conversion disorder is a somatoform disorder in DSM-IV but not in ICD. Both classifications include both relatively specific categories (e.g. *somatization disorder* and *hypochondriasis*) and also several very vaguely defined non-specific categories. These latter include *Undifferentiated Somatoform Disorder*, *Somatoform Autonomic Dysfunction* (ICD-10 only), and *Other Somatoform Disorders*. Although these latter have attracted less clinical and research attention, they are by far the most common forms of somatoform disorder in all epidemiological studies. So broad are the criteria that it is possible to use these categories for almost all persistent unexplained physical symptoms. Epidemiological comparisons of ICD and DSM show that the use of their rather different criteria results in substantially different prevalences of somatoform disorder in community and primary care populations.

Problems in the definition of somatoform disorder

It is widely recognized that there are serious problems[2] in the overall concept of somatoform disorders and in the definition of subcategories:

- There is no unifying theoretical basis for the whole category; it is a disparate group of problems that are not easily fitted into other parts of the classifcations.
- Comorbidity is very common, especially with anxiety disorder, depressive disorder, and personality disorder.
- Some types of somatoform disorder could be more satisfactorily reassigned to other parts of the classification (for example hypochondriasis might be renamed health anxiety and moved to anxiety disorder).
- The definitions of the less specific categories (pain disorder, Undifferentiated Somatoform Disorder) do not include any psychological criteria. Instead they rely on the description and the number of physical symptoms, the same symptoms that are used to make accompanying Axis III diagnoses. Somatization disorder has attracted disproportionate attention, but appears to be no more than an uncommon, arbitrary and unreliable extreme of the spectrum of multiple physical symptoms.
- Criteria have little meaning for cultures that do not share the western presumption of the separation of body and mind.

It has become apparent that the present classifications have no value in guiding treatment and that they are both confusing and unpopular with patients and with those who treat them.

DSM-V and ICD-11 can be expected to make large changes which will depend on the resolution of conceptual arguments and substantial further research. It is hoped that the new classification and terminology will be more reliable and valid and also be much more meaningful and acceptable.[2]

It is likely that the more specific subcategories (hypochondriasis, body dysmorphic disorder) will be reassigned to other parts of the classification and that there will be modifications in their criteria. The greatest problems relate to the much more prevalent non-specific categories. There is a consensus that a more rational operational approach is required to categorize multiple symptoms which should result in either a renamed grouping on Axis I or more logically a transfer to Axis III. It should be possible to give much greater prominence both in criteria and in accompanying text to underlying psychological and behavioural abnormalities.

Classification in clinical practice

The following chapters in this section of the book describe syndromes that have proved to have some administrative value despite the acknowledged lack of validity. Anxiety and depression are considered fully elsewhere. The recognition of anxiety and depression is important because of the therapeutic implications.

In everyday clinical practice it is rarely necessary (or helpful) to attach a somatoform label. It is more useful to be able to provide brief descriptions of the clinical problem, since these can be used as a basis for formulating treatment:

- acute or chronic
- number of physical symptoms
- the nature and pattern of symptoms (i.e. clinical syndromes such as fatigue)
- association with anxiety disorder, depressive disorder, or other specific psychiatric disorder
- beliefs about cause

Assessment and treatment

The majority of those presenting unexplained symptoms in primary care require no more than medically appropriate assessment and reassurance (Table 5.2.1.4). The latter should convey to the patient that the symptoms are accepted as real and provide an explanation for their origin as well as answering the patient's worries. It is also necessary to discuss the results of any negative investigations fully.

Symptoms that persist or recur despite reassurance are generally regarded as difficult to treat. Continuing symptoms without any specific medical explanation are likely to confirm and maintain worries about serious illness, which may be further exacerbated by secondary anxiety and behavioural consequences. Therefore

Table 5.2.1.4 General principles of assessment

Consider psychological factors from the outset
Use appropriate physical investigation to exclude physical cause
Clarify psychological and physical complaints
Clarify previous personality and concerns about physical illness
Understand patient's beliefs and expectations
Identify depression or other psychiatric disorder
Identify psychosocial problems

effective treatment depends upon sympathetic treatment that meets the needs of both the patient and the family. A multi-causal view of aetiology leads to conclusions about treatment and avoids psychiatric diagnoses that may be unacceptable to the patient. Much can be done by general practitioners or non-specialists.

The general principles of treatment (Table 5.2.1.5) are similar for all forms of unexplained symptoms, single or multiple, but individual treatment plans must take account of psychiatric diagnoses of anxiety or depression and the particular type of physical symptoms.

The treatments for particular forms of somatoform disorder are discussed in later chapters. It is important to be aware that the commonest type of somatoform disorder, Undifferentiated Somatoform Disorder is not discussed separately; treatment follows the general principles described in this and other chapters. The treatments of other functional syndromes such as irritable bowel syndrome, chronic fatigue, and atypical facial pain all depend on the therapist being familiar with these syndromes and being able to provide an appropriate combination of treatment methods. For example, the management of physical de-conditioning is central to the treatment of chronic fatigue, whereas antidepressant medication has a major role in the treatment of atypical facial pain. The chapter on chronic fatigue (Chapter 5.2.7) is an example of a functional syndrome.

Much can be achieved by components of good non-specialist care, such as the following:

- discussion and explanation of the aetiology
- treatment of any minor underlying physical problem
- anxiety management (including tapes and handouts)
- advice on diary monitoring and graded return to full activities
- specific self-help programmes (e.g. chronic fatigue, irritable bowel syndrome)
- including relatives in the assessment, discussion of the nature of the problems, and explanations of the treatment

Table 5.2.1.5 General principles of treatment

Emphasize that symptoms are real and familiar and that medical care is appropriate
Minimize and control physical care
Offer an explanation and discuss
Allow patients and families to ask questions
Discuss the role of psychological factors in all medical care
Treat any primary psychiatric disorder
Agree a treatment plan

However, chronic and recurrent problems may need specialist treatment:

- psychotropic medication (antidepressants, anxiolytics)
- cognitive behavioural therapy
- interpretative psychotherapy (individual and group)
- specific psychiatric treatment for associated psychiatric and social problems
- programme to co-ordinate and control all medical care

There is a lot of evidence on the effectiveness of a range of treatments in specialist care,[5,6] but there is much less evidence about simple routine measures. The outlook for simpler syndromes of relatively recent onset is good, but the prognosis for very prolonged chronic, multiple, or recurrent syndromes (e.g. somatization disorder) is not as good. In these circumstances the control of medical care and the prevention of further iatrogenic disability may be more realistic than cure.

5.2.2 Epidemiology of somatoform disorders and other causes of unexplained medical symptoms

Gregory Simon

While nearly every psychiatric syndrome may include some somatic signs or symptoms, a specific group of syndromes has been traditionally defined as somatoform. This group of disorders is distinguished by certain key features: prominent reporting of somatic

symptoms, concern about medical illness, and frequent presentation to general medical providers. As in other categories of mental disorder, the boundaries between individual syndromes are more distinct in our systems of classification than they are in nature. Understanding that various somatoform disorders often overlap, this review is organized according to the major categories of somatoform disorder described in the ICD and DSM classification systems.

Somatization disorders

Phenomenology

The term somatization has been used to refer to a variety of clinical phenomena. One traditional view defines somatization as an inability or unwillingness to express emotional distress,[1] so that somatic symptoms are an alternative 'idiom of distress'. An alternative view defines somatization as the presentation of somatic complaints to medical providers in the presence of an occult anxiety or depressive disorder.[2] A third view defines somatization as somatic symptoms, which have no clear medical explanation.[3] While these definitions appear closely related, they identify somewhat different groups of patients. The third definition (presentation of unexplained somatic symptoms) is used by official systems of classification and by most epidemiological studies, so this review will focus on that phenomenon.

Both the ICD and DSM classification systems define somatization disorder as a chronic condition characterized by the reporting of numerous unexplained somatic symptoms.[4, 5] Recent versions of both classification systems identify a core syndrome of somatization (a persistent tendency to report multiple unexplained somatic symptoms) using a simplified set of diagnostic criteria.

Prevalence

The reported prevalence of well-defined somatization disorder appears to depend significantly on the method used for assessment. Community and primary care surveys have typically relied on structured interviews to assess the lifetime prevalence of unexplained somatic symptoms. Community surveys in North America[6] and Western Europe[7, 8] have found prevalence rates of less than 2 per cent with primary care surveys finding only slightly higher prevalence rates.[9] Data from the World Health Organization (**WHO**) multicentre primary care survey indicate that recall during structured interviews may significantly underestimate the lifetime prevalence of somatization symptoms.[10] More accurate recall of lifetime symptoms (by either repeated assessments or the use of medical records) might yield significantly higher prevalence rates.

Correlates

The prevalence of somatization disorder and unexplained somatic symptoms is typically twice as high in women as in men,[11, 12] and this difference appears at time of menarche.[13] Community and primary care surveys demonstrate a substantial overlap between somatization disorder and anxiety and depressive disorders.[7, 14, 15] Anxiety and depressive disorders also predict the subsequent onset of somatization disorder.[16]

Available data show a mixed picture regarding cross-national or cross-cultural differences in the prevalence of somatization. Studies of clinical samples find that somatic symptoms are a common accompaniment of depressive and anxiety disorders worldwide.[17–19] The WHO primary care survey documented large differences in the prevalence of unexplained somatic symptoms with a markedly higher prevalence in South America than in Europe or the United States.[9] That same study, however, found that the association between unexplained symptoms and symptoms of depression or anxiety was similar across a wide range of cultures and levels of economic development.[14] One explanation for these apparently disparate findings is that the prevalence of unexplained somatic symptoms (like the prevalence of anxiety or depressive disorder) varies widely across nations and cultures, but the association between somatic and psychological distress is universal. Countries or cultures with higher rates of anxiety or depressive disorders would be expected to have higher prevalence of somatization disorder and other somatization syndromes. Given the consistent overlap between somatization disorders and other common mental disorders, some have questioned whether these conditions actually belong in a distinct category.[20, 21]

Controversies and questions

Available data do not support a specific diagnostic threshold based on the number or distribution of unexplained somatic symptoms. An increasing number of somatic symptoms is consistently associated with increases in comorbid mood or anxiety disorder, functional impairment, and use of health services.[14,15] Mindful of this continuum, both Escobar *et al.*[22] and Kroenke *et al.*[23] have described less restrictive somatization syndromes, which, despite their higher prevalence, are strongly associated with impairment and the use of health services. Both the ICD and DSM classification systems describe subthreshold or less extreme forms of this condition characterized by a smaller number of medically unexplained symptoms.[5, 24]

Longitudinal data raise questions about the presumed stability or chronicity of somatization disorder or medically unexplained somatic symptoms. Traditional descriptions of somatization disorder emphasize its stability and chronicity. Data from the WHO primary care survey, however, suggest that individual somatization symptoms vary considerably over time.[9] While the syndrome of somatization seemed somewhat more stable than anxiety and depressive disorders (typically regarded as episodic), only half of the primary care patients, satisfying Escobar's criteria for somatization syndrome at the baseline assessment, continued to meet the criteria one year later.

Hypochondriacal disorders

Phenomenology

Both the ICD and DSM classification systems define hypochondriasis by the triad of disease conviction, functional impairment, and refusal to accept appropriate reassurance.

Prevalence

Attempts to estimate the prevalence of hypochondriasis have been limited by the absence of proven standardized methods for standardized assessment. Community surveys find prevalence rates of 1 per cent or less,[25] while primary care surveys typically find rates of approximately 5 per cent,[26, 27] while the WHO multicentre primary care survey[28] found an overall prevalence of only 0.8 per cent.

In reviewing data from the WHO survey, Gureje *et al.*[28] found that a less restrictive definition more than doubled the prevalence rate (to 2.2 per cent). Cases added by this relaxed definition did not differ significantly from those satisfying CIDI/ICD criteria, suggesting that CIDI/ICD criteria may be somewhat too restrictive.

Correlates

Despite the variation in prevalence, primary care surveys yield similar results regarding demographic correlates of hypochondriasis. The prevalence of hypochondriasis is 1.5 to 2 times as great in women as men but does not appear to vary significantly with age.[28]

Controversies and questions

While the ICD and DSM classification systems suggest that hypochondriasis is distinct from anxiety and depressive disorders, available data suggests considerable overlap. In every sample examined, hypochondriasis is strongly associated with major depression, panic disorder, and generalized anxiety disorder.[26,28–30] Among those with hypochondriasis, clinical features do not clearly distinguish those with and without a comorbid psychiatric diagnosis.[30] In addition, changes over time in anxiety or depression are consistently associated with parallel changes in symptoms of hypochondriasis.[31] As with somatization disorders, some have recently argued that hypochondriasis be re-classified as a form of anxiety disorder.[20,21]

Pain syndromes

Phenomenology

While the ICD and DSM classification systems both define somatoform pain disorders, the two systems differ in their descriptions of the clinical features. In the ICD diagnostic system, somatoform pain disorder is defined as persistent pain without clear medical explanation.[5] The DSM system[4] specifies that 'psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain'. Both definitions are somewhat problematic. Basic research on neural changes associated with persistent pain raise doubts about the distinction between pain with and without a biomedical explanation.[32] As discussed below, longitudinal research supports the view that persistent pain causes psychological disorder as much as it supports the DSM view that pain results from psychological distress. Recent epidemiological research has attempted to avoid questions of aetiology and has examined the prevalence and correlates of persistent pain.

Prevalence

Epidemiological studies consistently find that pain syndromes are among the most common problems presented to general medical providers. Population surveys indicate that over 25 per cent of community residents suffer from recurrent or persistent pain symptoms and that 2 to 3 per cent experience disabling pain syndromes.[33] The recent WHO primary care survey[34] found that approximately 20 per cent of primary care patients suffered from persistent pain (one or more pain symptoms present for most of the last 6 months). Pain syndromes are approximately twice as prevalent in women as in men.[15]

The limited data available do not allow definite conclusions about cross-cultural or cross-national variability in pain syndromes. Some studies have documented cross-national or cross-cultural differences based on small samples of patients treated for pain syndromes—often in specialist pain clinics.[35] The WHO primary care survey[34] included both the largest number of patients with pain syndromes as well as the broadest range of cultures and levels of economic development. In that study, both the prevalence and correlates of persistent pain varied widely across sites. No clear pattern (e.g. a higher prevalence in developing or non-Western countries) was evident.

Correlates

All available data indicate that pain symptoms are strongly associated with anxiety and depressive disorders. This relationship has been consistently demonstrated in both community[36] and primary care[34] studies across a broad range of cultural and socioeconomic divides. Psychological distress is most strongly associated with pain occurring at multiple sites and pain associated with functional impairment.[37, 38] While epidemiological studies strongly support an association between pain complaints and psychological distress, this does not necessarily imply that pain is a consequence of psychological distress. Some studies find that the presence of psychological distress predicts the onset of pain syndromes,[39,40] while others support the opposite relationship—that persistent pain predicts subsequent psychological disorder.[41]

Other somatoform conditions

Specific somatoform syndromes

A number of specific somatic syndromes have been described over the last several decades. These specific syndromes are sometimes defined by the particular somatic symptoms experienced (e.g. fibromyalgia, irritable bowel syndrome, chronic fatigue syndrome) and sometimes by particular beliefs about aetiology (e.g. multiple chemical sensitivity, systemic candidiasis, electrical allergy). In every case, controversy persists about whether the somatic symptoms should be considered 'medically unexplained' (that is to say a somatoform disorder). Community surveys suggest that non-specific symptoms (such as fatigue or diffuse musculoskeletal pain) are common, but that the prevalence of strictly defined syndromes (such as fibromyalgia or chronic fatigue syndrome) varies considerably with the criteria applied.[42, 43] Most of these syndromes appear more often in women than in men.[44] Both community[43, 44] and primary care surveys[45, 46] have found several of these syndromes to be associated with anxiety and depressive symptoms. However, two studies of chronic fatigue[47] and irritable bowel[48] symptoms found that psychological distress was associated with seeking care for somatic symptoms rather than the presence or nature of the somatic symptoms themselves.

Body dysmorphic disorder or monosymptomatic hypochondriasis

Body dysmorphic disorder has recently been identified as a distinct clinical entity. The limited epidemiological data available suggest significant overlap with anxiety and depressive disorders.[8, 50] Prevalence estimates range from less than 1 per cent among unselected primary care patients,[8] to as high as 5 to 10 per cent among patients seeking cosmetic surgery[49] or outpatients with anxiety

Table 5.2.2.1 Summary of prevalence rates of specific somatoform disorders in community and primary care studies

	Community studies	Primary care studies	Notes
Somatization disorder	1%	1–2%	Diagnostic interviews probably under-count past symptoms, records reviews tend to find higher rates
Multisomatoform disorder or subthreshold somatization	5%	8–10%	Less extreme form of somatization, but still strongly associated with disability and symptoms of depression and anxiety
Hypochondriasis	1%	1–5%	Strongly associated with anxiety disorders
Persistent pain syndromes	2–3%	15–20%	Bi-directional relationship with depressive and anxiety disorders
Body dysmorphic disorder	1%	1–5%	Significantly higher in certain medical settings (dermatology, cosmetic surgery) and in people with anxiety disorders

disorders.[50] Some questionnaire studies find prevalence rates as high as 5 per cent among university students.[51]

Conversion disorders

Limited epidemiological data are available concerning conversion-type somatoform disorders. As with other varieties of unexplained somatic symptoms, these disorders appear to be more common among women[52] and are associated with increased prevalence of depressive and anxiety disorders.[53] Some evidence suggests that these conditions have declined in prevalence.[52] While many sources report that these conditions are more common in non-Western or developing countries, available epidemiological data do not necessarily support this view.[9]

Factitious disorders

No systematic data are available regarding the epidemiology of factitious disorders. The available data include numerous case reports and a small number of case series—typically drawn from medical inpatient or medical specialty settings. Because the syndrome is defined by deception, it is likely that a large proportion of cases go undetected.

5.2.3 Somatization disorder and related disorders

Per Fink

Introduction

The essential feature of somatization disorder and related disorders is that the patient presents multiple, medically unexplained symptoms or functional somatic symptoms. These physical complaints are not consistent with the clinical picture of known, verifiable, conventionally defined diseases, and are unsupported by clinical or paraclinical findings. The phenomenon of medically unexplained symptoms cannot simply be classified into one or a few diagnostic categories, but must be regarded as an expression of a basic mechanism by which people may respond to stressors as in the cases of depression and anxiety.[1–3] Somatization disorder and related disorders must thus be considered to possess a spectrum of severity.[3, 4] In this chapter, the focus will be on the chronic and multisymptomatic forms.

The somatization disorder diagnosis has its origin in the concept of hysteria. It was introduced in DSM-III in 1980 and was based on the criteria for 'Briquet's syndrome', a syndrome described in the early 1960s by Perley and Guze.[5] They listed 59 physical and psychological symptoms distributed in 10 groups: 25 of the symptoms from nine groups were required to qualify for the diagnosis of somatization disorder. All psychological symptoms were eliminated in the DSM-III modification to avoid overlapping with other diagnoses.

The diagnostic criteria for DSM somatization disorder varied until the introduction of the current DSM-IV. The diagnosis was included in ICD-10 in 1992, but the ICD-10 criteria list different

symptoms, and require a different number of symptoms compared with the corresponding DSM criteria.

The somatization disorder diagnosis has been criticized for being too rigid for clinical use. Only the most severe cases with a specific predefined symptom profile fulfil the diagnostic criteria, and the majority of those with multiple symptoms fall into one of the residual categories of 'undifferentiated' or 'not otherwise specified' somatoform disorders.[6]

To increase the sensitivity, Escobar *et al.*[7] introduced an abridged somatization index. This required 4 symptoms for males and 6 symptoms for females out of the 37 somatic symptoms listed in the DSM-III, compared with 12 and 14 symptoms respectively for the full DSM-III somatization disorder diagnosis. Kroenke *et al.*[8] have suggested a diagnosis of 'multisomatoform disorder', defined as three or more medically unexplained physical symptoms from a 15-symptom checklist along with at least a 2-year history of medically unexplained symptoms.

However, these abridged versions share the same basic problem as the original ones, namely that the chosen number of symptoms to qualify for the individual diagnoses is arbitrary and not empirically based. Recently a new empirically based construct was introduced, and this may have solved the problem. This new 'bodily distress disorder' diagnosis is based on positive criteria and not solely on the exclusion of all organic possibilities.[3] (Table 5.2.3.1)

This chapter will not differentiate between the different subcategories of somatoform and related disorders that are present along with somatic symptoms.

Table 5.2.3.1 Symptoms of and diagnostic criteria for bodily distress disorder

Yes	No	Symptom groups
		≥ 3 Cardiopulmonal/autonomic arousal Palpitations, heart pounding, precordial discomfort, breathlessness without exertion, hyperventilation, hot or cold sweats, trembling or shaking, dry mouth, churning in stomach, "butterflies", flushing or blushing
		≥ 3 Gastrointestinal arousal Frequent loose bowel movements, abdominal pains, feeling bloated, full of gas, distended, heavy in the stomach, regurgitations, constipation, nausea, vomiting, burning sensation in chest or epigastrium
		≥ 3 Musculoskeletal tension Pains in arms or legs, muscular aches or pains, feelings of paresis or localized weakness, back ache, pain moving from one place to another, unpleasant numbness or tingling sensations
		≥ 3 General symptoms Concentration difficulties, impairment of memory, feeling tired, headache, memory loss, dizziness
		≥ 4 symptoms from one of the above groups
Diagnostic criteria:		
1–3: 'yes': Moderate 'bodily distress disorder'		
4–5: 'yes': Severe 'bodily distress disorder'		

Clinical features

Physical symptoms and complaints

Patients with somatization and related disorders may complain of any medically unexplained non-verifiable subjective physical symptoms, and the symptoms may refer to any part or system of the body.

Complaints can be divided into:

- *Subjective symptoms*, which are sensations and other complaints that cannot be verified by another individual or by general methods of examination (e.g. pains and paraesthesia).
- *Objective symptoms*, which are complaints that can be verified if present at the time of examination (e.g. haematuria, icterus, etc.).

Findings can be divided into:

- *Provoked findings*, i.e. symptoms or signs (such as soreness resulting from pressure or sensory impairment), which the patient is unaware of until these are provoked during the physical examination
- *Certain findings*, which include objective symptoms that are verified and phenomena unnoticed by the patient but found during the physical examination (such as an abdominal tumor)

The symptom complaints in patients with somatization disorder and related disorders are dominated by subjective symptoms and provoked findings, whereas objective symptoms and positive certain findings and paraclinical findings are unusual.

Subjective symptoms may be considered to be psychological phenomena arising from personal experiences, which others cannot judge or measure, despite the fact that these symptoms could be fully explained by the presence of organic pathology. This means that there are considerable inter-individual, cultural, and historical variations in the symptom presentation, which are determined by the patient's life experience and sociocultural background, and the setting in which the patient is seen also plays a role.[9] However, the patients may also present verifiable symptoms and signs due to a physical disease or defect, which they exaggerate and incorporate into their illness. Incidental inborn errors or degenerative changes, which are asymptomatic in most individuals, may tenuously be assigned clinical importance by the doctor or the patient. For instance, degenerative changes in the spinal column are seen in most individuals when they become older, and most do not have any pain, but a patient's backache may be attributed to those changes. Furthermore, over time, the patient with a chronic condition is likely to have undergone multiple tests, invasive procedures, operations, and received medications for treatment or diagnostic purposes, and this may cause not only iatrogenic harm but also physical complications.[10] Finally, the patient may have a concurrent physical disease. The presented symptoms may thus be a difficult mixture of complaints of both organic and non-organic origin.[11]

The patients typically complain of *multiple physical symptoms*, but the number of symptoms reported by the patients vary considerably from one patient to another and over time in the same individual. The patients may complain of multiple, medically unexplained symptoms in numerous bodily systems at presentation, but sometimes the complaints are concentrated on one

symptom pattern at one time (e.g. a gastrointestinal illness) and on a different symptom pattern at another (e.g. a cardiopulmonary illness).[11] This single-organ illness picture may be due to physicians being inclined to focus their attention and investigation on the organ of their own specialty—especially in a multisymptomatic, complex patient, i.e. a gastroenterologist will focus on gastrointestinal symptoms and may ignore musculoskeletal symptoms. A new set of symptoms from another organ system may come to attention when diagnoses and treatment options have been ruled out for the current complaint. Iatrogenic factors may thus contribute significantly to the presented symptom pattern and changes in symptom pattern. Patients with somatization disorder are often inconsistent historians. They may supply incorrect information about previous episodes of their illness, minimizing or ignoring earlier instances of illness and exclusively focusing on the current symptom pattern. This may be because the patients find it difficult to account for their complicated medical history, or because they do not want to confuse the doctor with what they believe is irrelevant information. Therefore, the full clinical picture often only becomes evident after a full medical history has been obtained and the patient has been followed for some time.

Symptoms and findings are not idiosyncratic but need clarification or specification before becoming meaningful clinically. For instance, a patient complains of chest pain. There are multiple causes for chest pain, so for the doctor this is not very informative. A clarification or specification is needed. A retrosternal-localized pain of a pressing nature offers the doctor a very different diagnostic association than a chest pain that is described as being stabbing and located in the left side of the chest. In somatization disorder and related disorders, the patient usually presents a *vague illness picture* with symptoms of *non-specific* character and of low diagnostic value, i.e. symptoms that are common in the general population and which are found in many different mental and physical disorders (symptoms like fatigue, nausea, headache, dizziness).

The presentation of medically unexplained symptoms is *atypical*, that is to say the symptoms lie outside what is usual in an authentic physical disease.[11] However, the patients may have 'learned' the typical symptom presentation from different sources. For example, a patient with atypical asthma-like attacks shared a room with a patient with genuine asthma during her third hospital stay; subsequently, her attacks took on a more 'authentic' appearance.[11]

Descriptions of *symptoms are usually vague, imprecise, and inconsistent*, and the patients often have difficulties giving further details about their illness and symptoms, i.e. describing the quality, intensity, and chronology. The symptoms are described as being of maximum intensity all the time, but if the patients keep a diary of symptoms or if information is gathered from other sources like relatives or the family physician, a considerable variation in the symptom intensity from day to day or from year to year often surfaces. The patients may have difficulties in the chronology of symptoms, mixing current and past symptoms and illness episodes in a disorganized and confusing manner. It is difficult for the patients to identify relieving factors or behaviour and to identify triggering events or things that make them worse, or these are multiple, or vague and unspecific. This is in contrast to patients with physical disease, who usually describe their symptoms in a consistent and precise manner (Table 5.2.3.2).

Typically, there is a marked *discrepancy* between a patient's subjective complaints and reports on his or her functioning when this is compared with the way the patient is observed to act, move

Table 5.2.3.2 Characteristic differences in symptom description and other characteristics of well-defined somatic and related disorders including functional somatic syndromes

	Somatization disorder and related disorders	Physical disease
Symptom description		
Location	Vague, diffuse, alternating	Well-defined, constant
Intensity	Vague, indistinctly defined intensity, few variations, often at maximum at all times	Well-defined changes and levels of intensity
Periodicity	Diffuse, difficult to define, are often denied	Typically well-defined periods with aggravation or improvement
Relieving or aggravating factors	Vague, indistinct, numerous	Well-defined, few
Number of symptoms	Numerous, vague	Few, well-defined, clearly described
The nature of symptoms	Unspecific	Specific
The character of the symptoms	Uncharacteristic	Characteristic
Iatropic symptoms and main complaints	Vague, difficult to identify	Can be identified and delimited from comorbid symptoms
Description	Affective, emotional, interpreting	Clear and descriptive
Other characteristics		
Treatment and medication	Difficult to assess the effect, transitory	Level of effect well-defined
Previous treatment	Unclear what treatment the patient has undergone. Diagnostic tests are often interpreted as treatment	The patient can account for previous treatments
Emotionality	Inadequate, e.g. exaggerated or marked unaffectedness ('la belle indifférence')	Adequate - empathic

and perform during the examination, or compared with information from other sources like family. For instance, the patient moves and sits completely freely despite complaining of severe back pain or gives detailed information despite complaints of severe memory impairment.

There may be *emotional discrepancy* in which the patient shows a lack of concern about the nature and implications of the symptoms despite presenting severe symptoms that are threatening the patient's future functioning and quality of life. Other patients may in turn be very affected and emotional in their description of the symptoms and illness, describing in a colourful, dramatic, and strikingly graphic manner.

The patient's centre of attention is typically on the suffering, on the psychosocial consequences, and the restrictions that the symptoms impose on their life. On the contrary, patients with well-defined physical disease are concerned or worried about the implication of their disease for their future health, i.e. will they recover or will they die from the disease. This emotional or *psychosocial communication* among patients with somatization disorder may put pressure on the doctor to do something.

Patients with somatization disorder and related disorders usually attribute their symptoms to a physical disease, and in some cases they persistently may *refuse to accept medical reassurance* despite appropriate medical evaluations. The ICD-10 criteria for somatoform disorders include this refusal to accept medical reassurance, but recent research indicates that many patients are unsure what is wrong with them, and they do not necessarily refuse non-medical explanations if they are presented in a meaningful and understandable way.[12] Although the patients may recognize that their physical symptoms are caused by, e.g. stressful events, this does not make the symptoms disappear, and they still need treatment. The weight of the symptom (refusing to accept medical reassurance) in the medical literature therefore seems out of proportion. However, in the most severe cases, patients may be involved in patient organizations fighting for their illness to be recognized as an 'authentic' physical disease or fighting for a particular causality of their illness as, e.g. whiplash-associated disorder or hypersensitivity to electricity or chemicals (multiple chemical sensitivity). The patients may also fight for disability pension or financial compensation. This is often more a question of getting their illness recognized than receiving financial compensation. Some patients may be preoccupied with the idea that they have been mistreated or neglected by doctors, and this group will often become involved in conflicts with doctors and in legal disputes.

In some cases, there is a sudden onset of the disorder in connection with a medical condition or a trauma in a previously normal and healthy individual. It could be a whiplash trauma, a fracture, an infection, or an acute intoxication. The symptoms persist despite the original disease being cured according to a biomedical or a surgical judgement. Instead, the illness worsens and more symptoms may emerge. Our knowledge about such disorders with abrupt onset is sparse.

Psychological symptoms and comorbidity

At examination, the patients may deny emotional symptoms or conflicts, and when they do report them, they often blame them on their physical affliction. Patients may also be reluctant to display emotional difficulties because of bad experiences of doing so. They may have experienced that doctors did not believe them or accused them of making up their symptoms and have consequently felt that their physical problems are not taken seriously. However, sooner or later, most patients will exhibit emotional difficulties, and if the patients feel understood by the physician, emotional problems may as well be presented. Patients may present many different types of emotional symptoms, often unspecific, but prominent anxiety and depressive symptoms are prevalent. Although the symptoms may be as marked as in affective and anxiety disorders, they are usually more transient, changing from one day to another and especially related to specific events. At times, the psychological symptoms may fulfil the criteria for a mood or anxiety disorder; but it is characteristic that the illness picture shows variations in both bodily and emotional symptoms.

Suicidal attempts are unusual but may occur especially among severe cases, but suicide is rare. Substance abuse is frequent, whether or not this is iatrogenic sanctioned.

The way the patients present themselves is inextricably linked to personal style and possible personality disorder. As a broad spectrum of personality disorders or traits[13] is associated with somatization disorder, the presenting style varies greatly from one patient to another. Characteristically, three broad patterns of personality style may be found in these patients, especially in chronic cases: dramatic–emotional type, paranoid–hostile type, and passive–aggressive-dependent type. The same patient may show all three patterns. In less severe cases it is often observed clinically that the patients have previously been very active and hard working, have conformed socially, and had a strong social network with many responsibilities. The patients often display perfectionist traits and prefer to be in control of a situation.

Illness behaviour

Typically, patients with somatization disorder persistently exhibit consulting behaviour which results in an excessive use of medical services and alternative therapies. In chronic cases, they have often been subject to a large number of futile examinations, surgery, and medical/surgical attempts at treatment.[10,14,15] However, some patients realize quite early in the illness course that the doctors cannot help them, or they are well managed by their family physician, so they do not necessarily display this consultation behaviour.

Due to negative results of medical check-up and treatment attempts and the patients' persistent belief that they must have a physical disease, the patients may consult different physicians. The patients may have been, or may feel, mistreated or neglected by doctors and therefore want to get a second opinion, or they want to find a doctor who can help them. Sometimes this behaviour, together with the patients' personality, can result in disagreement and a mutual hostility between the patients and their doctors.

Furthermore, the different illness patterns at different times, combined with the patients' seductive, demanding personality style, may result in disagreements between the different health care professionals involved in their care, which may complicate their care.

In chronic cases, all aspects of the patients' social and family life may be centered around their illness, so that the whole of their family life is adjusted to the patients' demands ('illness as a way of living').[16]

Classification

The diagnostic criteria for somatization disorder and related disorders have varied, with different permutations of the diagnostic terminology reflecting difficulties in classification and in establishing valid criteria. The distinction between the individual somatoform disorders is unclear, which means that the majority of patients will exhibit clinical characteristics from different diagnostic categories.[6]

Except for hypochondriasis or health anxiety, the somatoform disorder categories are primarily based on the number or specificity of bodily symptoms and on the duration of illness.[17] The disorders can be divided into acute and chronic forms, into a multisymptomatic form, and into a form in which the patients only present few symptoms or symptoms mainly referring to a single organ system. The somatization disorder diagnosis includes the most chronic multisymptomatic cases lasting for 2 years or more.

The ICD-10 criteria require the following:

1 at least 2 years of multiple and variable physical symptoms for which no adequate physical explanation has been found;

2 persistent refusal to accept the advice or reassurance of several doctors that there is no physical explanation for the symptoms;

3 some degree of impairment of social and family functioning attributable to the nature of the symptoms and resulting behaviour.

The ICD-10 criteria require 'multiple physical symptoms' to include at least 6 out of 14 predefined symptoms, involving at least 2 of the following: gastrointestinal, cardiovascular, urogenital, or skin or pain symptoms. In contrast, the DSM-IV criteria demand four pain symptoms, two gastrointestinal symptoms, one sexual symptom, and one pseudoneurological symptom that are not fully explained by a medical condition. No specific symptoms are listed, but examples are given. Consequently, there is only poor to moderate agreement between the DSM-IV and ICD-10 diagnostic criteria.[16] Cases lasting less than 2 years are classified as undifferentiated somatization disorder. In ICD-10, multiple symptoms are required, which is not the case in DSM-IV.

Functional or somatoform diagnoses defined mainly by the number or specificity of bodily symptoms include, besides somatization disorder (F45.0 and 300.81), undifferentiated SD (F45.1 and 300.81), persistent somatoform pain disorder (F45.4 and 307.80), and somatoform disorder unspecified/NOS (F45.9 and 300.82). In ICD-10, this also includes somatoform autonomic dysfunction.[3–5] There may be reasons for also including neurasthenia (F48.0) into the group. The somatoform disorder concept has never been accepted among non-psychiatrists, which has led to the introduction of many different functional somatic syndromes, e.g. chronic fatigue syndrome (CFS), fibromyalgia, irritable bowel syndrome (IBS), and chronic benign pain syndrome, and new syndromes are intermittently introduced.[18]

The newly introduced diagnosis of bodily distress syndrome or disorder may be a solution to this classification problem, although it has not yet been sufficiently tested in daily clinical practice.[3] The suggested diagnosis is based on an analysis of a large sample of patients from different medical settings, and it seems to encompass the various functional syndromes advanced by different medical specialties as well as somatization disorder and related diagnoses of the psychiatric classification. The disorder may have different manifestations, i.e. GI, MS, or CP syndromes as shown in Table 5.2.3.1.

Diagnosis

A somatization disorder should be suspected in any individual with a vague or complicated medical history or unaccountable non-responsiveness to therapy. Patients with somatization disorder may not have or may deny emotional symptoms or conflicts, so the absence of significant emotional symptoms at the general psychiatric interview and history taking will not exclude the diagnosis. But the presence of a previous or current emotional disturbance does support the diagnosis, as do previous episodes of medically unexplained bodily symptoms. Taken at face value, the physical symptoms are only of modest diagnostic importance, whereas unspecific or atypical symptoms in several bodily systems, or a very unusual presentation, speak in favour of the diagnosis. Multiple fluctuating symptoms of obscure origin, and their onset before the age of 30, strongly support the diagnosis. The diagnostic criteria displayed in Table 5.2.3.1 may be used, or the criteria listed in the DSM-IV or ICD-10 diagnostic criteria for somatoform disorders may be used.

Differential diagnosis

Mental and somatoform disorders

In **malingering**, the patient feigns illness with a conscious motivation to avoid responsibility or to gain an advantage. In **factitious disorder**, the symptoms are intentionally produced and the patient may self-inflict or induce diseases and lesions. In contrast to malingering, there is no external incentive for producing the symptom(s), and the motive is unconscious and only understandable in a psychopathological context.[19, 20] In somatoform disorders, both the symptom-producing behaviour and the motive are believed to be unconscious. However, factitious or malingering symptoms, mixed with other non-intentional symptoms, may occur in somatization disorder and related disorders.[11]

Hypochondriasis or health anxiety is mainly defined in cognitive terms with the emphasis on a preoccupation with physical appearance or the fears of harbouring or developing a serious physical disease. The other categories of somatoform disorders put more emphasis on bodily symptoms. In **dissociative or conversion disorder** the patients usually present fewer symptoms, but these are almost exclusively pseudoneurological symptoms. The onset is sudden, and closely associated in time with traumatic events, insoluble and intolerable problems, or disturbed relationships. The symptoms are transient and often remit suddenly after a few days, although they may persist for longer, but seldom for more than a few months. Episodes of dissociative or conversion disorders frequently occur in patients with other somatoform disorders.

In **pain disorder**, the predominating complaints are of medically unexplained pain in one or more anatomical sites. Various aches and pains are common in somatization disorder but are more fluctuating and not so dominating in the clinical presentation since they merge with other complaints.

In **ICD-10 somatoform autonomic dysfunction**, the patients complain of symptoms associated with a specific system or organ

that is largely or completely under autonomic innervation and control. For example, the patient refers the symptoms to the heart and cardiovascular system, the gastrointestinal tract, respiratory system, genitourinary system, etc.

In most **other mental disorders** physical symptoms are prominent; it is the rule, rather than the exception, that patients with mental disorders consult their family physician because of physical and not emotional symptoms.[2, 21] The symptoms may be misinterpreted by the patient and the doctor as being caused by a physical disease. However, in these cases of 'presenting' or 'facultative' somatizing, the patient will accept the diagnosis of a psychiatric disorder when it is established and will accept that the symptoms are attributable to a psychic rather than a physical affliction.[2]

Autonomic bodily symptoms are prominent in panic disorder and generalized anxiety disorders, but the emotional component of the disorders is unmistakable and the patients will not, or only temporarily, attribute their symptoms to a physical disease.

In psychoses, particular schizophrenic physical symptoms and hypochondriacal belief are common. However, the complaints are of a paranoid quality and other psychotic symptoms are prominent, except in the case of hypochondriacal paranoia. Psychotic episodes may occur in somatization disorder, but these are usually transient.[22]

In depressive disorders, the patient's complaints are mood congruent, and the symptoms will disappear if the depression is treated. In a few cases, however, a depression may be expressed in mainly bodily complaints (i.e. masked depression), and if left untreated may result in a prolonged course.

In obsessive-compulsive disorder (OCD), the patient may fear contracting a disease from an outside source (e.g. dirt, germs, viruses, etc.). The OCD disorders share many similarities with hypochondriasis, i.e. cognitive and emotional complaints are the main problem, whereas bodily symptoms seldom are dominating.

Medical conditions

The onset of multiple physical symptoms after the age of 40, in a previously physically and mentally healthy individual, suggests a general medical condition. However, multiple vague physical complaints may be prominent in mental disorders with late onset such as mood disorders, dementia, and withdrawal states.

Only a limited number of general medical conditions present vague, non-specific, and multiple somatic symptoms (e.g. hyperparathyroidism, hyperthyroidism, acute intermittent porphyria, myasthenia gravis, AIDS, multiple sclerosis, systemic lupus erythematosus, lyme disease, and connective tissues disease). In most of these medical conditions there will be positive paraclinical findings.

In genuine physical disorders, the key symptoms will usually be characteristic from one patient to another and across illness episodes. In contrast, the constellation of symptoms in somatization disorder and related disorders will usually be incompatible with any known, authentic physical disease, and the symptom picture will be of a more fluctuating nature.

Epidemiology

The prevalence of somatization disorder is about 1 per cent in the general population and 1 to 6 per cent in primary care and in inpatient medical settings, but it is much higher if less restrictive, abridged criteria are used.[3, 7, 8, 21, 23–28] Both among primary care patients, newly referred neurological in and outpatients, and among internal medicine inpatients, the prevalence of severe bodily distress disorder is 3.3 per cent, whereas the prevalence of modest bodily distress is 25.3 per cent.[3] Regardless of the criteria used, females predominate with a male-to-female ratio of 1:2 to 1:6, and the prevalence is rather constant as to age.[21, 24–29]

The age of onset is usually before 30 to 40 years.[14] This patient group poses a considerable financial burden to health and social service provision, a loss to industry, and a dependence on invalidity benefits for long periods.[14, 24, 30, 31]

Somatization disorder and related disorders are associated with a wide spectrum of heterogeneous psychiatric disorders, including personality disorders and mental retardation. The comorbidity rates are highest in the most chronic cases, in which rates of 50 per cent or higher are reported.[3, 13, 22, 24] Cultural and ethnic factors may affect the prevalence rate. This may be due to the influence of these factors on the likelihood of presentation to health care rather than real prevalence differences in the general population.[7, 21, 23] The typical presentation of physical complaints has varied throughout history and with the sociocultural environment of the patient.[32]

Aetiology

The aetiology of somatization disorder is unknown, but it is most likely multifactorial including biological, physiological, psychological, social, cultural, and iatrogenic factors. Different factors may have different importance at different times in the natural course of the illness. For instance, it may be a psychological trauma that precipitates the illness—but iatrogenic factors that maintain the illness. Whether the behavioural, cognitive, and other typical disturbances in somatization disorder and related disorders develop as a consequence of a basic biological defect in interaction with the patient's life experiences, or vice versa, or whether the mentioned disturbances and other predisposing factors have an independent impact is, as yet, unresolved.

Viewing functional somatic symptoms as a common reaction of human beings to stressors, like in the case of depressed mood and anxiety, results in the conclusion that different unspecific predisposing factors common for different mental disorders are involved.[33] Relatively specific predisposing factors are physical or sexual abuse and parental complaints of poor physical health and medically unexplained symptoms during the patient's childhood, whereas neither parental nor childhood well-defined physical illnesses seem to be predisposing factors.[34, 35]

The reported family transmission in somatization disorder may be due to sociocultural learning. However, there is some support for genetic transmission in somatization disorder, although twin studies have been inconclusive.[36]

Psychological theories

In the classical psychodynamic drive theory, medically unexplained physical symptoms are believed to develop as a reaction to the repression of unacceptable wishes or instinctual impulses and internal psychic conflicts.[37]

According to the theory of self-psychology, the anxiety connected with a threatening defragmentation or disintegration of the self is

the most profound form of anxiety that a person can experience.[37] In a defence against the feeling of emptiness, the individual becomes directed on the outside world and on physical stimuli. This process has been called 'stimulus entrapment' meaning that in somatization disorder, the individual becomes addicted to stimuli to his or her body.[38]

Individuals with alexithymia have a poorly developed language of emotions, and it has been suggested that instead they might respond with bodily symptoms. It is, however, unlikely that alexithymia has a specific aetiological role in somatization disorder.

The cognitive theory endorses the importance of the patients' misinterpretation of benign symptoms and normal physical sensations that they erroneously attribute to a physical disease.[39]

Biological factors

It is beyond doubt that an important biological component is involved, although the specific nature has still to be discovered. A neurophysiological dysfunction in the attention process has been demonstrated in somatization disorder, which may be explained by a reduced corticofugal inhibition in the diencephalon and the brainstem of afferent bodily stimuli, resulting in insufficient filtering of irrelevant bodily stimuli. A dysfunction of the secondary somatosensory area in the brain, a hypersensitivity of the limbic system towards bodily stimuli, or other dysfunctions may also be aetiologically involved.[40–42]

Other factors

In a few cases, a simple compensation claim may be of aetiological importance.

Physicians are primarily trained in a biomedical illness model and may have insufficient knowledge about diagnosing and managing somatization disorder and related disorders. Physicians may thus have a tendency to pursue organic possibilities and feel compelled to evaluate and treat all symptoms, and consequently a considerable iatrogenic reinforcement of physical symptoms is often involved.

Course and prognosis

Somatization disorder and related disorders have a spectrum of severity ranging from cases that may be difficult to delimit from normality to severely ill patients.[17]

In severe cases, the patients are chronically ill for most of their lives, but there may be periods of partial, but seldom full, remission. Some patients are able to work, others are severely disabled and are chair or bed bound, and their families have to provide virtually all aspects of physical care. Patients with somatization disorder and related disorders are often subjectively more functionally handicapped than patients who have a comparable, yet fully explained medical condition.[31]

Assessment

The purposes of the initial assessment are to (a) establish the diagnosis and rule out differential diagnoses, (b) examine which specific management or treatment strategies are possible and best for the patient, and (c) engage the patient in therapy.[15]

A scheme for the initial assessment by the psychiatric specialist is given in Table 5.2.3.3. For primary care physicians and in general hospitals this may be too comprehensive, and step one in the TERM model (Table 5.2.3.5) or another more simple model may be used.[43]

Table 5.2.3.3 Clinical assessment of patients with somatoform and related disorders including functional somatic syndromes

Before the meeting with the patient	
Review medical records and other relevant material	
At the examination	
Attitude towards the referral and the treatment	
Physical complaints	Chronology, intensity, provoking / relieving factors etc.
Triggering factors	Physical trauma or disease
	Psychosocial stressors
Current and previous emotional and behavioural complaints	
Social, funtional level, strain and coping	
The patient's illness belief and perception of symptoms	
Expectations to treatment and investigation	Physical Psychiatric
Past medical, surgical, and psychological history	
Dispositions	
Physical examination	
Paraclinical tests: Obtain focused diagnostic tests if not already done	

Before meeting the patient

Before meeting the patient it is important to review medical case notes and to gather information from other sources, e.g. the primary care physicians or the family, as patients with somatization disorder and related disorders may be inconsistent historians as a result of their complex medical history. The aim is to get an overview of the patient's medical history, the illness picture and complaints, examinations and diagnostic tests, and treatments and the outcome of these. It must also be assessed whether the patient is sufficiently examined for relevant differential diagnoses. The review may furthermore impart important information about psychological and social issues.

The examination

(a) Attitudes towards the referral and treatment

Patients with somatization disorder and related disorders may be sceptical about seeing a psychiatrist as they believe their problem to be of a physical nature and not psychiatric. This should be addressed directly by asking the patients what they have been told by the referring doctor, their reasons for coming to see the psychiatrist, and their feelings about it. It is important that such thoughts are brought to light to avoid misunderstandings and misconceptions, and to help the patients feel understood and in safe hands. In acknowledging the patients' fears of being stigmatized, it may be helpful to discuss negative public attitudes to psychiatry.

(b) Current physical complaints

The patients' physical complaints should be reviewed in detail for diagnostic purposes and to make the patients feel understood and taken seriously, which is a precondition for a good rapport between doctor and patient. Each symptom is explored to establish their characteristics, location, intensity, chronology and variation in intensity, onset, duration, and impact on daily life. Besides, provoking/relieving factors, previous treatments and the outcome of these are explored. It may be helpful together with the patient to write down the medical history on a time axis as patients may have difficulties with the chronology of their illness.

(c) Triggering factors

It is explored if onset of the illness is associated with physical trauma or diseases or with exposure to psychosocial stress or trauma.

(d) Current and previous emotional and behavioural complaints

As to a high comorbidity between somatization disorder and related disorders and other mental disorders, it is necessary to methodically clarify if the patients have a depression, anxiety disorder, or another mental illness.

(e) Illness beliefs and perception of symptoms

The patients' illness beliefs and perception of symptoms are of paramount importance for their illness and functioning as the illness behaviour has its origin in those beliefs and in illness attitudes. To change an inappropriate behaviour, it is necessary to identify such dysfunctional beliefs. Also, the attitudes and behaviour of the family may be a crucial factor in understanding the presentation and in planning the intervention.

(f) Expectations to treatments and investigations

The patients are questioned about wishes for and expectations to treatment and diagnostics tests and about what they believe may help them. Patients with somatization disorder and related disorders often have an unrealistic expectation to the impact of diagnostic tests and the effect of medical or surgical treatments. This may result in an intensive use of consultations. The patients must be helped to face the limits of what medicine can do and to acknowledge that continued medical consultations will be fruitless.

(g) Past medical, surgical, and psychological history

The patients' history is reviewed and related to the information gathered during the medical case note review. Furthermore, it is attempted to elucidate the patients' premorbid psyche and personality.

(h) Dispostions

Somatoform and related disorders often run in families and are associated with other mental disorders, and hence dispositions are explored.

(i) Physical examination

If not already made, a clinical examination ought to be carried out. Besides excluding organic possibilities, it also has a psychological purpose in making the patients feel that their physical complaints are taken seriously and that the psychiatrist is not exclusively focusing on the psychological part of the problem.

Routine laboratory test battery may be; complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, calcium, phosphate, liver function test, total protein, thyroid-stimulation hormone, erythrocyte sedimentation rate or CPR, urinalysis, and if indicated by symptoms or history, serological tests for Epstein–Barr virus, lyme disease, and immunological function test. Other tests may be relevant depending on the patient's illness picture.

Feedback of the results

Feedback of the psychiatric examination results to the referring doctor must be done in a way that is intelligible to a doctor who may not be psychologically minded. Statements like 'no formal psychiatric disorders are found', which unfortunately are frequent in consultation notes, may be somewhat useful when dealing with a patient referred for functional somatic symptoms. Such a statement just proves that the psychiatrist is unfamiliar with somatization disorder and related disorders.

The psychiatrist must be careful not to become involved in criticism of medical colleagues and in the divisions that these patients sometimes try to create between different therapists.

Treatment and management

Evidence-based treatment

Many different therapies have been used in patients with somatization disorder and related disorders like family therapy, physical therapy, biofeedback, relaxation therapies, hypnotherapy, psychodynamic psychotherapy, cognitive-behavioural therapy etc. The focus in the management varies a lot from (a) focus on the patients (organ-oriented approach or cognitive interpersonal approach, i.e. pattern of bodily and emotional symptoms over time, focus on dysfunction of central processing and context factors, interventions aimed at sensations, cognitions, affects, behaviours, and restoring overall function), (b) focus on the doctor (early recognition, communication skills, avoidance of iatrogenic harm), and (c) focus on context factors (doctor reimbursement system, patient compensation schemes, health care system, workplace characteristics, cultural belief).[44]

It must be concluded that the evidence for an effective treatment of patients with multiple functional symptoms is unsystematic. The use of multiple treatment methods and outcome measurement makes it difficult to compare studies. However, there seems to be substantial evidence that a specialized assessment with discharge letter, CBT, brief psychodynamic psychotherapy, and antidepressants have some effect on one or more outcome parameters.[44–47]

Treatment setting

Functional somatic symptoms and functional somatic syndromes are common in all medical settings. The patients often believe that they have a physical and not a psychological problem and will primarily seek medical and not psychological care. Hence, the management of somatization disorder and related disorders is not only an issue for psychiatrists but for all settings within the health care system.

The management must follow a stepped-care model, in which it is defined at which level of specialization each patient should be treated and, for each step, who is responsible for which parts of the treatment. For example, the mild and uncomplicated cases are treated by the primary care physician, modest to severe cases mainly by the primary care physician but in collaboration with a specialist, whereas the severe and complicated cases are managed in specialized care.

Besides the severity of the disorder, defining the steps in the model includes considerations about feasibility both as to available treatment resources and what is acceptable to the patient and the skills and knowledge of the primary care physician. Patients with a chronic somatization disorder may be well cared for by their primary care physician, provided the latter has the necessary skills and knowledge.

Inpatient care may be appropriate in a few cases, but patients with somatization disorder and related disorders are difficult to treat in ordinary psychiatric wards, where they are often met with considerable resistance from the psychiatric staff. Specialized inpatient units only exist in a few places in the world, and this treatment has not been documented.

Non-specialiszed treatment and management

(a) General hospital departments and non-psychiatric specialists

Because of the prevalence and the risk of iatrogenic harm, it is important that non-psychiatric specialists know about somatoform and related disorders and know how to identify and diagnose them. If the assessing physician exclusively focuses on symptoms that he finds relevant for his own specialty, there is a great risk of pursuing a wrong diagnosis. The fear of overlooking a definite physical disease, as an explanation of the physical symptoms, is deeply rooted in doctors, and this may, together with a poor knowledge about somatoform disorders, result in the doctor attempting to rule out even the rarest physical causes before a somatization disorder is even considered. However, there is little evidence that important medical diagnoses are missed more often in patients with somatoform disorders than in patients with other disorders.[48–50] Unnecessary procedures and diagnostic tests are not only unpleasant and potentially risky for the patient but may also delay or hinder sufficient treatment resulting in an aggravation of the disorder or perhaps chronicity. However, it must always be borne in mind that patients with a somatoform disorder may also have or acquire a concurrent physical disease. Instead of viewing somatization disorder and related disorders as a diagnosis of exclusion, all diagnostic possibilities ought to be included in the diagnostic consideration and the examination plan from the initial contact in the same way as when it is a question about two well-defined organic diseases. Diagnostic tests should be on medical indication and not on patient demand.

The primary role of the non-psychiatric specialists in the treatment of somatization disorder and related disorders is to:

- Exclude physical disease or trauma that can be treated medically or surgically
- In an empathic way, make it clear to the patient that he or she does not have the physical disease he or she fears, and that there is no indication of any other physical disease or defect that needs medical attention.
- That there is no medical indication for further diagnostic tests or examinations
- Coordinate the management with the primary care physician and other doctors that the patient may be in contact with.
- Consider a referral to a psychiatrist for examination or treatment
- In chronic cases, follow the advice given in Table 5.2.3.4.

Table 5.2.3.4 General advice on the non-specialized management of chronic somatization

Physical
1. Make a brief physical examination focusing on the organ system from which the patient has (new) complaints. - Look for signs of disease instead of symptoms. - Avoid tests and procedures unless indicated by signs of disease or a well-defined (new) clinical illness picture.
2. Reduce unnecessary drugs. Do not use on demand prescriptions and avoid dependence-forming medication.
Psychological
3. Make the diagnosis and inform the patient that the disorder is known and has a name.
4. Acknowledge the reality of the symptoms.
5. Be direct and honest with the patient about the areas you agree on, those you do not agree on, but be careful as not to make the patient feel ignorant or not respected.
6. Be stoical; do not expect rapid change or cure.
7. Reduce expectations of cure and accept the patient as being chronically ill. Aim at containment and (iatrogenic) damage limitation, i.e. use the management rather than treatment.
8. Perceive worsening of/or new symptoms as emotional communication rather than as a manifestation of a new disease.
9. Apply a specific therapeutic technique if you master it and consider referral to specialist treatment.
Psychopharmacological treatment
10. Consider treatment with psychoactive mediation (primarily antidepressant).
11. Choose non-habit forming medication and, if possible, choose medication that can be serum monitored.
12. Start with a smaller dosage than usual and increase slowly. Be stoical about side effects.
13. Take regular serum values to compliance issued and for validating complaints of adverse effects.
14. Treat any co-existing psychiatric disorders according to usual guidelines.
Administrative
15. Be proactive rather than reactive. Agree on a course with fixed, scheduled appointments with 2–6-weeks intervals and avoid consultations on patient demand (if needed, accept on demand a maximum of 1 phone appointment per week).
16. If the patient has a job, avoid giving him sick leave if at all possible.
17. Try to become the patient's only physician and minimize the patient's contact to other health care professionals, doctors on call, and alternative therapists.
18. Inform your colleagues of your management plans and develop contingency plans for when you are not accessible.
19. Inform the patient's nearest relative and try to co-opt a relative as a therapeutic ally.
20. If necessary, arrange support/supervision for yourself.
21. If necessary, motivate the patient to receive psychiatric treatment.

As previously mentioned, patients with somatization disorder are often resistant to psychiatric referral as they believe they have a physical and not a psychological problem. They may construe the referral as a sign that the physicians are not taking their symptoms seriously. It is important that the referring physicians avoid giving the message that the patients are not genuinely ill, that they trouble the doctors unnecessarily, or that they are 'mad'.[51] Instead, the

physician must try to meet the patients' wishes about knowing the cause of their illness, being taken seriously, getting explanations, information, advice, and reassurance.[52] A close liaison with medical colleagues guiding them in making a psychiatric referral in an acceptable way is important for engaging the patient in treatment.

Primary care

The TERM model (the extend reattribution model) is a simple cognitive-behavioural orientated treatment method to improve the primary care physicians' detection and management of patients presenting with medically unexplained symptoms. The method can effectively be taught to primary care physicians and will improve the outcome of their patients' treatment.[43] The TERM model is one of several different models that have been developed on the basis of the original reattribution model.[53,54]

The first stage of the TERM model (Table 5.2.3.5) is called 'understanding', as the important point, besides assessment of the patient, is that the patient feels understood and taken seriously by the doctor. The second stage is called 'the physician's expertise and acknowledgement of illness', in which the physician feeds back the results of his examination, but at the same time acknowledges the reality of the symptoms. The third stage is called 'reframing', in which a new model of understanding of the patient's problem is negotiated between patient and doctor. As a fourth stage, the model includes techniques for negotiating further treatment.[43]

Finally, the model includes principles for management of chronic, somatizing patients (Table 5.2.3.4). In chronic cases, damage limitation is a more realistic therapeutic goal than cure, and management is thus a more realistic aim than treatment.[51,55,56] The main aim is to stop the pathological cycle of interventions and consultations and the consequential somatic 'overtreatment' (i.e. treatment on obscure indication), and then, if possible, gradually to motivate the patient to accept specialized care if available in the area. Management according to these principles has shown to be effective in randomized controlled studies and should therefore always be implemented either solely or combined with one of the treatments described below.[57]

Table 5.2.3.5 The TERM model

1. **Understanding**
Take a full history of the symptoms
Explore emotional clues
Inquire directly about symptoms of anxiety and depression
Explore life events, stress, and other external factors
Explore functional level
Explore the patient's health beliefs
Explore the patient's expectations to treatment
Make a brief, focused physical examination
2. **The physician's expertise and acknowledgement of illness**
Provide feedback on the results of the physical examination
Acknowledge the reality of the symptoms
Make it clear that there is no (or that there is indeed) indication for further examination of nonpsychiatric treatment
3. **Negotiating a new model of understanding (reframing)**
Simple explanations
Physical symptoms are common reactions to, for example, stress and strain/nervousness
Depression lowers the threshold of pain
Muscular tension in anxiety and nervousness causes pain
Demonstrations
Practical (hyperventilation, muscular tension)
Establish the association between physical discomfort, emotional reactions, and life events
"Here and now" (nervous about consulting the physician)
Severe cases
Known phenomenon with a name: somatization
Basically the cause is unknown, but nothing indicates a hidden physical disease
Biological explanation: some are bodily sensitive than others, which explains their more intense symptoms
Individual symptom coping and reactions determine one's future well-being
4. **Negotiating further treatment**
Sum up agreements made during the consultation
Agree on specific objectives, contents, and form for the future course
Acute cases: no further appointments
Subacute cases: therapy sessions, regular scheduled appointments
Chronic: consider status consultation, regular scheduled appointments
Consider referral to psychiatrist, psychologist, or specialist service
5. **Chronic cases**
See Table 5.2.3.4

Specialized treatment and management

Cognitive-behavioural therapy is the best documented and most widely used therapy and is hence the focus in this section along with pharmacotherapy. The general principles of CBT are described elsewhere, so this section concentrates on the general techniques used in somatization disorder and related disorders, and how they differ from the CBT techniques applied in other disorders.

(a) Goal setting

Early in the therapy, the goals for the therapy are established. It is important to set up goals that are realistic in the light of the patient's illness and the framework of the therapy.

(b) Engagement and motivation

Treatment of somatization disorder and related disorders differs from the treatment of other mental disorders on several points, one being that it is very important to work systematically by engaging the patients in therapy. As the patients believe they have a medical condition, they may have very low belief in psychological treatment. It may be helpful to discuss the idea that all illnesses have an emotional component and that a psychological treatment focusing on the emotional component is often helpful in reducing suffering. The motivation and engagement should preferably be established during the assessment interview.

(c) Psychoeducation

The patient needs to be taught about somatoform and related disorders and about the body's normal reactions to stress and how stress may be expressed in physical symptoms. It is important that the patient learns about the possible biological and physiological basis in the CNS for the symptoms. This will make the reality of the symptoms clear to the patient and emphasize that the illness is not imaginary or made up. The education may be supported by written information. Parts of the information ought to be repeated during the therapy when it, in a relevant way, can be linked to the patient's personal experience.

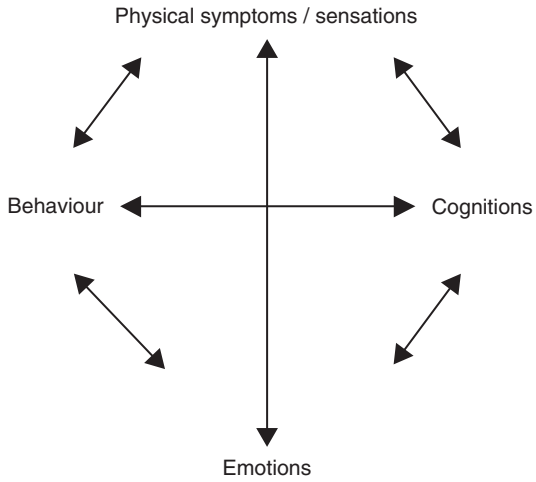

Fig. 5.2.3.1 Basic model in cognitive behavioural therapy.

(d) Physical symptoms and symptom attribution

Figure 5.2.3.1 illustrates the relationship between symptoms, cognitions, emotions, and behaviour in the cognitive-behavioural model. The first step in the therapy is to clarify the patient's dysfunctional automatic thoughts and basic beliefs about illness and symptoms, i.e. cause, consequences for future health and function, treatment, etc. Those thoughts are related to feelings and illness behaviour.

In the next step, the patient's disease model and symptom attributions are challenged. The therapist asks the patient to consider alternative possibilities, in which process even the most unlikely explanations are welcome. The therapist and the patient then explore which explanation is the most likely by investigating pros and cons for each possible explanation.

Finally, it is clarified how the patient would behave and react to a particular understanding or belief and which feelings this would produce.

(e) Behaviour and coping

Even if the patient does not want to or cannot work with his or her illness perception and symptom attribution, it would still be possible to work with the way the patient copes with illness. Illness behaviour and coping with symptoms and illness are scrutinized, and the behaviour is linked to the underlying thoughts and feelings if possible. When an example of a behaviour or coping strategy is elucidated, it is listed with arguments for and against a particular behaviour or coping strategy. A brainstorm on alternative possibilities is advisable, and pros and cons for each of these are also scrutinized. In a negotiation with the therapist, the patient chooses an alternative possibility, which is tested by the patient as homework, and at next session the effect of this is explored.

It is important to go slowly for the patient to experience success. The therapist is obliged to make sure that the patient sets up realistic goals with a good chance of success.

(f) Links between symptoms and stressors

The cause of somatization disorder and related disorder may be viewed as a combination of personal vulnerability and the stress and strain an individual is exposed to. The patients are often unaware of their patterns of reaction, but this can be established by careful registration of variations in symptom intensity and then relating them to what the patients are doing or thinking at that time. Based on variation in symptom intensity and stressors, potential important stressors in everyday life may be identified. This may provide a focus for intervention.

(g) Family and social network

The patient's health beliefs are often shared with the family and social network. Therefore it is necessary to create an alliance with the family to make sure they support the patient and not counteract the therapy. Family members are invited to a consultation and informed about the nature of the disorder and about the planned treatment. Misunderstandings and prejudgements about somatization disorder are eliminated.

(h) Treatment and help seeking behaviour and the physicians' handling

For patients with somatization disorder, social and family life is often centered on their illness, and an objective of the therapy is to reduce the importance of the illness and try to build up other interests and aspects of life. The patient's consulting behaviour may result in multiple fruitless diagnostic tests, referrals, and treatment attempts, which expose the patient to iatrogenic harm. Often, the patient grows tired of the doctors responding to their questions merely by referring or prescribing medication. In therapy, the patients are taught how to present their problems to the physicians in a way that prevents referrals and medication.[58] A patient may for instance tell the doctor that he or she is worried about some new symptoms, because he or she does not know whether the symptoms are just part of his or her somatoform disorder or something else, and that the doctor's expertise is required in order to clarify this.

Medication

Coexisting mood, anxiety, or other mental disorders are as effectively treated with psychotropic medication in patients with a somatoform disorder as in patients without.[59] Patients without coexisting mental disorders also seem to benefit from psychopharmacological treatment, antidepressants being the first choice.[44] In some cases, medication with peripheral action may be helpful as symptomatic treatment, for example in case of gastrointestinal symptoms like IBS.[44] Tricyclic antidepressants seem most effective, but due to side effects SSRI or SNRI ought to be the first choice. A useful strategy in the psychopharmacological treatment of somatizing patients is to start on a lower dosage than is usually recommended and to increase the dosage only gradually in order to avoid side effects. Antidepressants with the fewest interactions should be chosen as polypharmacy is common in these patients. The use of benzodiazepines and other dependence-producing drugs should be avoided. Stronger painkillers usually only produce a partial and temporary improvement, but they may result in misuse and should be avoided. Mild painkillers and tricyclic antidepressants are to be preferred.

In general, a degree of stoicism is required on the part of the clinician as patients may have varying symptom intensity and motivation and because patients may complain of side effects as a result of increased sensitivity to bodily sensations. Drugs that can be serum-monitored are preferred so that compliance and the likelihood of side effects can be assessed.

Possibilities for prevention

Patients with medically unexplained symptoms are often unpopular both with general psychiatrists and other doctors. The patients are seen as neither physically nor mentally ill, but simply as individuals complaining in order to avoid normal life responsibilities. Overcoming these negative attitudes is a matter of proper training of doctors and education of medical students.

Since an early diagnosis is important for preventing physical fixation, iatrogenic harm, and chronicity, doctors must be taught to view somatization disorder and related disorders with the same seriousness as well-defined physical diseases. The dominating dualistic way of thinking in medicine must be counteracted.

5.2.4 Conversion and dissociation disorders

Christopher Bass

Introduction

Of all the disorders characterized by symptoms in the absence of disease, conversion disorders are perhaps the most difficult to explain. How, for example, can one explain functional blindness or a loss of function of both legs in the absence of conspicuous organic disease? The ancient Greeks recognized that if we suffer emotional disturbance as a result of some serious stress (such as personal injury or bereavement), this causes a change in the nervous system which leads in turn to symptoms in different parts of the body according to the underlying pathophysiology. Nineteenth century neurologists made significant advances when they identified specific ideas at the root of the symptoms. In the early nineteenth century Collie[1] also observed that the significance of, and attention to, a symptom or set of symptoms may depend more on what they mean (or their value) to the individual than on the biological underpinnings of the symptom itself.

Spence has recently argued that the problem in hysterical motor disorders is not the voluntary motor system *per se*: rather, *it is in the way that the motor system is utilized in the performance (or non-performance) of certain willed, chosen, actions.*[2] This model invokes a consciousness that acts upon the body and the world. By contrast, the psychodynamic ('conversion') model, which Freud introduced and which held sway for most of the twentieth century, invokes an unconscious mechanism 'acting' independently of consciousness, to interfere with voluntary movement. Spence has further argued that hysterical paralyses are maintained not by unconscious mechanisms, but by conscious processes. The maintenance of these symptoms requires the patient's attention, a characteristic of higher motor acts; the paralyses break down when the subject is distracted, consciousness is obtunded, or when it (the 'paralyses') is circumvented by reflexive motor routines. Hysterical paralyses, Spence avers, are quintessentially disorders of action (or inactions), which the patient disavows, when faced with some overwhelming situation, which threatens the identity of the self.[2]

One regrettable development of psychiatry's adoption of Freudian theory was the fracture in communication between the disciplines of psychiatry and neurology, which has only recently been restored by the sort of collaborative research currently being carried out by neurologists and psychiatrists.[3] In the last decade there have also been exciting advances in neuroimaging, which have stimulated research into the neurophysiology of hysteria, and these will be described later. This chapter will also emphasize contemporary approaches to management of these difficult clinical problems.

Problems with definition

There are a number of problems with the definition of the conversion disorders (CD). First, physical disorder must be excluded, but neurological co-morbidity is known to be high in patients with CD,[4] and distinguishing which symptoms are accounted for by organic disease and which are not can be difficult. Second, it is stated that a temporal association between a psychological stressor and the onset on the disorder should be identified, but in practice this is often impossible to establish and depends to a large extent on the skill of the interviewing doctor. Finally, by definition (according to the glossaries ICD-10 and DSM-IV)[5, 6]; the process should be unconsciously mediated, but it is difficult (some would say impossible) to distinguish between symptoms that are not consciously produced and those that are intentionally manufactured. The DSM-IV provides no criteria to distinguish conscious from unconscious intent, and many authors have argued that the criteria for whether the patients are consciously aware of producing these symptoms should be dropped from the diagnosis of CD.[7]

In clinical practice it is often difficult for a physician, faced with a patient in a hospital bed unable to use his or her legs despite normal tests and clinical findings, to differentiate between conversion disorder, factitious or fabricated disorder, or frank malingering. What the clinician is being asked to do is to determine whether or not the symptoms are being produced intentionally or not; and what the motives are. Table 5.2.4.1 attempts to provide a framework, but it highlights the shortcomings of psychiatric glossaries, which in turn expose the limitations of the medical model, which forces doctors to place patients in categories without taking into account the normal moral capacity of many individuals to exercise choice and determine (at least to some extent) their actions.[8] These medical conundrums have been explored in more detail in the chapter on factitious disorders and malingering (Chapter 5.2.9).

The role of volition

Central to recent debates about hysteria and conversion disorders is the extent to which a person's illness presentation is considered a product of free will and hence social deviance or the result of psychopathology and/or psychosocial influences beyond the volitional control of the subject.[9] The proposal that voluntary processes are involved in some way has a very long history: something prevents a specific voluntary behaviour from being executed through a 'negative', lack of movement (as in paralysis), or a 'positive', abnormality of movement (as in psychogenic tremor). If 'will' is regarded as a conscious capacity that humans possess to choose what to do or refrain from doing, then the problem in CD appears to be that the will fails to produce normal action.[10] Hence, the diagnostic importance is placed on the patient's veracity: if we believe him when he says that he cannot act normally we conclude that his will is impeded pathologically; if we do not believe him we conclude instead that his will is deployed to deceive us. This is the distinction required by the diagnostic systems.

Table 5.2.4.1 Relationships between conversion hysteria, factious disorder, and malingering

	Subject insight		Target of deception		Perceived outcome	Motivation/ reason
	Aware	Unaware	Conscious self	Other		
Hysterical conversion		+	+		Sick and disabled role	Care/ dependency
Factious disorder	+			+	Sick and disabled role	Care/ dependency
Malingering	+			+	Sick and disabled role	Personal benefit, e.g. financial, avoiding prison

(Reproduced from Halligan, P. Bass, C. and Oakley, D. Wilful deception as illness behaviour. In *Malingering and illness deception* (eds. P. Halligan, C. Bass, and D. Oakley), pp. 3–28. Copyright 2003, with permission from Oxford University Press).

Conversion and dissociation

The word *conversion*is conventionally applied to somatic symptoms whereas if the symptom is psychological (e.g. a loss of memory or an external hallucination) rather than bodily (e.g. a loss of power) it is regarded as dissociative. *Dissociation* has attracted considerable recent interest, and it has been argued that the available evidence is more consistent with a model that identifies at least two distinct categories of dissociative phenomena—'detachment' and 'compartmentalization'—that have different definitions, mechanisms, and treatment implications.[11] These have been referred to as Type 1 (compartmentalization) and Type 2 (detachment), respectively (see Table 5.2.4.2).

Compartmentalization phenomena are characterized by impairment in the ability to control processes or actions that would usually be amenable to such control and which are otherwise functioning normally. This category encompasses unexplained neurological symptoms (including dissociative amnesia) and benign phenomena such as those produced by hypnotic suggestion. By contrast, *detachment phenomena* are characterized by an altered state of consciousness associated with a sense of separation from the self, the body, or the world. Depersonalization, derealization and out-of-body experiences constitute archetypal examples of detachment in this account. Evidence suggests that these phenomena are generated by a common pathophysiological mechanism involving the top-down inhibition of limbic emotional processing by frontal brain systems. Although these two types of dissociation are typically conflated, evidence suggests that different pathological mechanisms may be operating in each case.

Table 5.2.4.2 Classification of two types of pathological dissociation

Type 1 dissociation (compartmentalisation)	Type 2 dissociation (detachment)
Conversion disorders	Depersonalization/derealization
Dissociative amnesia	Peri-traumatic dissociation
Dissociative fugue	Out of body experiences
Dissociative identity disorder	Autoscopy (?)

(Reproduced with permission, from R. Brown (2002))

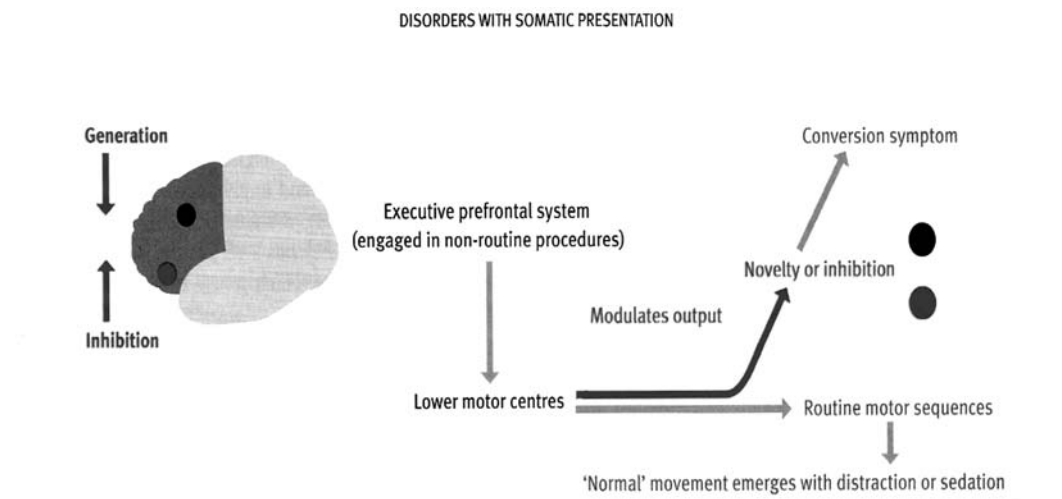
Support for the compartmentalization model comes from psychophysiological research, which suggests that psychogenic illness is associated with a deficit in attentional, conscious processing and the preservation of preattentive, preconscious processes. According to Brown[12] there is very little difference between 'negative' symptoms such as sensory loss, paralysis, etc. and 'positive' symptoms such as tremor, dystonia, etc. in terms of basic underlying mechanisms. By this view, all symptoms result from a loss of normal high-level attentional control over low-level processing systems; in this sense, all symptoms can be thought of as involving a form of compartmentalization.

Pathophysiology

There has been considerable progress in cognitive neuroscience and functional imaging over the last decade, which has provided a conceptual and empirically based platform for developing a neuroscience of not only hysterical symptoms but also free will.[13,14]

Recent functional neuroimaging data suggest that neural circuits linking volition, movement, and perception are disrupted in CD.[13] There are many studies examining the role of specific prefrontal regions in action generation (particularly the dorsolateral prefrontal and supplementary motor areas) and action suppression (especially the orbitofrontal cortices). These 'higher' executive centres supervene only when a change of behaviour is required: inappropriate behaviour must be suppressed or difficult procedures attended to, as when concentration is necessary. Hence, if the problem in hysteria is one of the will, and of abnormality emerging only when subjects attend to their actions, then this suggests the hypothesis that the prefrontal cortex is pivotal to the conversion process (see Fig. 5.2.4.1).

Further evidence that the prefrontal cortices play a key role in the control of action comes from a study of a woman with a left-sided conversion disorder affecting her leg. Marshall *et al.*[15] demonstrated that her attempt to move her paralysed leg was associated with increased activation of orbitofrontal (inhibitory) prefrontal regions, in the absence of motor cortical activity. They argued for an inhibition of motor behaviour by higher centres. Spence and colleagues[16] demonstrated that in three men with conversion symptoms affecting their upper limbs, hypokinetic movement was associated with reduced activation of dorsolateral (action-generation) areas of prefrontal cortex. Moreover, these areas of hypoactivity differed from those exhibited by four healthy men who were asked to feign the same motor impairments (see Fig. 5.2.4.2). It is possible that the application of functional neuroimaging techniques might allow clinicians to distinguish conversion from feigning on objective, empirical grounds.



The executive supervenes on lower motor centres when there is need for novel action generation (black circle) or suppression of inappropriate action (red circle), each implicating specific prefrontal regions: the dorsolateral and orbitofrontal cortices, respectively. Under conditions where the executive may be hypothesized to be disengaged (by distraction or sedation) normal movements emerge (as would be expected of routine actions). Conversion movements seem to require attention, and hence the engagement of the executive. There are 2 mechanisms by which conversion might emerge: failure to generate new actions, consequent upon dorsolateral hypofunction (black circle) or suppression of ongoing motor action, secondary to orbitofrontal activation (red circle). Other mechanisms may also operate. Acknowledgement: Mrs Jean Woodhead.

(Reproduced with permission (sought) from Spence, S. (2006). Hysteria: a new look. In *Psychiatry*, **5**(2), pp. 56–60, Elsevier Ltd.

In another recent case report using fMRI a patient with right-sided paralysis was asked to recall traumatic memories using a standard life event schedule: cued recall of the event was associated with regional brain activities characteristic of emotional arousal, including the amygdala and right inferior frontal lobe. Such recall was also associated with reduced motor activity in the area corresponding to the subjective paralysed limb.[17] This case study provides neuroimaging evidence for a connection between traumatic events and ongoing neurological symptoms (see Problems with definition, above).

Epidemiology

It is ironic that these research advances have occurred at a time when social historians have confidently asserted that hysteria has disappeared from clinical practice:

The most consequential development in the history of hysteria in the last century was the rapid decline in the medically recorded incidence of the disorder . . . . . .Hysteria—considered variously as a term, a theory, and a behaviour—is vanishing.[18]

It is extraordinary that this was written in 2001, at a time when symptoms considered 'functional, psychogenic, medically unexplained or hysterical' account for up to a third of new referrals to neurology outpatient departments.[3] and up to 9 per cent of admissions to a UK neurology in patient ward.[19] Akagi and House[20] concluded that the lowest prevalence figures suggested a rate of about 50 per 100 000 for cases of CD known to health services at any one time, with perhaps twice that number affected over a 1-year period. These figures suggest that hysteria is as common as other disabling conditions such as multiple sclerosis and schizophrenia. Furthermore, the burden of disability associated with chronic hysteria is far higher than a typical practising psychiatrist might expect, or than is reflected in standard textbooks of psychiatry or clinical neurology.[21]

It is regrettable therefore that it receives none of the resources or media attention that these disorders attract.

Clinical features

Conversion disorder: motor symptoms

The most typical motor symptoms are paralyses, functional weakness, gait disturbances, fits resembling epilepsy, and abnormal movements.

In the last decade diagnostic procedures have improved and the availability of non-invasive, accurate imaging has drastically reduced the rates of undetected organic pathology in patients with diagnoses of hysteria. Indeed, several recent studies have reported rates of misdiagnosis of between 0 and 4 per cent in regional and tertiary neurological centres,[22] which suggests that a diagnosis of CD can be made relatively confidently and accurately. In the following section the process of diagnosis will be briefly outlined through the history, examination, and investigation.

(a) The history

The onset, temporal sequence, and character of the presenting complaint may not be typical of a neurological disorder, and a number of other features may emerge, especially after an interview with a family member or a review of the hospital and general practitioner notes. If the patient is admitted to a general hospital bed the psychiatrist should routinely telephone the patient's primary care doctor and request a recent print out of his/her medical records (with consent). These often reveal key information about life events and/or antecedent illnesses, investigations, etc.

(i) Age of onset and sex

The average age of onset is the mid-30s, and patients with functional paralysis are less likely to be female than patients with pseudo seizures.

(ii) Mode of onset/recent life events or difficulties

An increased number of life events in the year preceding symptom onset have been recorded in small controlled studies of unexplained motor symptoms[23,24]. When patients are interviewed carefully, some report symptoms of panic just before the onset of, for example, functional weakness.[25] Judicious questions about sensations of sweating, dizziness, and difficulty breathing may reveal these somatic symptoms of anxiety, which may also be reported before the onset of sensory symptoms (see below). There is also an important literature describing unilateral somatic symptoms (which may present with sudden onset of functional weakness in a limb) following hyperventilation/panic.[26,27] These patients may present acutely in the A and E department of a general hospital, where they

may be admitted to the hospital stroke unit, or be sent to the general hospital as an emergency with an accompanying letter from the patient's GP describing the patient as 'off legs-please see and investigate.' The following clinical vignette is typical:

A 40-year-old woman was admitted as an emergency to the Stroke unit of the general hospital after collapsing at home. She had been involved in a dispute with her employers for weeks, and on the morning of the referral had an argument with her mother which made her very upset, and during the course of this she became distressed and developed paraesthesiae down the left side of her body, slurred speech, and collapsed, losing consciousness for 30 s. An ambulance was called and she was admitted to the A and E department, where she was noted to be hyperventilating and agitated, and to have weakness of the left leg, unintelligible speech, and claimed not to be able to see. All neurological investigations were normal, and after 12 days in hospital she made a gradual recovery, but was left with functional weakness in the left leg (requiring a wheelchair), and her speech was intermittently 'child-like'. History revealed a similar episode 3 years previously, a recent 2-year history of treatment for irritable bowel syndrome, and considerable work and domestic stress.

She was followed up by the liaison service and community mental health team, but despite the efforts of a community physiotherapist, psychologist, and nursing support her limb weakness continued and she remained disabled; 1 year after admission she was in receipt of disability benefits.

(iii) Previous unexplained symptoms

Evidence is accumulating that the more unexplained symptoms the patient has, the more likely the primary symptom is to be unexplained by disease.[28] In a recent study of patients with medically unexplained motor symptoms, additional unexplained symptoms including paraesthesia (65 per cent), pseudo epileptic seizures (23 per cent), and memory impairment (20 per cent) were reported.[4] It is often useful therefore, when CD is being considered as a diagnosis, to obtain a print out of the patient's past history from the primary care doctor (having obtained the patient's consent). This may reveal repeated presentations to different specialists as well as a history of repeated surgical procedures, particularly without clear evidence of pathology. It is also worth noting that patients with a diagnosis of somatization disorder (what used to be referred to as Briquet's syndrome) have high rates of conversion disorders, which punctuate their illness careers, often after a life event or physical injury/procedure.[29]

(iv) Psychiatric co-morbidity

Rates of depression (38 to 50 per cent) and anxiety (10 to 16 per cent) have been identified in a number of studies. In a recent small prospective controlled study there was a fourfold increase in depression in comparison with matched control with similar organic disability.[30]

(v) Neurological disease and other physical factors

A diagnosis of functional paralysis can be made in a patient who already has some paralysis from another cause, for example, the 'disproportionate disability' in a patient with multiple sclerosis. In a recent study of patients with unexplained motor symptoms 42 per cent had a co-morbid neurological disease and half of these had a peripheral origin.[4] Epilepsy is thought to coexist in a significant percentage of patients with non-epileptic attacks.[31]

It is also important for the physician or surgeon to be aware of the diverse ways in which conversion symptoms can present in the general hospital. In the last decade the author has seen many patients with conversion disorders after surgical procedures, investigations, and operations such as hysterectomy, minor injuries in the workplace, and after (often trivial) road traffic accidents. Numerous case reports implicating accidents, minor surgical procedures, and general anaesthetics as initiating factors have been described, for patients with both non-epileptic seizures and functional neurological syndromes.[32–34] These presentations are more likely to be seen in a medico legal setting, where the symptoms are shaped by the prospect of financial gain.

(vi) Secondary gain/litigation

This is a complex issue but impending litigation has been described in a number of studies of patients with unexplained motor symptoms and tremor.[4,35] One group of patients who may develop abnormal movements are those with reflex sympathetic dystrophy (RSD) which has been renamed Complex Regional Pain Syndrome Type I (CRPS I). It has been reported that patients with CRPS I with abnormal movements typically exhibit pseudo neurological (non-organic) signs, and in some cases malingering has been documented by secret surveillance.[36] The authors concluded that abnormal movements in CRPS I are a key clinical feature that differentiates CRPS I from CRPS II. Psychiatrists will often be asked to express opinions on patients with chronic painful extremities (often labelled as 'CRPS') in which abnormal movements have developed, especially in a medico legal setting. Pearce[37] has remarked that CRPS is best construed as a reaction to injury, or to excessive, often iatrogenic, immobilization after injury; but should not be seen as an independent disease. He asserts that the diagnosis of CRPS groups together ill-defined symptoms under a convenient, but medically untestable label, and that patients, lawyers, and support groups commonly deny psychogenesis, with the sadly mistaken notion that this implies a bogus or spurious cause.

(vii) Laterality of the symptoms

The idea that left-sided symptoms are more common than right has a long history but a recent systematic review found no evidence to support this view.[38]

(viii) History from relative/informant

There is a considerable amount of evidence to suggest that the observations and attitudes of carers may be important in the perpetuation of medically unexplained symptoms, especially motor conversion symptoms. For example, Davison *et al.*[39] found carers to be ill-informed and dissatisfied with the advice they had received from doctors about their relatives' diagnosis and disabilities. The education of carers and relatives is essential and will be dealt with in the section on management.

(b) The examination and diagnostic discrepancies

There is often a discrepancy between the patient's concept of the symptoms and the physician's knowledge of the anatomy and physiology. The way in which a patient moves or undresses may indicate a global affection that is incompatible with a specific nerve lesion or with a hemiplegia.

When considering any sign of functional weakness it is important to remember the following caveats:

1 Any sign that depends on inconsistency does not distinguish 'hysterical' from 'malingered' weakness.

2 The presence of a positive sign of functional weakness does not exclude the possibility that the patient also has an organic disease as well.

3 All physical signs, whether for organic or non-organic signs, have a limited reliability and inter-rater reliability.[22]

Another myth wedded to the concept of hysteria (I have already referred to the mistaken but common belief that it has 'disappeared' and that symptoms are more common on the left) is that the patients exhibit 'la belle indifference' or are inappropriately under concerned about their symptoms. In a recent systematic review Stone *et al.*[40] found that the median frequency of la belle indifference was 21 per cent (range 0–54 per cent) in 356 patients with conversion symptoms and 29 per cent (range 0–60 per cent) in 157 patients with organic disease. Indifference to symptoms is more likely to be noted in patients with factitious disorder (see Chapter 5.2.9).

Give way weakness is often used as a diagnostic test of hysterical paralyses, but it is unreliable. Unilateral functional weakness of a leg, if severe, tends to produce a characteristic gait in which the leg is dragged behind the body as a single unit, like a sack of potatoes. The hip is either held in external or internal rotation so that the foot points inwards or outwards. The most impressive quantitative discrimination to date between hysterical and neurological weakness is reported in a study of Hoover's sign—the involuntary extension of hysterically paralysed leg when the 'good leg' is flexing against resistance. Ziv and colleagues[41] demonstrated a clear difference in the pattern of response between neurological and psychogenic patient groups. It should be borne in mind however that the patient may have both a functional and organic disorder.[4]

Individual symptoms

(a) Paralyses

Paralyses may affect one or more limbs, or one side of the face. They may be flaccid or occur with contractures. In hysterical spasm both arm and leg are contracted on the same side of the body, the hand is closed tightly, the knee is flexed, and perhaps the leg and the foot are drawn up. Paralysis with contractures is one of the most extreme examples of disability caused by hysterical illness.

Hysterical paraplegia has been described,[42] and both spinal and orthopaedic surgeons, as well as rehabilitation specialists and neurologists, should be alert to the development of this disorder in their patients.[43] These patients have the potential to use considerable health care resources.[21]

(b) Abnormal movements

Psychogenic movement disorders are thought to account for 1 in 30 of all patients attending a movement disorder clinic[35] and have been the subject of a recent book.[44] During the last two decades a number of case series of patients with psychogenic dystonia have been reported.[45,46] Clinical features that suggest a psychogenic movement disorder are shown in Table 5.2.4.3.

In a recent systematic study of patients with fixed dystonia Schrag *et al.*[47] found that 37 per cent fulfilled criteria for psychogenic dystonia and 29 per cent criteria for *somatization disorder*, which is characterized by chronic, multiple, persistent, medically unexplained symptoms. Despite the fact that many patients fulfilled strict criteria for a somatoform disorder/psychogenic dystonia, in a proportion of patients the diagnosis remained uncertain, and whether the disorder was primarily neurological or psychiatric remains an open question. These patients require the services of a multi-disciplinary team.

Table 5.2.4.3 Features that suggest a psychogenic movement disorder

Abrupt onset
- Inconsistent movements (changing characteristics over time)
- Incongruous movements (movements do not fit with recognized patterns or with normal physiological patterns)
- Presence of additional types of abnormal movements that are not consistent with the basic abnormal movement pattern or are not congruous with a known movement disorder, particularly:
  - Rhythmical shaking
  - Bizarre gait
  - Deliberate slowness in carrying out the requested voluntary movement
  - Bursts of verbal gibberish
  - Excessive startle (bizarre movements in response to sudden, unexpected noise or threatening movement)
- Entrainment of the psychogenic tremor to the rate of the requested rapid successive movement the patient is asked to perform
- Demonstrating exhaustion and fatigue
- Spontaneous remissions
- Movements disappear with distraction
- Response to placebo, suggestion, or psychotherapy
- Presence as a paroxysmal disorder
- Dystonia beginning as a fixed posture

(Adapted with permission, from S. Fahn (1995))

The most common form of psychogenic movement disorder however is *psychogenic tremor*.[48] Almost 75 per cent of presenting patients are female and preceding events include work-related injuries and other accidents. A positive entrainment test (see Table 5.2.4.3), absence of finger tremor, and slowness of voluntary movements are suggestive of psychogenic origin. One-third has co-morbid somatoform disorders and one-fifth is involved in litigation or compensation. Prognosis is relatively poor if the condition has persisted for over 1 year, and in the long-term 80–90 per cent of patients continue to have abnormal movements.

(c) Seizures (psychogenic non-epileptic seizures or PNES)

It is estimated that more than 25 per cent of patients receiving a diagnosis of refractory epilepsy in a chronic epilepsy clinic do not have epilepsy.[49] Although the population incidence of PNES may be only 4 per cent that of epilepsy, PNES comprises a large share of the workload of neurologists and emergency and general physicians. Unlike patients with epilepsy however, those with PNES often do not have designated nurses or health care workers assigned to help with the management of this potentially disabling disorder.

PNES can be distinguished from epileptic seizures: PNES generally occur in the presence of an audience or when one is close at hand. They may be precipitated by stress, but more often seem to occur in response to the social setting. The fall to the ground is not usually abrupt, and movements may follow the fall with clutching, but the characteristic regular tonic–clonic sequence of epilepsy is not found. Tongue biting and incontinence of urine are rare in

hysterical fits, the corneal reflexes are preserved and the plantars are flexor, unless previously abnormal. Firm handling and pressure on the supra orbital nerves to the point of pain may arouse the patient. PNES occur most often among epileptic patients or among others who have seen epileptic fits. A few epileptic patients learn how to induce ictal discharges and can produce extra fits. Although rarely available during a fit, the EEG is generally abnormal in epilepsy and normal during hysterical fits.[31]

If PNES is not diagnosed and managed early, significant iatrogenic harm may occur. The outcome is not always favourable in these patients: in one recent study carried out at a mean of 11.9 years after manifestation and 4.1 years after diagnosis of PNES, 71 per cent of patients continued to have seizures and 56 per cent were dependent on social security. Outcome was better in patients with greater educational attainments, younger onset and diagnosis, attacks with less dramatic features, and fewer additional medically unexplained complaints.[50]

It has recently been reported that patients with PNES have a consistently different psychosocial profile from patients with motor conversion symptoms. In a prospective study of consecutive neurological inpatients with either motor conversion or pseudo seizures of recent onset, patients with PNES were younger, more likely to have both an emotionally unstable personality disorder and a lower perception of parental care, to report incest, and to have reported more life events in the 12 months before symptom onset than patients with motor conversion symptoms.[24] Recently a helpful fact sheet has been produced to help patients with PNES, which explains the nature of the disorder and approaches to management.[51] Although cognitive–behavioural therapy has been shown to be helpful in an open trial of patients with PNES, these findings need replication in a controlled setting.[52]

Sensory symptoms

(a) Sensory disturbance

The clinical detection and localization of sensory dysfunction is probably one of the least reliable areas of the neurological examination. Sensory loss may involve half the entire body from top to toe or from right to left. It may affect the whole of a limb, and characteristically has a glove or stocking distribution on the arms or legs, or both. The sensory loss generally fails to fit in with known anatomical boundaries but conforms more with the patient's concept of physiology and anatomy. Thus hysterical sensory loss is likely to stop sharply at the midline, while non-hysterical sensory change will only approach the midline since at this point segmental nerves overlap by one or two centimetres on each side.

Unfortunately these classical signs are often unreliable. 'Psychogenic' features on sensory examination and diminished vibration sense over the affected part of the forehead have been found in over half of patients with neurological disorders.[53, 54] Rolak also found that 'midline splitting' of sensory function was not helpful in determining whether there was an underlying neurological disorder.[54] These clinical findings should clearly be interpreted with circumspection.

Toth has recently described 34 patients with the 'hemisensory' syndrome, in which patients present with hemisensory disturbance and intermittent blurring of vision in the ipsilateral eye (asthenopia) and sometimes ipsilateral hearing problems as well.[55] Hemisensory symptoms are increasingly recognized in patients with chronic pain and in patients with reflex sympathetic dystrophy.

(b) Visual disturbances

Ophthalmologists have estimated that psychogenic visual disorders account for up to 5 per cent of their practice.[56] Simple observation of visually guided behaviour will sometimes reveal telling inconsistencies, particularly in the case of severe apparent visual loss. A number of reliable optometric techniques are available to support bedside tests and the diagnosis of psychogenic visual loss, field disturbance, or gaze abnormality (for more details see Stone *et al.*[23]). Disabling hysterical blindness presents more difficulties. Evoked potential studies will help to demonstrate intact visual pathways.

The disability associated with chronic conversion disorders

This topic is under-researched, but it is worth noting that, as the prognosis of CD is often poor, (not infrequently because patients are not diagnosed promptly, and even after diagnosis there are no resources to treat the patient). In the experience of the author this clinical conundrum is not improving: with the increase in provision of psychiatric services to the community and those with 'serious mental illness', patients with CD, even if they are profoundly disabled, often do not receive the appropriate treatment. Much of the disability is iatrogenic, and these patients will, not infrequently, be referred to the psychiatric service after having become confined to a wheelchair and/or in receipt of long-term disability benefits.[21,39] By this time the patients are usually entrenched in the sick role and it is very difficult to change the status quo.

Prognosis

The aetiological implications accruing from recent follow-up studies[4, 57] suggest that a short history and young age are held to be predictors of good outcome, while the presence of a personality disorder, chronicity of symptoms, receipt of disability benefits, and involvement with litigation predict poor recovery. As regards social circumstances, a change in marital status, good family functioning, and the elimination of a stressor has been shown to have a positive effect on outcome.[58] There is little chance of improvement once the symptoms have become chronic and enduring.

Patients with chronic motor symptoms, e.g. unilateral functional weakness, as well as those with sensory symptoms, appear to do particularly poorly. In particular, patients with unexplained motor symptoms who are referred to tertiary care centres continue to do very poorly following discharge. Despite the stability of the diagnosis, a pattern of multiple hospital referrals continues for many of these patients once they have been discharged from the tertiary care centre. Interviews of patients conducted on an average of 6 years after their original admission to a tertiary care centre revealed that many continued to be referred to neurologists and other specialists, but that subsequent psychiatric referral was rare.[59] Many changed their primary care doctor after discharge from hospital and a disproportionate number of re-referrals were made by primary care doctors who had known their patients for less than 6 months. Psychological attribution of symptoms was rare, and many patients felt dissatisfied with the treatment they had received. Many were exposed to unnecessary iatrogenic harm. These consistent findings of very poor outcome following discharge from neurological outpatient and inpatient services in patients with both

unexplained motor disorders as well as PNES suggest that without appropriate treatment the prognosis is poor.

Management

It is remarkable that a disorder as common as schizophrenia and multiple sclerosis should have attracted so little research interest or treatment resources. One reason for this is that there have been no randomized controlled treatment studies of CD, and so at the time of writing there is no good evidence about the best intervention for conversion disorder. There has been considerable interest in this topic however, which has been the subject of a recent Cochrane review.[60] All of the studies in this review were of poor methodological quality. On the credit side there is evidence that interest in CD is increasing and attracting more research funding.

Resources

Before any discussion of treatment it is important to consider the resources available to the neurologist to manage these patients. It is anomalous that, unlike disorders such as MS and schizophrenia, which have a similar prevalence, there are no designated resources for these patients. Some neurologists may have no access whatever to mental health resources, whereas others may have close collaborative links with either clinical psychology or psychiatry services. There is no doubt that the successful management of these patients requires the co-operation of a number of clinical specialties, including psychologists, nurses, physiotherapists, and occupational therapists (OTs). Some patients may be so disturbed or disabled (or both) that they may require inpatient admission to a specialized unit with access to both, mental health care and medical nurses, as well as physiotherapists and OTs. In the opinion of this writer every neurology service should have access to a specialist liaison psychiatry service.[61]

Management strategies for the neurologist

First, the diagnosis has to be established by a neurologist after relevant organic disease has been excluded. Second, the neurologist has to not only explain to the patient that there is no serious underlying organic disease but also provide an explanation for the symptoms that is comprehensible to the patient.

It is worth noting at this stage that patients prefer the term 'functional' rather than 'hysterical', when their unexplained weakness, fits, etc. are being referred to.[62] It is also important to avoid verbal landmines—for example using the phrase 'not sinister' instead of 'not serious'; or 'not structural' instead of 'not physical'. In patients who are generally hostile to psychological explanations it is best to use the word 'functional' instead of 'psychological'.

An example of an explanation to a patient with functional weakness and sensory disturbance may be something like: *you have what we call functional weakness. This is a common medical problem. Your nervous system is not damaged—we can see that from the examination and scans, etc. This is why why when you try and send the messages to your limbs they do not move properly. Similarly this is why the sensations from your body are not being felt properly. The most important thing about this condition is that because your nervous system is not damaged, the problem is potentially reversible. All the parts of the nervous system are there but are just not working properly, so that when you try to move your leg it doesn't do it as well as it should. Sometimes stress can cause these symptoms, which are often accompanied by worry and low mood but these are not the cause of the problem. Stress is a common problem and can lead to headache and abdominal pain as well as what we call functional weakness.*

This explanation can be supplemented by giving the patient a **fact sheet** containing information about functional weakness, which contains information about how to become involved with rehabilitation[51] (Fig. 5.2.4.3).

Further management

Ideally the neurologist and psychiatrist should interview the patient together at the bedside, but this is not always possible. At the very least however close collaboration between the two is essential before the patient is reviewed by the psychiatrist and a formulation proposed (and any potential for iatrogenic illness or diagnostic confusion eliminated).

Traditional behavioural approaches to treatment are based on the premise that the symptoms reported by the patient are interpreted as physical but are amenable to recovery. Treatment aims to bring about a gradual increase in function through a combination of physical and occupational therapies. The patient receives rewards and praise for improvement of function, and withdrawal of reinforcement for continuing signs of disability. Avoiding direct confrontation of psychological problems and providing 'face-saving' techniques are also regarded as key components.[63] More recently the approach to patients has moved from a predominantly medical one, to one in which psychological and sociocultural aspects are equally important, and the need for organized specialist rehabilitation services involving a multi-disciplinary team is recognized as essential.

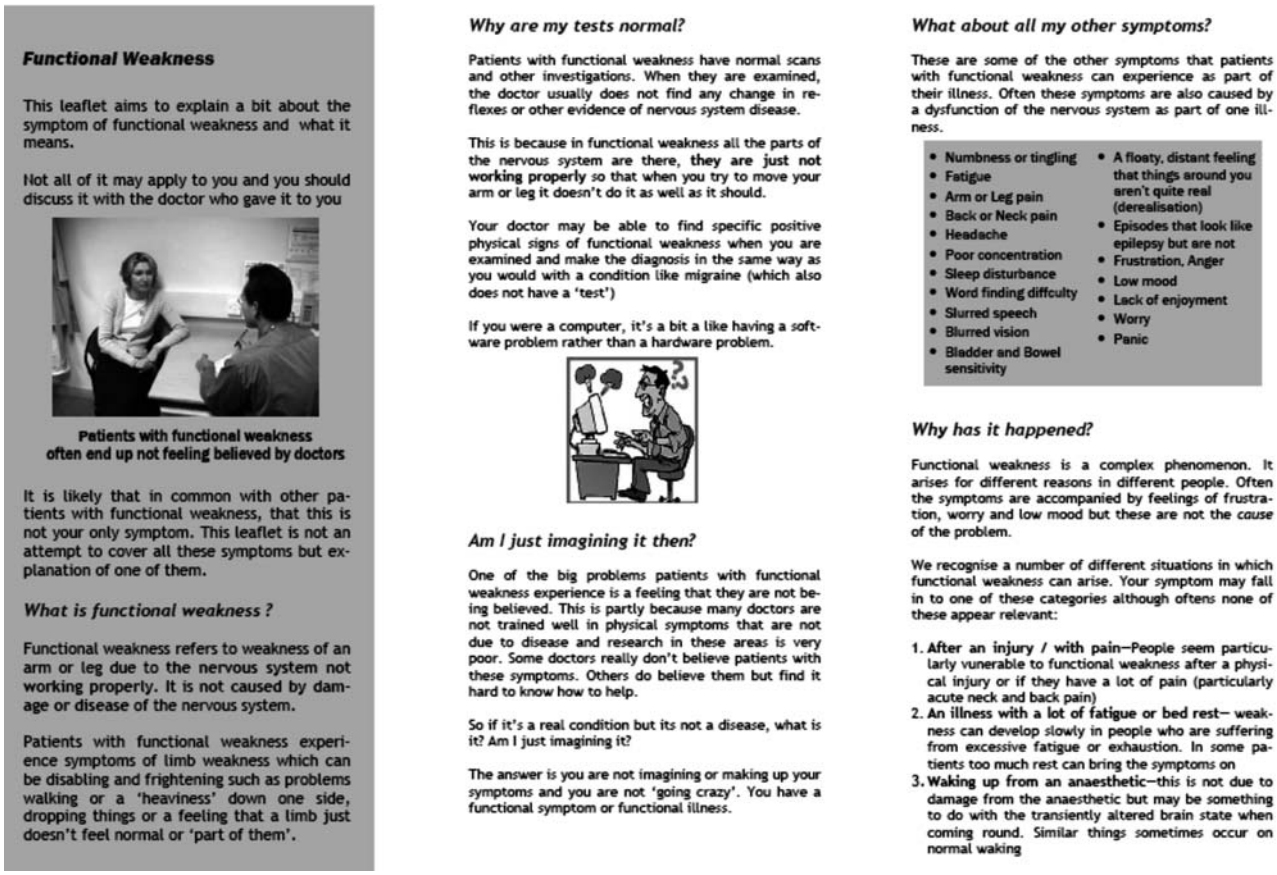
What is the evidence?

With one or two recent exceptions,[64] there are no large, randomized controlled studies of treatment in patients with CDs. Neither is there any good evidence to support the use of one specific intervention, e.g. biofeedback, hypnosis, psychotherapy. Although repeated case series have documented the effectiveness of multidisciplinary inpatient behavioural treatment, there is little controlled research.

In the absence of good experimental evidence a possible framework for future research has been developed which is based on published evidence and described in the WHO ICIDH.[65] This is particularly useful for patients in whom there is a disability that is out of proportion to known disease and signs. The model provides opportunities for intervention, and is well suited to the kind of multi-disciplinary approach that is likely to be successful in these patients.

The model emphasizes that whatever the primary cause of an illness, many factors (both individual and systemic) will have an influence on its manifestations. *For example: a vignette here.*

A 20-year-old woman was referred to the liaison service with functional paraplegia of 12 months duration. Onset was temporally related to a back strain caused by lifting a chair. She was confined to a wheelchair and lived with her parents and 14-year-old brother in an adapted house (specially adapted chair and stair rails) and was in receipt of benefits. A home visit was carried out and the patient denied any current problems or recent life events, although she described a long history of medically unexplained symptoms, multiple food allergies, and previous treatment in an adolescent unit for chronic



Functional Weakness

This leaflet aims to explain a bit about the symptom of functional weakness and what it means.

Not all of it may apply to you and you should discuss it with the doctor who gave it to you

Patients with functional weakness often end up not feeling believed by doctors

It is likely that in common with other patients with functional weakness, that this is not your only symptom. This leaflet is not an attempt to cover all these symptoms but explanation of one of them.

What is functional weakness ?

Functional weakness refers to weakness of an arm or leg due to the nervous system not working properly. It is not caused by damage or disease of the nervous system.

Patients with functional weakness experience symptoms of limb weakness which can be disabling and frightening such as problems walking or a 'heaviness' down one side, dropping things or a feeling that a limb just doesn't feel normal or 'part of them'.

Why are my tests normal?

Patients with functional weakness have normal scans and other investigations. When they are examined, the doctor usually does not find any change in reflexes or other evidence of nervous system disease.

This is because in functional weakness all the parts of the nervous system are there, **they are just not working properly** so that when you try to move your arm or leg it doesn't do it as well as it should.

Your doctor may be able to find specific positive physical signs of functional weakness when you are examined and make the diagnosis in the same way as you would with a condition like migraine (which also does not have a 'test')

If you were a computer, it's a bit a like having a software problem rather than a hardware problem.

Am I just imagining it then?

One of the big problems patients with functional weakness experience is a feeling that they are not being believed. This is partly because many doctors are not trained well in physical symptoms that are not due to disease and research in these areas is very poor. Some doctors really don't believe patients with these symptoms. Others do believe them but find it hard to know how to help.

So if it's a real condition but its not a disease, what is it? Am I just imagining it?

The answer is you are not imagining or making up your symptoms and you are not 'going crazy'. You have a functional symptom or functional illness.

What about all my other symptoms?

These are some of the other symptoms that patients with functional weakness can experience as part of their illness. Often these symptoms are also caused by a dysfunction of the nervous system as part of one illness.

- Numbness or tingling
- Fatigue
- Arm or Leg pain
- Back or Neck pain
- Headache
- Poor concentration
- Sleep disturbance
- Word finding diffculty
- Slurred speech
- Blurred vision
- Bladder and Bowel sensitivity
- A floaty, distant feeling that things around you aren't quite real (derealisation)
- Episodes that look like epilepsy but are not
- Frustration, Anger
- Low mood
- Lack of enjoyment
- Worry
- Panic

Why has it happened?

Functional weakness is a complex phenomenon. It arises for different reasons in different people. Often the symptoms are accompanied by feelings of frustration, worry and low mood but these are not the *cause* of the problem.

We recognise a number of different situations in which functional weakness can arise. Your symptom may fall in to one of these categories although oftens none of these appear relevant:

1. **After an injury / with pain**—People seem particularly vunerable to functional weakness after a physical injury or if they have a lot of pain (particularly acute neck and back pain)
2. **An illness with a lot of fatigue or bed rest**— weakness can develop slowly in people who are suffering from excessive fatigue or exhaustion. In some patients too much rest can bring the symptoms on
3. **Waking up from an anaesthetic**—this is not due to damage from the anaesthetic but may be something to do with the transiently altered brain state when coming round. Similar things sometimes occur on normal waking

Fig. 5.2.4.3 Fact sheet for patient with functional weakness (Reproduced from Stone, J. Carson, A. and Sharpe, M. (2005), Functional symptoms in neurology: management. *Neurology in Practice,* **71**(Suppl. 1), i13–i21. Copyright 2005, BMJ Publishing Group Ltd.)

fatigue syndrome. She was seeing a chiropractor for her symptoms, and had been told that she had nerve damage (not confirmed). Her brother was off school with chronic fatigue and her mother had a long history of emotional problems. At interview, the family were polite but could not identify any link between recent events and her disabling symptoms. Discussion with the GP did not reveal any other relevant information and a follow-up was arranged 1 month later. Before this appointment the patient telephoned the psychiatrist to say that she had not disclosed certain facts at the initial meeting, and revealed that she had confronted her physically abusive step father and asked him to leave the house to live with his mistress (which he duly did). At follow-up there was a great deal of expressed relief, and the patient agreed with our formulation that, to some extent, she had developed weakness in the legs and become wheelchair bound in order to avoid being hit by her step father. She agreed to a brief admission to a rehabilitation unit, was encouraged to mobilize gradually and had regular sessions with a clinical psychologist. She responded well to treatment, commenced a college course, and learned to drive a car. At 3 year follow-up she was symptom free and in gainful employment. [the first vignette in this chapter].

Psychological treatments

Because patients with conversion disorders share features in common with patients with other medically unexplained syndromes, treatments that have been used in these latter disorders may have potential. Most of the evidence-based treatments in this field involve cognitive–behavioural therapy (CBT,[66] or interpersonal therapy (IPT)). These usually have to be undertaken by trained clinical psychologists or other clinicians. However, increasing numbers of specialist nurses are being trained to deliver these treatments, so they should become more widely available.

CBT is concerned mainly with helping the patients overcome identified problems and ascertain specified goals. It discourages 'maintaining factors' such as repeated body self-checking and excessive bedrest, and challenges patients' negative or false beliefs about symptoms. Chalder has described specific CBT based treatment for patients with conversion disorders.[67]

Hypnosis and intravenous sedation

In an inpatient trial of hypnosis both patients with CD and controls improved equally and no extra effect from hypnosis was found.[68] Others have found the use of intravenous sedatives, particularly propofol, helpful in persuading some patients with whom a good relationship has been established, that they can eventually make a recovery.[51]

Pharmacological treatments

There is evidence from randomized controlled trials (RCTs) and systematic reviews that antidepressants (both tricyclics and selective

serotonin reuptake inhibitors (SSRIs)) can be useful in the treatment of patients with medically unexplained symptoms (such as poor sleep and pain), whether or not depression is present.[69]

5.2.5 Hypochondriasis (health anxiety)

Russell Noyes Jr.

Introduction

Hypochondriasis is a preoccupation with the fear that one has, or may develop, serious disease despite evidence to the contrary. So defined, the disorder affects between 2 and 7 per cent of patients attending general medical clinics and is a cause of physical dysfunction and disability.[1] It is also a reason for increased health care utilization and dissatisfaction with care received. To their physicians, patients with this disorder are an enigma and a source of frustration.

Unfortunately, relatively little is known about hypochondriasis. Primary care physicians have had little interest and psychiatrists see few patients with the condition. It is a pejorative label that, even if entertained, is rarely communicated. And, even if communicated, the diagnosis would not, until very recently, have led to effective treatment.

History

Hypochondria was used by Hippocrates to refer to a region below the cartilage of the ribs. In the second century, Galen linked it to organs in this area as well as humours and animal spirits. The symptom picture was ill-defined and only gradually took on the characteristics recognized today. From earliest times the disorder was associated with melancholia, a temperamental disturbance caused by an excess of black bile. Burton (1621) described hypochondriacal melancholy in terms of vague physical symptoms, disturbances of mood, and fears. In the seventeenth century, Sydenham viewed hypochondria in men as the counterpart of hysteria in women, but the first modern description was published in 1799 by Sims.

By the eighteenth century, hypochondria became part of a fashionable disturbance that Cheyne attributed to the English way of life and environment. However, as notions of aetiology began to shift under the influence of Cartesian dualism, hypochondria was increasingly seen as a weakness and moral failing. Falret (1822) was

Table 5.2.5.1 Essential and associated features of hypochondriasis

Essential features
Fear of disease
Disease conviction

Somatic symptoms
Reassurance-seeking
Associated features
Fear of aging and death
Overvaluation of health
Low self-esteem
Sense of vulnerability to illness

perhaps the first to identify it as a mental disorder, one of the neuroses. Freud viewed hypochondria as an 'actual neurosis', having a physiological basis and not amenable to psychoanalysis. However, present-day descriptions began with Gillespie,[2] who in 1928 defined hypochondriasis as 'a mental preoccupation with a real or supposititious physical or mental disorder'.

Conceptualizations

Authors disagree about how hypochondriasis should be conceptualized. Some look upon it as a personality trait; its early onset and long-term stability in many patients fit this conception. Others view it as a dimension of psychopathology. They see illness worry as a continuum with hypochondriasis falling on the severe end. For those who take a categorical approach, the issue of whether hypochondriasis is primary or secondary remains unsettled. High rates of comorbidity create doubt about its independent status. Based on existing evidence, some question whether hypochondriasis can be regarded as a discrete psychiatric disorder.[3]

Clinical picture

Essential features

The essential characteristics of hypochondriasis are shown in Table 5.2.5.1. These include fear of serious disease, the consequences of which may include pain, suffering, disability, and death. Such fears take the form of alarming thoughts and images of specific diseases. They also include conviction or belief that the feared disease is already present. This belief is overvalued meaning that it is strongly held despite lack of evidence; it is not delusional.

Bodily preoccupation is perhaps the most important feature.[4] This takes the form of intense interest in, and attention to, what is happening in the body. The focus is upon somatic symptoms which tend to be multiple and diffuse. Attention is also directed to bodily sensations, bodily functions, and minor abnormalities as well as related concerns such as diet, exercise, and environmental exposures. The activities and conversation of patients are dominated by medical concerns. As a consequence of their self-absorption, interest in other people and pursuits is withdrawn.

Reassurance-seeking is the main behavioural feature. Patients repeatedly check their bodies for signs of serious disease. They check their pulse, look for lumps, examine themselves in the mirror, etc. In addition, they search medical sources for the meaning of their symptoms. Such patients also ask friends, family, and medical professionals for reassurance. Their search may lead to excessive utilization of health services.

Associated features

Associated characteristics include fears of aging and death, which appear to be an integral part of hypochondriasis. Overvaluation of health and appearance is another related feature. Hypochondriacal patients may become preoccupied with eating natural foods, achieving physical fitness, and living a healthy lifestyle, activities that reflect their idealized conception of good health.

Patients with hypochondriasis feel unworthy and unlovable.[4] As a consequence of their low self-esteem they have negative expectations of others including medical professionals. In addition, they have a sense of vulnerability to illness.[5] These characteristics have to do with fundamental aspects of the self that the hypochondriacal patient views as deficient.

Subtypes

Hypochondriacal patients are heterogeneous and subtypes may exist. Separate dimensions of disease phobia and disease conviction have consistently been identified; in some patients fears are prominent and in others conviction dominates the picture. Others may resemble patients with obsessive-compulsive disorder or personality disorders of one kind or another.

Classification

Criteria

Hypochondriasis initially appeared in DSM-II as one of the neuroses. In DSM-III, it was moved to the somatoform disorders, and diagnostic criteria were provided. In a revision of the classification (DSM-III-R), a duration of 6 months was added, and patients with delusional beliefs were excluded. The DSM-IV criteria are shown in Table 5.2.5.2. They exclude patients whose symptoms are better explained by other anxiety, depressive, or somatoform disorders.[1] Also, in DSM-IV, specific phobia of illness is separated from hypochondriasis. The illness phobic is said to fear contracting an illness whereas the hypochondriac fears disease already present.

The ICD-10 criteria for hypochondriacal disorder differ from those in DSM-IV. They require a persistent belief about having one or more specifically named serious physical diseases.[6] In addition, they include body dysmorphic disorder. With respect to illness behaviour, the ICD-10 criteria state that hypochondriacal concerns cause persons to seek medical investigation or treatment. They also state that patients may accept reassurance in the short-term, but that in the long run they are not likely to respond.

Table 5.2.5.2 Abbreviated DSM-IV diagnostic criteria for hypochondriasis

(a) Preoccupation with fears of having, or the idea that one has, a serious disease based on misinterpretation of bodily symptoms
(b) The preoccupation persists despite appropriate medical evaluation and reassurance
(c) Belief not of delusional intensity
(d) Preoccupation causes significant distress or impairment
(e) Duration of at least 6 months
(f) Not better accounted for by other anxiety, depressive, or somatoform disorders

The somatoform disorders category to which hypochondriasis belongs is controversial, and many question its inclusion in the classification.[7] They see these disorders as ill-defined, of questionable validity and based more on illness behaviour than on distinctive features. They also view them as creations of Western biomedicine that serve to devalue patients who challenge the theoretical model upon which it is based.[8] According to that model, illness is a response to disease, and the person who is ill without disease, e.g. hypochondriasis, is marginalized.

Were the somatoform disorders to be eliminated, some have proposed moving hypochondriasis to the anxiety disorders (health anxiety) or to a proposed grouping, the obsessive-compulsive spectrum disorders.

Validity

Evidence for the validity and utility of the diagnosis of hypochondriasis remains limited. In studies aimed at demonstrating validity, Barsky *et al.*[9] showed that distinguishing characteristics of the disorder aggregated in some medical outpatients but were less common in others. The same patients had other features of hypochondriasis indicating external validity. Using a structured interview for hypochondriasis, these investigators and others[10,11] observed a positive correlation between interview and physician ratings (concurrent validity). Hypochondriacal patients also had more ancillary features of hypochondriasis than did control patients (external validity). Also, other clinical characteristics distinguished interview positive from interview negative patients, indicating discriminate validity. Follow-up studies have shown a degree of diagnostic stability suggesting predictive validity.[12,13]

Measures

A variety of measures have been developed to screen for hypochondriasis and assess the severity of hypochondriacal concerns.[14] These are shown in Table 5.2.5.3. The Whiteley Index, a self-report instrument based on the observed characteristics of hypochondriacal psychiatric patients, is one of the most widely used.[15] It consists of 14 yes versus no items, but recent work suggests that a 7-item version is satisfactory for screening. The Illness Attitude Scales is a 27-item measure of psychopathology associated with hypochondriasis.[16] A principal components' analysis yielded two factors, one measuring health anxiety and the other illness behaviour. The health anxiety subscale has been used to distinguish hypochondriacal from non-hypochondriacal patients.

Recently, self-assessment measures have been developed to assess the various dimensions of health anxiety and hypochondriasis. The Health Anxiety Inventory contains 47 items covering a range of hypochondriacal features.[17] An advantage of this scale is that it distinguishes patients with high health anxiety from those with physical illness.

The Structured Clinical Interview for DSM-IV (SCID) and the Composite International Diagnostic Interview (CIDI) are comprehensive diagnostic interviews that contain somatoform disorder modules. The CIDI has been used in epidemiologic surveys. Its stem question for hypochondriasis is, 'In the past 12 months, have you had a period of 6 months or more when most of the time you worried about having a serious physical illness or deformity?'

Based on the SCID, Barsky *et al.*[10] developed a structured interview that focuses exclusively on hypochondriasis. It begins with a series of probe questions that, if answered affirmatively, trigger the remaining interview. It is suitable for confirming the diagnosis in a screened population.

Diagnostic assessment remains less than satisfactory because the threshold for caseness has not been established, medical and psychiatric comorbidity make diagnostic decision-making difficult, and independent medical evaluation is rarely part of the process.

Differential diagnosis

Physical disorders

A few hypochondriacal patients suffer from undetected physical disease. Consequently, it is important to exclude medical conditions that, in their early stages, may cause vague symptoms with few signs or laboratory abnormalities. These include neurological conditions, such as multiple sclerosis or myasthenia gravis; endocrine conditions, such as thyroid or parathyroid disorders; multisystem disease such as systemic lupus erythematosus or occult malignancies. Because of such possibilities, a physical cause warrants continuing consideration even after the initial work-up has been completed.

Psychiatric disorders

Patients with **panic disorder** may be difficult to distinguish from those with hypochondriasis because they commonly have hypochondriacal features. A diagnosis of hypochondriasis should not be made if illness concerns are better accounted for by panic disorder. Patients with hypochondriasis tend to fear the long-term consequences of illness (such as cancer) whereas those with panic fear the immediate consequences of illness events (such as a heart attack); the former fear death, the latter dying. Also, those with hypochondriasis misinterpret a range of bodily sensations, whereas those with panic misinterpret the symptoms of autonomic arousal.

Hypochondriasis must be distinguished from **specific phobia, illness subtype**.[1] Patients with hypochondriasis are preoccupied with a disease they believe is already present, whereas illness phobics fear developing a disease they do not yet have. Illness phobic symptoms are triggered by external as well as internal cues. For instance, exposure to a person with the feared disease may elicit a fear response.

Hypochondriasis must be distinguished from **obsessive-compulsive disorder**. Patients with the latter often have intrusive thoughts about disease or contamination and rituals that involve

checking or reassurance-seeking. They differ from patients with hypochondriasis in having other obsessions and compulsions. Obsessive-compulsive patients tend to regard their ideas as senseless and resist them, whereas those with hypochondriasis regard them with conviction.

Hypochondriasis must also be distinguished from **generalized anxiety disorder** which is characterized by excessive worry about a number of areas. These may include health but other areas are generally involved as well. If worry is confined to illness, then a diagnosis of GAD should not be made. Patients with GAD tend to have health worries that are general, whereas those with hypochondriasis involve specific diseases such as cancer.

Hypochondriasis that develops during an episode of **major depression** and remits with treatment of the mood disturbance may be better accounted for by the depressive disorder. In that case, the patient is likely to focus concern upon the vegetative symptoms of depression and interpret these as irreversible loss of health. On the other hand, a diagnosis of hypochondriasis may be appropriate when hypochondriacal concerns are not confined to an episode of depression and are not focused on symptoms of the mood disorder.

Hypochondriasis and **somatization disorder** are both characterized by somatic symptoms. However, patients with hypochondriasis worry about the meaning of symptoms rather than the symptoms themselves. They are concerned about the consequences of serious illnesses rather than securing the gains of illness (e.g. sick role) as are patients with somatization disorder. Patients with hypochondriasis have an equal sex distribution whereas those with somatization disorder are predominantly women.

Hypochondriacal beliefs of a delusional nature may occur in patients with psychoses, but these patients usually have other psychotic features. However, delusions of disease may be the main or only manifestation of **delusional disorder, somatic type**. Such delusions may be bizarre or unrealistic, whereas the beliefs of patients with hypochondriasis are overvalued.

Epidemiology

Prevalence

The prevalence of hypochondriasis in the **general population** has not been established. Major surveys of psychiatric disorders have either excluded the somatoform disorders or identified few cases. For instance, Looper and Kirmayer[18] found that 6 per cent responded affirmatively to screening for illness worry, but only 0.2 per cent met full criteria for hypochondriasis according to a structured interview. Two studies that focused exclusively on somatoform disorders obtained higher estimates (4.5 and 7.7 per cent).[19, 20] Two other surveys focusing on illness worry found that half the respondents with such worry had the illness they worried about.[18, 21] Among such people it may be difficult to distinguish excessive from normal worry.

The prevalence of hypochondriasis among **primary care outpatients** had been examined in a number of studies. In a cross-national survey, Gureje *et al.*[22] noted that, if the criterion of failure to respond to reassurance were set aside, 2.2 per cent of patients qualified for this diagnosis and were as impaired as those meeting full criteria. In studies based on structured interviews, prevalence estimates have ranged from 2.2 per cent to 9.4 per cent.

Hypochondriasis may be prevalent in **medical specialty populations** where patients with functional disturbances are common. For instance, one survey found the disorder in 13 per cent of otolaryngology clinic patients. Also, hypochondriacal concerns are higher in patients with functional than with organic illnesses. For example, in one study higher hypochondriasis scores were obtained from patients with irritable bowel syndrome than from patients with organic gastrointestinal disease. Hypochondriacal concerns and health anxiety are especially high in patients with chronic pain.

High health anxiety is one of the factors shared by functional somatic syndromes in the general population.[23] However, it is not clear whether this represents a vulnerability factor or a consequence of unexplained symptoms.

Risk factors

Risk factors for unexplained somatic symptoms include female gender, older age, non-white race, less education, and lower income. With respect to hypochondriasis, few of these demographic factors appear important although findings have been inconsistent. The risk for men appears to be equal that for women. Some studies have shown persons with illness worry and hypochondriasis to be older and to have more physical illness. Two studies found them to have less education.

Comorbidity

Hypochondriacal patients in primary care have high levels of psychological as well as somatic symptoms. Strong positive correlations have been observed between hypochondriacal concerns and depressive ($r = 0.58$), anxiety ($r = 0.55$), and somatic symptoms ($r = 0.52$). In one study, the proportions of hypochondriacal and control patients, having one or more comorbid disorder, were 62 and 30 per cent respectively. Anxiety and depressive disorders accounted for most of the excess.

Family and twin studies

Taylor *et al.*[24] used a twin study to examine the genetic and environmental contribution to excessive health anxiety. After controlling for medical morbidity, which may be a source of health anxiety, they found that genetic factors accounted for 37 per cent of the variance in fear of disease and 10 per cent in disease conviction. For both dimensions the remainder of the variance (63 and 90 per cent respectively) was accounted for by non-shared environmental factors. These and other results suggest that some dimensions of health anxiety are moderately heritable. They also suggest that such anxiety is largely a learned phenomenon.

A family study compared the first-degree relatives of probands with and without hypochondriasis obtained from a general medicine clinic.[25] No difference in the frequency of hypochondriasis was found between these groups of family members. However, certain traits and attitudes, such as hostility, low agreeableness, and dissatisfaction with care, were significantly higher among the relatives of hypochondriasis probands. Such traits and attitudes may confer vulnerability to hypochondriasis and/or other somatoform disorders.

Morbidity and service utilization

Hypochondriasis is associated with impairment in physical functioning and work performance. Patients with this disorder view their health as worse, and experience more physical disability as well as impairment in occupational roles than patients without hypochondriasis.[10, 11] They use more medical services yet are less satisfied

with them than non-hypochondriacal patients. This increased utilization includes physician visits, laboratory tests, outpatient costs, and hospitalizations. Hypochondriacal patients tend to feel that their medical problems have not been thoroughly evaluated and as a consequence consult many physicians (i.e. doctor-shopping).

Hypochondriasis and health anxiety tend to be associated with increased symptom reporting and functional impairment, although the findings from various clinical populations have been inconsistent. For instance, hypochondriacal concerns are associated with higher disability and lower quality of life among patients with irritable bowel syndrome, chronic fatigue, and fibromyalgia.[26] One study found hypochondriasis the strongest predictor of pain due to osteoarthritis, and another showed high health anxiety predictive of abdominal pain 1 year later. Hypochondriasis was also a predictor of disability in patients with coronary artery disease. Consistent with these observations, hypochondriasis is associated with increased reporting of, and distress from, medication side effects.

Aetiology and pathogenesis

Personality

Hypochondriacal concerns are strongly related to the major personality dimension of neuroticism or negative emotionality.[27] Positive correlations between neuroticism and hypochondriacal concerns ranging from 0.4 to 0.5 have consistently been observed in non-clinical samples. Neuroticism refers to a tendency to experience and report negative emotions and overreact to stress. Persons high on this dimension are prone to find bodily sensations noxious and interpret them as signs of serious illness. Neuroticism may represent a vulnerability factor for hypochondriasis.

Certain personality traits may have more to do with difficult patient–doctor relationships than with hypochondriasis itself. Patients with hypochondriasis have been described as angry and mistrustful. Such characteristics might reflect negative emotions belonging to the domain of neuroticism or the negative pole of agreeableness, another of the major personality dimensions. They might also reflect obsessive-compulsive or masochistic personality traits observed in some patients.

Developmental factors

Childhood influences appear to be important in the development of hypochondriasis. Reports of **traumatic events during childhood**, including physical and sexual abuse, have been elicited more frequently from hypochondriacal than non-hypochondriacal patients. Although findings are preliminary, they are consistent with a literature linking childhood neglect and abuse to unexplained somatic symptoms in adults.

Childhood experience of illness may contribute to the development of hypochondriasis. For instance, Noyes *et al.*[28] obtained reports of serious illness or injury before age 17 from a third of adults with hypochondriasis. Similar findings from patients with hypochondriasis and somatization have been reported by others. Early illness may create a sense of physical vulnerability in susceptible individuals. Childhood exposure to serious illness or death of a family member or friend may do likewise.

Parental attitudes may also contribute to hypochondriasis. Excessive concern for a child's health or overprotection on the part of a parent may lead to anxiety about health as may special caretaking and rewards for illness. A child may also model exaggerated illness behaviour displayed by a parent. The importance of developmental factors—early adversity, experience of illness, over solicitous parents—suggest that hypochondriasis is in large measure learned behaviour.

Life events

Stressful life events appear to be related to increased reporting of physical symptoms and hypochondriasis, although there have been few studies. Events involving illness and death may have a specific role as the symptoms of hypochondriacal patients sometimes resemble those of family members who have been ill or died. In addition, illness events may give rise to hypochondriacal symptoms; 'cardiac neurosis' following myocardial infarction is an example. Transient hypochondriasis has been observed following medical illness in predisposed individuals.

Cognitive and perceptual factors

According to the cognitive-perceptual model, hypochondriasis is based on misinterpretation of bodily symptoms as signs of serious disease and on the experience of somatic sensations as intense, noxious, and disturbing.[29] In this model, the faulty attribution of innocuous sensations is the central defect. A number of studies have shown that, when symptoms are attributed to pathological processes, they become intensified. Such attribution may focus attention on symptoms thereby amplifying them. Misinterpretation of this kind may arise from cognitive schemata that were established through earlier experience with illness.

The tendency to experience bodily sensations as intense and disturbing has been termed somatosensory amplification. One study that used the Somatosensory Amplification Scale found a positive correlation of 0.56 between amplification and hypochondriasis. This finding suggests that individuals with hypochondriasis have a constitutionally lowered threshold for physical symptoms or that they have a heightened attentional focus and increased physiological arousal.

Evidence of physiological abnormalities was obtained by Gramling *et al.*[30] In a preliminary investigation, they observed physiological reactivity that distinguished women with hypochondriasis from those without. Hypochondriacal subjects had a higher mean heart rate and lower mean hand temperature during a cold pressor test compared to controls. These subjects terminated the test more frequently and rated it as more unpleasant than did controls.

Interpersonal factors

According to the interpersonal model, hypochondriasis is a form of care-eliciting behaviour that finds expression in physical complaints. Through unexplained somatic symptoms and expressions of illness worry, patients with this disorder seek emotional and interpersonal support from family members and physicians. Need for support of this kind arises from insecure attachment that originated in early relationships with caregivers. In a test of this model, Noyes *et al.*[31] found that hypochondriacal concerns among primary care patients were associated with various insecure attachment styles. These concerns were also associated with interpersonal problems and lack of reassurance from medical care.

Social and cultural factors

Social and cultural factors are important determinants of hypochondriasis. Throughout the world physical symptoms are common vehicles for the communication of distress. Somatic distress

gains the attention of **family and community** because it signals impairment in functioning that could alter social roles. Such distress not only calls forth caretaking but also obtains the sick role for those with acute illness. This social role with its privileges and responsibilities protects society from the disruptive effects of illness and promotes the return to health and social functioning of its members. Persons who are socially isolated or lacking in social support are more likely to manifest care-eliciting behaviour such as hypochondriasis.

Physicians play an important role in the development of hypochondriasis. They may make alarming statements or fail to provide reassurance that is based on thorough evaluation. In addition, they may order unnecessary tests, diagnose undetected disease, or treat injudiciously. They may add to concerns by failing to diagnose the psychiatric disturbance—hypochondriasis—telling patients instead that nothing is wrong. In doing this, they challenge and reject patients thereby contributing to suffering and alienation from the health care system.

Cultural attitudes may contribute to hypochondriasis. The American lifestyle, which emphasizes fitness and attractiveness, fosters preoccupation with health and encourages people to see their distress in terms of physical illness. There are, for example, cultural differences in the threshold for pain, pain tolerance, patterns of arousal, and physiological and behavioural responses to pain.

Course and outcome

Course

Hypochondriasis may begin at any age including childhood. The onset may be associated with stressful life events that in some instances involve illness. Some individuals develop hypochondriacal concerns transiently and others lastingly in reaction to physical illness. Among family medicine patients, those who became hypochondriacal a year after initial assessment were found to have had more illness worry and unexplained symptoms and to have rated their health as worse at baseline than non-hypochondriacal patients. Ambiguous symptoms or illness events may contribute to hypochondriacal concerns in patients so predisposed. Hypochondriasis appears to follow a chronic, fluctuating course.

Outcome

Follow-up studies show that, after their initial clinic visit, most patients with hypochondriasis improve. Still, a substantial proportion continue to meet criteria for the disorder and many more have persisting symptoms. For instance, among hypochondriacal general medicine patients, Noyes *et al.*[12] and Barsky *et al.*[13] found that, after 1 to 4 years, two-thirds continued to qualify for the diagnosis and the remaining one-third had persisting symptoms. Thus, despite improvement, the patients continued to be more hypochondriacal, more impaired, and more symptomatic than non-hypochondriacal patients.

Like patients in general, those with hypochondriacal concerns tend to seek care when they are most distressed. Their subsequent improvement may represent a natural fluctuation, a response to physician contact or to non-specific treatment. Some patients report having responded to reassurance. In a few instances, serious medical illness may relieve hypochondriacal concerns by legitimizing symptoms.

Studies indicate that greater severity and longer duration of symptoms are predictive of worse outcome. Failure to remit in one or more follow-up studies was predicted by more severe hypochondriacal concerns and somatic symptoms, longer duration of hypochondriasis, more psychiatric comorbidity, poorer perception of health, and greater neuroticism.

Complications

There is little information concerning complications of hypochondriasis. Because some patients utilize extensive medical care, one might expect complications resulting from repeated or unnecessary evaluations, tests, procedures, or treatments. Such iatrogenic complications have been reported for somatoform disorders but there is little documentation for hypochondriasis. On the other hand, physical illness may be overlooked in patients whose problems are considered psychiatric. There is almost no information on mortality. Suicide is said to be rare in hypochondriasis unless accompanied by severe depression in which case the risk may be increased.

Treatment

Until recently, the treatment of hypochondriasis was regarded with pessimism. It now appears that effective psychological, even pharmacological, interventions are being developed. A variety of approaches have been proposed but controlled trials of cognitive-behavioural therapy have established its efficacy, and preliminary trials of antidepressant medication have shown promise.

Psychological therapies

Most hypochondriacal patients, referred to mental health professionals, receive **psychotherapy** although such treatment has received little study. In one controlled trial a small number of patients with hypochondriasis were randomly assigned to explanatory therapy or a waiting list. The therapy yielded significant improvement in illness behaviour and health care utilization compared to no treatment, and gains were maintained for 6 months. This form of therapy involves repeated physical examinations, reassurance concerning symptoms, and information about psychophysiologic processes. Additional controlled trials of this and other forms of psychotherapy (e.g. psychodynamic, interpersonal) are clearly needed.

Four randomized, controlled trials for patients with hypochondriasis have shown that **cognitive behavioural therapies** are superior to no therapy with benefits sustained for up to 12 months.[32–35] These trials show that psychological treatment is efficacious for referred patients. However, one study showed that behavioural stress management, a non-specific intervention, was effective as well,[33] and another showed that cognitive and behavioural procedures, by themselves, were equally effective.[34]

Cognitive procedures include identifying and challenging dysfunctional thoughts and formulating more realistic beliefs. Behavioural procedures involve exposure *in vivo* with response prevention. These techniques include exposure to feared internal and external stimuli (e.g. physical exercise, visiting sick persons, reading about feared diseases, writing one's obituary) and prevention of checking and reassurance-seeking behaviours.

These trials showed that psychological treatment is effective but leave important questions unanswered. For instance, is psychological

therapy acceptable to most hypochondriacal patients in primary care? Are the techniques specific or do the benefits result from non-specific factors (e.g. therapeutic attention, therapist–patient relationship, credible procedures)? Also, are these treatments cost-effective? One trial involved up to 16 sessions over 4 months, which is expensive in terms of time and resources.

In consideration of these issues, several authors have advocated a **group approach**. For example, one study showed that group treatment is feasible. To improve acceptance, the authors referred to their intervention as a course in stress management and carried it out in a general practice setting.

Pharmacological therapies

There is evidence that patients with secondary hypochondriasis respond to drug therapy for the primary disorder. For example, Noyes *et al.*[36] assessed hypochondriacal concerns in patients receiving pharmacological treatment for panic disorder and agoraphobia. At the completion of treatment, a significant reduction in concerns was observed among those whose anxiety symptoms had improved. Observations of a similar kind have been made in patients with major depression.

No randomized controlled trials of pharmacotherapy for hypochondriasis have yet been completed, but a series of open label studies suggest that medication has promise. For example, Fallon *et al.*[37] reported that 10 or 16 patients with primary hypochondriasis given fluoxetine were very much improved after 12 weeks. And others have reported similar results with paroxetine, fluvoxamine, and nefazodone. Of the more than 50 patients enrolled in these trials, two-thirds responded to an SSRI. In these trials, drugs were relatively well tolerated and few patients dropped out because of side effects. This is noteworthy in view of the sensitivity to adverse effects observed in such patients. Controlled trials are needed to show proof of efficacy in primary hypochondriasis.

Management

Most hypochondriacal patients are best managed by their primary physicians. Few are successfully referred for specialty care because the focus of their concerns is, at least initially, on unexplained somatic symptoms. Although for some the ultimate goal is specific treatment, such treatment is not yet widely available.

Successful management depends upon a trusting relationship with a physician. To establish this, the physician should first **legitimize the patient's symptoms** by listening carefully and completing a thorough evaluation. Respectful treatment and statements to the effect that unexplained symptoms are nonetheless real are often helpful (see Table 5.2.5.4).

The scheduling of **regular visits** is an important strategy. Such visits serve several purposes. First, they reduce the reward for more severe or new symptoms that patients often present at unscheduled calls or visits. Next, they assure patients that the physician has an ongoing interest in their well-being. Finally, they provide reassurance through continued health monitoring.

Physicians should use **restraint in evaluating** hypochondriacal patients. New symptoms must be thoroughly evaluated, but overly aggressive diagnostic evaluation can be counterproductive. Extensive and dramatic tests can generate alarm, and when testing is repeated, it may convey physician uncertainty. Physicians should also avoid making diagnoses simply to have something to treat.

Physicians should also **approach treatment cautiously**. Medications, even when prescribed for benign indications, cause patients to worry about the conditions for which they are given. And too often they result in intolerable side effects and iatrogenic complications.

Hypochondriacal patients need an **explanation for their distress**, one that counters the notion of serious disease. Patients may be told their problem lies in the central nervous system processing of bodily sensations; this means they have a sensitive nervous system that amplifies discomforts and dysfunctions. Such an explanation gives legitimacy to the problem and avoids the stigmatizing label of hypochondriasis. Alternatively, patients may be told that they suffer from excessive health anxiety or worry. An explanation of the role of anxiety in altering attention, amplifying bodily sensations, and generating physiological symptoms may also be acceptable.

The goal of medical management is not to remove symptoms but help patients cope with them. The expectations of patients seeking elimination of symptoms may need to be modified. Reduced dependence on the technical aspects of care (namely, diagnostic testing and corrective intervention) is an important aspect of this overall objective. Patients need assistance in managing their lives so as to minimize continuing symptoms. The **aim is improved functioning**, a greater sense of control, and improved self-esteem. These objectives may accompany a gradual return to work and meaningful activity, and may be enhanced by improvements in exercise, diet, and daily routine.

Developing and **maintaining a therapeutic relationship** with the hypochondriacal patient is often challenging. The patient may be mistrustful and feel that his or her suffering is not understood. Masochistic and obsessional personality traits may contribute to a difficult doctor–patient relationship. A patient with such traits may seek mistreatment and thwart the physician's attempts to be helpful. Yet, a positive relationship is the key to successful management and can be achieved with acceptance, empathy, and understanding.[38]

Table 5.2.5.4 Management strategies for patients with hypochondriasis

Legitimize the patient's symptoms
Establish a regular schedule of visits
Base diagnostic evaluation on objective findings
Approach treatment of physical symptoms cautiously
Provide a plausible explanation for symptoms
Establish a goal of improved functioning

Specific treatment

Many hypochondriacal patients have psychiatric comorbidity, and treatment of comorbid anxiety and depressive disorders may yield significant improvement. If hypochondriasis has arisen during the course of an anxiety or depressive disorder, then successful treatment of the primary disorder may bring remission of hypochondriacal symptoms.

Specific treatments, to be acceptable, must be available in the primary care setting. Treating professionals must let patients know that their concerns are legitimate and their suffering understood. Beyond this, they must place a premium on engaging the patient, techniques for which have been described by a number of authors.

These patients are prone to drug side effects and often discontinue medication. For this reason, initial doses should be small, with gradual increases according to a modifiable schedule. Treating physicians should acknowledge the patient's sensitivity, and indicate that side effects are likely but may be dealt with.

Hypochondriasis is a significant medical condition for which treatment is now available.

5.2.6. Pain disorder

Sidney Benjamin and Stella Morris

Introduction

Persistent somatoform pain disorder is an ICD-10 diagnosis, which is included in the group of somatoform disorders. The term **pain disorder** is used in DSM-IV, and for convenience that is the term used here to refer to both classifications, unless a distinction needs to be made. This chapter aims to clarify the relationship of pain to mental disorders, the diagnosis of pain disorder and its differential diagnosis, and then considers how psychosocial factors contribute to pain, the treatments that stem from them, and the psychiatrist's potential contribution.

Pain has been defined by the International Association for the Study of Pain (**IASP**) as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage'. 'Pain' is used here in this sense; it is not used primarily to indicate mental distress or anguish. As a perception, pain is essentially a subjective experience, and is directly accessible only to the patient. By contrast, tissue damage can be assessed by others, and its relationship with the subjective characteristics of pain have been shown to be variable, modulated by social and cultural experience, as well as within the central and peripheral nervous system.

Pain and the psychiatrist

Psychiatrists are likely to see patients with pain in psychiatric, general hospital, and community settings. Pain is associated with a wide range of mental disorders, and there are different ways in which this relationship may arise.

Pain may contribute to the cause of a mental disorder; for example, when a patient with cancer has pain, which is unrelieved by analgesics, and becomes depressed. This can result in additional distress and disability, and subsequently an exacerbation of pain. Treatment of depression may contribute to the relief from pain and improve the quality of life.

In a general hospital psychiatrists may see patients with **acute pain**, like the patient described above, but more often will see patients with **chronic pain**. Whatever the initial cause, the longer pain persists the more likely is it to result in the development of inappropriate patterns of illness behaviour and to have a profound effect on relationships with the family and other carers, presenting more complex challenges for management and poorer prognosis.

Pain disorder

Diagnostic and clinical features

Persistent somatoform pain disorder in **ICD-10** is the only somatoform disorder that is essentially characterized by pain. The **diagnostic requirements** are as follows:

1 'persistent, severe, and distressing pain';

2 pain 'cannot be explained fully by a physiological process or a physical disorder';

3 'pain occurs in association with emotional conflict or psychosocial problems that are sufficient to allow the conclusion that they are the main causative influences'.

There are also likely to be many of the features that occur in the other somatoform disorders, which have been described in previous chapters. The pain can be localized, as in low back pain, or generalized, as in fibromyalgia.

In **ICD-10**, the diagnosis is excluded if pain, presumed to be mainly psychological in origin, occurs in the course of schizophrenia or depressive disorder, or is believed to be due to psychophysiological mechanisms such as muscle tension. The main **differential diagnosis**, according to ICD-10, is the histrionic elaboration of pain primarily due to organic causes, particularly if this has not yet been diagnosed. In practice, it is uncommon for pain that has been properly investigated, and has persisted for more than 6 months, to be found subsequently to have a specific organic cause.

The **DSM-IV** diagnosis of '**pain disorder**' also needs to be considered because the requirements for diagnosis and the underlying rationale are rather different. This diagnosis is divided into three **subtypes**:

1 '**Pain disorder associated with psychological factors**', in which psychological factors are judged to play the major role, and physical disorders play either no part or only a minor part in its onset or maintenance.

2 '**Pain disorder associated with both psychological factors and a general medical condition**', in which both psychological processes and an organic disorder are judged to make important contributions to causation.

3 '**Pain disorder associated with a general medical condition**', due to an organic disorder and in which psychological factors are judged to make no contribution or to play only a minor role. This subtype is not regarded as a mental disorder but is coded on Axis III.

For the first two subtypes the diagnostic criteria, all of which must be satisfied, are summarized as follows:

(a) Pain, localized or more general, is the predominant symptom and its severity warrants clinical attention

(b) Pain results in distress, and impairment in social, occupational, or other areas of functioning.

(c) Psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of pain.

(d) It is not intentionally produced or feigned (factitious disorder and malingering are specifically excluded).

(e) Pain is not better accounted for by a mood, anxiety, or psychotic disorder and does not meet criteria for dyspareunia.

Pain disorder can also be coded according to whether it is acute or chronic (less or more than 6 months duration).

Comparison of ICD-10 and DSM-IV

The diagnoses of pain disorder in ICD-10 and DSM-IV share a number of characteristics. Pain disorder should be diagnosed as a mental disorder if psychological factors are thought to make a significant contribution to predisposition, precipitation, or maintenance, or to the severity of pain. In ICD-10, there should be evidence that emotional conflict or psychosocial problems are the main 'causative influences', whereas in DSM-IV psychological factors are judged to play either the 'major role' or 'an important role'. In both, the diagnosis can be made even though there may be possible or definite evidence of an organic disorder that contributes to pain (for instance, a prolapsed intervertebral disc), provided that this is judged to be insufficient to account fully for the features of pain. Both classifications stress the severity of pain and the distress caused by it, but only DSM-IV specifically requires a degree of disability as a diagnostic feature. The implication is that diagnosis requires detailed physical and psychiatric evaluation, including an assessment of the family and social context, as well as of disability.

Differential diagnosis of pain disorder

Pain can occur in the setting of virtually any mental disorder. Table 5.2.6.1 lists the ICD-10 diagnoses and their DSM-IV equivalents in which pain may be a predominant feature. The general description of most of these disorders is provided in other chapters of this book and the following account focuses only on aspects relevant to pain.

(a) Organic disorders

Many painful disorders have a well-recognized organic pathology that accounts for the occurrence of pain (for example, angina, sickle cell arthropathy), but psychosocial processes tend to modify the severity of pain and associated disability. Thus, psychological and social interventions may make an important contribution to management, and as pain becomes more chronic, or fails to respond to usually effective physical treatments, psychosocial interventions assume greater significance. These disorders can be diagnosed in ICD-10 within the diagnoses headed '**Psychological interactions with physical disorders**' in Table 5.2.6.1.

(b) Pain syndromes of uncertain origin

There are many disorders characterized by pain, which are essentially syndromes with no known consistent organic pathology (Table 5.2.6.2). Psychological and social factors are thought to contribute to the development and maintenance in many cases,[1] but psychological causes specific to these different syndromes have not been identified. Patients with these pain syndromes tend to have a greater prevalence of non-psychotic mental disorders than is found in the general population. The pain itself can usually be accommodated in ICD-10 within the categories of **somatoform autonomic dysfunction** or **somatoform pain disorder** (see below). The 'diagnoses' listed in Table 5.2.6.2 tend to be used by non-psychiatrists to describe clusters of medically unexplained symptoms and are terms which are likely to be acceptable to patients. Treatments for these disorders generally include physical approaches, often of limited efficacy, as well as a range of psychosocial interventions, which are described below.

(c) Pain and mental disorders

(i) Psychoses

At the beginning of the twentieth century, French psychiatrists described **coenestopathic states** as disorders characterized by unpleasant sensations, particularly pains, thought to be of central origin, but unrelated to organic brain disease.[2] Such disorders were a daily occurrence in psychiatric clinics, commonly associated with the psychoses, and in this setting were related to **somatic hallucinations** and **systematized delusional states**. Such presentations are now described infrequently in Europe and North America.

Patients with any psychosis may complain of pain, sometimes with bizarre descriptions of quality and **delusional attribution**. In practice, it is difficult to differentiate between a **somatic hallucination** and an illusion (arising from physiological or pathological processes). Complaints of pain in psychotic disorders have no psychiatric diagnostic specificity. Pain has been described particularly in association with schizophrenia and depressive psychoses, but may occur in any psychotic disorder. In the course of a psychotic disorder, illusions and delusional interpretations of pain may arise from unrelated organic disorders and therefore require careful **physical assessment**.

(ii) Mood- and anxiety-related disorders

These are by far the most common mental disorders associated with pain in most settings. In the general population, 12 per cent of adults have experienced **chronic widespread pain** (defined according to the criteria of the American College of Rheumatologists) in the previous 3 months and their prevalence of mental disorders is three times that of the pain-free population.[3] Most of these diagnoses are mood and anxiety disorders, with the former being more common in those with chronic pain. In **pain clinic settings**, the prevalence of mental disorders varies according to referral patterns, but about 30 to 40 per cent of patients have depressive disorders, and this is similar in those with and those without a relevant physical disorder.[4] Those without organic disorders tend to have lower ratings for both mood disorders and pain severity. Those with mood disorders report more severe pain.

Diagnosis of mood and anxiety disorders is based on the usual standardized criteria, but may be missed due to the process of **somatization**, particularly where patients attribute their depressed mood to pain and an underlying physical condition (whether present or not) and invite their doctors to share this belief.[5] In the past, pain has been thought of as a proxy for depression, giving rise to the concept of a '**depressive equivalent**' or '**masked depression**'. This has been based mainly on evidence for the psychogenicity of chronic pain rather than a specific relationship to depressive disorders, has received widespread criticism, and has not advanced theoretical knowledge or clinical practice.

(iii) Post-traumatic stress disorder

Many patients with post-traumatic stress disorder (PTSD) have been subjected to actual or threatened physical injury, so it is not surprising that pain is one of the commonest symptoms that they report, the prevalence ranging from 20 to 80 per cent. Further, 10 to 50 per cent of patients with chronic pain satisfy criteria for PTSD, and patients with musculoskeletal pain are four times more likely to develop PTSD than those without it.[6] **Pain disorder and PTSD** can be diagnosed jointly, if criteria for both are satisfied. Mechanisms including shared vulnerability, fear-avoidance, and

Table 5.2.6.1 Mental disorders included in the differential diagnosis of pain disorder

ICD-10		DSM-IV

F55	Abuse of non-dependence-producing substances		
Personality disorders			
F60–62	Personality disorders and changes	301	Personality disorders

mutual maintenance have been postulated to account for this comorbidity.[7] This has implications for assessment (described below), and treatment programmes may need to be modified accordingly.

(iv) Somatoform disorders

Somatoform disorders are uncommon in people with chronic pain in the general population.[3] Prevalence varies considerably in clinical samples, but somatoform disorders have been reported in 12 to 52 per cent of patients,[4] so they include highly selected samples.

Complaints of pain occur commonly in each of the somatoform disorders and may be the predominant symptom. Multiple physical complaints, often including pains at different sites, fluctuate from time to time usually for many years, providing a characteristic feature of **somatization disorder**. In **hypochondriacal disorder** pain is a common complaint, and forms the focus for concern and overvalued beliefs about unidentified disease.

The diagnosis of **somatoform autonomic disorder** is based on autonomic arousal (palpitation, sweating, tremor), which must be a prominent feature of the clinical picture, together with physical complaints, often pain, referred to specific organs, systems, or parts of the body. As with other somatoform disorders, the patient will be distressed about the possibility of underlying physical disease and is not reassured by negative findings on appropriate assessment and explanation. This diagnosis is sometimes appropriate for syndromes listed in Table 5.2.6.2.

Pain, as a form of **conversion**, has a traditional place in the literature on **hysteria**, based on the concepts of psychogenicity, the

Table 5.2.6.2 Disorders of uncertain origin, presenting primarily with pain, in which psychosocial factors are thought to contribute to predisposition, precipitation, or course

Generalized
Fibromyalgia
Relatively localized
Tension headache—acute or chronic
Temporomandibular pain and dysfunction syndrome
Atypical facial pain
Atypical (non-cardiac) chest pain
Abdominal pain of psychological origin
Non-ulcer dyspepsia
Irritable bowel syndrome
Chronic pelvic pain
Irritable bladder syndrome
Procatalgia fugax

contribution of stressful experiences with dissociation, and primary gain. In recent years, however, research has focused on other psychological processes, and the concept of conversion as a primary mechanism now seems to be of limited interest. The category of **dissociative (conversion) disorder** in ICD-10 specifically includes sensory loss but excludes pain (sensory amplification), which therefore should not be diagnosed as a dissociative disorder. DSM-IV also excludes pain from the diagnosis of conversion disorder, unless other diagnostic criteria are satisfied.

The uncertain relationship and limited value of the different diagnoses included within the group of somatoform disorders in ICD-10 have been discussed in Chapter 5.2.1, and are well illustrated by the fact that pain may be a prominent feature of each category. Somatoform disorders presenting with pain are usually diagnosed as **somatization disorder or pain disorder**, with the former taking precedence if the diagnostic criteria are satisfied.

Comorbidity

Any physical or mental disorder may be diagnosed in addition to pain disorder. Anxiety and depression are common, and an additional diagnosis of **anxiety disorder** or **mood disorder** can be made if the criteria are satisfied. This dual diagnosis can be useful if, for example, a depressive disorder develops in the presence of a long-standing pain disorder. Any temporal relationship can occur, however, with pain onset preceding, developing simultaneously with, or following the onset of a mood disorder.

Other common comorbid diagnoses include **substance abuse** and dependence, sometimes of iatrogenic origin, and their management is an important component of pain-treatment programmes.[8] **Personality disorders** are an additional category of comorbidity. No single disorder predominates but histrionic, narcissistic, anxious (avoidant), and dependent features are all common in clinical practice, and anankastic traits may feed an inflexible focus on physical illness.

Epidemiology

Although the association of psychiatric symptoms with chronic pain has been studied in the general population, the prevalence of pain disorder, and other mental disorders presenting with pain, is uncertain because large-scale surveys of mental disorders do not include an assessment of pain and of related physical conditions.

Assessment of pain

Clinical assessment

The psychiatric assessment requires a full **psychiatric history** and **mental state examination**, with particular attention to those additional features relevant to pain. **The pain history** should include total duration (often underestimated by the patient), a detailed inquiry about the location and distribution of pain, including direct questions aimed at a total body survey, and the timing of first onset, subsequent periods of relapses and remissions, and their relationship to life events and difficulties. The **family history** should include assessment of severe, chronic or disabling physical disorders, and the patient's involvement with them. The **personal history** should include adverse childhood experiences (discussed below) and the **past history** of physical disorders and disability is particularly important.

Patients who **somatize** will tend to deny concurrent psychosocial events and their significance. For example, one of our patients was consistently unable to recall any distressing events in the year prior to the onset of severe, persistent, and disabling headache. His wife gave an account of the deaths of his father, brother, and closest friend during that year, and moreover described him as so distressed by these bereavements that he felt unable to attend any of the funerals. It is essential to take a **history from other informants**, and this can also provide an opportunity to assess the attitudes, knowledge, and beliefs of carers, and their interaction with the patient.

The patient's **pain beliefs and behaviours** (described below) are key aspects of the **mental state examination**. Patients often attribute chronic pain to an organic disorder and offer diagnoses; it is essential to review their **medical records** to assess the clinical findings and investigations, and the extent to which they support any diagnosis which is offered. Chronic pain associated with an underlying organic disorder may be exacerbated when the patient suffers a stressful life event, so it is important to **avoid assumptions of a dichotomy** of either **'organic' or 'psychogenic' pain**.

Standardized psychometric assessments

Many standardized questionnaires have been developed for the assessment of patients with chronic pain. They can be valuable for identifying mechanisms that contribute to pain, planning treatment, and monitoring changes during and after treatment. The evaluation of pain and associated beliefs and behaviours requires measures developed specifically for this purpose, and these are described below.

Other assessments, for example of **mood**, **illness behaviour**, and **social dysfunction**, have been developed within the field of pain research. Some measures are rather idiosyncratic, with uncertain psychometric properties, aimed at restricted diagnostic groups and clinical settings. This undermines the need to use consistent methods that allow comparison of different groups of patients, with physical, mental, and mixed disorders, at different places and times.

(a) Pain

The **severity** of pain can be assessed[9] using standardized **visual analogue scales** and **numeric analogue scales**. Such scales may have anchor points ranging from 'no pain' to 'the worst possible pain'.

The **quality** of pain can be assessed with **verbal descriptor scales**.[9] Factor analysis has resulted in the emergence of two that have best survived the test of time: an '**affective**' **dimension** (represented by words such as exhausting, terrifying, vicious), and a '**sensory**' **dimension** (e.g. stabbing, crushing, burning). They have been found consistently when administered in different languages and to different cultural groups. Ratings on both these scales are positively correlated with pain severity and mood ratings and, in the presence of mental disorders, contribute little to diagnosis.

The **topographical distribution of pain** can be assessed by using outline drawings of the body (front, back, and sometimes sides), which the patient is asked to shade to indicate the distribution of pain. These can help to identify pain that does not conform to physiological distributions and also widespread pain. Measures of pain intensity, quality, and distribution can be used toget her to capture the rather elusive and entirely subjective experience of pain.

(b) Pain behaviours

Although the experience of pain is entirely personal, it may be communicated to others by a range of verbal and non-verbal behaviours, which in some cases may be maladaptive, and which in turn influence the responses of others. Using a **learning theory model**, Fordyce[10] classified all pain into **'operant' and 'non-operant' pain**. The former includes all pain that is modified by positive or negative reinforcement, whether or not organic pathology is present. Standardized **structured assessments** are available to measure a range of well-defined **behaviours**.[11] These may include complaints of pain, requests for medication, groaning, facial expression, restricted mobility and the use of aids, time spent resting, and postures such as guarding and bracing. Such behaviours have been shown to fluctuate in response to changes in the environment, including different **attitudes and responses of carers**. This has led to the assessment of pain behaviours and their **environmental reinforcers**, and the development of pain-treatment programmes that originally focused on behavioural change by modifying reinforcement. Recent interest has focused on **pain-related fears** (e.g. of exacerbating pain by injury) and the management of consequent **avoidance**.[12]

(c) Pain beliefs

The belief that chronic as well as acute pain signals an underlying physical disease, which requires and should respond to physical intervention, whilst avoiding usual activities and functions, contributes to the development and maintenance of chronic pain and non-adherence to treatment, and the widespread dissatisfaction often expressed by patients and their doctors. Inappropriate beliefs that are relevant to pain assessment fall into three groups[13]:

1 beliefs about the nature of reality—for example, 'life should be pain-free';

2 beliefs in response to challenging circumstances, such as pain—including **locus of control**, **attributional style**, **cognitive errors**, and **coping strategies**;

3 specific ideas about the cause of a pain, appropriate management, and outcome.

The questionnaire assessment of pain-related beliefs has assumed increasing importance in the field of pain research,[13] with the recognition that pain beliefs interact with pain, cognitions, behaviours, affects and disability, and contribute to the prediction of outcome. Thus cognitive approaches to treatment are often integrated with behavioural management.

Psychosocial contributions to the development of pain

The origins of chronic pain are, in several respects, similar to those of somatization and other somatoform disorders. Current models of causation involve the interaction of biological, psychological, and social factors, each contributing to predisposition, precipitation, and maintenance.

The **family and personal histories** of patients with chronic pain include an excess of mood disorders, pain and disability, substance abuse, and personality disorders. Engel[14] described the dynamics of 'the **pain prone patient**' involving abusive childhood experiences, and noted how pain can become a pathway for the expression of guilt and expiation. Recent research[15] has reconsidered the significance of reports of **physical and sexual abuse** and other **adverse childhood experiences**. The relationship between chronic pain in adults and these childhood experiences appears, at least to some extent, to be determined by **selective reporting**, particularly in those with associated mental disorders,[16] but these experiences may make a significant contribution to pain in some individuals.

Precipitation of chronic pain is, in effect, **transition from acute to chronic pain**, and factors associated with this transition[17,18] include current mood and anxiety disorders, negative life events including physical illnesses and trauma, the social support network and dissatisfaction with work. A population based prospective study[19] found that new episodes of chronic widespread pain were predicted by the number of previous non-pain somatic symptoms and by a measure of illness behaviour which assessed numbers of consultations, treatments and perceived disability, and these two measures had an additive effect. Recent research has indicated the potential value of interventions designed to prevent the progression from acute to chronic pain.[17,18]

The psychiatric and psychological management of pain

Treatment of mental disorders

The treatment of chronic pain has presented a challenge to the ingenuity of health professionals, particularly because no single specialty or profession has the range of skills that is required. The treatment of mental disorders,[5] such as depressive or anxiety disorders,[20] is similar in most respects, whether or not pain is a prominent feature. In the presence of pain, however, mental disorders tend to be missed, and when recognized are treated inadequately. Depressive disorders with features indicating a good response to **antidepressants** should be treated with full therapeutic doses, but not with **narcotics**. **Anxiolytic drugs** including **benzodiazepines**, which result in dependence, should not be used in the treatment of these chronic disorders.

The use of antidepressants for pain relief

Antidepressant drugs are often used for the treatment of pain in patients who are not depressed. Randomized controlled trials[21] indicate that antidepressants, in doses within the usual therapeutic

range, provide more effective **analgesia** than placebo preparations in the treatment of diabetic neuropathy, postherpetic neuralgia, and atypical facial pain, as well as chronic non-malignant pain. Different **tricyclic antidepressants** (TCAs) appear to be equally effective and are more effective than **selective serotonin-reuptake inhibitors**. Data on **seretonin noradrenaline-reuptake inhibitors** are increasing and suggest that they may be effective, and preferable to TCAs because of a superior side effect profile.[22] The analgesic effect of antidepressants occurs in patients who are not depressed and is independent of any antidepressant effect.

Psychological treatments

Psychological treatments[5,23] are derived from different theoretical formulations of the aetiology of chronic pain. These include behavioural, cognitive, and psychodynamic approaches. Reviews of randomized controlled trials of **behavioural and cognitive approaches**[24] that have been developed specifically for the treatment of chronic pain illustrate the problems in assessing outcome due to different sampling methods, different types of control groups, non-standardized treatment components, and the different assessments that are included. Despite these limitations, the best studies demonstrate that these treatments are more effective than 'usual' medical treatment, remaining on a waiting list, or exercise programmes, and improvements can be sustained during lengthy follow-up periods.

Other approaches include various forms of 'stress management' including **relaxation techniques**, **biofeedback**, and **hypnosis**. Their value is uncertain; although pain ratings tend to be reduced, this is not a consistent finding on all measures.

Psychological treatments are rarely used in isolation, either from each other or from additional interventions, and integrating different approaches may enhance their effects.[23]

Multi-disciplinary pain management clinics

Pain-treatment centres[25] have been established in many countries and provide a diverse range of professional skills, treatments, and models of service delivery. In some, management is based mainly on anaesthetic techniques and medication, but psychological approaches are provided in others by **clinical psychologists** and **nurse therapists**. The management of problems due to inappropriate medication and **substance abuse** is an essential component of treatment.[8] Many clinics offer **structured programmes** of education and rehabilitation, with increments of **exercise**, to overcome **disability**, rather than aiming primarily at pain relief, and to which **physiotherapists or occupational therapists** may contribute. There is often an emphasis on the patient assuming increasing responsibility, rather than maintaining **dependence on medical services**.

Direct input from **psychiatrists** is variable and some centres specifically exclude the treatment of patients with serious mental disorders because their response to treatment is less certain. Although it is well recognized that social and environmental factors contribute to chronic pain problems, and can undermine progress following treatment, few specialized centres involve **carers** routinely in treatment or offer **family therapy**.

A range of physical, psychological, and social approaches should be offered, based on an **individual structured assessment** of needs. Members of the multi-disciplinary team require specific **training** in the management of pain. The work of the team has to be carefully coordinated, both within the team and with other health professionals, to avoid any ambiguity concerning the methods and goals of treatment.

Many pain clinics provide a treatment package in which cognitive therapy and graded exercise are predominant features. A similar approach is used for a number of other conditions, including **somatization disorder**, **hypochondriacal disorder**, **fibromyalgia**, and **chronic fatigue**, but the extent to which they may have similar origins and outcomes is uncertain.

Effects of treatment

The **outcome of psychological and psychiatric treatment** has been studied extensively,[5,24] but is difficult to evaluate because reports differ with regard to the characteristics of patients and disorders, inclusion criteria, assessments, and treatments as well as details of treatment delivery, attrition rates, choice of control groups, and the duration of follow-up. Many patients with chronic pain are unwilling to accept treatment and others are considered unsuitable. Nevertheless, psychological and rehabilitation treatments can have a sustained effect, based on the range of assessments that have been described. In addition, they can result in reductions in **sickness and benefit payments**,[26] **return to work**[27] and reduced **use and costs of medical services**.[28]

The outcome for patients with different mental disorders has not been assessed systematically. Patients involved in seeking **compensation** tend to have a poorer outcome, even after **litigation** has been concluded, but they can also benefit from treatment. There is some evidence that **secondary prevention** programmes may help to avoid the transition from acute to chronic pain in those who are particularly vulnerable.

5.2.7 Chronic fatigue syndrome

Michael Sharpe and Simon Wessely

Introduction

Chronic fatigue syndrome is a controversial condition, conflicts about which have frequently burst out of the medical literature into the popular media. Whilst these controversies may initially seem to be of limited interest to those who do not routinely treat such patients, they also exemplify important current issues in medicine. These issues include the nature of symptom-defined illness; patient power versus medical authority; and the uncomfortable but important issues of psychological iatrogenesis.[1,2] The subject is therefore of relevance to all doctors.

Fatigue as a symptom

Fatigue is a subjective feeling of weariness, lack of energy, and exhaustion. Approximately 20 per cent of the general population report significant and persistent fatigue, although relatively few of these people regard themselves as ill and only a small minority seek a medical opinion. Even so, fatigue is a common clinical presentation in primary care.[2]

Fatigue as an illness: chronic fatigue syndrome

When fatigue becomes chronic and associated with disability it is regarded as an illness. Such a syndrome has been recognized at least since the latter half of the last century. Whilst during the Victorian era patients who went to see doctors with this illness often received a diagnosis of neurasthenia, a condition ascribed to the effect of the stresses of modern life on the human nervous system the popularity of this diagnosis waned and by the mid-twentieth century it was rarely diagnosed (although the diagnosis subsequently became popular in the Far East—see Chapter 5.2.1). Although it is possible that the prevalence of chronic fatigue had waned in the population, it is more likely that patients who presented in this way were being given alternative diagnoses. These were mainly the new psychiatric syndromes of depression and anxiety, but also other labels indicating more direct physical explanations, such as chronic brucellosis, spontaneous hypoglycaemia, and latterly chronic Epstein–Barr virus infection.[2]

As well as these sporadic cases of fatiguing illness, epidemics of similar illnesses have been occasionally reported. One which

occurred among staff at the Royal Free Hospital, London in 1955 gave rise to the term myalgic encephalomyelitis (ME), although it should be emphasized that the nature and symptoms of that outbreak are dissimilar to the majority of those now presenting to general practitioners under the same label.

A group of virologists and immunologists proposed the term chronic fatigue syndrome in the late 1980s.[3] This new and aetiologically neutral term was chosen because it was increasingly recognized that many cases of fatigue were often not readily explained either by medical conditions such as Epstein–Barr virus infection or by obvious depression and anxiety disorders. Chronic fatigue syndrome has remained the most commonly used term by researchers. The issue of the name is still not completely resolved however: Neurasthenia remains in the ICD-10 psychiatric classification as a fatigue syndrome unexplained by depressive or anxiety disorder, whilst the equivalent in DSM-IV is undifferentiated somatoform disorder. Myalgic encephalomyelitis or (encephalopathy) is in the neurological section of ICD-10 and is used by some to imply that the illness is neurological as opposed to a psychiatric one. Unfortunately the case descriptions under these different labels make it clear that they all reflect similar symptomatic presentations, adding to confusion. Official UK documents have increasingly adopted the uneasy and probably ultimately unsatisfactory compromise term CFS/ME.[4] In this chapter, we will use the simple term chronic fatigue syndrome (CFS).

Clinical features

Symptoms

Chronic mental and physical fatigue, tiredness, or exhaustion that is typically exacerbated by activity is the core symptom of CFS. Commonly associated symptoms include impaired memory and concentration, muscular and joint pain, unrefreshing sleep, dizziness and breathlessness, headache, tender lymph glands, and sore throat. Patients often describe day-to-day fluctuations in symptoms, irrespective of activity. Periods of almost complete recovery may be followed by relapse, often described as sufficiently severe to make normal daily activity impossible. Depression and anxiety are common, and a proportion of patients suffer panic attacks.

Physical signs

Physical examination is typically unremarkable. Complaints of fever and lymphadenopathy are not confirmed on examination. The presence of definite physical signs (such as objectively measured fever) should not be ascribed to the syndrome and alternative diagnoses should be sought.

Other common characteristics

As well as the symptoms described above patients with CFS commonly have additional clinical characteristics. These are listed in Table 5.2.7.1.

Patients are often worried that remaining active despite fatigue will harm them and consequently avoid activity or oscillate between rest and bursts of activity, which produces fatigue, leading to a return to rest and so on.

Some patients feel strongly that their illness is 'medical' rather than 'psychiatric' and are particularly concerned that a psychiatric diagnosis implies that the illness is their fault, an indication of personal weakness or even an accusation of malingering. Perfectionist and high achieving lifestyles often with low underlying self-esteem are commonly observed in patients referred to hospital clinics.

Table 5.2.7.1 Common characteristics of patients with CFS

Thoughts beliefs and attitudes	Thought that symptoms indicate harm Belief that the illness is purely 'medical' Perfectionist attitudes
Coping behaviours	Avoidance of activities associated with symptoms Reduced activity level Oscillation in overall activity level
Physiology	Poor sleep Physiological deconditioning Effects of inactivity
Interpersonal and social	Dependence on carer Psychological iatrogenesis Occupational difficulties

Although there are no physical signs there may be measurable effects of reduced activity with so-called physiological deconditioning leading to poor tolerance of activity, and in cases where rest has been prolonged other physiological changes such as postural hypotension. Sleep is often unrefreshing and fragmented.

Some patients can become markedly dependent on a carer. Occupational stresses and difficulties are common and it can be difficult to determine if these were contributors to, or are consequence of their illness. Finally many patients have received unhelpful medical attention. Such psychological iatrogenesis includes, on the one hand dismissal of their complaints and on the other over investigation.[5]

Case study

A typical patient is found in the infectious disease department of the general hospital. She is a 30-years-old nurse and her principal complaints are of fatigue, poor concentration, and muscle pain. Her symptoms fluctuate and are made worse by physical and mental exertion. She is no longer able to work and has substantially reduced her daily activities. The history is of an acute onset of symptoms after a 'viral illness'. Enquiry reveals symptoms suggestive of depression or anxiety, but without obvious mood change. The patient strongly believes the illness to be 'medical' rather than 'psychiatric'.

Classification and diagnosis

There are several published case definitions for CFS. The currently most widely used definition is based on an international consensus of researchers is shown in Table 5.2.7.2.[6] A guide on its application has also been published.[7] It should be remembered that this definition represents nothing more than a working definition of a clinical problem, pending further understanding, and as with most psychiatric diagnoses, does not delineate a single disease.

Issues for a definition of chronic fatigue syndrome

The case definition shown in Table 5.2.7.2 has been useful in unifying the field and providing a widely used operational definition. However, it also has significant limitations.

Table 5.2.7.2 International consensus definition of chronic fatigue syndrome

1	Complaint of fatigue
	Of new onset
	Not relieved by rest
	Duration at least 6 months
2	At least four of the following additional symptoms
	Subjective memory impairment
	Sore throat
	Tender lymph nodes
	Muscle pain and joint pain
	Headache
	Unrefreshing sleep
	Post-exertional malaise lasting more than 24 h
3	Impairment of functioning
4	Other conditions that might explain fatigue excluded

(Reproduced from Fukuda, K. Straus, S.E. Hickie, I.B. *et al.* Chronic fatigue syndrome: a comprehensive approach to its definition and management, *Annals of Internal Medicine*, **121**, 953–9. Copyright 1994, The American College of Physicians.)

- It excludes fatigue associated with known organic disease.
- It overlaps with other functional medical diagnoses.
- It overlaps with psychiatric diagnosis.
- The homogeneity of the patient group it identifies is doubtful.

(a) Differentiation from fatigue associated with organic disease

Fatigue is a common symptom of most medical and psychiatric conditions. CFS refers only to fatigue where there is no clear alternative diagnosis (but does not exclude depression and anxiety unless the depression is of melancholic type or a manifestation of a bipolar disorder). It therefore only refers to idiopathic fatigue. This means that the definition highlights an important clinical problem but also means that the interesting equally important and probably informative phenomenon of fatigue in patients with diseases such as multiple sclerosis is excluded from this definition.

(b) Overlap with other medically unexplained syndromes

A number of medical diagnoses are defined only by symptoms. These functional syndromes are medical diagnoses where there is no identifiable pathology. They include chronic pain, fibromyalgia, and irritable bowel syndrome. Although chronic pain syndromes are principally characterized by pain, fibromyalgia by tender points, and irritable bowel syndrome by symptoms of bowel disturbance, all these syndromes are also associated with chronic fatigue, and patients diagnosed with one of these syndromes often meet the diagnostic criteria for CFS.[8]

(c) Overlap with psychiatric syndromes

Most patients who meet criteria for CFS also fulfil criteria for a psychiatric diagnosis. Many meet criteria for anxiety and depressive disorders and others merit diagnoses of somatoform disorder or neurasthenia. This issue is discussed further below.

(i) Depression

If patients with a depressive disorder are asked about a wide range of somatic symptoms including fatigue and/or muscle pain (which they are usually not) they often report these. If the diagnostic criteria for depressive disorders are applied to patients with fatigue a high proportion meet these.[9] Furthermore the prevalence of major depressive disorder in patients referred to hospital with CFS is substantially higher than in patients with chronic disabling medical diseases suggesting that depression is not simply a reaction to disability.[10] In practice, the diagnosis of depression can be difficult in patients presenting with fatigue: depressed mood is often not prominent and anhedonia can be hard to distinguish from the inability to pursue previously enjoyed activities because of fatigue. Finally, whilst there is a strong association between major depressive disorder and CFS, for as many as half of the patients seen in hospital clinics the symptoms cannot be readily given that diagnosis.

(ii) Anxiety disorders

Although less attention has been given to the association between fatigue and anxiety, an examination of diagnostic criteria for anxiety disorders reveals that the typical somatic symptoms of anxiety include fatigue and other symptoms listed as typical of CFS. If sought, generalized anxiety disorder can often be diagnosed in patients with CFS and panic can often be diagnosed in patients with severe episodic symptoms.[11] As with depression, however, anxious mood is rarely obvious and may be hard to distinguish from reasonable concern about consequences of being ill. Likewise, true phobic avoidance may be hard to distinguish from the consequences of fatigue and/or weakness.

(iii) Neurasthenia

ICD-10 differs from DSM-IV in including this diagnosis. It requires that the patient suffers from fatigue which is exacerbated by exertion, as well as several other somatic symptoms, and does not meet the criteria for a depressive or anxiety disorder (see Chapter 5.2.10). One study found that almost all of the referrals to a medical CFS clinic met the criteria for neurasthenia as defined by ICD-10.[12]

(iv) Somatoform disorders

According to DSM-IV patients with severe persistent fatigue who do not meet criteria for anxiety or depressive disorders are assigned to a somatoform disorder diagnosis. These are a controversial group of psychiatric syndromes characterized by medically unexplained symptoms and of presumed psychological origin.[13] There are a number of subcategories:

- Somatization disorder (Briquet's syndrome) is used to describe patients who report multiple, recurrent, medically unexplained symptoms; a minority of patients with CFS will meet the criteria for this disorder.
- Hypochondriasis describes a syndrome in which the patient's main concern is with the possibility that they are suffering from an organic disease. Whilst this diagnosis would seem to be applicable to many patients with CFS, it is problematic when the cause of the illness in question, which is regarded as uncertain by doctors as well as patients.
- Almost all patients with CFS not meeting the criteria for any of the above DSM disorders are likely to fall into the undemanding residual category in DSM-IV of 'undifferentiated somatoform disorder'. This diagnosis is of dubious practical use, and in effect merely confirms that the patient has multiple physical symptoms of unclear aetiology.

(v) Conclusion

Many patients with CFS meet the diagnostic criteria for a depressive or anxiety disorder, although in practice the presentation is often 'atypical'. It is likely that patients who do not meet the criteria for either of these could be diagnosed as having either neurasthenia (ICD-10) or undifferentiated somatoform disorder (DSM-IV).

Should we use the diagnosis of CFS?

From the psychiatrist's perspective it is parsimonious to ask whether a diagnosis of CFS is ever necessary or appropriate when the symptoms can always be described by a psychiatric diagnosis? This unsatisfactory situation is an artefact of parallel medical and psychiatric diagnostic systems for patients with somatic symptoms unexplained by disease. Consequently whether one uses a 'medical' diagnosis of CFS or a 'psychiatric' diagnosis of somatoform disorder is merely a matter of choice. When making that choice the following must be considered:

- A diagnosis of CFS only describes a presenting clinical syndrome, rather than a specific disorder or disease process.
- Pragmatically the relative acceptability of the alternative diagnosis to the patient is important. There is no point in giving a diagnosis that is rejected by the patient and impedes any therapeutic relationship and chances of treatment.
- One approach to overcoming the issue of parallel classification systems is to combine the medical diagnosis of CFS and the psychiatric diagnoses: According to such a scheme CFS would be subclassified into CFS/depression, CFS/anxiety, and CFS without depression or anxiety disorder (i.e. CFS/somatoform or CFS/neurasthenia). Psychiatric diagnoses that have important clinical utility such as major depressive disorder should obviously be made if present. The usefulness of diagnoses such as undifferentiated somatoform disorder is less clear.
- Finally rather than becoming side-tracked by the unanswerable question of whether the patients symptoms are ultimately 'medical' or 'psychiatric' in nature an open-minded and pragmatic approach is required.

Epidemiology

Prevalence

Fatigue is common but CFS is rare. As it can be difficult to differentiate CFS from depressive and anxiety disorders estimates that have attempted to exclude these diagnoses are lower than those that have not. Population studies in the United Kingdom and United States suggest that only approximately 0.5 per cent of the population can be regarded as having CFS.[1] Most of these persons are aged between 20 and 40 with a predominance of females. The syndrome is also seen in children and adolescents but less commonly.

Epidemics

Epidemics of a chronic fatigue-like syndrome have been described from various parts of the globe. This observation is compatible with, but does not establish, an infective cause. It remains unclear whether these were true epidemics and also whether the clinical picture reported is similar to that of cases of sporadic chronic fatigue syndrome.

Aetiology

Limitations in the available data

Although a considerable amount of research has been devoted to investigating the nature and causes of CFS there are few firm conclusions that can be drawn. This partly because many of the studies have had major methodological shortcomings:

- Patients have often been recruited from tertiary care clinics, using various diagnostic criteria inconsistently applied.
- Only a minority of studies have included comparison groups of patients with diagnoses of depression or anxiety disorders.
- Because most studies have used a case–control design, it is often impossible to know whether the findings they report are causes or consequences of the illness (for instance, as the result of reduced activity or sleep disturbance).
- CFS is almost certainly heterogeneous.

Considering these caveats there are a number of areas where positive findings have been reported.

Pathophysiology

Clinical observations of patients with CFS have led to the investigation of a number of hypotheses about the underlying pathophysiological mechanisms.

(a) Genetics

Twin studies suggest that CFS is moderately heritable.[1] Preliminary studies suggesting the involvement of specific genes require replication. Gene expression studies are likewise in their infancy—one problem being that the number of genes studied usually exceeds by several orders of magnitude the numbers of patients studied. Another problem is confounders—a large Swedish twin registry study for example suggested that genetic factors contributed to the risk of CFS both directly and via personality type.[14]

(b) Cardiovascular and respiratory abnormalities

Several investigators have reported abnormalities in the cardiorespiratory systems that may underpin the exercise intolerance. Hyperventilation has been suggested as a mechanism of symptom production, but only a minority of patients have biochemically confirmed hyperventilation. Low blood pressure has long been associated with the symptom of fatigue, and in some parts of Europe unexplained fatigue is confidently ascribed to this. Postural hypotension has been noted in some patients and whilst this may be a cause of fatigue it may also be a consequence of inactivity. Finally, various abnormalities in cardiac function have also been reported but are of uncertain significance.

(c) Infection

Perhaps because patients commonly describe their illness as beginning with 'flu-like symptoms' and because of the apparent epidemics, many investigators have sought objective evidence of an initiating or ongoing viral infection. Viral infection can probably initiate CFS. A prospective follow-up of people with positive evidence of acute Epstein–Barr infection did find that some patients went on to develop a fatigue syndrome.[15] Other infectious agents that may trigger CFS include Q fever and viral meningitis. If viruses do play a role in precipitating CFS, it would appear that it is only when certain types of viruses infect vulnerable persons. If CFS can be

precipitated by viral infection does persistence of the virus cause the ongoing symptoms? On current evidence the answer to this question seems to be no.

(d) Immune dysfunction

The evidence for an association between immunological abnormalities and CFS is more consistent than that for infective agents, with several studies suggesting abnormalities in lymphocyte numbers and function. However, similar changes can be found in patients with depressive disorders, and, although some studies have attempted to control for emotional disorder, both the specificity and causal importance of these observations remain unclear.[16]

(e) Sleep

Unrefreshing sleep is an almost ubiquitous complaint of people suffering from CFS. While studies have identified major sleep disorders such as sleep apnoea and narcolepsy as alternative diagnoses for small number of patients with daytime fatigue, simple disruption of slow-wave sleep is a much more common observation. While inefficient sleep could contribute to the daytime fatigue reported in both conditions, its specificity and aetiological role are uncertain.[16]

(f) Neuroendocrine and neurotransmitter abnormalities

The prominent fatigue of Addison's disease has led to the hypothesis that adrenal function is impaired in patients with CFS. In support of this suggestion there is reasonable evidence that patients with chronic fatigue and fibromyalgia have both low levels of cortisol, a point of difference from major depression. However it remains unclear if this apparent abnormality is cause or effect of the illness and associated inactivity. Patients with CFS also have evidence of abnormal functioning of cerebral serotonergic systems, which differ from those found in patients with depression. Like the abnormalities in adrenal function these findings are preliminary but of potential interest.[17]

(g) Brain imaging

Finally, a variety of techniques have been used to examine both the function and structure of the brain in patients with CFS. Cerebral perfusion studies have shown abnormalities, although similar, if not identical, abnormalities are also found in patients with depression. Possible white-matter changes reported on magnetic resonance scans are more controversial, and harder to interpret.[1,16]

(h) Conclusions

Despite a considerable research effort, so far no single pathophysiological process has been conclusively identified as causal of CFS. There is some evidence for a loss of physical fitness and possibly for abnormalities of neuroendocrine function. Viral infection can play a role as precipitating agent, although its importance as a perpetuating factor is less certain. Immunological abnormalities are common but of uncertain specificity, and appear not to be related to chronic symptoms. The current attention on neuroendocrine function takes the focus of investigation closer to those features known to be associated with depressive states. However, the evidence suggests that the changes in neurotransmitter and neuroendocrine function in patients with CFS may differ from those commonly observed in patients diagnosed with depressive disorder. Further studies are needed to confirm all these abnormalities and to clarify whether they are causal or merely epiphenomena.

Psychopathology

If there are no substantial biological abnormalities are there psychological ones? The initial psychiatric explanation of CFS was that it was misdiagnosed depressive disorder. However, whilst such misdiagnosis does occur, more complex explanations are required to adequately explain many cases of CFS.

(a) Somatization

It has been hypothesized that depression may still be 'behind' CFS even if not apparent. It is argued that a process referred to as 'somatization' (making the mental physical) is responsible. Whist the idea that the somatic symptoms of CFS are readily understandable as part of an emotional disturbance is a parsimonious alternative to some of the more elaborate mechanisms outlined above, as there is no 'marker' for somatization this hypothesis is hard to prove.

(b) Attribution

Patients attending specialist clinics with CFS typically attribute their illness to organic disease even when no evidence of this can be found by their physicians. Perhaps more importantly, some strongly resist psychological explanations for their illness, although most take a more mixed view. Whether these patients are biased in their views about illness or simply wiser than their physicians is unclear. However, strong and exclusively physical disease attributions may be a marker for an important illness-perpetuating process in CFS as they predict a poorer clinical outcome.

(c) Perceptual processes

Patients with CFS report a greater sense of effort in response to both psychological and physical demands than is explicable from objectively measured impairments. This observation raises the possibility that they are especially sensitive to bodily sensations such as effort, that is they 'amplify' or focus on them. Thus, one may hypothesize that as in panic disorder, the patients' beliefs about their symptoms may lead them to focus attention on to bodily sensations. Although plausible there is so far only limited evidence that this process is important in patients with CFS.[1]

(d) Coping behaviour

A tendency to avoid activities that exacerbate symptoms has been shown to occur in patients with CFS. The avoidance may be persistent or episodic in response to exacerbations of symptoms resulting in a 'boom and bust' pattern. Avoidance is associated with persistent disability, and has been suggested as the mechanism by which disease attributions for symptoms predicts poor outcome.[1]

(e) Personality characteristics

Both research studies and clinical experience suggest that many persons with CFS have a tendency towards hard driving, perfectionist, or obsessive–compulsive personalities, and associated overactive lifestyles. Evidence from the UK 1946 birth cohort for example indicates that ratings of physical activity in early life predict later CFS. In a large prospective Swedish twin registry measure of stress and emotionality are consistently associated with subsequent CFS. Those CFS sufferers may be predisposed to becoming physically and emotionally exhausted, and biased towards presenting emotional distress in a somatic form.[14]

(f) Stigma, misinformation, and iatrogenesis

Psychiatric diagnoses are stigmatized in the popular mind as indicating weakness or even unreal illness. Patients with CFS may be

susceptible to those social pressures and consequently prefer a medical diagnosis for their distress and inability to function. It has also been suggested that CFS may serve as culturally defined function of social communication, allowing a socially acceptable and hence 'non-psychiatric' expression of distress and protest about intolerable occupational and personal pressures. Much the same was said of neurasthenia in the People's Republic of China (see Chapter 5.2.1).

Another potentially important social factor is the controversy and the often misleading information about the illness that patients are exposed to. Self-help books the media and some doctors have frequently given the impression that the medial profession is more divided than it actually is in its understanding of CFS and have emphasized 'medical' explanations such as myalgic encephalopathy (ME) as the only appropriate diagnosis.

(g) Conclusions

Psychological and social factors are important perpetuating factors and include focusing of attention on symptoms avoidance of activity and a strong and exclusive medical disease attribution.

A comprehensive view of the cause of CFS

It now seems clear that rather than regarding pathophysiological and psychopathological studies as separate and competing approaches to the problem, it is more useful to consider a formulation of CFS that combines these factors. Table 5.2.7.3 summarizes relevant aetiological factors.

According to this integrated scheme causal factors are divided into those that may predispose to the illness, those that precipitate it, and those that perpetuate an established illness. Predisposing factors include previous episodes of major depressive disorder, and perhaps also certain personality characteristics, particularly achievement orientation and perfectionism associated with chronic stress, especially occupational stress. The precipitation of CFS by a viral infection is clinically plausible and proven in certain circumstances, whilst life stresses also seem to be important. Perpetuating factors may include neuroendocrine dysfunction, emotional disorder, and physical disease attributions, as well as coping by avoidance, chronic unresolved personal difficulties, and misinformation about the illness. They may be effectively combined in a cognitive–behavioural model of the illness that provides a basis for treatment with CBT.[1,18]

Course and prognosis of CFS

Anecdotal reports of the prognosis of CFS make gloomy reading. What is more, systematic studies are hardly more encouraging, suggesting that the commonest outcome of those attending a specialist CFS clinic is continuing ill health, up to and beyond 5 years.[19] However, these observations need elaboration. The rather dispiriting prognostic studies all refer to patients seen in specialist centres. Nearly all had several years of illness prior to referral, and it is unsurprising to find that chronicity predicts chronicity. Patients seen in specialist clinics often have strong views about illness aetiology and illness management that may negatively influence their acceptance of and adherence to potentially effective treatment. Primary care and community samples and patients appear to have a better outcome, as do children and adolescents. Finally, the current generation of outcome studies refer to the situation without treatment as potentially effective treatment was rarely given. Later sections of this chapter suggest that this view requires revision.

Table 5.2.7.3 An aetiological formulation of CFS

	Predisposing	Precipitating	Perpetuating
Biological	Genetics Previous depression	Infection	Effects of inactivity CNS dysfunction Reduced HPA activity
Psychological	Personality (perfectionism)	Response to stressor	Focus on symptoms Disease attribution Avoidant coping
Social	Chronic stress	Social/occupation stress	Life conflicts Psychological iatrogenesis

Evidence for treatments

Drug treatment

Many pharmacological treatments have been suggested for CFS. To date, none are of proven efficacy and several are potentially harmful.[4, 20] The evidence for antidepressant agents is mixed. Of available agents none is clearly superior for this patient group, although clinical experience suggests that the selective serotonin-reuptake inhibitor antidepressants may be better tolerated.

Graded activity (exercise) therapy

Well-conducted randomized controlled trials suggest that graded increases in physical activity is helpful in improving function and relieving symptoms.[4, 20]

Cognitive behaviour therapy

Systematic reviews have concluded that the strongest evidence for efficacy is for a rehabilitative type of cognitive–behaviour therapy (CBT).[4, 20]

Practical management

Assessment

Both a medical and psychiatric assessment is required in every case of suspected CFS.[21]

(a) Excluding organic disease

A small minority of those patients who present with severe chronic fatigue will be found to have occult organic disease. How frequently organic disease is found will depend on how thorough an assessment the patient has already received. The differential diagnosis is listed in Table 5.2.7.4.

There are no specific diagnostic tests and no characteristic abnormalities on laboratory investigations in CFS. Tests are conducted purely to exclude other diseases. All patients should have a full blood count, erythrocyte sedimentation rate or C-reactive

Table 5.2.7.4 Conditions to be considered in the differential diagnosis of chronic fatigue syndrome

Nature of symptoms	Possible condition
General	Occult malignancy Autoimmune disease Endocrine disease Cardiac, respiratory, or renal failure
Gastroenterological Neurological	Malabsorption including celiac disease Disseminated sclerosis Myasthenia gravis Parkinson's disease Early dementia Cerebrovascular disease
Infectious disease	Chronic active hepatitis (B or C) Lyme borreliosis HIV Tuberculosis
Respiratory disease	Nocturnal asthma Obstructive sleep apnoea
Chronic toxicity	Alcohol Solvents Heavy metals Irradiation
Psychiatric	Major depressive disorder Dysthymia Anxiety and panic disorder Somatoform disorder

protein, basic biochemistry screen, creatine kinase, random blood glucose, urine analysis, thyroid function, and possibly antinuclear antibody tests. Further investigation depends on the clinical findings and differential diagnoses under consideration. In our clinical experience unusual clinical features, such as weight loss, an absence of mental fatigue/fatigability, or a history of recent foreign travel, should all increases suspicion of alternative diagnoses.

(b) Excluding psychiatric diagnoses

All patients should have a psychiatric history taken and their mental state examined. The assessment should seek evidence of major depression, anxiety, and panic disorder, and also evaluate any suicidal intent. The psychiatric assessment should be systematic, as hidden distress is common and casual estimates of the patient's degree of distress may be misleading.

Making the diagnosis

As explained above the choice of diagnosis should be pragmatic; there is little merit in giving a diagnosis of CFS if the patient's symptoms are clearly those of depression or anxiety. In other cases, a diagnosis of CFS may be the most appropriate and useful; it offers the patient a coherent label for their symptoms and will therefore lessen the risk that they will embark on a fruitless search for a 'better' explanation. Above all, it is most important that neither the physician nor the patient stops at this diagnosis, but goes on to explain what it does and does not mean.

Making a formulation

An adequate individual patient assessment must identify all the important obstacles to recovery. It often needs to go beyond diagnosis to include a systematic individualized description of the aetiological factors in each case. These should include those factors listed in Table 5.2.7.1.

(a) Case formulation

A multidimensional description of the patient's illness provides a comprehensive picture of the factors that may be relevant to the patient's illness and is an important supplement to diagnosis. Its use can be illustrated by returning to the case example described above.

Case Study

Assessment of the patient described earlier revealed that she believed that her symptoms were by an ongoing virus infection and associated immune disturbance and that she should beware of exacerbating them. She consequently avoided activity and had been profoundly inactive for over a year, often lying in bed and sleeping for long periods. Therefore she had become physiologically deconditioned. She was frustrated with her inability to do things and sometimes felt low in mood about her predicament. Her previous job had been very stressful, but since becoming ill she had been unable to work. She had now lost her job and was cared for by her mother who also believed she had a permanent disability. Her doctor said that the best thing was rest. She had rejected a psychiatric consultation but was paying to see an alternative medicine therapist.

The findings can be summarized in an individualized form of Table 5.2.7.3 with an emphasis on the perpetuating factors, which can be seen as reversible barriers to recovery.

General management

The five basic steps essential to the care of patients with CFS are listed in Table 5.2.7.5.

The doctor should listen to the patient's story and ask about his or her own understanding of the illness. It is usually also worth seeing the partner or relevant family members. It is important to address misunderstandings about the nature of the illness and especially to make clear that it is not progressive or life threatening. A positive explanation of CFS as a 'dysfunction of the central nervous system' emphasizing reversibility is often helpful. Anxiety and depression can be explained as understandable consequences of illness and treatment given for them. The adverse physiological and psychological effects of prolonged bed rest should be explained, and the patient encouraged to avoid extremes of both inactivity

Table 5.2.7.5 Principles of management of CFS

1. Acknowledge the reality of the patient's symptoms and disability
2. Provide appropriate education about the nature of the syndrome
3. Treat identifiable depression and anxiety disorder
4. Encourage a very gradual return to normal functioning
5. Help the patient overcome occupational and interpersonal obstacles to normal functioning

and exertion. Finally there are often problem in relationships and with employers than the patient may need help to address.

An initial hospital appointment that achieves all the above usually requires at least 45 min. An evidence-based self-help book may be recommended.[22]

(a) Pharmacological treatments

Patients are often reluctant to take antidepressants and careful explanation and follow-up are required. Other pharmacological agents should only be used with care and preferably only as part of randomized controlled trials.

(b) Graded activity and exercise therapy

This should be considered for patients who are physically inactive. However, they need to be slowly graded and tailored to the patients' ability and progress; a simplistic application of fixed exercise regimens, particularly if given without adequate explanation is unlikely to be helpful, and may exacerbate symptoms and damage confidence.

(c) CBT

Whilst CBT is currently the mainstay of management it is not effective in all patients and requires both careful explanation and therapists skilled in its delivery to patients with CFS. It is particularly important that patients do not interpret referral for a behavioural treatment as the doctor implying that their illness is imaginary. It can be explained that the most likely cause of fatigue in CFS is changes in brain and neuroendocrine function and that these can be reversed by these therapies. It is also both useful and true to draw attention to studies showing the effective of CBT in improving symptoms, quality of life and outcome in conditions such as diabetes, cancer, and rheumatoid arthritis. General physical rehabilitation services may be useful for patients with chronic severe disability.

Potential management problems

Several issues may complicate the management of patients with CFS. These include:

(a) Strong illness beliefs

Difficulties are most likely to arise when patient and physician hold differing beliefs about the nature and best management of the illness. This problem can often be overcome by the physician acknowledging the patient's beliefs without either agreeing with them or arguing about them. If the patient's family, friends, or acquaintances suggest or encourage views that the physician regards as unhelpful the problem is more difficult and a meeting with the other parties may be necessary.

(b) Alternative therapies

Patients with CFS often turn to alternative and complementary medicine. Whilst some of these therapies may be easily continued in parallel with rehabilitative management, others may interfere either by the explanation of the illness they offer or by their practical requirements. In such cases it can be helpful to explain the need to pursue one approach at a time in order to learn what helps.

(c) Official reports and financial benefits

Perhaps the greatest difficulty is when patients ask the physician to write reports on their behalf, confirming that they suffer from permanent disability. The physician wants to help the patient and ensure that they get appropriate benefits but also to avoid a self-fulfilling prophecy. This dilemma has no easy solution, but it seems important not to confirm a negative prognosis until potentially effective treatment has been tried.

(d) Poor prognosis patients

For patients who have been identified as having a poor prognosis because of a long history of severely impaired functioning, or poor response to treatment, regular (albeit infrequent) long-term follow-up is, at the least, likely to limit iatrogenic harm from unnecessary investigations and ineffective treatments. Often in such cases the best strategy is simply to tell the patient how well they are managing in difficult circumstances.

Possibilities for prevention

We do not know how to prevent CFS, but its development can probably be modified.

The most important place for such intervention may be the transition from an acute fatigue state to chronic disability. For example, although most of us have been exposed to Epstein–Barr virus infection by the time we reach 30 years of age, few go on to develop CFS. Encouraging modest amounts of activity in the weeks after an acute infection has been shown to be effective in reducing the duration of symptoms. Intervention that maintain activity and prevent a slide into a vicious circle of symptoms, reduced activity, demoralization, disability, and depression might therefore offer an opportunity for prevention. The second area for intervention is in achieving better attitudes to symptoms and distress. Simplistic depictions of illness as either physical or psychological and the corresponding division in medical services are clearly unhelpful. The third area is in employment practice. CFS is often associated with work stress and dissatisfaction and only a minority of employers allow a flexible return to work. Finally, a doctor–patient relationship that both allows the patient to be ill and encourages recovery is probably the most important preventive strategy.

Conclusions and future directions

Chronic fatigue syndrome is best regarded as a descriptive term for a clinical presentation, rather than as a discrete condition. The group of patients it defines is almost certainly aetiologically heterogeneous. While psychiatric diagnosis provides one approach to subclassification of CFS, both the medical and psychiatric current diagnostic systems have significant limitations, and a multidimensional description of the patient's characteristics may be more clinically useful.[23]

The illness defined by the term chronic fatigue syndrome is important because it represents potentially treatable disability and suffering. It is also important because the clinical problems it gives rise to highlight shortcomings in our present approach to illness. Whatever is ultimately discovered about the causes of CFS, the attention it is receiving offers a golden opportunity to reappraise our understanding and classification of human illness and to re-examine our current organization of medical care.

5.2.8 Body dysmorphic disorder

Katharine A. Phillips

The dysmorphophobic patient is really miserable; in the middle of his daily routines, talks, while reading, during meals, everywhere and at any time, he is caught by the doubt of deformity . . . . Enrico Morselli, 1891[1]

Introduction

Body dysmorphic disorder (BDD), also known as dysmorphophobia, is a relatively common, severe, and sometimes difficult-to-treat condition that has been described for more than a century.[1–3] BDD consists of a distressing or impairing preoccupation with an imagined or slight defect in one's physical appearance. BDD is classified as a separate disorder in DSM-IV and a type of hypochondriasis in ICD-10. This disorder can cause severe distress and notably impaired functioning. In addition, risk behaviours—suicidality, violence, problematic substance use, and compulsive tanning—appear common in BDD. Despite its severity, BDD is underrecognized in clinical settings.

Clinical features

Demographic characteristics

BDD occurs in all age groups.[3–5] It appears about equally common in females and males or may be somewhat more common in females.[3] Most individuals with BDD have never been married, and a high proportion is unemployed, often because of their psychopathology.[3–7]

Bodily preoccupations

People with BDD are preoccupied with the idea that some aspect of their appearance is ugly, unattractive, deformed, flawed, or defective in some way.[1–6, 8–10] Concerns usually focus on the face or head but can involve any body area.[3–6, 8–10] Skin (e.g. acne, scars, lines, or pale skin), hair (e.g. thinning or excessive body or facial hair), and nose (e.g. size or shape) concerns are most common. Most patients are preoccupied with several body areas. The preoccupation usually focuses on specific areas but may involve overall appearance.

BDD preoccupations are distressing, time consuming (occurring for an average of 3–8 h a day), and usually difficult to resist or control.[3] They are often associated with low self-esteem, shame, rejection sensitivity, and high levels of neuroticism, introversion,

depressed mood, anxiety, anger-hostility, and perceived stress.[3] Patients often believe that they are unacceptable—e.g. worthless, inadequate, unlovable, and an object of ridicule and rejection.[3,9]

Insight/delusionality

Insight is usually poor or absent; 27–39 per cent of patients are currently delusional (completely convinced that their belief is accurate and undistorted).[3,11,12] Most do not recognize that their belief is due to a mental illness or has a psychological/psychiatric cause.[3,12] In addition, a majority have ideas or delusions of reference, believing that others take special notice of the supposed appearance defects—for example, stare at them or mock the person because of how they look.[3,12] Referential thinking can fuel feelings of anger and rejection as well as social isolation.

Compulsive and safety behaviours

Nearly all patients perform BDD-related compulsive or safety behaviours (Table 5.2.8.1), which are time consuming (occurring for hours a day) and difficult to resist or control.[3–6,10] The behaviours usually aim to examine, improve, hide, or obtain reassurance about the perceived defects. These behaviours typically do not alleviate distress and may even worsen it.

Compulsive skin picking, which 27–45 per cent of BDD patients do to try and improve their appearance, can cause considerable skin damage.[3,5] Emergency surgery is sometimes required—for example when sharp implements used for picking rupture major blood vessels. Compulsive tanning to darken 'pale' skin or minimize perceived acne, scarring, or 'marks' can cause skin damage and may increase cancer risk.[3]

Psychosocial functioning and quality of life

Functioning and quality of life are usually very poor.[3,4,7] Some people, with effort, function adequately despite their distress, although usually below their potential. Those with severe BDD may be profoundly impaired by their symptoms—for example, housebound for years, unemployed and socially isolated, and chronically suicidal.

Social impairment is nearly universal.[3,7] People with BDD feel embarrassed and ashamed of their 'ugliness', are anxious around others as a result, and fear being rejected because of how they look. Thus, they may have few or no friends; avoid dating, physical intimacy, and other social interactions; or get divorced. Impairment in academic or occupational functioning is common, due to the time consuming and distracting nature of BDD symptoms and a desire to avoid interactions with others.[3,7] In a broadly ascertained BDD sample (n = 200), 36 per cent of individuals were not currently working and 32 per cent were not able to be in school or do school work because of psychopathology (BDD was the primary diagnosis for most).[7] In two BDD series, more than a quarter of individuals had been completely housebound for at least 1 week because of BDD symptoms, and more than 40 per cent had been psychiatrically hospitalized.[5,13] Mental health related quality of life is markedly poorer than for the general population and even poorer than for patients with diabetes, a recent myocardial infarction, or clinical depression.[7]

Table 5.2.8.1 Common compulsive and safety behaviors in body dysmorphic disorder

- Comparing one's appearance 'defects' with the same body areas of other people
- Checking the perceived defects directly, in mirrors, or in other reflecting surfaces
- Excessive grooming—for example, applying make-up, shaving, hair cutting or removal, hair styling
- Camouflaging—for example with a hat, clothes, sunglasses, hair, body position, hand, or make-up
- Seeking reassurance from others or trying to convince others of the 'defect's' ugliness
- Skin picking
- Excessive exercising or weightlifting
- Tanning
- Frequent clothes changing
- Touching the perceived defect
- Dieting
- Body measuring
- Compulsive shopping for beauty products, remedies, or clothes
- Seeking surgical, dermatologic, and other cosmetic treatment for the perceived deformity

Suicidality

Suicidal ideation and attempts appear very common. Reported lifetime rates of suicidal ideation and suicide attempts are 78–81 and 24–28 per cent, respectively.[9,13,14] Among adolescent inpatients, those with BDD have significantly greater suicidality than those without BDD. The rate of completed suicide, while preliminary, appears markedly high. In a prospective study, the annual suicide rate was 0.35 per cent, which is approximately 45 times higher than for the US population (adjusted for age, gender, and geographic region) and higher than for most other mental disorders.[15] A study of dermatology patients who committed suicide found that most had acne or BDD.[16] Indeed, individuals with BDD have many suicide risk factors.[3,14]

Aggression and violence

In several BDD studies, 36–38 per cent of patients reported lifetime aggression/violence due specifically to BDD symptoms.[3,10] Such behaviour may be fuelled by anger about looking 'deformed', an inability to fix the perceived defect, and misperceptions of being rejected, ridiculed, or mocked because of the appearance 'defects'. Individuals with BDD tend to misinterpret self-referent facial expressions as contemptuous and angry,[17] misinterpret ambiguous social (and other) situations as threatening,[18] and have high levels of anger/hostility.[3] Surgeons and dermatologists may be victims of violence—even murder—fuelled by dissatisfaction with the outcome of cosmetic procedures.[3] In a survey of 265 plastic surgeons, 12 per cent reported that a BDD patient had physically threatened them.[19]

Comorbidity

Major depressive disorder is the most frequently comorbid disorder, occurring in about 75 per cent of individuals with BDD.[5,13] Social phobia, OCD, and substance use disorders are also common.[5,8,13] Of note, one study found that 49 per cent of 200 BDD subjects had a lifetime substance use disorder, 70 per cent of whom reported that BDD contributed to their substance use.[5] Muscle dysmorphia,

a preoccupation with the idea that one's body is insufficiently lean or muscular, may lead to anabolic steroid abuse.[3]

Gender

Men and women appear to have largely similar clinical features.[10, 13, 20] However, in two United States studies (n = 200 and n = 188[13, 20]) males were more likely to be single, have a substance use disorder, and be preoccupied with thinning hair and small body build. Females were more likely to be preoccupied with weight, hips, and excessive body hair, and were more likely to pick their skin and use their hands or make-up for camouflage. One of these two studies, and a study from Italy (n = 58[10]), found that females were more likely to be preoccupied with their breasts/chest and legs, check mirrors, and use camouflaging. In all three studies, a concern with genitals was more common in males, and a comorbid eating disorder more common in females.

BDD in children and adolescents

BDD usually begins during early adolescence and can occur in childhood.[4, 5, 10] While data are limited, BDD's clinical features in youth appear largely similar to those in adults. Of note, children and adolescents appear to have lifetime rates of functional impairment similar to those in adults, despite having had fewer years over which to have developed these problems.[3] In the one study that directly compared adolescents to adults, adolescents were more likely to have delusional BDD beliefs and had a significantly higher lifetime suicide attempt rate (44 per cent versus 24 per cent), underscoring the importance of recognizing BDD in this age group.

Cross-cultural aspects of BDD

Case reports and series from around the world suggest that BDD's clinical features are generally similar across cultures but that cultural factors may produce nuances and accents on a basically invariant, or universal, expression of BDD.[3] It is unclear whether koro (a belief that one's penis is shrinking, which occurs primarily in Southeast Asia) is a form of BDD.

Classification and relationship to other disorders

A clinically important classification controversy is whether delusional and non-delusional BDD are the same or different disorders. Whereas BDD is classified as a somatoform disorder, its delusional variant is classified as a psychotic disorder—a type of delusional disorder. DSM-IV, however, allows delusional patients to be diagnosed with both BDD and delusional disorder, reflecting data suggesting that its delusional and non-delusional variants may constitute the same disorder, which spans a spectrum of insight. Indeed, delusional and non-delusional BDD appear more similar than different, although delusional BDD appears more severe.[11,12] Of clinical significance, delusional and non-delusional patients both appear to respond to serotonin-reuptake inhibitors (SRIs) as monotherapy but not to antipsychotic monotherapy.[21]

Another important question is whether BDD is related to OCD, social phobia, major depressive disorder, or eating disorders.[3] BDD is widely conceptualized as an OCD-spectrum disorder. Supporting this conceptualization, OCD often co-occurs with BDD, and BDD appears more common in first-degree relatives of OCD probands than control probands.[3] Data from a variety of domains suggest that BDD and OCD have many similarities.[3] However, BDD and OCD have some differences and do not appear to be identical disorders.[3] Although BDD's relationship to other disorders has received less investigation, preliminary data suggest that BDD may also be related to major depressive disorder. However, BDD does not appear to simply be a symptom of depression.[3] Although ICD-10 classifies BDD as a type of hypochondriasis, no studies have examined their relationship.

Diagnosis

BDD can be diagnosed using questions at the top of Table 5.2.8.2, which follow DSM-IV's diagnostic criteria. Clinicians should adequately probe for examples of clinically significant distress and impairment in social, occupational, and other aspects of functioning. BDD is diagnosed if the person is excessively preoccupied with a non-existent or slight physical flaw (for example, thinks about it for at least an hour a day), and the concern causes clinically significant distress or impairment in functioning. The appearance concerns should not be better accounted for by an eating disorder. However, BDD and eating disorders may co-occur, in which case both disorders should be diagnosed.

The bottom of Table 5.2.8.2 includes questions that are ***not*** recommended for screening for or diagnosing BDD. The word 'imagined' is problematic, because most patients have poor or absent insight and do not think their appearance problem is imagined. Terms such as 'deformed' or 'disfigured' are too extreme for some patients to endorse. Asking if there is something wrong with one's body is too broad, as patients may interpret this to refer to bodily functioning.

ICD-10's criteria require that patients persistently refuse to accept the advice and reassurance of several different doctors that they do not have an abnormality. However, many people with BDD do not disclose their appearance concerns to doctors or even seek medical care because they are housebound, ashamed, believe they cannot be helped, lack medical insurance, or do not have access to

Table 5.2.8.2 Questions to diagnose BDD

Recommended questions for diagnosing BDD:

1 Are you very worried about your appearance in any way? ***OR:*** Are you unhappy with how you look? ***If yes:*** Can you tell me more about your concern?

2 Does this concern preoccupy you? Do you think about it a lot and wish you could worry about it less? How much time would you estimate you spend each day thinking about how you look, if you were to add up all the time you spend?

3 What effect does this preoccupation with your appearance have on your life? Has it caused you a lot of distress (for example, anxiety or depression)? Has it significantly interfered with your social life, relationships, school work, job, or any other activities? Has it affected your family or friends?

*Questions that are **not** recommended when screening for or diagnosing BDD:*

1 It is recommended that patients ***not*** be asked if they are concerned with an 'imagined' defect in their appearance, whether they think they are 'deformed' or 'disfigured', or whether there is something 'wrong with (their) body'

2 To diagnose BDD, it should not be required that patients refuse to accept the advice and reassurance of doctors that they do not have an abnormality

health care for other reasons. Using this diagnostic criterion will underdiagnose BDD. BDD is also underidentified in many mental health databases because its ICD-9 diagnostic code identifies it as hypochondriasis.

BDD usually goes undiagnosed in clinical settings.[3,4,22] Sufferers often conceal their symptoms due to embarrassment and shame.[3,4,22] They may volunteer only depression, anxiety, or discomfort in social situations. The compulsive and safety behaviours in Table 5.2.8.1 may be clues to BDD's presence. BDD may be misdiagnosed as another disorder[3]: social phobia or agoraphobia (due to secondary social anxiety and isolation), panic disorder (because panic attacks may occur after looking in the mirror or when feeling scrutinized by others), trichotillomania (when hair is cut or plucked to improve perceived flaws, such as uneven eyebrows), or OCD (due to obsessional preoccupations and compulsive behaviours). Delusional patients are sometimes misdiagnosed with schizophrenia, psychotic depression, or psychotic disorder NOS. To diagnose BDD, patients must usually be asked directly about BDD symptoms.

Epidemiology

BDD has been reported in 0.7–1.7 per cent of community samples.[3] In the largest study, a nationwide survey in Germany (n = 2552), BDD was present in 1.9 per cent of women and 1.4 per cent of men.[23] In smaller non-clinical student samples, BDD's prevalence has ranged from 2.3–13 per cent.[3] A prevalence of 9–12 per cent has been reported in dermatology settings, 3–15 per cent in cosmetic surgery or plastic surgery settings, 8–37 per cent in patients with OCD, 11–13 per cent in social phobia, 26 per cent in trichotillomania, and 14–42 per cent in atypical major depression.[3] In a study of 122 general psychiatric inpatients, 13 per cent had BDD's, which was higher than for schizophrenia, OCD, PTSD, and eating disorders.[22]

Pathogenesis

BDD's pathogenesis is likely to be complex and multifactorial.[3] Aetiologic factors likely involve a complex interplay of genetic and environmental risk factors.[3] Preliminary data indicate an association of the $GABA_A$-γ2 gene with BDD. Environmental risk factors may include perceived childhood neglect and/or abuse, teasing, and low parental warmth. A role is also likely for socio-cultural and evolutionary pressures (e.g. symmetrical features may signal reproductive health).

Neuropsychological studies indicate a tendency to focus on isolated details of visual and verbal stimuli rather than more global, configurational attributes[24]—consistent with clinical observations that patients selectively attend to specific aspects of their appearance or minor flaws. Cognitive processing studies indicate that BDD patients tend to misinterpret ambiguous social (and other) situations as threatening and misinterpret self-referent facial expressions as contemptuous and angry.[17,18] These interpretive biases may combine with rejection sensitivity, perfectionism, and a focus on aesthetics to contribute to BDD's development.[3] High neuroticism and low extroversion may also play a role.[3] Many potential risk factors (e.g. neuroticism) are not specific to BDD, but the overall combination of risk factors may be. BDD's neurocircuitry is unknown but likely involves a complex interplay of dysfunction in several neural systems,[3,25] including circuitry involved in OCD (orbitofrontal cortex, anterior cingulate cortex, caudate, thalamus). BDD's shared features with other anxiety disorders and depression points to possible dysfunction in amygdala, prefrontal cortex, and anterior cingulate cortex. Brain regions involved in body image and facial emotion perception (e.g. right parietal cortex, amygdala, occipitotemporal cortex [e.g. fusiform face and extrastriate body areas]) may also be involved.

Course and prognosis

Prospective and retrospective studies indicate that BDD is usually chronic.[5,13,26] More severe BDD, a longer duration of BDD, and the presence of a personality disorder predict a lower probability of remission. However, when BDD is accurately identified and its treatment optimized, the prognosis appears much more favourable.

Treatment

BDD's treatment is described in more detail elsewhere, including in a guideline from the United Kingdom's National Institute of Clinical Excellence (NICE).[3,21,27,28] Serotonin-reuptake inhibitors (SRIs, or SSRIs) and cognitive–behavioural therapy (CBT) are currently recommended as the first-line treatments.[3,21,27,29] Treatment studies are limited, and more research is needed. However, available data consistently indicate that a majority of patients improve with these treatments.

Evaluation of treatments

Surgical, dermatologic, and other cosmetic treatment

A majority of BDD patients seek often-costly cosmetic treatment.[3,8,9,13,30] Dermatologists and surgeons are most often consulted, but any type of physician may be seen. It appears that most BDD patients are dissatisfied with such treatment.[3,9,13,30] Occasionally, dissatisfied patients sue, or are violent towards, the physician. Some patients perform their own surgery[3,6]—e.g. cutting open one's nose with a razor blade and trying to replace nose cartilage with chicken cartilage in the desired shape.

Pharmacotherapy and other somatic treatments

All SRI studies to date indicate that SRIs are often efficacious for BDD.[3,21] These studies include a placebo-controlled fluoxetine study (n = 67), a controlled and blinded cross-over study comparing the SRI clomipramine to the non-SRI antidepressant desipramine (n = 29), and open-label trials of fluvoxamine, citalopram, and escitalopram (n = 15–30). In these studies, 53 per cent to 73 per cent of patients responded to the SRI. The cross-over trial found greater efficacy for clomipramine than desipramine, suggesting that SRIs may be more efficacious than non-SRI antidepressants for BDD. This important finding is consistent with clinical series and retrospective data suggesting that SRIs are more efficacious than a broad range of non-SRI medications for BDD.[3,21]

Response to an SRI usually develops gradually and may require up to 12–14 weeks of treatment (while reaching a relatively high dose) to be evident.[3,21] Although dose-finding studies are lacking, relatively high SRI doses (higher than typically used for depression)

appear to often be needed.[3,21] Response to medication usually includes a decrease in appearance preoccupations, distress, and compulsive/safety behaviours, as well as improved functioning. Suicidality, depressive symptoms, anxiety, and anger-hostility often improve.[3] Of note, delusional patients often improve with SRI monotherapy, whereas limited data suggest that antipsychotic monotherapy is usually ineffective for delusional BDD.[3,21]

Patients who do not improve with one SRI may improve with another SRI.[3, 21] Regarding SRI augmentation, a small double-blind randomized controlled trial found that pimozide was not more efficacious than placebo as a fluoxetine augmenter.[3,21] Clinical series suggest that augmentation of an SSRI with buspirone, lithium, or clomipramine may be helpful.[3,21] (SSRIs may increase clomipramine blood levels, however, which may cause toxicity; thus, if this approach is tried, clomipramine should be started at a very low dose with monitoring of levels.) Clinical observations suggest that SSRI augmentation with venlafaxine, atypical neuroleptics, or bupropion may be helpful for some patients.[3,21]

Monotherapy with agents other than SRIs has not been well studied.[3, 21] A small open-label trial (n = 11) suggests that venlafaxine may be efficacious.[3] For severe and treatment-refractory cases an MAO inhibitor may be worth trying (but should never be combined with an SRI). Available case series and reports, while very limited, suggest that ECT is generally ineffective for BDD and secondary depressive symptoms.[3,21]

Clinical experience suggests that many patients relapse after SRI discontinuation and that long-term treatment may be needed, with efficacy usually sustained over time.[3,21] For patients who appear at high risk of suicide or violence, lifelong treatment with an effective SRI is recommended, as suicides have been known to occur after SRI discontinuation.

Cognitive behavioural therapy (CBT)

Preliminary data suggest that CBT is often efficacious for BDD.[3,27,29] CBT typically includes:[3,27–29]

1 *Cognitive restructuring* to identify cognitive errors and develop more accurate and helpful BDD-related thoughts and beliefs
2 *Behavioural experiments* to test the accuracy of BDD beliefs
3 *Exposure* to avoided situations (e.g. leaving the house, attending social gatherings)
4 *Response prevention* to decrease or stop compulsive behaviours (e.g. stopping excessive mirror checking, limiting grooming time)

In two randomized studies (n = 54 and 19), patients improved more with CBT than on a waiting list.[3,29] Several case series (n = 5–13) found that CBT was efficacious for BDD.[3,29] The number of sessions in these reports ranged from twelve 60-min sessions to sixty 90-min sessions.

Data on exposure and response prevention alone—without a cognitive element—is limited to a retrospective study and small case series with up to 10 subjects.[3,29] These reports note favourable outcomes, although in the author's experience cognitive approaches are a helpful, even necessary, component of treatment for most patients. It can be particularly helpful to work on core beliefs, which typically involve feelings of inadequacy and being unwanted by others.[3, 9] Clinical experience additionally suggests that the following are beneficial components of CBT:[3, 28]

1 *Mirror retraining*, which involves learning to see one's entire body in a non-judgemental and 'holistic' way (rather than focusing on disliked areas), while refraining from excessive mirror checking
2 *Habit reversal* for skin picking and repetitive hair pulling or plucking
3 *Mindfulness skills*
4 *Activity scheduling* and *scheduling pleasant activities* for more severely ill, depressed, and inactive patients
5 *Motivational interviewing*, which may be needed to engage and keep patients in treatment

Future studies (e.g. dismantling studies) are needed to determine which specific components of CBT are necessary and effective.

Other types of psychotherapy have not been well studied and are not currently recommended as first-line treatments.[3] Nonetheless, clinical experience suggests that insight-oriented or supportive therapy—in addition to an SRI and/or CBT—may help some patients cope with their illness or with co-occurring problems or disorders.[3]

Management

Management approaches are described in more detail elsewhere.[3, 21, 27, 28]

1 First try to engage the patient and establish an alliance so they are willing to try treatment. This can be difficult to accomplish, as many patients are delusional, prefer cosmetic treatment, are rejection sensitive, and do not want other people (including a clinician) to see them.
2 Empathize with the patient's suffering.
3 Take patients' appearance concerns seriously, neither dismissing their concerns about how they look nor agreeing that there is something wrong with their appearance. Trying to convince patients (especially delusional patients) that their beliefs are irrational or that they look normal is usually not helpful.
4 Instead, focus on the potential for psychiatric treatment to diminish their distress and preoccupation and improve their functioning and quality of life.
5 Provide psychoeducation about BDD and recommend reading.
6 For patients who wish to pursue cosmetic treatments, explain that such treatment appears ineffective for BDD.
7 Provide education about recommended treatments. It can be helpful to explain, for example, that SRIs are usually well tolerated, are not habit forming, appear to normalize the brain (and do not cause brain damage), and often diminish suicidal thinking in people with BDD. CBT is a practical 'here-and-now' treatment in which patients actively collaborate with the therapist and learn helpful skills by attending sessions and doing homework.

Treatment should be initiated with an SRI and/or CBT. SRIs are also the first-line medication for delusional BDD. All severely ill patients, especially those who are highly suicidal, should, in the author's opinion, receive an SRI. Patients with severe comorbid depression also warrant SRI treatment. Other comorbidity may warrant additional medication.

Before concluding that an SRI is ineffective, it should be tried for 12–16 weeks, reaching the highest dose recommended by the manufacturer or tolerated by the patient (if necessary) for at least 2–3 of those 12–16 weeks. If tolerated, higher doses than those recommended by the manufacturer can be cautiously tried to obtain or optimize a response (excluding clomipramine). If this is not effective, an augmentation strategy or switching to another SRI is indicated. For patients who refuse or are ambivalent about treatment motivational techniques should be tried. Patients who are not improving with CBT may need more frequent sessions, longer sessions, or a change in the current CBT focus. At least 4–6 months of weekly or more frequent CBT sessions, plus daily homework, is generally recommended. More severely ill and delusional patients may require much longer or more intensive treatment. Maintenance/booster sessions following CBT may reduce relapse risk. It may be helpful to add CBT to an SRI, or vice versa, if either treatment alone is insufficient.

For certain patients, adjunctive individual supportive therapy or family therapy may be helpful.[3] Families can be an invaluable support and facilitate treatment.[3] Mental health professionals may need to interface with dermatologists, plastic surgeons, and other physicians from whom patients have requested or are receiving cosmetic treatment.

Prevention

Because little is known about BDD's pathogenesis and risk factors, the disorder cannot currently be prevented. However, BDD should be treated in its early stages, before it causes substantial morbidity or interferes with a child's, adolescent's, or young adult's development.

Conclusions

Although this disorder has received far less investigation than many other serious mental illnesses, BDD research is rapidly advancing. It is important that clinicians screen patients for this often-secret disorder and be aware that it typically goes unrecognized in clinical settings, causing significant morbidity. While much more research is needed, available treatments are often very helpful for this distressing and often-disabling disorder.

Further information

Further information about BDD and its treatment is provided in references 3, 27, and 28 below and at www.bodyimageprogram.com.

5.2.9 Factitious disorder and malingering

Christopher Bass and David Gill

Factitious disorder

Introduction

Patients with factitious disorder feign or simulate illness, are considered not to be aware of the motives that drive them to carry out this behaviour, and keep their simulation or induction of illness secret. In official psychiatric nomenclature, factitious disorder has replaced the eponym Munchausen syndrome, introduced by Asher[1] to describe patients with chronic factitious behaviour. Asher borrowed the term from Raspe's 1785 fictional German cavalry officer, Baron Karl von Munchausen, who always lied, albeit harmlessly, about his extraordinary military exploits.

The criteria for factitious disorder in DSM-IV[2] are (a) the intentional production or feigning of physical or psychological signs or symptoms; (b) motivation to assume the sick role; and (c) lack of external incentives for the behaviour (e.g. economic gain, avoidance of legal responsibility, or improved physical well-being, as in malingering) and lack of a better classification for the disorders.

In the last 10 years there has been increased interest in deception in medical practice, with specific focus on pathological lying and the diagnostic dilemmas in this field: specifically, how to differentiate between hysteria, factitious disorders, and malingering. Some of these topics will be discussed in the next section.

This chapter concentrates on factitious physical complaints; fabricated psychological symptoms are considered under malingering.

Diagnostic problems

The DSM-IV criteria have recently come under attack. Turner[3] has argued that criterion B (motivation to assume the sick role) has no empirical content and fulfils no diagnostic function. He also argues that criterion A, the intentional production of physical or psychological signs or symptoms, emphasizes symptoms and cannot accommodate pseudologia fantastica (PF), voluntary false confessions, and impersonations. He concludes that the two criteria need reformulating in terms of lies and self-harm, respectively. Bass and Halligan[4] have also suggested that because the conceptual justification for factitious disorders is 'empirically unsubstantiated' and the motivation for diagnostic purposes (conscious versus unconscious; voluntary versus involuntary) essentially unknowable, it seems reasonable to question the clinical status and legitimacy of factitious disorder. More recently there has been a resurgence of interest in **pathological lying**, because this is often easier to identify than, for example, the degree of 'voluntariness' or 'motivation' to attain the sick role (however that is defined).

Pathological lying (pseudologia fantastica): a key component of factitious disorder

It is possible to identify pathological lying if the clinician has sufficient information at his disposal (most often the medical notes). If the patient reports, for example, that they are being treated for leukaemia, and when there is evidence that contradicts this, then this suggests dissimulation. On some occasions the patient will admit to lying, but this is rare.

Because pathological lying is often a key component in factitious disorders, evidence for it should be actively sought by the clinician. But what distinguishes the pathological liar from the person who just lies a lot? Dike *et al.*[5] suggest that the diagnosis is made when lying is persistent, pervasive, disproportionate, and not motivated primarily by reward or other external factors. They also suggest, however, that a key characteristic of pathological lying may be its compulsive nature, with pathological liars 'unable to control their lying'. Psychiatric conditions that have been traditionally associated with deception in one form or another include malingering, confabulation, Ganser's syndrome, factitious disorder, borderline personality disorder and antisocial personality disorder. Lying may also occur in histrionic and narcissistic personality disorders. It is important to note however that pathological lying can occur in the absence of a psychiatric disorder, and that there may be different types of pathological lying, e.g. the benefit fraudster and the stereotypical wandering Munchausen patient describe different subgroups. Furthermore, it has been reported that up to 40 per cent of cases of pseudologia fantastica have a history of central nervous system abnormalities, which suggests that brain dysfunction in these patients requires closer study.[6]

In recent years, functional neuroimaging techniques (especially functional magnetic resonance imaging) have been used to study deception. Attempted deception is associated with activation of executive brain regions (particularly prefrontal and anterior cingulate cortices), while truthful responding has not been shown to be associated with any areas of increased activation (relative to deception).[7] Furthermore, Yang *et al.*[8] reported that pathological liars showed a 22–26 per cent increase in prefrontal white matter and a 36–42 per cent reduction in prefrontal grey/white ratios compared with both antisocial controls and normal controls. These findings suggest that increased prefrontal white matter developmentally provides a person with the cognitive capacity to lie, although Spence[9] has urged caution in the interpretation of these results.

Clinical features of factitious disorder

Clinical features are diverse, and attempts to subtype patients have not always been helpful. The majority of patients with factitious disorders are non-wandering, socially conformist young women (often nurses) with relatively stable social networks.[10–12] These patients

are likely to enact their deceptions in general hospitals, especially accident and emergency departments, and the liaison psychiatrist should be alert to these clinical problems, which can be referred from a variety of different medical and surgical specialties.

Factitious disorders typically begin before the age of 30 years;[13,14] there are often prodromal behaviours in childhood and adolescence (see below). These individuals often report an unexpectedly large number of childhood illnesses and operations, and many have some association with the health care field.[10] High rates of substance abuse, mood disorder, and borderline personality disorder have been reported.[10,12] Approximately four-fifths of factitious disorder patients are women, and 20–70 per cent work in medically related occupations.[12]

Clinicians should be alert to the presentation of more exotic forms of factitious presentation. For example, some women present themselves to family cancer or genetic-counselling clinics and provide a false family history of breast cancer to their medical attendants.[15] Another recent example is 'electronic' factitious disorder,[16] used to describe patients who falsify their electronic medical records to create a factitious report (e.g. of cancer). Another important group is encountered in pregnancy, and this will clearly have important implications for child protection.[17]

In medico-legal practice factitious disorders have been described in patients with a diagnosis of reflex sympathetic dystrophy (RSD), specially involving the forearm,[18] and others have reported that the abnormal movements commonly associated with RSD (CPRS Type I) are consistently of somatoform or malingered origin.[19] Cases have been described where patients involved in litigation have died of factors directly related to factitious physical disorder.[20]

It is being increasingly recognized that these disorders can occur in childhood and adolescence, and child psychiatrists need to be alert to factitious presentations, especially in departments of infectious diseases.[21] Unlike adult patients, many of these children admit to their deceptions when confronted, and some have positive outcomes at follow-up. The descriptions of some of these children as bland, depressed, and fascinated with health care are remarkably similar however to adults with factitious disorders.[22]

Classification

Four main subtypes are distinguished in DSM-IV.[2]

1 Factitious disorder with predominantly psychological signs and symptoms. This is more difficult to diagnose than factitious disorder with physical complaints, because there is no way of excluding a 'true' psychiatric disorder by physical examination or laboratory investigation: see below under malingering.

2 Factitious disorders with predominantly physical signs and symptoms. Almost every illness has been produced factitiously. However, four subgroups describe most cases[23]:

   (a) self-induced infections

   (b) simulated illnesses, for example adding blood to urine

   (c) interference with pre-existing lesions or wounds

   (d) surreptitious self-medication, for example self-injection of insulin

   These categories are not mutually exclusive or jointly exhaustive.

3 Factitious disorders with combined psychological and physical symptoms

4 Factitious disorders not otherwise specified. This includes factitious disorder by proxy (see below and Chapter 9.3.3).

Diagnosis

Clinicians should become suspicious that a patient may be fabricating symptoms if the following features are noted:

- The course of the illness is atypical and does not follow the natural history of the presumed disease, e.g. a wound infection does not respond to appropriate antibiotics (self-induced skin lesions often fall into this category, when 'atypical' organisms in the wound may alert the physician).
- Physical evidence of a factitious cause may be discovered during the course of treatment, e.g. a concealed catheter, a ligature applied to a limb to induce oedema.
- The patient may eagerly agree to or request invasive medical procedures or surgery.
- There is a history of numerous previous admissions with poor outcome or failure to respond to surgery (these patients may overlap with the chronic somatoform patient with 'surgery prone behaviour').[24]
- Many physicians have been consulted and have been unable to find a relevant cause for the symptoms.

Additional clues include the patient being socially isolated on the ward and having few visitors, or the patient being prescribed (or obtaining) opiate medication, often pethidine, when this drug is not indicated. When these findings occur in someone who has either worked in or is related to someone who has worked in the health field, the caregivers should have a high index of suspicion for a factitious disorder. Obtaining collateral information from family members, prior physicians, and hospitals is crucial.

Differential diagnosis

Factitious disorder must be distinguished from authentic medical conditions. It is not uncommon in clinical practice however to find patients with **both** factitious disorder and coexisting physical illness. For example, patients with brittle diabetes are usually young females who deliberately interfere with their treatment, causing unstable diabetic control.[25] A syndrome of severely unstable asthma ('brittle asthma') which also affects young females has also been described;[26] this can occur (especially in A and E departments) with paradoxical adduction of the vocal cords during inspiration.[27] Such patients can neglect to take medication at appropriate times and then ignore adequate management of the potentially dangerous consequences. This may lead to repeated admissions to hospital with medical emergencies such as diabetic ketoacidosis, status asthmaticus, or even pseudo status (simulated status epilepticus).

Factitious disorders are differentiated from somatoform disorders, where physical symptoms, although not caused by physical disease, are deemed not to be intentionally produced. Patients with factitious disorder, although they may state that they are not aware of the motives that drive them, voluntarily produce their physical or psychological symptoms. The disorders may overlap, however, and non-wandering female patients with factitious physical disorders may have more in common with those females who have somatoform disorders than with men with factitious disorder or with malingerers. Fink[28] found that 20 per cent of patients with

persistent somatization (i.e. patients with more than six admissions to the general hospital with medically unexplained symptoms) also had a factitious illness. One of the authors (Christopher Bass) has also found coexisting chronic somatoform and factitious disorders in the female perpetrators of factitious or induced illness.[29]

A more difficult distinction is between factitious disorder and malingering. Malingerers, described below, have clear-cut goals, often personal profit, and lack a history of hazardous, unnecessary invasive procedures. In our opinion the boundaries between the two disorders are more porous than the glossaries would have us believe, and we have stated above that the differentiation between conversion disorders, factitious disorders and malingering is extremely difficult in clinical practice. Case reviews have demonstrated how behaviour may shift from somatization to factitious to malingering when patients are followed longitudinally.[30] In our opinion the clinical status and diagnostic legitimacy of factitious disorder as a selective medical disorder is questionable, because it fails to take account of a morally questionable but volitional-based choice to deceive others by feigning illness. Considered as an act of wilful deception, illness deception can be meaningfully conceptualized within a socio-legal or moral model of human nature that recognizes the capacity for choice and the potential for pursuing benefits associated with the sick role. This model, which recognizes the human capacity to exercise free will, is shown diagrammatically in Fig. 5.2.9.1.

Epidemiology

Factitious disorders are relatively uncommon but probably underdiagnosed. Prevalence depends on clinical setting and the investigators' index of suspicion. Factitious disorder (probably underreported) is probably more common than full-blown Munchausen syndrome (probably overreported). In a recent survey of physicians from Germany, frequency estimates of factious disorder among their patients averaged 1.3 per cent, with dermatologists and neurologists giving the highest estimations.[31]

Of 1288 liaison psychiatric consecutive referrals, seen in a North American general hospital, 0.8 per cent had factitious disorder.[13] Similar figures have been reported by Dutch investigators.[14]

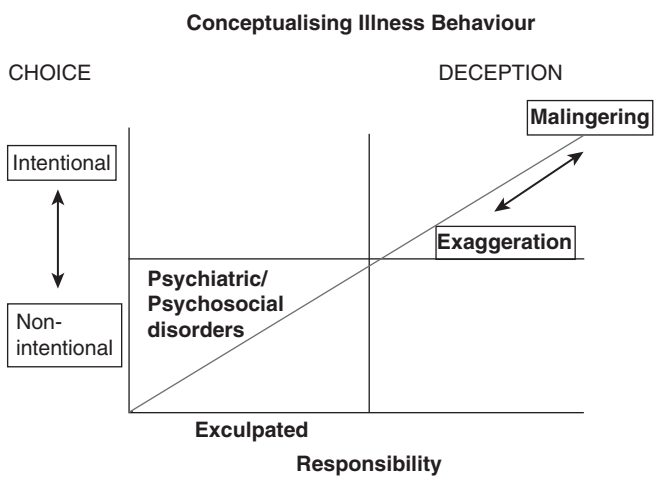

Fig. 5.2.9.1 Model of illness deception incorporating patient choice, free will and intentionality. (Reproduced from Bass, C. and Halligan, P. Illness related deception: social or psychiatric problem? Journal of the Royal Society of Medicine, **100**, 81–4. Copyright 2007, The Royal Society of Medicine Press.)

Prevalence rates for factitious disorder with psychological symptoms in patients under the age of 65 in a psychiatric hospital are approximately 0.4 per cent.[32]

Aetiology

There is little aetiological information, as large studies are lacking and the self-reported histories of many patients are fallacious. However, a number of themes are apparent[13]:

Developmental

- Parental abuse, neglect, or abandonment: Many factitious disorder patients experienced significant deprivation in childhood that left them with unfulfilled cravings for attention and care. These patients then seek to gratify these dependency needs by creating illness to obtain the 'attention and care' of the medical system
- early experiences of chronic illness or hospitalization

Medically related

- a significant relationship with a physician in the past
- experiences of medical mismanagement leading to a grudge against doctors
- paramedical employment

Physical

- Organic brain disorder: There is increasing evidence that neurobiological factors have a role in some patients, and it has been recommended that screening for evidence of brain dysfunction be carried out in these patients.[33] It is thought however that it is the pseudologia fantastica, and not the factitious disorder per se, that is associated with brain dysfunction (see previous section on Pathological Lying), though such a distinction may be difficult to support in clinical practice.

The authors have found it useful to conceptualize the problem using a cognitive behavioural formulation suggested by Fehnel and Brewer.[34] This allows the assessors to examine for relevant developmental factors and recent life events (especially losses or threatened losses and separations; see Fig. 5.2.9.2).

Course and prognosis

Factitious disorder may be limited to one or more brief episodes, but is usually chronic. For example, of 10 patients identified in a general hospital setting and followed up, at least one was known to have died as a result of factitious behaviour 4 months after the index admission.[13] Only one of the remaining nine patients accepted psychiatric treatment after discharge from hospital. Other authors have, however, reported a less gloomy outcome.[10] Outcome may be determined by how patients are managed, once their deceptions become manifest. Regrettably, the unmasking of the disorder is often the end of the story. Psychological support following hospital discharge may be associated with improved outcome.[10] Non-wanderers with more stable social networks may have a better prognosis than wanderers.[14] Engaging a patient with factitious disorder in long-term psychological treatment occurs so rarely that it often becomes the subject of a case report. One such report, of a 20-year follow-up of a patient with factious disorder with a favourable outcome is, in the opinion of the authors, the exception to the rule.[35]

Treatment

There are no systematic or controlled treatment studies on patients with factitious disorders. This is hardly surprising, as the patient's primary motive is deception, and the doctor's is to understand or unmask these motives, usually leading to rapid discharge from hospital after the deception has been exposed.

Management

Once the diagnosis is established, the doctor–patient relationship may have become irreparably damaged: negative emotions in the doctor may need to be dealt with before any consideration can be given to 'engaging' the patient in any therapeutic endeavour. Ethical and legal issues may also intrude (see below) and affect management. Although psychotropic medications have been used, the main treatment is psychological, using either confrontational or non-confrontational strategies.

Before treatment takes place however, it is important to establish the diagnosis, which is nearly always initially made by a non-psychiatrist, e.g. A and E physician, infectious disease specialist. A meeting should take place between the physician/surgeon and the psychiatrist and a strategy worked out before any confrontation or other approach is embarked on. These preliminary procedures are important and preparation before the joint interview is crucial (Table 5.2.9.1).

(a) Confrontational approaches

This process is easier if the physician has tangible evidence of fabrication, for example catheters, or medication used in the patient's deception. It is also desirable to have the psychiatrist present when

Table 5.2.9.1 Supportive confrontation: preparation and process (for non-psychiatrists)

- Collect firm evidence of fabrication, e.g. catheter, syringe, medication
- Discuss with psychiatrist (or hospital legal team if no psychiatrist available)
- Arrange meeting to marshall the facts; discuss strategy. Discuss with GP
- CONFRONTATION with patient should be non-judgemental, non-punitive, with . . .
- Proposal of ongoing support/follow-up
- If patient is a health care worker, the doctor should discuss with his/her medical defence organization
- Discuss the outcome of the confrontation with the patient's GP
- Document full record of the meeting and proposed outcome in patient's notes

the physician confronts the patient. The approach during confrontation and thereafter should be non-punitive and supportive, stressing continuity of care, and that the patient is a sick person who needs help. This approach was adopted in perhaps the largest published series of patients with factitious disorder treated systematically.[10] Thirty-three patients were 'confronted' with objects found in their room or with clinical data showing that their conditions were factitious. Only 12 (36 per cent) patients acknowledged the truth; the remaining 21 continued to deny that they played any role in creating their disorders. No confronted patient developed serious psychological disturbance or became suicidal, or discharged themselves against medical advice. Four of the most chronic cases became asymptomatic. Most, however, greeted the idea with either overt hostility or passivity and covert negativism.

More recently Krahn *et al.*[12] replicated these findings, but found that only one in six of their patients acknowledged their factious behaviour. Many patients will experience confrontation as humiliating and seek care from a different hospital. Others will refuse to see the psychiatrist with the treating clinician to discuss the deception, and discharge themselves against clinical advice.

(b) Non-confrontational strategies

These approaches, advocated by Eisendrath and Feder,[36] are less concerned with the origin of the illness and more with shaping future behaviours. Face-saving is a key element, and it is important for the patient to subsequently explain their 'recoveries' without admitting that their original problems were psychiatric.

One strategy is the therapeutic 'double-bind'. In this approach the patient is presented with two choices: prove that his or her disorder is not factitious by responding to a relatively minor and benign medical intervention, or prove that the disorder is factitious by failing to respond. For example, a woman was offered the double-bind for a wound that had failed to heal in 4 years despite numerous surgical closures. Following this strategy the plastic surgeon told her that her wound should respond to a skin grafting procedure. If it did not, it would mean that her disorder was factitious in origin. The graft took place, and there was no recurrence of infection at 2-year follow-up.[36] This approach has also been used with some success in the rehabilitation of three patients with factitious motor disorders.[37] The strategy was successful in providing patients with a face-saving legitimization of both their illnesses and recoveries.

Another face-saving approach uses 'inexact interpretations', i.e. suggesting a relationship between certain events or stressors, for example being abandoned, and emergence of factitious symptoms. It involves presenting a brief formulation of the problem to the patient, stopping short of overtly identifying the factitious origin. By avoiding confrontation the doctor makes it safe for the patient to relinquish the symptom with a feeling of control. Regrettably, none of these non-confrontational techniques have been evaluated in a systematic fashion.

(c) Systemic interventions

Patients with factitious disorders can create havoc on medical and surgical wards. They often elicit negative and hostile emotions in general hospital staff, especially after the deception has been exposed. The psychiatrist can help staff members to vent and reduce the anger they experience when a factitious diagnosis is confirmed, and also help the staff to understand the likely mechanisms underlying the factitious behaviour. These issues are often best addressed at a multi-disciplinary staff meeting. The major task of this group, which should include a member of the hospital medico-legal department as well as the patient's family doctor, is to develop practical treatment guidelines and to discuss the complex legal and ethical issues raised with factitious physical disorders. Some of these issues are discussed in the next section.

Ethical and legal issues

Patients with factitious disorders create unique ethical and medico-legal issues, some of which will be described below.

(a) Confidentiality

If no meaningful doctor–patient relationship exists or can be established, it has been argued that the physician is not bound by ethical codes, and that drastic solutions such as keeping 'blacklists' and the use of a central register can therefore be justified.[38] Objections to these approaches include breach of doctor–patient confidentiality and possible denial of treatment for genuine illness. Anyway, the use of aliases and poor record-keeping reduces the effectiveness of blacklists. Furthermore, physicians who disclose information without patient consent may have to justify the decision to their licensing body. In the United States, there is a consensus that disclosure should only occur where there is a specific risk to the patient and/or another party. In such situations, a multi-disciplinary staff meeting can help to develop treatment policy, and share responsibility for difficult decisions (see above).

(b) Invasion of privacy

The medical literature contains many descriptions of how the diagnosis of factitious disorder was established following a search of the patient's room or belongings. Some physicians, however, consider that such behaviour infringes patients' rights, and that no search should be undertaken without the patient's knowledge and consent. One way of avoiding this dilemma is to make it clear to the patient that factitious disorder is among the differential diagnoses, and then request permission for a room search. If needles or syringes are discovered during the course of treating the patient, the ethical issue of invasion of privacy does not arise.

(c) Involuntary hospitalization or treatment

Because the patient with factitious disorder may engage in behaviour that leads to permanent maiming or even death, it has been argued that in such cases a compulsory order may be used to protect the patient from himself or herself. This will provide time for

not only a more in-depth psychiatric assessment but also the development of a more trusting relationship with a therapist. This is a contentious subject, but some case reports do indicate that extended involuntary hospitalization may result in therapeutic progress.[39]

Induced factitious illness (Munchausen syndrome by proxy)

Meadow[40] first described this disorder as 'the deliberate production or feigning of physical or psychological symptoms or signs in another person who is under that individual's care', which has recently been renamed fabricated or induced illness or FII.[29] The perpetrator is usually the mother and the victim her child: the syndrome is considered to be a form of child abuse. The parent's aim is to have the child considered seriously ill: this may involve providing false histories, poisoning, or persuading doctors to carry out invasive and potentially dangerous procedures.

Factitious disorder and FII can be interrelated. Psychiatrists (and general practitioners) should be aware of the implications of a diagnosis of factitious disorder for any children of the index patient. For example, 75 per cent of mothers of these children have a history of a factitious or somatoform disorder, and most meet criteria for personality disorder.[41] With the birth of a child some mothers with pre-existing factitious disorder abandon dissimulation themselves, only to extend it to the next generation through factitious disorder by proxy. Because factitious disorder and FII can co-occur, the finding of one should always trigger judicious efforts to establish, or hopefully disconfirm, the other.

Long-term outcome in factitious disorder by proxy is poor, so active early intervention is recommended, with child protection agencies working closely with paediatric and psychiatric services (see also Chapter 9.3.3).

Factitious disorder in health care workers

If factitious disorder is diagnosed in a health care worker, the investigating psychiatrist should consider whether their continuing clinical work would pose risks to either patients (often children) with whom that person comes into contact (i.e. of factitious disorder by proxy), and/or the health of the factitious disorder patient himself or herself. These issues have been thrown into sharp focus by some highly publicized cases in both the United States and the United Kingdom.[42,43] Any employee who manufactures crises, for example multiple cardiac arrests and resuscitations, is obviously of great concern. The British commission that investigated the 1993 case made several stringent recommendations, for example 'We recommend that no candidate for nursing in whom there is evidence of major personality disorder should be employed in the profession'.[44] Nevertheless, psychiatrists should seek medico-legal advice before communicating concerns about such patients to any third party, including the employing hospital.

Malingering and exaggeration

Introduction

Malingering is the deliberate simulation or exaggeration of physical or psychiatric symptoms for obvious and understandable gain (e.g. financial compensation, disabled status and benefits, avoidance of criminal prosecution or conscription).

Treating doctors have been understandably reluctant to diagnose malingering lest it adversely affect the patient. However, recent research indicates that it may not be uncommon, especially where financial rewards attach to disability status, such as benefits for sickness or compensation for injury. We here describe some types of malingering seen in psychiatry, and discuss newer specialist psychological tools, especially *symptom validity testing*, which are emerging as useful additions to the overall assessment.

Definition

Malingering is not coded as a mental disorder in either ICD-10 or DSM-IV, although in the latter it is denoted as an 'additional condition that may be the focus of clinical attention'.

DSM-IV[2] suggests that malingering should be 'strongly suspected' when two or more of the following factors apply:

1 medico-legal context

2 antisocial personality disorder

3 discrepancy between complaints and objective findings

4 lack of co-operation with the assessment

This actually sets a very low bar: in effect, DSM advises it should be 'strongly suspected' in any disputed medico-legal case (where points 1 and 3 apply), but does not give guidance as to how this 'suspicion' should be followed up. The ICD-10 definition ('the intentional production or feigning of either physical or psychological symptoms or disabilities, motivated by external stresses or incentives') is broad, but again does not give practical suggestions regarding assessment.

Malingering includes:

1 Pure malingering: complete fabrication of symptoms

2 Partial malingering: exaggerating real symptoms or saying that past symptoms are continuing

3 False attribution: falsely saying that real health problems are due to a compensable accident or other circumstance

Epidemiology

Until recently, there has been little systematic information on prevalence, although it has generally been agreed that exaggeration of real symptoms is more common than outright faking expect them to dissimulate. Exaggeration, dissimulation, or feigning can be considered one of several rational/economic/adaptive options open to patients when seeking health care and/or limited social and welfare resources.

Using the 'Composite Disability Malingering Index' Griffin *et al.*[45] suggested that 19 per cent of disability claimants in the United States malingered to some degree. A recent study of 131 practicing members of the American Board of Clinical Neuropsychology provided estimates of the prevalence of malingering and symptom exaggeration for a variety of different clinical conditions.[46] In this study, estimates of the base rate of malingering/symptom exaggeration were calculated using over 33 000 annual cases seen by a group of clinical neuropsychologists. The reported base rates (when statistically adjusted to remove for the influence of referral source) were 29 per cent for personal injury, 30 per cent in the case of disability or workers compensation, 19 per cent in criminal cases, and 8 per cent in medical or psychiatric cases. The same rates

broken down by diagnosis revealed 39 per cent in the case of mild head injury, 35 per cent in fibromyalgia and chronic fatigue, 31 per cent in chronic pain, 15 per cent for depressive disorders, and 11 per cent in the case of dissociative disorders. In a separate review of 1363 compensation-seeking cases, Larrabee[47] found similar figures for mild head injury of 40 per cent. The use of symptom validity testing has confirmed these high rates of exaggeration (see under 'Psychological tests'). For example, about 42 per cent in the Canadian series of Richman *et al.*[48] and about 60 per cent in the United Kingdom in a series studied by one of the authors (Gill *et al.* submitted for publication).

Clinical features

(a) Malingered neurosis: post-traumatic stress disorder

The archetypal disorder after trauma is post-traumatic stress disorder. Malingering of other disorders seen after trauma, notably depression is less frequent, confirming malingerers' preference for dramatic positive symptoms such as nightmares and flashbacks.

In 1983 Sparr and Pankratz[49] described five men who claimed to have been 'traumatized' in the Vietnam War; three claimed to have been PoWs. It turned out that none had been PoWs, four had never been in Vietnam and two had never been in the services. The patients were seeking the generous benefits, which the United States accords to ex-service (Veterans' Administration) personnel. The key point in this paper was that the authors *supplemented their clinical assessment by seeking external data*, in this case service records; relying on clinical assessment alone would have led to wrong diagnosis. Seeking corroboration is vital in the assessment of possible malingering.

Rosen, in another classic paper, documented malingered PTSD in the case of the *Aleutian Enterprise*, a fish-processing ship, which sank in the Bering Sea in 1990.[50] Of the 31 on board, 9 were lost, 2 went back to sea, and the remaining 20 sued. Nineteen (86 per cent) of these 22 survivors consulted psychiatrists or psychologists with the key features of PTSD. But this is much higher than the expected rates: most individuals exposed to a traumatic event do not develop PTSD. Even if they do, it resolves over a few weeks or months in many cases, whereas here the claimants' symptoms did not show any tendency to resolve. Furthermore, they all had almost all of the classic features of the condition, in other words, they did not display the case to case variability, which would be expected in real individuals. Rosen documented that the patients had in fact 'shared symptoms' and had been 'coached' by their attorneys, some of whom had advanced the claimants money so they would not have to settle.

Most cases of suspected malingered post-traumatic stress disorder involve less dramatic civilian trauma, most commonly road accidents. Again, exaggeration of genuine symptoms is much more common than outright fabrication. For example, a person involved in a car accident, with apparently genuine phobic travel anxiety, may report that they have nightmares and 'flashbacks', but their description of these experiences lacks vividness on close enquiry. Holistic assessment is vital; if a minor accident is to be accepted as causing a severe psychiatric condition such as PTSD, there must be some evidence of pre-existing vulnerability. Otherwise, the apparent result will be disproportionate to the cause, and the possible influence of external incentives on symptom presentation will need to be considered.

(b) Malingered psychosis

This disorder can occur in various circumstances, for example in homeless persons wishing to obtain shelter in hospital, in previously psychotic inpatients whose discharge is imminent, in illegal migrants seeking to avoid deportation or in criminal defendants trying to avoid standing trial or to influence sentencing.

A (perhaps somewhat academic) distinction can be made between malingered and factitious psychosis, in that malingerers are conscious of their motivation, and their goal is not merely confined to gaining patient status. However, the following description covers both. It is 'positive' symptoms, which are usually mimicked (e.g. hallucinations). They are often dramatic or bizarre. Patients are keen to describe them at interviews, unlike, for example, most patients with schizophrenia. Symptoms are obvious during assessments, less so when the patient is unobserved. More subtle features of genuine psychosis, such as thought disorder and negative symptoms, are absent. Florid hallucinations may be unaccompanied by delusions, which would be unusual in genuine psychosis.

For example, Jaffe and Sharma[51] described nine defendants on serious criminal charges that developed uncommon symptoms such as coprophagia and 'seeing little green men'. Eight were judged to be malingering, and fit to plead, based on evidence such as the association between visual hallucinations and organic brain syndromes, of which there was no evidence on investigation. Malingering in forensic settings also includes feigned memory deficits, when isolated amnesia for an alleged crime would place malingering in the differential diagnosis. Forensic psychiatry is dealt with elsewhere in this book.

Ganser syndrome does not appear in current classifications. It was originally described in prisoners, as comprising confusion and so-called 'approximate answers' (or Vorbereiden: *Question*: for example: how many legs has a horse? *Answer*: three). If true confusion (diminished level of consciousness) is present, the diagnosis is the cause of this. Approximate answers may be seen in several conditions, including mental retardation, organic brain disorders, and malingering; again, the diagnosis will be the underlying condition. The term Ganser syndrome has now largely and rightly been dropped.

(c) Malingered cognitive deficit

Study of cognitive deficits following brain injury has recently led to advances in understanding of malingering, through the development of special neuropsychological tests, especially *effort testing*, to gauge the effort the patient brings to cognitive testing. These tests seem likely to have broader application than just brain injury assessment.

Discussion of the question of malingering post head injury has until recent years been rich in opinion, though comparatively light on facts. Miller's view,[52] long influential, was that many patients malingered their memory and other cognitive symptoms and that symptoms were in inverse proportion to injury severity and were only resolved with receipt of compensation. He used the term 'accident neurosis'. Mendelson, by contrast,[53] found that disability continued after settlement in many patients, and inferred from this that disability was generally not malingered.

The question is obviously not capable of being resolved scientifically without data. But such data is now becoming available. Recent findings however have supported Miller's original observations that embellishment rises as injury severity decreases in a

compensable context.[54] Moving forward from mere debate, the American Academy of Neuropsychologists recently published a consensus statement which concluded that 'Symptom exaggeration or fabrication occurs in a sizeable minority of neuropsychological examinees, with greater prevalence in forensic contexts', and that the use of effort testing is mandatory in neuropsychological assessments.[55]

In clinical assessment, immediate recall (e.g. digit span) is important, as even organic amnesic patients (e.g. Korsakoff's syndrome) perform normally; poor performance suggests that poor motivation or malingering should be among the differential diagnoses. Claims of being unable to remember personal information (e.g. name and birthday, also preserved in organic amnesia), yet having been able to come to the assessment independently, are highly suggestive of malingering, but seen only in gross cases. However, these 'bedside' tests are only a guide: psychiatric assessment of brain injury patients is not complete without quantitative assessment of cognitive function, including effort testing (see below).

(d) Malingered physical disease

This usually presents either as a referral to a liaison psychiatrist, or in a medico-legal context. A frequent example is a patient with post-injury back or neck pain who is involved in litigation or seeking disability payments. Often, some form of accident has undoubtedly occurred, so the potential for initial physical injury is not in doubt; but the length and severity of symptoms, disability, and distress may seem out of proportion, and raise the possibility of malingering.

In a seminal paper, Richman[48] administered effort testing to 106 people claiming injury or sickness benefits. Forty-five (42 per cent) failed. On one easy subtest, those who failed the effort test overall had a similar score on average to patients with dementia tested previously, even though none of them had a clinical diagnosis of dementia. Schmand et al.[56] found that 61 per cent of litigants after whiplash neck injury had evidence of underperformance on memory testing compared with 29 per cent of outpatient controls. The underperforming litigants scored as low as controls with definite evidence of closed head injury.

Classification

Malingering should be distinguished from factitious disorder, and from other syndromes such as hypochondriasis, other somatoform disorders, and conversion/dissociation disorder. These distinctions may involve difficult judgements such as how 'intentional' is the production of a symptom, or how 'genuine' it is. As an alternative, it has been suggested that such patients lie on a continuum between those in whom the production of symptoms is assumed to be wholly unconscious (conversion/dissociation disorder) and those in whom it is wholly conscious (malingering, factitious disorder).

However, use of the concept of the unconscious has to be very cautious when there are external incentives. It stretches credulity to think that a claimant would be conscious of there having been an accident so as to pursue litigation, and conscious that the outcome could include financial compensation, but somehow unconscious that presentation of symptoms could form a desired link between the two.

It is possible that the emergence of effort testing may cast new light on the area of unexplained physical symptoms. For example, the concept of somatoform disorders assumes that the symptoms are not consciously produced. However, if large-scale studies reveal that a substantial proportion of somatoform patients turn out to fail effort tests, or in other words to display evidence of conscious symptom exaggeration, then the concept of somatoform disorders may need to be re-examined.

Diagnosis and differential diagnosis

Doctors' training and culture rightly encourage the treating physician towards a generally trusting relationship with his patients. However, assumptions that patients' accounts are generally trustworthy and that malingering is rare are not appropriate if the main responsibility of the doctor lies elsewhere, for example, to the Court, if he is preparing an expert report.

Identifying ungenuine cases requires an enquiring approach, and the methodical use of all sources of information:

- awareness of the possibility of exaggeration or faking of symptoms
- neutral attitude
- open questions initially; use closed questions with caution
- unlikely questions (see below)
- mental state—changes appropriately as sensitive topics discussed?
- informants (but they may also have vested interests)
- observation—overt (e.g. in a ward) or covert (e.g. video surveillance)
- medical records (and legal documents if applicable)
- look for consistency of accounts
- standard psychometric tests—consistency of results across measures
- specialist instruments: symptom validity tests

The medical notes should be read, ideally before interview, especially the general practice records, and any discrepancies noted for specific enquiry. Legal assessments, case papers and previous reports should be studied.

In the clinical interview, a neutral attitude is essential; a confrontational approach, even if malingering is strongly suspected, may cause further exaggeration of symptoms. Open questions should be used at first. Closed questions should be avoided (e.g. 'Do you ever get nightmares where you seem to re-experience the accident?'). The careful use of unlikely questions can be useful. For example, in suspected malingered post-traumatic stress disorder the answer 'Yes' to the question 'Have you had any problems with colour vision since the accident?' would be suggestive, but would still need clarification with open questions. 'I am now colour-blind' might suggest malingering, but 'Red makes me nervous—it was a red car which crashed into me' might not.

Questions must be appropriate to the case, ideally prepared beforehand and introduced tactfully to prevent the patient feeling that the interviewer is attempting to 'catch him out'. The interviewer should look for the clinical characteristics of the particular malingered disorder in question.

Surveillance by video or other means may be used by lawyers or insurers, although is seldom initiated by clinicians, for ethical reasons (except perhaps in suspected factitious disorder by proxy—see Chapter 9.3.3).

Psychological tests

Since the last edition of this book, consensus has developed that symptom validity testing is essential in neuropsychology, that is, in the field primarily concerned with memory problems and brain injury. The tests in practical use are in fact specialized memory tests, and it is likely that their use will be extended from head injury cases to other cases in which memory complaints occur (such complaints are in fact very common in patients with pain or distress for any reason). We are about to discuss what currently appear to be the leading symptom validity tests in UK neuropsychology, the Word Memory Test[57] and the ToMM,[58] but first we mention some other tests by way of historical background.

Inconsistent patterns of response on standard instruments (e.g. high scores on one measure of depression and low on another) might be suggestive. However, this should not be overinterpreted, because there is substantial test–retest variation on many tests, and there is also variation between subscales on the same occasion. Certain subscales of the Minnesota Multiphasic Personality Index have been proposed as measures of tendency to malinger. Specialist instruments have been developed, for example the Structured Inventory of Malingered Symptoms,[59] which identifies features associated with malingering such as endorsement of rare symptoms, which occur only infrequently in clinical populations. However, consensus on such tests remains some way off and they are not in general use in the United Kingdom.

Tests for malingered memory deficits present memory tasks, which appear difficult but are in fact easy. For example, 50/50 psychiatric and 10/16 mentally retarded inpatients were able to recall nine of the 15 items on the Rey 15-item.[60] Forced choice testing (e.g. Portland Digit Recognition Test) is another approach. A sequence of digits is presented. Subjects must identify it among two further sequences, one identical and the other different. By chance alone, they must score around 50 per cent on a large number of items, and so below chance scores (below 50 per cent) strongly suggest malingering.[61] However, this is very gross, and will miss many cases where the degree of exaggeration is less. Again, these tests are not in general use in the United Kingdom.

In the United Kingdom, the Word Memory Test and the ToMM have become established as leading symptom validity tests in neuropsychology. They are regarded as having the best research support and are administered in standard formats.

TOMM stands for *Test Of Malingered Memory*.[58] It is a pictorial test, not computerized, and is mainly used by psychologists. Word Memory Test (WMT) (Green: wordmemorytest.com) is available either on paper or on computer. It is mainly used by psychologists as part of a 'battery' of neuropsychological tests. An abbreviated form for physicians, the Medical Symptom Validity Test, is available.[57] The key point is that patients are given a test of memory, which looks difficult, but is in fact known to be easy from previous administration to control subjects.

Someone making a **good effort:**

- scores well on tests which are in fact easy (even though they may look hard)
- scores lower on more difficult tests

Someone making an **inconsistent or poor effort**:

- may score low on tests which look hard (though they are in fact easy)
- may not score lower on more difficult tests

If the patient's scores are low, where even say primary school children score almost perfectly, it would suggest that he might not have been making a full effort on the test. If at the end of the test he said that he had made a full effort, this would be evidence that his self-report of effort brought to cognitive testing is not accurate. This would be consistent with the proposition that he might have been exaggerating at least the memory aspects of his complaints, and by extension, possibly other symptom areas also.

Aetiology

Malingering is not a mental disorder, so complex general theories about causation are unlikely to be helpful. It has been suggested for example that[62] 'adaptation' is the simplest model for malingering: ' . . . malingering is more likely to occur when the evaluation is perceived as adversarial, when the personal stakes are very high, and when no alternatives appear to be viable'. However, this really just restates the problem in different terms. Nor do the 'response styles' described by psychologists seem to offer fundamental insights. It is more helpful to consider each case in a common sense way, bearing in mind the presence or absence of external incentives, and the results of the holistic assessment process outlined above, in combination with the results of symptom validity testing.

Course and prognosis

Malingerers are so heterogeneous that it is impossible to state prognosis in general. There are few adequate follow-up studies.

In forensic and inpatient settings, malingering is usually episodic, associated with particular circumstances such as impending discharge, trial, or change in conditions of imprisonment (e.g. transfer to a single cell or hospital wing). The behaviour often stops when the circumstances no longer remain, although they may recur. Similar situations occur in persons facing conscription, or in migrants at risk of repatriation.

The prognosis of malingering *in personal injury litigants* is unknown. Studies indicating poor outcome of many compensated litigants cannot be extrapolated, as the number of malingerers in these samples is unknown. Clinical experience suggests that patients with long-standing disability, even if partly or wholly non-organic, often fail to recover fully in any event.

Treatment

There is very little evidence on management, which will largely be dictated by whether the clinician has clinical responsibility, or whether he or she has been asked to give an opinion to a third party. Even if the diagnosis of malingering is clear, it may be appropriate to inform the referrer, rather than the patient directly, as the patient may become very angry. If there is a psychiatric disorder present when, as it were, the dust has settled, then this should be treated in standard fashion.

Clinical experience is that patients for whom the exercise of attempted malingering seems worthwhile do often have substantial pre-existing psychosocial problems, including lack of skills or employment; there is a tendency towards a regionality of such claims, with areas of deprivation ('rust-belt') overrepresented.

Efforts at retraining and vocational rehabilitation may be more likely to be of assistance in the long-term than specialist psychiatric care.

Possibilities for prevention

These seem mainly confined to malingering after injury. First, systems of litigation should be expedited. Prolonged cases certainly make for exaggeration of symptoms and disability. Second, some patients with chronic disability, irrespective of cause, do respond to rehabilitative treatment (e.g. programmes assisting in return to work or in the management of chronic pain), even at a late stage. If such programmes were easily and generally available at an earlier stage in the evolution of the disorder, symptoms and subsequent disability could certainly be ameliorated or even prevented in some patients.

Ethical legal and personal issues

As previously indicated, malingering poses a number of particular challenges to the doctor himself and to the doctor–patient relationship, including amongst others the following.

There is no doubt that seeing substantial numbers of likely ungenuine patients has the potential to affect the practitioner himself. Appropriate 'supervision', as in psychotherapy, may be appropriate.

If the doctor has a treatment responsibility to the patient, he naturally tends to give the patient the benefit of doubt, for example in respect of disability payments. But he will be wise to be cautious: if, for example, he signs a form saying that the patient cannot undertake certain activities of daily living, but without direct observation of that, he could potentially be considered to be an accessory if the claim was subsequently found to be fraudulent.

The use of the word 'malingering' itself in reports must usually be avoided, as it is tantamount to an accusation of a criminal offence such as deception. The medical duty is to present the evidence to the Court, which can then decide the question itself.

Finally, it must not be forgotten that the Data Protection Act gives patients the right to see personal information about themselves such as medical reports. Any suggestion of ungenuine presentation in reports must therefore be well-founded on evidence and properly argued.

5.2.10 Neurasthenia

Felice Lieh Mak

Introduction

The term neurasthenia has had a variegated history, and although retained as a diagnostic entity in the ICD-10 it does not appear in the DSM-IV. In cultures where neurasthenia still enjoys popular professional and lay acceptance it has a variety of usages:

- a nosological entity
- an idiom for expressing distress
- a culturally sanctioned illness behaviour
- an explanatory model for a constellation of somatic symptoms
- an euphemism for avoiding the stigma of mental disorder.

Therefore, in diagnosing, understanding, and managing neurasthenia the clinician has to be aware of the context in which the term is used.

Concept and diagnostic entity

The concepts of nervous weakness and asthenia (debility, lack of strength) have existed throughout the history of medicine. Hippocrates described the illness of the Scythians as a general asthenia linked to damage to the genitalia caused by horseback riding. In France, Bouchut (1764) described a syndrome similar to the latter-day neurasthenia, which he called 'neuropathie'. Cullen (1772) conceived muscles and nerves as a unitary nervous force and all diseases as movements against the nature of that nervous force. He coined the word neuroses for this process and postulated that diseases were due to the various alternations of excitement and atony in the nervous system. A few years later, his pupil Brown (1780) elaborated on the hypothesis by dividing diseases into sthenic diseases, which were due to excessive excitement, and asthenic diseases, which were due to deficient excitement. These views on the polarity of the nervous system as a cause of mental illness set the scene for neurasthenia to become a disease entity.

By the beginning of nineteenth century the term neurasthenia was already in use. In 1869, Van Deusen in Holland published a monograph on neurasthenia. This was quickly followed by the publication of a paper, which Beard[1] had presented to the New York Medical Journal Association. Beard based his description of the disorder on a series of 30 cases. In reorganizing the subjective nature of the complaints and the unique clustering of symptoms in each patient, Beard had difficulties in attempting to limit the number of symptoms that constituted the syndrome; he started with 50 symptoms and expanded it to 75 in later publications.

Eventually it became clear that the expanding kaleidoscope of symptoms should be managed in a way that made some sense. Beard approached this problem by organizing the symptoms into subtypes of neurasthenia: cerebrasthenia (cerebral exhaustion) characterized by symptoms that were directly or indirectly connected with the head; myelasthenia (spinal exhaustion) was defined by symptoms related to the involvement of the spinal cord; digestive asthenia was characterized by dyspepsia, constipation, and flatulence. As time went on more subtypes were added by other investigators and specific treatment approaches were developed.

Despite the over inclusiveness of the term, Beard maintained that neurasthenia belonged to one family with a common pathology, prognosis, history, and treatment. As more cases were reported, he felt able to claim that neurasthenia was predominantly an American illness.[2] He attributed the increase in prevalence to the pressures of modern civilization.

Notwithstanding its vagueness, or perhaps because of its vagueness, neurasthenia gained popular acceptance not only by the medical profession but also by the general public. Although by the turn of the century it had become practically a household word, its popularity did not preclude dissent. Most of the criticisms focused on the disorder's over inclusiveness and lack of precision; for instance, Brill called it 'the newest garbage can' in medicine.

The first two decades of the twentieth century witnessed an increasing number of discoveries of more specific causes of disease. This period also saw greater attention being paid to the taxonomy of neuroses. These forces combined to bring about the decline of neurasthenia as a diagnostic entity.

In 1895, Freud published two seminal papers in which he drew up the blueprint for reconfiguring the various neurotic disturbances that were grouped together under the term neurasthenia. In the paper entitled 'On the grounds for detaching a particular syndrome from neurasthenia under the description of 'anxiety neurosis'[3] he questioned the validity of continuing to allow neurasthenia to cover all the symptoms described by Beard. He saw the need to classify different categories of neuroses based on the following:

- collection of symptoms that were more closely related to one another
- common aetiology
- common psychical mechanism.

In the paper 'Obsessions and phobias: their psychical mechanism and their aetiology',[4] Freud removed obsessions and phobias from neurasthenia. As a result of these two papers, neurasthenia ceased to be an amorphous concept and was differentiated into the following categories:

- neurasthenia proper
- anxiety neuroses
- obsessions
- phobias
- pseudoneurasthenias due to cachexia, arteriosclerosis, early stages of the general paralysis of the insane, and psychoses.

Intermittent and periodic types of neurasthenia were to be included under melancholia.

The first list of symptoms Freud proposed for neurasthenia proper included headache, spinal irritation, dyspepsia with flatulence, and constipation. Later, he added sexual weakness and fatigue.

The possibility of including some neurasthenic symptoms under melancholia was mentioned but not expanded on by Freud. This task was taken up by Kraepelin.[5] He distinguished three major types of depression: manic–depressive disorder, involutional melancholia, and a milder form of neurasthenic depression. He asserted that all these types of depression were due to an underlying disordered brain function.

Having been so denuded, the use of the term neurasthenia as a diagnostic entity by the medical professions had declined in the United States by the time of the First World War. The first edition of the DSM-I published in 1952 gave no formal recognition to neurasthenia. Instead, it was replaced by the category of 'Psychophysiological nervous system reaction', the predominant symptom of which was general fatigue. In an effort to make DSM-II congruent with ICD-8, neurasthenia reappeared in American psychiatry as neurasthenic neurosis.

In DSM-III neurasthenia disappeared as an entity and appeared only in the index where readers were asked to refer to 'Dysthymic disorder'. However, unlike the DSM classification, neurasthenia consistently remained a subtype of neurosis throughout the many versions of the ICD. ICD-9 defined neurasthenia as follows.

> A neurotic disorder characterized by fatigue, irritability, headache, depression, insomnia, difficulty in concentration, and lack of capacity for enjoyment (anhedonia). It may follow or accompany an infection or exhaustion or arise from continued emotional stress.

The following categories were included:

- fatigue neurosis
- nervous disability
- psychogenic asthenia
- general fatigue.

Spread to other countries

One of the most fascinating aspects of the history of neurasthenia is its ready acceptance by countries other than the United States where it was originally conceived as a peculiarly American phenomenon. The diagnostic entity took firmer root in some countries than in others. In many countries the concept was indigenized and took on local cultural colour.

The reasons for its spread can be summarized as follows:

- The all-embracing nature of the entity provided a foothold for almost everyone involved.
- The concept provided a blend of scientific theory, thus lending legitimacy to a cluster of symptoms, which are mostly subjective.
- It is considered to be a disease resulting from overwork, which affects the upper social class.

Asia and Australia

In all probability neurasthenia was introduced into China in the 1920s by American psychiatrists and returning Chinese doctors who were trained in the United States. Up to the end of the Second World War, Chinese physicians accepted and used the diagnostic concept of neurosis and neurasthenia from the United States. With the firm establishment of communism in 1949, Pavlovian theory was adopted as the sole model on which Chinese psychiatrists practice, teach, and research.[6] In China, as in the former USSR, neuroses were divided into neurasthenia, psychasthenia, and hysteria. The cause of neurasthenia, as indeed of neuroses, followed the Pavlovian theory of overstrain in the excitation and inhibition processes and mobility of the higher nervous system.

The concept of neurasthenia or *shenjing shuairuo* (nerve weakness), as translated by the Chinese, was not an entirely alien idea. The symptoms associated with neurasthenia (fatigue, loss of memory, poor attention span, headache, tension, insomnia, and all varieties of vague pains) are similar to those in patients suffering from a deficiency in *qi* (vital essence), that is weakness of the kidney, spleen, or heart in traditional Chinese medicine. In addition, the theory of nerve weakness and depletion of nervous energy as causes of neurasthenia fits in with the traditional Chinese medicine concept of organ weakness and *yin–yang* deficiency. Thus in no time at all neurasthenia was incorporated into the body of the practice of traditional Chinese medicine and the vocabulary of the lay public.

In the 1950s, the number of patients suffering from neurasthenia increased enormously. Medical or neurology clinics reported that 80 to 90 per cent of their outpatients were suffering from neurasthenia. It was particularly rampant among the 'brain or mind workers'. The Chinese government regarded it as a serious public health problem, so much so that in its First Five Year Plan (1958–1962) a large-scale national campaign was initiated to eradicate neurasthenia. Research on neurasthenia carried out during this period focused on the role of stress as the external factor, and on heredity and personality as endogenous factors. Treatment included intensive group re-education, herbal medicine, and tranquillizers. Lin[7] postulated that the marked increase in neurasthenia was due to the presence of a deep-seated tension in the revolutionary development of China during the 1950s. Neurasthenia became the vehicle to express political, social, and physical stresses.

About a decade after China's 'open-door policy', an epidemiological survey was conducted in 12 districts in China. The instrument used was the Present State Examination. The results showed that neurasthenia affected 12.59 per cent of persons aged from 15 to 59 years, accounting for 56.7 per cent of all neurotic disorders.[8] In 1982, Kleinman[9] conducted a study of 100 patients diagnosed with neurasthenia in the Psychiatric Outpatient Clinic of the Hunan Medical College. He found that 89 patients satisfied the DSM-III diagnostic criteria for 'Major depressive disorder', 70 per cent of whom responded substantially to antidepressant medication. Despite their improvement, few experienced decreased help-seeking behaviour. This led him to conclude that neurasthenia should be regarded as a special form of somatization related to culturally sanctioned idioms of distress.

In Taiwan, neurasthenia attracted little interest among western-trained doctors. However, it became enormously popular among traditional Chinese doctors, and consequently neurasthenia established itself as a major disease in the minds of the Taiwan public during the 1940s and 1950s.[10]

The mostly British-trained doctors in Hong Kong largely ignored neurasthenia as a diagnostic entity. As in Taiwan, neurasthenia became the domain of traditional Chinese doctors.[11]

In the late nineteenth century psychiatry in Japan was essentially German in orientation. Psychiatrists applied the diagnosis of neurasthenia to patients who presented with weakness, headaches, mental distraction, fatigue, and reduced psychic productivity.[12] The diagnostic entity became a popular term until Morita[13] supplanted it with the term *shinkeishitsu* (nervous or nervous disposition). He described this disorder as basically a psychological reaction to anxiety in predisposed personalities—the personality type being characterized by introversion, perfectionism, hypochondria, hypersensitivity, and self-consciousness. He developed a specific treatment aimed at breaking up the vicious cycle of sensitivity and anxiety, the initial phase of which consisted of isolated bed rest followed by a second phase of work therapy.

Doctors in Malaysia, Singapore, India, Pakistan, Burma, and Sri Lanka are mostly trained in the British tradition. After the First World War neurasthenia lost its popularity in Britain. Standard British textbooks regarded the disorder as rare and outmoded. As a result psychiatrists in these countries tended not to diagnose neurasthenia. However, neurasthenia is used in the Chinese communities where traditional Chinese medicine maintains a stronghold. In India and countries where Ayurvedic medicine is practised, neurasthenia was not added on to the more traditional ways of explaining fatigue, pain, dizziness, and headaches. Instead, concepts such as *dhàtu* loss (loss of semen) and *vàta roga* (wind disease) remained the preferred explanation.

In Australia, Paterson[14] reported that over a 15-year period from 1950 to 1965 neurasthenia was one of the 10 major illness categories reported by a large Sydney-based industry. He claimed that, since he had a fairly representative sample, the 10 categories of illness could very well apply to the rest of Australia.

Europe

From 1880 to 1920 neurasthenia was one of the diseases most frequently discussed. From an 'American nervousness' it rapidly evolved into a western European bourgeois illness. Practically every academic neurologist and psychiatrist wrote a major piece on neurasthenia (see Drinka[15]).

In England, neurasthenia was described in Osler's *The Principles and Practice of Medicine* published in 1900.[16] During the First World War it was a common diagnosis used for invaliding out many soldiers. In order to cope with its diagnosis, treatment, and disposal, the Army instituted a short course of training for medical officers who graduated with the title of 'neurasthenic expert' (see Sims[17]).

Russian psychiatry is largely based on Pavlovian psychophysiological theories. The Pavlovian classification of the principle of neuroses was adopted by all countries that came under the influence of the former USSR. Opinions on the subdivisions of neurasthenia were divided in Russia. One school of thought based its classification on the course of the illness, and the other was based on aetiology.[18] Neurasthenia as a cause of inefficiency and low productivity in the workplace was a recurrent theme in both Russia and Eastern Europe.

Current usage

In ICD-10,[19] neurasthenia is classified as a neurotic disorder in which two main, but overlapping, types of neurasthenia are described:

- the predominant symptom is increased fatigue after mental effort
- predominant feelings of bodily or physical weakness and exhaustion after only minimal efforts.

For a definite diagnosis ICD-10 requires the following:

(a) either persistent and distressing complaints of increased fatigue after mental effort, or persistent and distressing complaints of bodily weakness and exhaustion after minimal effort;

(b) at least two of the following:

- feelings of muscular aches and pains
- dizziness
- tension headaches
- sleep disturbances
- inability to relax
- irritability
- dyspepsia;

(c) any autonomic or depressive symptoms present are not sufficiently persistent and severe to fulfil the criteria for any of the more specific disorders in this classification.

The following are excluded:

- asthenia not otherwise specified
- burn-out
- malaise and fatigue
- postviral fatigue syndrome
- psychasthenia.

DSM-IV does not include neurasthenia as a nosological entity. Instead, it is replaced by 'Undifferentiated somatoform disorder'.

In the third edition of the *Chinese Classification of Mental Disorders*[20]neurasthenia is classified under 'Neurotic disorder'. The criteria for diagnosis have been made more stringent, requiring three symptoms out of five non-hierarchical groups of symptoms, which include weakness, emotionality, excitement, nervous pain, and sleep disturbance. The duration of the symptoms should be at least 3 months. Other psychiatric disorders have to be excluded. Because of the different connotations of fatigue and weakness in Chinese culture, fatigue is not included in the list of symptoms.[21]

Differential diagnosis

Fatigue is a ubiquitous symptom. It can occur in many psychiatric illnesses and in a wide range of physical illnesses. In cultures where the term neurasthenia is loosely used, many of the cases would probably meet the ICD-10 or DSM-IV diagnostic criteria for depressive disorder or anxiety disorder. Physical illness is a common cause of fatigue. In this respect, a detailed history and judicious investigation will be necessary.

Epidemiology

Merikangas and Angst[22] studied a cohort of young adults from a community sample in Zurich, Switzerland, and reported the prevalence of neurasthenia, defined according to the ICD-10 criteria, as 1 per cent across 10 years. The sex ratio across the 10 years of follow-up revealed an equal prevalence among males and females during the initial stages of the study, but females exhibited an l.6-fold greater rate than males during the later stages.

The World Health Organization (WHO) international study[23] of patients with psychological problems seen in primary-care settings reported a prevalence of 1.7 per cent of pure neurasthenia. The prevalence rate increased to 5.4 per cent when the syndrome was diagnosed comorbid with depression or anxiety. The prevalence rate in each centre is shown in Table 5.2.10.1.

The differences in the prevalence rate can be due to many factors, including perception of what health services can treat and the existence of alternative sources of care.

The results of an epidemiological study conducted in 1998 in seven areas in China showed a prevalence rate of 2 per cent.[24]

In a national survey by the Australian Bureau of Statistics Hickie *et al.*[25] reported that 1.5 per cent of the general population met the ICD-10 criteria for neurasthenia in the past year.

All the studies were consistent in demonstrating that the syndrome tended to affect patients below the age of 45 and the absence of significant gender differences.

Aetiology

Although theories abound, the predisposing, precipitating, and perpetuating causes of the syndrome remain unclear.

Table 5.2.10.1 Prevalence of neurasthenic syndrome among patients contacting general health care facilities

Centre	Overall prevalence (%)	Males (%)	Females (%)
Ankara	4.1	1.0	5.6
Athens	4.6	3.3	5.2
Bangalore	2.7	1.7	3.7
Berlin	7.4	4.0	9.7
Mainz	7.7	7.4	8.0
Groningen	10.5	7.1	12.8
Ibadan	1.1	3.4	0.2
Manchester	9.7	6.1	11.3
Nagasaki	3.4	3.8	3.0
Paris	9.3	5.0	14.2
Rio de Janiero	4.5	2.3	5.3
Santiago	10.5	6.4	12.1
Seattle	2.1	2.3	2.0
Shanghai	2.0	1.5	2.2
Verona	2.1	1.8	2.3

Course and prognosis

The 10-year follow-up study conducted by Merikangas and Angst[22] revealed that approximately 50 per cent of patients continued to exhibit symptoms. The WHO study[23] reported that patients with a diagnosis of neurasthenia had, on average, been disabled for 8 to 7 days during the month preceding the examination. Hickie *et al.*[25] confirmed the chronicity of the condition. They reported that 80 per cent of people who met the ICD-10 criteria in the past 12 months were also current cases.

Comorbidity

In the Australian study Hickie *et al.*[25] showed that there was more comorbidity with major depression, panic disorder, and generalized anxiety disorder than could be expected by chance after adjustment for the prevalence of the comorbid disorder and the average level of comorbidity of that disorder.

Treatment

Although there are reports that antidepressants can be effective these are not supported by published data on randomized double-blind controlled trials. Indeed, no such trials have been carried out on any form of psychiatric treatment for neurasthenia. In the absence of such data the clinician will have to rely on the adage of 'When not able to do any good, avoid doing any harm'. Thus aggressive treatment and investigations should be avoided. Patients are best managed in a supportive relationship with due regard given to their psychological and psychosocial needs.

General and non-specific strategies may also be used. These can include regular graded increase in exercise, promotion of sleep hygiene, cognitive techniques to break the cycle of symptoms leading to decreased activities, and improving social support.

Clinicians working in an environment where people with mental illnesses are stigmatized might find it easier to accede to social demands. Clinicians work at two levels in these situations. At one level he or she will have made a diagnosis of a psychiatric disorder and have prescribed the appropriate treatment. At another level the practitioner will be using neurasthenia as a euphemism for mental illness. Therefore, until stigmatization can be reduced or abolished, this unenviable state of affairs will continue.

Complementary medicine

The extracts of leaves from the *Ginkgo biloba* tree contain ginkgoflavone glycosides and trepenoids. *Ginkgo* is widely used as a cognitive enhancer. The roots of the *Panax ginseng* contain several triterpine glycosides, which are believed to have physical performance enhancing properties. This root is used in traditional Chinese medicine to treat a large variety of diseases including neurasthenia. Wesnes *et al.*[26] evaluated the effects of a *Ginkgo biloba/ginseng* combination on 64 healthy volunteers who fulfilled the ICD-10 criteria for neurasthenia. This was a 90-day, double-blind, placebo-controlled, parallel group study. They reported that the combined dose of 120 mg *Ginkgo* extract and 300 mg of *ginseng* extract was significantly better than placebo in reducing the symptoms of neurasthenia by day 90. Adverse effects were nausea and abdominal pain.

The mushroom, *Ganoderma lucidum*, known as lingzhi in China has been widely used to treat cancer, diabetes, and neurasthenia. It is the only known source of ganoderic acid, which has a molecular structure similar to steroid hormones and is a source of biologically active polysaccharide. *Ganoderma* is one of the most highly ranked herbal medicines by Asian people. Tang *et al.*[27] conducted a randomized, double-blind, placebo-controlled parallel study to investigate its efficacy and safety in the treatment of Chinese patients who fulfilled the ICD-10 diagnostic criteria for neurasthenia. Their findings indicated that *Ganoderma* was significantly superior to placebo with respect to the clinical improvement of symptoms in neurasthenic. Adverse effects were mild consisting of nausea, dry mouth, and vomiting.

Complementary medicine is increasingly being used either as an alternative or in addition to conventional psychotropic medications. Refer to Chapter 6.2.9 for further information.

Future directions

As to whether neurasthenia will be replaced by chronic fatigue syndrome (Chapter 5.2.7) or subsumed under somatoform disorders (Chapter 5.2.1), and thus be relegated to a footnote in the history of medicine, or will enjoy resurgence with a new set diagnostic criteria will be determined by future research and clinical data.

5.3

Medical and surgical conditions and treatments associated with psychiatric disorders

5.3.1 Adjustment to illness and handicap

Allan House

Introduction

Not everybody who develops a serious physical illness will have psychiatric problems as a consequence. To understand why, it is useful to have a model of the normal process of adjustment to stress; psychiatric disorder can then be seen as arising when that process, often called coping, is either maladaptive or is adaptive but only partially successful. This chapter will start with an outline of one theory of stress and coping as it applies to physical illness, followed by a review of disorders of adjustment to illness. A distinction will be drawn between recent-onset illness, which provokes an acute response, and long-standing illness, where the challenge is more often to adjust to chronic disability.

Adjustment to illness and handicap

A number of diseases are reviewed in later chapters, and therefore this chapter will deal with general principles. For more details on particular diseases, the reader should consult specialist textbooks of psychiatry or health psychology.

Illness as a stress

Stress is a word that is used in different ways. Sometimes it refers to an environmental stimulus—a threat or demand from the outside world. This definition lies behind various measures, such as the Social Readjustment Rating Scale[1] or the Bedford College Life Events and Difficulties Schedule[2] which characterize life experiences and produce standardized measures of their severity. According to this view, experiences have properties—as losses, or challenges, or dilemmas—that can be identified by knowing something of the social circumstances of the subject of those experiences but without knowing about the meaning given to them by the person experiencing them.

Another meaning of stress is that it is a bodily state, so that events are only regarded as stressful if they produce changes in the individual. The best-known example of this usage comes from physiology.[3] Stress as a psychological state is also a common lay meaning; when people describe themselves as 'stressed' they are usually referring to a state of tension or autonomic arousal.

Yet another way to understand stress, which is useful in considering physical illness, is that it arises out of an interaction between environmental demands and the resources available to deal with them. This view is articulated in the transactional model of Lazarus and Folkman.[4] According to the theory, when faced with a new experience individuals assesses its likely impact (the primary appraisal) and assess their resources (the secondary appraisal). Stress arises when this double appraisal identifies a mismatch between demands and resources that cannot be narrowed by coping manoeuvres.

(a) Illness as a demand or threat (the primary appraisal)

There are a number of characteristics of an experience that increase the chances of it being appraised as threatening. These include immediacy, ambiguity, uncontrollability, or undesirability. The probability that many people will share an interpretation of a particular episode explains the similarity of people's responses to certain illnesses. The possibility of individual, even idiosyncratic, interpretations can explain sharp differences between people with apparently the same disorder.

A useful way to construe individual appraisals of illness is outlined by Leventhal *et al.*[5] in their theory of internal illness representations. The common elements of the illness representation can be identified from a simple self-report questionnaire[6].

Illness beliefs cannot be assumed solely on the basis of the illness from which a person is suffering, or from his or her social context.[7] Individuals may hold unpredictable beliefs—that an illness is inherited from a family member, or that it is a punishment for a misdemeanour, or that it may be curable by adopting an unusual diet. For some, the representation of illness overlaps with the representation of self, so that sufferers see themselves as living their illness rather than suffering from it.[8] (see Box 5.3.1.1)

The characteristics of a particular disease are not the only component of the illness that can make it threatening. Illness occurs in a social and interpersonal context, and while the responses of other people may be helpful, they may in some cases contribute to the demands of the situation. For example, a partner may withdraw or become depressed, or family members may become intrusive or overcontrolling. Being ill confers a special status, the so-called sick role, but it is a status acquired at a cost in the loss of independence and certain rights. While disability may arise largely from the impairments caused by a disease, much handicap is socially determined.

(b) Resources for responding to illness (the secondary appraisal)

The focus of secondary appraisal is twofold: the person's personal resources, and the resources external to them, mainly in the immediate social network.

Personal resources may be defined in a number of ways, for example cognitive attributes, personal characteristics, or personality traits.

The other resource for the individual is social support. There are many approaches to understanding support, but a useful one[9] is to regard it as having four components:

1 emotional support, conveying a sense of being cared about or loved

2 esteem support, conveying a sense of being valued or respected

3 instrumental support, conveying practical help

4 informational support, conveying knowledge relevant to tackling the problem

Box 5.3.1.1 Components of the illness representation

- identity (label and associated symptoms)
- causal ideas
- consequences (severity and likely impact)
- time-line (natural history)
- curability or controllability

The family's reaction to illness has an important impact on the type of support available. If they are rejecting, intolerant of dependence, or unsympathetic to the needs of the patient—for example, to change their diet, or stop smoking, or take more (or less) exercise—then they may offer too little support. On the other hand, they may be overprotective, refusing to allow the patient a reasonable degree of autonomy and discouraging active coping. Sometimes, members of a family will hold different views about the nature of an illness, leading to conflict, which is not always revealed to doctors. More often, they share views. If such views are inaccurate (so-called family myths) and yet strongly held, then they can be a powerful barrier to the patient accepting medical advice. It is a common observation that patients with chronic illness who are depressed often have a carer who is depressed, and this tendency to share (often dysfunctional) beliefs and coping styles is one reason for that.

(c) Coping with illness

Coping refers to efforts to reduce the gap between demands and resources. Coping is described according to its aims, the techniques used to achieve those aims, and according to the overall coping style adopted.

The ***aims*** of coping are either problem focused, designed to modify the demands of the situation, or emotion focused, designed to modify how one feels about a situation.[4] Emotion focused coping generally works well but only transiently. It is best reserved for brief stresses, such as unpleasant medical procedures, or for situations in which nothing can realistically be done to modify the stress.

The ***techniques*** for coping serve to mobilize available resources. Vocabularies differ for describing them. Cognitive coping techniques include information seeking, downplaying, or adopting a defiant or overoptimistic attitude. In psychodynamic terms, the two most commonly used techniques are probably denial and regression. In common usage, the techniques referred to by these vocabularies overlap. Behavioural coping may involve changing ones lifestyle, such as exercising more or excessive drinking of alcohol. Social coping is a particular form of behavioural coping, and may involve increasing contacts or accepting help from professional agencies. In chronic illness, successful coping may be accompanied by a slower process of reappraisal—in which the patient comes to a different understanding of the illness, from that apparent at initial diagnosis—through for example *benefit-finding* and *downward comparison* (with others who have worse disability, pain, or whatever).

Coping ***styles*** are more general approaches to coping. Two contrasted styles are active/engaged (sometimes called 'approach') coping and passive/disengaged (sometimes called 'avoid') coping.[10] While it is appealing to characterize people as having a particular coping style, and while it is possible to think of typical examples from personal experience, in fact most people do not have a sufficiently unchangeable repertoire of coping techniques to merit the label of a style.

Adjustment disorders

(a) Definition and classification

The emphasis in ICD-10[11] is on emotional disturbance as the characteristic feature of adjustment disorders—some disturbance of behaviour is acknowledged, particularly in adolescence.

However, it is common to encounter cognitive or behavioural changes that interfere with social functioning and quality of life, and yet which are not attributable to the consequences of mood disorder. DSM-IV[12] acknowledges this possibility more directly, including a category of 'Adjustment disorder, unspecified', which covers 'maladaptive reactions (e.g. physical complaints, social withdrawal, or work or academic inhibition)'.

Examples of cognitive problems are extreme helplessness, denial of the existence of illness, or of the handicap associated with it. Behavioural problems may include marked social withdrawal or lack of self-care, or irrational non-adherence to treatment. Emotional problems are typically thought of as anxiety or depression, but irritability is also common.

(b) Diagnosis and differential diagnosis

The diagnostic features of adjustment disorders are relatively non-specific, comprising mood symptoms and behaviour disturbances, which do not meet the criteria for a diagnosis of another disorder, and yet which are sufficient to amount to a mental disorder. The two main diagnostic questions are as follows.

- Does the patient have a diagnosable mental disorder?
- If there is a mental disorder, should it be given another more specific label than 'adjustment disorder'?

What distinguishes normal adjustment from a disorder? The first criterion is whether the symptoms are persisting beyond the time when they might be attributable to the stressor. This judgement is relatively straightforward when the stressor is a single event. However, if illness is more persistent or intermittent—such as cancer followed by intensive treatment, or multiple sclerosis—then it is less easy to judge.

The second criterion is whether the response is causing avoidable social dysfunction. For example, in many cultures illness is followed by a period of convalescence, during which activity is reduced and a return to full social responsibilities is deferred. This may be a healthy avoidance of activity, if it allows full recovery from illness, but prolonged avoidance of activity may lead to secondary physical problems as well as social isolation and loss of role.

When adjustment disorders are associated with chronic illness and handicap, the duration criterion cannot apply. An individual may present symptoms because his or her response is outside the culturally acceptable range; for example, he or she may be too demanding or uncooperative, or too passive and dependent. It is unwise to regard a presentation as disordered simply on these grounds. The best indicator is whether the individual is achieving the highest level of function and the lowest level of distress of which they are capable under the circumstances. This means that each person must be diagnosed according to his or her own context, and that a standardized set of criteria cannot be applied.

The differentiation of adjustment disorders from other psychiatric disorders is more straightforward, and depends on the presence or absence of key symptoms. The main conditions found in association with physical illness are depressive disorders, anxiety disorders, and occasionally post-traumatic stress disorder.

(c) Epidemiology

Little is known about the epidemiology of adjustment disorders other than those involving mood disturbance, because of the absence of standardized diagnostic criteria.

Psychiatric symptoms are distributed in the general population, with a positive skew to the distribution. In the physically ill, the same pattern of distribution is seen, but the curve is shifted to the right. The increase in psychiatric symptoms is contributed to by a general increase in all the common symptoms. The usual way to identify cases is to select those who cross an accepted threshold for symptom levels—as determined, for example, by one of the standardized self-report questionnaires—and then to apply diagnostic criteria. Adopting this approach, rates of diagnosable mood disorder among the physically ill are about double what they are in the general population. That is, 30 to 50 per cent (depending on the population studied and the diagnostic criteria employed) of the physically ill have a mental disorder. Approximately two-thirds of these cases are adjustment disorders, the rest meeting criteria for another disorder (usually depressive).

The elderly report lower rates of psychiatric disturbance. This may be a cultural effect, with the elderly disposed to report fewer symptoms of distress as a result of stoicism learned through experience of adversity earlier in life. Alternatively, the elderly may genuinely respond differently to physical illness.

Mood symptoms and adjustment disorders are commoner in response to acute illness than they are in chronic illness.

(d) Aetiology

There are several reasons why coping might fail.

First, demands may be overwhelming. The news that one has a terminal illness takes time to assimilate—to understand all its meanings, grasp all the threats and losses involved. While that process of appraisal is going on, it is difficult to marshal resources and use them effectively. This explains, in part, why mood disorder is more commonly associated with acute than chronic illness.

Second, resources may be inadequate or missing. One problem associated with physical illness is that it may impair personal resources as a primary effect of the disease process—most importantly when the illness has effects on the central nervous system by virtue of the direct involvement of the brain or through the neurological effects of systemic disturbance.

Third, coping responses may be ineffective. There are few rules about what makes effective coping. In general, a broad and flexible repertoire is desirable, with a strong element of active problem-focused techniques. However not all illnesses, nor all aspects of a particular illness, are likely to be amenable to problem-focused coping. Probably the most effective coping is matched to the situation. That is, the coping matches the demands, so that heavy reliance is not placed on problem-focused coping when little in the situation can change, nor excessive use made of emotion-focused coping when active involvement in illness management is needed.

A common problem of failure to match coping to the situation is found in patients with chronic illness, who are responding to their circumstances as if they none the less have an acute illness. In acute illness, problem-focused coping often involves seeking reversal or even cure of the illness process, while emotion-focused coping involves dealing with the anxiety of uncertainty, or grieving if the prognosis is clearly poor. On the other hand, in chronic illness, problem-focused coping involves symptom management and maximizing function, while emotion-focused coping requires a degree of acceptance.

It is not easy to predict who will develop an adjustment disorder. Certainly the risk is not strongly linked to physical diagnosis, or

within a particular diagnostic group to physical disability. The most robust finding is that a previous history of psychiatric problems increases the risk of psychiatric problems associated with physical illness.

(e) Course and prognosis

By definition, adjustment disorders arise shortly after diagnosis. In practice, there is variation; some people respond immediately and develop symptoms within days, while others develop symptoms weeks or even months after diagnosis. The losses associated with illness may only become apparent when a person leaves hospital and faces functional impairment at home. Carers and others in the social network respond differently to acute and chronic illness, and it may take time for that to become clear. The greater the delay from the onset of illness to the emergence of symptoms, the harder it is to make a diagnosis of adjustment disorder. In clinical practice, it is reasonable to set an upper limit of a year.

Most adjustment disorders provoked by a newly onset illness, resolve within weeks. Slower recovery takes place over 12 or 18 months. If recovery has not occurred by then, the patient has usually developed another mental disorder, such as a depressive disorder. Accurate data are few, but probably no more than 10 per cent of patients develop a prolonged adjustment disorder.

The psychiatric symptoms of adjustment disorder impair quality of life, so much so that all standardized quality-of-life measures include mood symptoms in their profile. Psychiatric morbidity associated with physical illness is also a risk factor for self-harm and for completed suicide. Adjustment disorders are likely to have an effect on the outcomes of treatment for physical disease.[13] Health service costs are greater for patients with physical illness and psychiatric co-morbidity; lengths of stay are longer for hospital inpatients; the functional outcomes of rehabilitation may be poorer, and there is some evidence that there may also be an increased mortality. The mechanism for these effects may be broadly behavioural or physiological. Examples of the former are increased rates of smoking, lack of exercise, and poor adherence to treatment regimes among people with mental disorders. Examples of the latter include activation of the hypothalamic–pituitary–adrenal axis or increased cytokine production associated with chronic emotional disorder.

(f) Treatment

(i) Drug treatments

Antidepressants can be effective in the presence of physical illness.[14] There is no good evidence to support claims for a great superiority in efficacy of serotonin-reuptake inhibitors. Although their long-term tolerability may be greater than older drugs in patients with physical disease, they are not without toxicity—for example they have been associated with increased falls and gastrointestinal haemorrhage. Tricyclic antidepressants have advantages in treating patients with insomnia or chronic pain. Cost differences are substantial.

(ii) Psychological treatments

A number of brief psychological therapies have been shown to be effective in treating depression; namely cognitive-behaviour therapy, problem-solving therapy, interpersonal therapy, and brief dynamic therapy. Such therapies may also be effective in treating adjustment disorder in the physically ill,[15,16] although they may have disappointingly weak effects upon physical outcomes. Therapy may need to be modified to allow for fatigue or concentration problems, and sessions need to be arranged flexibly to accommodate hospital appointments and other treatment needs.

(g) Management

(i) Identifying cases

A major difficulty in delivering treatment to people with adjustment disorders is the difficulty in identifying cases. There are several self-report questionnaires, which may be used to screen for patients with mood disorder. In certain settings such questionnaires can be delivered routinely to all patients, for example by means of computers with touch screen technology, and they are useful for alerting staff to the presence of mood symptoms—but their positive predictive value is too low to allow for accurate use in identifying those who need referral to specialist services. Their use is also difficult to integrate into routine clinical practice, and response rates outside research studies are usually low.[17] Their use is best restricted to specialist services where the clinical staff are clear about what response they will make to a high score, since this is where there is some evidence for the benefits of case-finding. There are no useful standardized instruments for the detection of other problems with adjustment.

Instead, clinicians should be encouraged to consider the possibility of psychiatric disorder when there is a gap between impairment and handicap so that the patient is doing worse in rehabilitation than the severity of their disease would suggest they should be, when there are multiple complaints that are difficult to explain, or when multiple drug treatments are being administered without conspicuous benefit. The clinical interview is the mainstay of diagnosis.

There are a number of common reasons for failing to recognize adjustment disorders. First, the questions simply are not asked, or attempts by the patient to introduce the topic of psychological problems are blocked or sidestepped. Second, questions may be asked, but in circumstances where it is difficult for the patient to answer honestly—when there is no privacy, or the person asking is obviously too busy to listen to any but a conventional answer. Third, expressions of distress may be normalized, and thus dismissed: 'Of course it's natural you will feel like that' means to the patient 'So please don't mention it again'.

(ii) Broadening the repertoire of psychological responses

No single intervention is going to be effective for all patients with psychological problems arising from difficulties with adjustment to illness. Realistic management therefore involves offering what has been called a 'menu of interventions'.[18] A currently favoured model is a so-called ***stepped care*** model in which intervention is organized in a hierarchy according to intensity of treatment and the expertize needed to deliver it e.g. see Box 5.3.1.2. While unfocused 'support' is of limited value (because it does not encourage active secondary appraisal and experiments with different coping strategies) there are now many brief and flexible psychological therapies available, some of which may be deliverable by staff in the primary care or physical healthcare service (see Box 5.3.1.3). In ***collaborative care*** such first line psychological treatments, along with medication management and simple social care, are delivered by non-mental health staff and monitored by a case manager, with a mental health professional providing supervision and back-up consultation. Successful trials have been conducted in (for example) heat disease[19] and diabetes.[20]

Box 5.3.1.2 Stepped care in the treatment of depression (NICE clinical guideline 2004)

	Who is responsible for care?	What is the focus?	What do they do?
Step 5	Inpatient care, crisis teams	Risk to life, severe neglect	Medication, combined treatments, ECT
Step 4	Mental health specialists including crisis teams	Treatment-resistant, recurrent, atypical and psychotic depression, and those at significant risk	Medication, complex psychological interventions, combined treatments
Step 3	Primary care team, primary care mental health worker	Moderate or severe depression	Medication, psychological interventions, social support
Step 2	Primary care team, primary care mental health worker	Mild depression	Watchful waiting, guided self-help, computerized CBT, exercise brief psychological interventions
Step 1	GP, practice nurse	Recognition	Assessment

Box 5.3.1.3 Brief psychological treatment of use in the medically ill

- **Motivational interviewing** is an approach developed to encourage people to attempt change in addictive behaviours. It may be useful in engaging people in demanding treatments, or in improving adherence to treatment regimes.
- **Graded activity** has been used to treat negative symptoms in mental illness like schizophrenia or depressive disorder. It is effective in improving function in chronic fatigue syndrome, and is worth using in other conditions where inactivity and passivity is out of proportion to physical disability.
- **Anger management** is a modification of cognitive-behaviour therapy, which may be useful where irritability or aggressive behaviour is complicating adjustment.
- **Interpersonal therapy**[21] was initially developed for the treatment of depression, but it has obvious applications in the field of physical illness. In the terminology of interpersonal therapy, illness represents a role transition, and the focus in therapy is therefore on negotiating that transition with key others in the patient's life.
- **Family therapy and couples therapy** are rarely considered (or available) for adults with physical illness, and yet many of the external resources needed for coping are in the family.

For more severe or persistent problems, referral to specialist services is appropriate—ideally liaison services that operate in the primary or secondary care settings where patients receive their main care. Psychiatric treatment of the physically ill, especially in hospital, requires a number of modifications to routine clinical practice, which are sometimes overlooked.

First, an extra effort has to be made to meet the family and carers. They may be reluctant to attend if there is hostility in the family, or if missed time from work is creating financial pressures, but failure to interview others makes it near impossible to come to a full and accurate formulation of the problem.

Second, personal contact with the referrer is highly desirable. The 'real' question may not be that posed in the referral, and can only be identified by probing. Advice is much more likely to be followed if it is delivered face to face, and followed up with a later visit to check on compliance! This direct contact with non-psychiatric colleagues is one of the defining characteristics of liaison psychiatry, and its importance cannot be overemphasized.

Third, it must be recognized that the course of psychiatric treatment needs to be modified. Appointments will be missed, or interrupted, by the demands of physical treatment. And psychological issues may well not be resolved by a single clinical encounter; a relapse of illness may provoke a further episode with new features, and patients often have to return repeatedly to work through themes in therapy, as they are re-challenged with new physical problems.

(h) Prevention

There are two broad approaches to prevention, namely education and support.

Education and the provision of information and advice about the illness and its management is desirable as an informed patient is more likely to be an effective partner in treatment, and because it is popular with patients. Disappointingly, however, it is not an effective means of preventing psychiatric problems. This is probably because, while it facilitates primary appraisal, it does nothing to facilitate secondary appraisal or the use of effective coping strategies.

Provision of support is also popular. It takes a number of forms, including self-help groups, volunteer visiting, and professional support workers—usually with knowledge of a particular disease such as AIDS or a stroke. Again, there is little evidence that it prevents psychiatric problems. Perhaps this is because it usually provides emotional support; which in itself may be worthwhile but which is insufficient if not combined with a more problem-focused approach.

In conclusion, there are no clear indications that we can prevent the development of adjustment disorders. The mainstay of current management is therefore to identify existing cases and to offer specialist care to those who are most symptomatic or handicapped, and to those who are not improving spontaneously.

Adjustment to terminal illness: care of the dying

Adjustment to terminal illness has much in common with adjustment to other severe illness, and is not specifically the province of psychiatrists. For a detailed discussion of the care of the dying, the reader is referred to a more specialized text.[22] Here we will discuss two issues that are commonly presented to the psychiatrist in this setting: the diagnosis of depression and other adjustment disorders, and the issue of suicide.

Diagnosis of depression and adjustment disorders in the terminally ill

As with physical illness, somatic complaints are common in the dying and thus, individually, lose their diagnostic or predictive usefulness in the major depressive syndrome. Even psychologically, a degree of hopelessness may be appropriate. Anxiety is a common symptom in the dying, but it is not necessarily pathological. Like depression, it may result from physical disability, uncontrolled pain, or pre-existing anxiety disorders. In these circumstances a more detailed examination of the attitudes of the patient is necessary. Pervasive global hopelessness, feelings that life has had no meaning, strong feelings of guilt or punishment, and suicidal thoughts are pointers towards depressive illness in the terminally ill.

Assessing suicidal thoughts in the terminally ill

Several studies have shown that the prevalence of suicidal thoughts among patients with terminal cancer is less than 10 per cent.[23] However, this contradicts the clinical impression that most patients admit to either suicidal thoughts or thoughts of assisted suicide as an escape from the imaged consequences of losing control. In some patients, having a belief in a 'way out' can be positive in offering a sense of control.

Completed suicide is an important complication in patients with a terminal illness. General predictors of suicide apply, with the addition of severity of functional impairment, isolation, and delirium. The two most important factors to watch out for are uncontrolled pain and depression. These two factors greatly increase suicide risk but are nevertheless treatable in the terminal illness setting.[24]

People who express a desire to die are nearly always ambivalent. The expression of suicidal ideas should never be accepted as rational without a searching enquiry for evidence of subtle external pressures, fear of terminal symptoms or of being a burden on others, and treatable depression.

Pharmacological management of psychiatric disorders in the dying

Alleviation of distress rather than cure is the guiding principle of the management of the terminally ill. Caution is needed in the selection and prescription of psychotropic drugs.

Anxiolytic medication is usually well tolerated and the concern over dependence and tolerance is less of an issue. Terminal metabolite benzodiazepines, such as lorazepam and oxazapam, can provide symptomatic relief for a variety of conditions even in patients with hepatic impairment. Occasionally, opiates are used in this role where first-line treatments are unsuccessful.

Antidepressant use in the dying may be more problematic due to the adverse effects of sedation, seizures, hypotension, and constipation and urinary retention. For this reason, the choice of drug needs to be individually tailored. Dosage has to be carefully adjusted, beginning at low doses and increasing gradually. The use of psychostimulants (dextroamphetamine, methylphenidate) is worth considering. These drugs are used infrequently in general psychiatry because of the risks of dependence, but in the terminally ill they may have advantageous 'energizing' properties, including increased energy, improved concentration, increased appetite, and possibly, a faster onset of action.

5.3.2 Psychiatric aspects of neurological disease

Maria A. Ron

Psychiatric abnormalities are an integral part of neurological disease and their study can improve our understanding of the neural basis of psychiatric illness. This chapter deals with common neurological diseases where psychiatric symptoms are prominent.

Stroke

Stroke is defined as the sudden loss of blood supply to an area of the brain resulting in permanent tissue damage and is the commonest neurological disorder. The incidence of stroke for those aged between 35 and 65 is between 90 and 330 per 100 000. It is commoner in men and the incidence increases with advancing age. Ischaemic stroke is commoner than haemorrhagic stroke and accounts for 80 to 85 per cent of all cases.

Depression

Its prevalence is around 30 per cent in the first few weeks after a stroke—two-thirds of the patients fit the criteria for major depression and the rest for minor depression. Survivors remain at an elevated risk for depression for many years.

(a) Clinical features

- Diurnal variation of mood, weight loss, anergia, insomnia, and loss of libido are prominent in the early stages.
- Anhedonia, suicidal ideation, loss of self-esteem, and feelings of guilt become evident later.
- Irritability and aggressive behaviour are common, especially in those with cognitive impairment.[1]
- The onset of depression may occur acutely in the early post-stroke period or be delayed for 6 months or more.

(b) Factors associated with post-stroke depression

Early after stroke, anterior left-sided lesions involving the cortex and subcortical regions, especially the basal ganglia, and right posterior lesions are more frequently associated with depression.[2] In time these associations become less marked.[3] Cognitive impairment is closely associated with depression early after stroke,[4] and is present in 70 per cent of those with major and 43 per cent of those with minor depression. Old age, a past or family history of depression, and negative life events in the preceding 6 months substantially increase the incidence of post-stroke depression.

Disruption of fronto-subcortical circuits, directly or as a distant effect of stroke, plays a central role in the causation of depression. Decreased metabolism in orbitofrontal, anterior cingulate, and inferior temporal regions has been reported using **PET**.[5] Serotonergic mechanisms have been implicated, with a reduction of 5-hydroxytryptamine-2 receptor binding in the temporal cortex, especially in left hemisphere stroke.

(c) Course and prognosis

The average duration of major depression is around 1 year, with spontaneous remission in many patients. Symptoms of minor depression may persist for 2 years or more. The presence of depression and other psychiatric diagnosis in the first 3 years after a stroke substantially increases the risk of death after controlling for cardiovascular and other risk factors.

Anxiety

- About a quarter of patients fulfil criteria for generalized anxiety disorder during the acute post-stroke phase.
- Rates are lower in community studies (5 per cent)[6] and 1 or 2 years after stroke (4 to 18 per cent). Half of those with anxiety disorder also satisfy criteria for depression.
- Right-sided subcortical lesions may be more common in anxiety disorder, while left-sided pathology, usually involving cortical regions, is more likely when anxiety and depression coexist.[2] Serotonergic abnormalities are also likely to be relevant.

(a) Course and prognosis

Anxiety in the acute post-stroke phase is associated with high mortality rates, comparable to those in depressed patients.

Emotionalism (abnormal crying or laughing)

Emotionalism is usually mood-congruent and is triggered by sad or emotional events. Most patients have some degree of voluntary control.

Emotionalism occurs in a quarter of patients during the first year post-stroke, with a peak in the first month and decreasing gradually thereafter.[7] It is associated with the severity of depression and with left-anterior lesions disrupting serotonergic pathways.

Management

The first step in treating the psychiatric manifestations of stroke is for these to be recognized, and patients need to be routinely assessed for the presence of psychiatric symptoms.

Treatment

Double-blind placebo-controlled trials using nortriptyline, trazodone, and selective serotonin reuptake inhibitors (**SSRI**s) have shown these drugs to be effective.[4] Improvement in depression also results in lasting improvement in cognition and physical activity. Treatment within 3 months of stroke may be followed by the best outcome.

The treatment of anxiety symptoms has been less well documented. Short-acting benzodiazepines, buspirone, and SSRIs are the main pharmacological approaches. The usefulness of psychotherapeutic or behavioural interventions has not been established

and may depend on the severity of symptoms and cognitive impairment.

Emotionalism responds well to treatment with SSRIs and tricyclic antidepressants, even in those without associated depression.

Parkinson's disease

The neurological and cognitive features of Parkinson's disease are dealt with in Chapter 4.1.6 and only commonly encountered psychiatric symptoms will be considered here.

Depression

Its overall prevalence is approximately 40 per cent.[8] Depressive symptoms are more common early in the disease (50 per cent) and in those with onset before the age of 55. For many people, adaptation to the disease results in a return to normal mood. Depression becomes more frequent again in the advanced stages of the disease, particularly in those with rapidly progressive disability.

Major depression is commoner in those with akinetic Parkinson's disease (38 per cent) than in those with classical forms of the disease (15 per cent), but dysthymia is equally common in both. Depression, severe in some patients, has also been reported in the first few weeks after bilateral subthalamic stimulation, a successful treatment for the motor symptoms of Parkinson's disease,[9] but mood changes were less commonly observed a year after surgery.

(a) Clinical features

- Anxiety, agitation, and depressed mood are prominent.
- Depressive symptoms are not closely associated with the severity of motor signs, but may be more severe during 'off' periods and are commoner in those with cognitive impairment.
- Early awakening, motor retardation, and apathy in the absence of mood abnormalities may not be indicative of depression.
- Major depression is associated with functional deterioration at 1-year follow-up.[10]
- Three-quarters of patients with depression also fulfil criteria for anxiety disorder, but only 10 per cent have symptoms of anxiety in isolation.[11]

(b) Mechanisms underlying depression

Studies using PET have suggested that depression and anxiety in Parkinson's disease are associated with a specific loss of dopamine and noradrenaline innervation in the limbic system.[12] Postmortem studies have also described loss of dopaminergic neurones in the ventral tegmental area.[13] Degeneration of these neurones leads to dysfunction of the orbitofrontal cortex with secondary effects on the serotonergic cell bodies of the dorsal raphe.[5]

(c) Management

Optimal control of neurological symptoms may lead to improvement in depression and should be a management aim. Repeated assessment may be needed to differentiate features of the disease, such as apathy, from the symptoms of depression.

(d) Treatment

There are few studies describing the treatment of depression in Parkinson's disease. When antidepressants are clinically indicated because of the severity or persistence of symptoms, the antidepressant profile of side-effects should be considered. Antidepressants with strong anticholinergic effects, such as amitriptyline, may increase cognitive impairment and SSRIs may be preferable. Electroconvulsive treatment is also effective for Parkinson's disease patients with depression and may also transiently improve motor symptoms.

Psychotic symptoms

(a) Clinical features

- Up to 40 per cent of patients on long-term treatment experience visual hallucinations.
- Long duration of illness, age, cognitive impairment, and depression are associated with visual hallucinations.
- Visual hallucinations in clear consciousness are usually fully formed images of people or animals, non-threatening, fleeting, and stereotyped. They are recurrent and tend to occur at night, more commonly in the 'on' periods.
- Sleep disturbances (fragmented sleep, alteration of sleep rhythms, and vivid dreams) often precede daytime hallucinations and may be part of a continuum.
- Delusions are less frequent than hallucinations but are more stressful and difficult to manage. They are usually paranoid, with conspiracy and infidelity themes.
- Severe psychosis is associated with institutional placement, progressive dementia, and increased risk of death (over a quarter of patients within 2 years).

(b) Mechanisms

Psychotic symptoms may represent intrusion of REM sleep imagery into wakefulness. They may be more frequent in those receiving anticholinergics and dopamine agonists, but there is no clear association with dosage or duration of treatment. Stimulation of hypersensitive dopaminergic receptors in the nigrostriatal system by dopaminergic drugs may explain psychosis early in the disease, but it is unlikely to explain late psychosis. The therapeutic efficacy of atypical neuroleptics suggests a role for mesolimbic dopaminergic and serotonergic pathways. Cholinergic deficiency may also be relevant, in patients with dementia and atrophy of the nucleus basalis.

(c) Management

In patients with clouded consciousness, infection, cerebrovascular accidents, and other relevant pathologies need to be excluded. Revision of dopaminergic medication should come next, with reduction of polypharmacy and dose tapering. Anticholinergics, selegiline, amantadine, and dopamine agonists may need to be discontinued, as they are more likely to trigger psychosis.

(d) Treatment

In most patients antipsychotic drugs are needed, as dopaminergic medication is needed to preserve acceptable motor function. Atypical neuroleptics such as clozapine, with its low D2 receptor affinity and few extrapyramidal side-effects, are preferable to typical neuroleptics. Clozapine is effective at doses of less than 100 mg per day. Initial recommended doses of 6.25 to 12.5 mg daily should be gradually increased until the symptoms are controlled. The danger of agranulocytosis and the need to monitor the blood picture

are the main drawbacks, and other atypical neuroleptics (particularly quietiapine) may be preferable. Cholinesterase inhibitors may also be helpful in treating psychotic symptoms in patients with cognitive impairment.

Dopamine dysregulation syndrome

The syndrome is characterized by the compulsive use of dopaminergic medication beyond that needed to control motor symptoms. It is commoner in males with young onset and may affect 4 per cent of patients. Drug-hoarding and drug-seeking behaviour, impaired social functioning, aggression, and reluctance to reduce medication despite severe dyskinesias are common features. Hypomania and frank psychosis may follow.[14]

(a) Management

Reduction of medication resolves symptoms, but a withdrawal state characterized by dysphoria and irritability follows. Treatment is difficult and often unsuccessful, and primary prevention is preferable.

Tourette syndrome

The syndrome is characterized by motor and phonic tics of fluctuating severity.

- Motor tics appear early, between the ages of 3 and 8 years. Simple tics, e.g. eye blinking, are followed by complex stereotypies (i.e. touching, licking). Phonictics (sniffing, throat clearing) appear later.
- Severity of tics peaks by the age of 20 and may lessen thereafter, but total recovery is rare. Severe cases may start in adulthood.
- Tics, preceded by premonitory urges, occur many times a day and are exacerbated by anxiety, boredom, fatigue, and excitement and lessened by alcohol, relaxation, and sleep. Patients may be able to suppress tics for long periods at the expense of a build-up of tension.
- Coprolalia (utterance of obscenities), copropraxia (obscene gestures), echolalia and echopraxia (repetition of words and actions), and self-harm are also common.

Tourette syndrome is part of a spectrum that includes transient childhood tic disorders. Secondary tic disorders following trauma, encephalitis, rheumatic fever, and metabolic and toxic encephalopathies, and those present in inherited degenerative conditions such as Huntington's disease and neuroacanthocytosis, need to be considered in the differential diagnosis.

Epidemiology

Tourette syndrome is more frequent in males (4:1). Its prevalence in male adolescents is around 4 per 10 000, but it may be higher (49 per 10 000) in children with behavioural disturbances[15] and is as high as 1 to 3 per cent in school children if a broad definition of chronic motor and phonic tics is used.

Aetiology

Major gene effects with an autosomal mode of inheritance seem likely. Monozygotic twins have a concordance rate between 50 and 70 per cent for the syndrome compared with 10 to 20 per cent for dizygotic twins, and a third of relatives may have features of the syndrome. Several candidate genes have been assessed including dopamine receptors, the dopamine transporter, and various noradrenergic and serotonergic genes, and although isolated changes in a single locus are unlikely to lead to the syndrome, these alleles could have a significant cumulative effect. Gestational and perinatal risk factors may also play a role. Multiple streptococcal infections in the months preceding symptom onset are commoner in Tourette patients than in controls, suggesting that the paediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS) may be the cause of Tourette syndrome in vulnerable patients.

The efficacy of dopamine antagonists and SSRIs in the treatment of tics and obsessive–compulsive symptoms has implicated dopaminergic and serotonergic pathways and the regions where dopaminergic and serotonergic neurons interact (i.e. striatum, substantia nigra, and prefrontal cortex). The beneficial effects of basal ganglia deep brain stimulation also point to basal ganglia dysfunction. PET studies have suggested decreased metabolism and blood flow in basal ganglia–thalamo-cortical projection systems.[16] Post-mortem studies have not shown consistent abnormalities in D1/D2 receptors, and *in vivo* receptor-binding studies have been conflicting, as have structural brain-imaging studies.

Psychiatric comorbidity

(a) Clinical features

- About half of the patients meet criteria for other psychiatric disorders,[17] but it is uncertain whether they should be considered part of the phenotype.
- Depression and anxiety occur in about 25 per cent of patients.
- Personality disorder is present in two-thirds of patients. Borderline, obsessive–compulsive, and paranoid types are the commonest types.
- Attention-deficit hyperactivity disorder may be more common in males and may have educational and behavioural implications. Wide variations in prevalence have been reported (8 to 80 per cent).
- Obsessive–compulsive disorder may be more common in females, reaching its peak in late adolescence. Concern for symmetry, violent and sexual thoughts, forced touching, fear of harming self and others, and a need to do things 'just right' are common features.
- Intellectual ability tends to be normal, but poor performance in complex attentional tasks is associated with attention-deficit hyperactivity disorder.

(b) Management

Explanation and reassurance are often enough in mild cases; for the rest, drug treatment or cognitive-behaviour therapy may be indicated.

(c) Treatment

Neuroleptics are useful in treating tics. Haloperidol, pimozide, and sulpiride are commonly prescribed and atypical neuroleptics (e.g. risperidone, zipresidone, and olanzapine) are also useful, although few controlled trials are available. Clonidine, a $\alpha 2$ adrenergic agonist, is useful, with less severe side-effects. Behavioural interventions (e.g. habit reversal training and bio-feedback techniques) may also suppress tics. Deep brain stimulation of the

centromedian-parafascicular complex of the thalamus or the internal segment of the globus pallidus is reported to ameliorate tics and self-harm.

Variable success has been achieved with behavioural techniques, SSRIs (fluoxetine), and risperidone in the treatment of obsessive–compulsive disorder. The treatment of attention-deficit hyperactivity disorder is more controversial, but benefits may follow the use of clonidine and stimulants such as methylphenidate, pemoline, and dextroamphetamine without increasing tic severity. (See also Chapter 9.2.4.)

Multiple sclerosis

Multiple sclerosis is a common neurological disease, with a prevalence of 50 to 60 per 100 000; it is more common in women. It usually starts between the ages of 20 to 40 and is characterized by multiple demyelinating lesions with a predilection for the optic nerves, cerebellum, brainstem, and spinal cord. In most cases the disease initially follows a relapsing–remitting course, entering a secondary, progressive phase after some years. For a few patients the disease is progressive from the outset.

Purely psychiatric presentations of multiple sclerosis other than dementia are rare, but psychiatric symptoms are common in the course of the illness.

Depression

- Depressive symptoms occur in about 50 per cent of patients in cross-sectional studies[18] and their lifetime prevalence is also around 50 per cent.
- The rates of suicide are more than twice those of the general population, and young males and those socially isolated or with drinking problems are at a greater risk.
- Low mood, negative thoughts, anhedonia, and suicidal ideation are common features of depression.
- Fatigue and poor concentration may be features of multiple sclerosis and have less diagnostic value.

Euphoria

- It is only present in about 10 per cent of patients and is characterized by mild, continuous elation.
- It is best considered as an organic type of personality change.

Emotional lability

- It is as frequent as euphoria.
- Excessive crying is more frequent than laughter.
- It tends to be more severe in those with significant depression.[19]

Psychosis

- It is uncommon, but brief affective or schizophrenia-like psychoses may occur in patients with well-established multiple sclerosis, sometimes coinciding with a relapse.[20]
- Persecutory delusions and lack of insight are common.
- In most patients these are single episodes lasting 4 to 6 weeks that respond well to symptomatic treatment.

(a) Mechanisms of psychotic symptoms

Severity of brain disease, as measured by magnetic resonance imaging (**MRI**), and duration of illness are not closely correlated with **depression**, but they are a risk factor. The personal and social limitations imposed by the disease are an important risk factor for depression.[18] A **genetic predisposition** has been reported in multiple sclerosis patients with bipolar illness.

Euphoria and **emotional lability** tend to occur in patients with advanced disease and cognitive impairment and are more closely related to MRI indices of brain damage. MRI lesions tend to cluster around the temporal lobes in patients with **psychotic symptoms**.

(b) Management of psychotic symptoms

All patients should be assessed for the presence of depression. Fatigue and poor concentration have limited diagnostic value, as they may be features of multiple sclerosis. Although disease-modifying treatments do not increase the overall risk of depression, they may do so in the first 6 months of treatment in those with a previous history of depression.[21] Regular psychiatric assessment in the early stages of treatment is, therefore, important.

(c) Treatment of psychotic symptoms

Few studies have assessed the effect of antidepressants in patients with multiple sclerosis, but SSRIs and other antidepressants appear to be effective. Their side-effects need to be carefully considered for their potential to aggravate or improve neurological symptoms. Cognitive-behaviour therapy aimed at improving coping strategies is also useful. **Emotional lability** responds well to small doses of SSRIs or tricyclic antidepressants but tends to recur when these drugs are discontinued.

Psychotic episodes may require the use of neuroleptics for brief periods, but the long-term use of these drugs is rarely required.

Cognitive impairment

Cognitive impairment is present in about 40 per cent of multiple sclerosis patients[22] and contributes significantly to the overall disability. The pattern of impairment is characterized by the following:

- Attention deficits and slowing of information processing speed are often the first manifestations and may be present early in the disease.[23]
- Memory disturbances, with greater impairment of recall over recognition, appear later.
- Executive function deficits, with poor working memory, abstract reasoning, and use of strategy, are common.
- Language skills and visuospatial functions tend to be preserved.

Cognitive impairment is greater in those with progressive, severe disease, although cases presented as dementia have also been described.[24] Depression worsens cognitive impairment by slowing down information processing and interfering with learning and working memory. Cognitive impairment correlates with MRI markers of disease severity, in particular brain atrophy.

(a) Management of cognitive impairment

Disease-modifying treatments may slow down cognitive impairment, but evidence is insufficient. The same applies to cholinesterase inhibitors. Cognitive rehabilitation has so far been disappointing.

Space-occupying lesions

Brain tumours

Their clinical manifestations are determined by location and by the effects of raised intracranial pressure. Psychiatric symptoms occur in 50 per cent of patients[25] and are of three main types:

- Confusional states and/or progressive cognitive deterioration occur in a third of patients. Disorientation with clouding of consciousness, euphoria, apathy, and loss of insight are prominent in those with confusional states. Progressive memory impairment, loss of initiative, and bradyphrenia occur in patients with a more protracted course and may coexist with signs of raised intracranial pressure.
- Behavioural and mood disturbances occur in 20 per cent of patients. Irritability, euphoria, depression, and, less frequently, psychosis are part of the picture.
- Paroxysmal disturbances such as poorly formed visual hallucinations and automatisms, indicating temporal lobe involvement, are less common.

Fast-growing tumours are more likely to cause psychiatric symptoms (60 per cent in patients with gliomas and 42 per cent in those with meningiomas). Frontal lobe tumours may present with psychiatric symptoms in the absence of other neurological abnormalities.[26] Medial and orbitofrontal tumours lead to emotional symptoms while disinhibition and irritability or marked apathy occurs when the anterior cingulate is involved. Tumours involving the dorsolateral prefrontal regions are more likely to produce abnormalities of executive function (planning, goal-directed behaviour, ability to monitor effective performance). Disturbances of micturition are specifically associated with frontal tumours.

(a) Management

Brain tumours should be suspected in patients with the above syndromes or when psychiatric symptoms are accompanied by neurological abnormalities or appear *de novo* late in life. Imaging usually confirms the diagnosis.

Neurofibromatosis

There are two types of neurofibromatosis, both inherited as autosomal dominant disorders.

Neurofibromatosis 1 is the commonest (incidence 1/3000) and is characterized by cutaneous manifestations (café-au-lait pigmentation) and neurofibromas, which are benign nerve sheath tumours. Gliomas and hamartomas, especially in the eye and optic pathways, and bone dysplasia are also features. Severe learning disability occurs in 4 per cent of patients, but milder cognitive impairment is commoner (80 per cent of cases). Attentional difficulties are common and a third of patients fulfil criteria for attention-deficit hyperactivity disorder. Perceptual and executive functions are worse than memory functions.[27, 28] Epilepsy is twice as common as in the general population. Ventricular enlargement and T_2 MRI hyperintensities in the basal ganglia, internal capsule, thalamus, brainstem, and cerebellum not closely related to the severity of the learning disability are often present.

Neurofibromatosis 2 is much less common (incidence 1/40 000) and is characterized by bilateral vestibular schwannomas, which may also occur in other peripheral nerves. Meningiomas and ependymomas also occur. Hearing loss, vestibular disturbances, and cataracts are the commonest clinical presentations. Cognition is normal.

The loci for neurofibromatosis 1 and 2 have been located to 17q 11.2 and 22q 12.2 respectively. The rate of spontaneous mutations is high and both genes may have tumour-suppressant roles.

Management is aimed at dealing with attention-deficit hyperactivity disorder, learning disability, and epilepsy.

Tuberous sclerosis

Tuberous sclerosis is a rare autosomal dominant disorder with a prevalence of 1/27 000, variable expressivity, and a high spontaneous mutation rate. There is genetic heterogeneity, with loci described in chromosomes 9 and 16. It is characterized by the presence of skin lesions (adenoma sebaceum), calcified subependymal nodules (tubers), and cortical dysplasias. Hamartomas and other neoplasms of the brain, heart, kidney, and liver are part of the picture.

- **Epilepsy** occurs in 60 to 80 per cent of patients, and infantile spasms, a type of epilepsy, with onset in the first 6 months of life, are particularly common.
- Moderate to severe **learning disability** is present in over 50 per cent of patients and is associated with the presence of infantile spasms and poorly controlled epilepsy.[29]
- **Autism** is 200 times more common in tuberous sclerosis than in the general population and tuberous sclerosis occurs in 1 per cent of autistic patients.[30]
- The number of cortical tubers detected by MRI is a marker of disease severity and is related to the degree of learning disability.[31] The presence of tubers in the temporal lobes has been reported to be associated with autism in patients with tuberous sclerosis.

Management is aimed at control of epilepsy and learning disability.

5.3.3 Epilepsy

Brian Toone

Introduction

An epileptic seizure has been defined as 'a clinical manifestation presumed to result from an abnormal and excessive discharge of a set of neurones in the brain'.[1] A diagnosis of epilepsy applies with the recurrence of two or more discrete and unprovoked seizures (febrile and neonatal seizures are excluded from this definition).

Epilepsy is one of the more common neurological disorders. It carries with it a greater psychiatric morbidity than is to be found in other neurological disorders of comparable severity. Many of its manifestations resemble and may be confused with psychiatric phenomenology. It is often associated with learning difficulties; it may be a manifestation of acquired brain damage or disease; seizures may occur in the course of substance abuse or be caused by psychiatric treatment. For these and for many other reasons psychiatrists should be familiar with epilepsy, its manifold aetiologies, presentations, and treatment.

Classification: epileptic seizures and epilepsy

A comprehensive taxonomy should embrace classifications of both seizure semiology (i.e. the manifestations of abnormal discharge activity) and of epilepsy syndromes. The position of each seizure type in a seizure classification system is determined by its clinical manifestations, by electroencephalographic changes during the seizure, and by the interictal electroencephalographic abnormalities. A classification of epilepsy syndromes takes into account seizure subtype, and also anatomical substrate, aetiology, age of onset, and other characteristics. Seizure classification is dependent upon entities that are immediately ascertainable; epilepsy syndrome classification depends upon entities (e.g. neuroanatomical substrate) that are more speculative. The International League Against Epilepsy

(ILAE) has chosen to give the former priority, while recognizing the importance of the latter.

A familiarity with terminology, with the more common seizure subtypes, and the more commonly encountered epileptic syndromes, will assist in an understanding of the psychiatric disorders that occur in patients with epilepsy. The aura is a simple partial seizure, i.e. a seizure of focal onset in which consciousness is retained. It may progress to a complex partial seizure in which consciousness is disturbed, or into a generalized tonic, clonic, or tonic–clonic seizure. It may subside without further development. It rarely lasts for more than a few seconds, although patients often find time estimation difficult. It is to be distinguished from the epileptic prodrome, a period characterized by dysphoria, impaired memory and concentration, and minor motor manifestations, which precede the seizure and may last for hours or even days. An automatism may be defined as 'a state of clouding of consciousness which occurs during or after a seizure, and during which the individual retains the control of posture and muscle tone and performs simple or complex movements without being aware of what is happening'.[2] The initial phase, consisting of staring or simple chewing movements, may progress to more complex, stereotyped, and repetitive movements such as fumbling or picking. Automatisms rarely last more than a few minutes and are often very brief. They usually arise from temporal lobe discharges, but may be associated with orbital and mesial frontal lesions. The ictus refers to the period of manifest seizure activity. If this persists for 30 min or more it is described as status epilepticus and constitutes a medical emergency (Table 5.3.3.1).

Seizure types

Partial seizures

Partial seizures have a focal onset and may or may not generalize. They may be simple or complex, depending upon whether or not consciousness remains undisturbed. For this purpose, consciousness is defined as the ability to remain aware or to respond.

(a) Simple partial seizures

The content of the simple partial seizure depends upon the site of the focus. One that arises from motor territory may present as a Jacksonian 'march' or as a versive turning of the head. Speech arrest may be present. A focus in the primary sensory cortex may give rise to poorly formed sensations. The more elaborate sensations and the psychic symptoms that arise, respectively, from the association cortex and from the mesial frontotemporal structures are more likely to progress to complex partial seizures.

(b) Complex partial seizures

These may begin as a simple partial seizure or 'aura', or consciousness may be impaired from the beginning. Characteristic auras include epigastric sensations rising into the thorax and olfactory and gustatory hallucinations, elaborated auditory and visual hallucinations, complex changes in perception (e.g. micropsia, depersonalization), and psychic phenomena such as *déjà vu*. As discharge activity spreads, automatic behaviour may supervene or a secondary generalized seizure may ensue. Complex partial seizures commonly arise from temporal, particularly mesial temporal, structures. Hence the obsolete term 'temporal lobe epilepsy'. They may also arise from the orbital and mesial frontal cortices. Complex partial status, previously known as temporal lobe status, is uncommon. It may present as an organic confusional state and may be mistaken for a florid psychosis. Electroencephalography will usually confirm the diagnosis.

Generalized seizures

Both hemispheres are initially and simultaneously involved, the ictal electroencephalographic pattern and motor manifestations are bilateral and consciousness may be impaired from the onset.

Tonic–clonic seizures

This is the common 'major' seizure formerly referred to as 'grand mal'. A brief tonic phase leads into clonic activity, the entire seizure lasting about 2 min. Generalized seizures may be primary, arising from both hemispheres simultaneously, or they may be due to secondary generalization from a focal onset.

Absence seizures

An absence attack is characterized by abrupt cessation of ongoing activity, a vacant stare, and a period of unresponsiveness lasting from a few seconds to half a minute. The absence may be accompanied by brief clonic movements, especially of the eyelids, a reduction in tone causing the body to slump, or automatic movements. Absence seizures occur more commonly during childhood. The absence must be distinguished from the complex partial seizure, which it may resemble. Absence status is not uncommon in childhood and may be mistaken for inattention.

Myoclonic seizures

These are brief shock-like contractions of groups of muscles.

Table 5.3.3.1 Classification of seizures

1 Localization (partial, focal) seizures
(a) Simple partial seizures
(b) Complex partial seizures
(c) Partial seizures evolving to secondary generalized seizures
2 Generalized seizures
(a) Absence seizures
(b) Myoclonic jerks
(c) Clonic seizures
(d) Tonic seizures
(e) Tonic–clonic seizures
(f) Atonic seizures

The epilepsy syndromes

The ILAE, in order to embrace a wider range of clinical features than is possible in a classification based on seizure types, introduced a classification of seizures and epilepsy syndromes. In this classification the broad division lies between the localization-related or partial epilepsies, the great majority of which, in adults, is made up of symptomatic epilepsies (i.e. epilepsy arising from a known or suspected cause) and the generalized epilepsies. The characteristics of the partial epilepsies are determined by the function of the cortical site from which the seizure emanates. The more common generalized epilepsies are age-related. Though admirable in concept, the classification has proved unwieldly and

the terminology clumsy: as such it seems unlikely to displace the seizure-type classification.

Epidemiology

The cumulative incidence (i.e. lifetime risk) is 3.4 per cent for males, 2.8 per cent for females, but the prevalence is only 7 per 1000. This is because prevalence represents the balance between newly diagnosed cases and permanent remission or death, and epilepsy has a good prognosis with 76 per cent of newly diagnosed cases entering long-term remission.[3] Approximately half can be classified as partial seizures and 40 per cent as generalized. Prognosis varies according to the epilepsy subtype, with partial epilepsy having a poorer outcome. Consequently, people who attend a hospital clinic are unrepresentative, in that they are more likely to have treatment-refractory partial seizures along with the other adverse prognostic factors such as mental handicap, neurological dysfunction, or psychiatric disorders.

Aetiology

Aetiology varies according to the age of onset. In childhood- and adolescence-inherited disorders of metabolism, ante- and perinatal complications, infection, migrational errors, and the consequences of febrile convulsions predominate, in middle life trauma and tumour are most common, and in advanced years cerebrovascular disease and degenerative disorders are predominant.

Only one-quarter to one-third of cases of epilepsy are due to known causes. Many others fall into recognizable syndromes about which much is understood. The partial epilepsies are, by definition, due to focal areas of damage and dysfunction usually involving the cortex. However, although the site may be suggested by the seizure semiology, comprehensive investigation may fail to identify any abnormality. Even when it does so, the radiological appearance may lack aetiological specificity. Some generalized seizures may be identified as primary generalized epilepsy syndromes; for example, juvenile myoclonic epilepsy. These are of uncertain aetiology, though genetic factors are considered important; onset is in childhood or adolescence and the prognosis favourable.

In psychiatric practice seizures may arise iatrogenically; they are usually due to pharmacotherapy, less commonly to electroconvulsive therapy. They may result from the overhasty withdrawal of benzodiazepines or to the use of antidepressant or antipsychotic drugs, most of which are epileptogenic. Such seizures are thought to be provoked and do not form grounds for a diagnosis of epilepsy. Adjustment of drug dosage is usually all that is required. Provoked seizures may also occur during alcohol intoxication ('rum fits') or withdrawal; a genetic predisposition may play a part.

Diagnosis

The diagnosis of epilepsy depends first and foremost on historical information; the patient's own account of the seizure and the observations of a reliable informant are of tantamount importance. A family history of epilepsy should be sought; age of onset should be determined when possible. A history of birth complications, febrile fits, early head injury, or cerebral infection is of particular importance in seizures starting in childhood, adolescence, or early adult life. In middle life symptoms suggestive of developing intracranial pathology and in later life cerebrovascular and degenerative disorders should be sought. The clinician should be aware of specific circumstances and situations that may provoke seizures: alcohol or substance abuse, prescribed drugs that have epileptogenic properties, and intermittent photic stimulation. Physical examination will detect not only gross congenital abnormalities such as tuberosclerosis, but also more subtle features, for example facial or skull asymmetries. The differential diagnosis varies according to age group, but will include vasovagal attacks and pseudoseizures, particularly in the young, vertigo and transient ischaemic attacks in the elderly, and cardiogenic syncope, hypoglycaemic episodes, and migraine at any age.

The role of physical investigation is to confirm the diagnosis of epilepsy when this is in doubt and to identify the cause; it may also help to determine the type of epilepsy and, in the partial epilepsies, the site of seizure onset. Magnetic resonance scanning is now widely available and all new cases of adult-onset epilepsy and patients of any age with partial epilepsy should have the benefit of this technology. A sleep electroencephalograph is still mandatory and may be invaluable not only in differential diagnosis, but in determining the epilepsy subtype and seizure localization. Video-telemetry is invaluable when there is continuing diagnostic uncertainty, and in those cases in which precise localization is necessary for presurgical assessment. Functional neuroimaging may also aid localization.

In psychiatric practice epileptic seizures must be distinguished from psychogenic pseudoseizures, panic attacks, and aggressive episodes. The pseudoseizure may take different forms: the patient may fall or slump to the ground and remain still as in a syncopal attack; or there may be jerking or thrashing of limbs resembling a major tonic–clonic seizure. The absence of tongue-biting, incontinence, or significant injury is often said to distinguish the pseudoseizure from the epileptic seizure, but such guides are frequently unreliable. A history of other conversion disorders or illness behaviour may be obtained, but pseudoseizures also occur in individuals with epilepsy. A detailed description of the attack from the patient and from a witness will be of the greatest assistance in diagnosis, but when in serious doubt video-telemetry may offer a definitive answer. Other useful investigations include serum prolactin levels, which rise postictally to reach a peak between 20 and 30 min after a major epileptic seizure. Episodes of panic are sometimes mistaken for epileptic seizures. Extreme anxiety, especially when accompanied by hyperventilation, may lead to a subjective diminution in awareness, altered perception, and other features suggestive of complex partial seizures. The context in which the attack occurs, a description of initial autonomic arousal, and other symptoms of anxiety should lead to the correct diagnosis. Sudden outbursts of aggressive behaviour, particularly when out of character and context, often give rise to suspicions of epilepsy. Aggression, especially directed aggression, is extremely unusual as a feature of the epileptic seizure, though it may occasionally be seen during the phase of postictal confusion or postictal psychosis.

The psychiatric consequences of epilepsy

The prevalence of psychiatric morbidity among persons with epilepsy is greater than in the general population, but the increase in prevalence will vary according to the type of epilepsy, the presence and extent of brain damage, and the presence of cognitive and physical disability. The more reliable studies are drawn from

community samples. Of children between the ages of 5 and 14 years, 29 per cent showed some psychiatric disorder compared with 6.8 per cent of the general population. The figure rose to 58 per cent when brain damage was present.[4] Pond and Bidwell[5] surveyed 14 general practices and reported a prevalence of 29 per cent in adults, increasing to over 50 per cent in patients with temporal lobe epilepsy. Neurotic disability accounted for the great majority of cases. Psychiatric morbidity is over-represented in clinic attenders and in patients with partial epilepsy.[6]

Personality disorder and social development

Notions of an epileptic personality arising out of a hereditary 'taint' persisted well into the present century. The person with epilepsy was said to be explosively aggressive, rigid, egocentric, and irritable. These beliefs were formed by observations of often oversedated inmates of epileptic institutions. The concept of a specific epileptic personality has now largely been abandoned, though it is acknowledged that some features associated with, but not specific to, epilepsy may exercise a powerful influence on personality development. Many of these are consequences of brain damage rather than epilepsy as such. Thus learning difficulties, leading to limited educational opportunity, adult unemployment, and socioeconomic disadvantage may be significant personality determinants. But even in the epileptic individual without brain damage the sedative actions of anticonvulsant medication, the continuing stigma of seizure activity, and the social and occupational constraints are not without their effects on the developing personality.

A particular link between temporal epilepsy and abnormalities of personality has long been debated[7] and certain exaggerated traits (e.g. hypergraphia) are consistently reported,[8] but many of the personality difficulties may be explained by the refractory nature of temporal lobe seizures and the need for increased medication.

Psychoses

(a) Chronic interictal psychoses

Throughout the first half of this century the relationship between epilepsy and schizophrenia was debated at length, usually in terms of whether the presence of one condition encouraged or discouraged the development of the other—the affinity and antagonism hypotheses, respectively. In recent years, particularly following the publication of Slater's seminal studies,[9] informed opinion has moved firmly behind the first view. Epidemiological studies based on national registers[10,11] find a higher prevalence of chronic psychosis in epileptic subjects than in the general population. A neurology outpatient clinic study[12] reported schizophrenia to be nine times more common in epilepsy than in a migraine control group. The onset, cause, and clinical characteristics are, to a very large extent, indistinguishable from those of more usual forms of schizophrenia, although negative symptoms occur less frequently, thought disorder is rarely encountered and the outcome may be more benign. Psychosis usually develops 11–15 years following the onset of epilepsy. The aetiology remains uncertain. Cases in which the epilepsy takes the form of complex partial seizures arising from the mesial temporal or frontal lobes are over-represented; there may be a slight left-sided predominance. A family history of schizophrenia was thought to be unusual, but some recent studies have cast doubt on this assumption. Neuropathological examination, more readily available with the increasing practice of epilepsy surgery, has proved less informative than had been hoped, but subjects undergoing temporal lobectomy for resection of small neurodevelopmental lesions, e.g. ganglioglioma, dysembryoplastic neuroepithelioma (DNET)[13] appear at greater risk of developing a post-operative chronic interictal psychosis. The results of structural neuroimaging studies have been inconclusive with reports of both reduction and increase in amygdala size. The risk of bipolar illness or affective psychosis does not appear to be increased in epilepsy.

(b) Postictal psychosis

The other common form of epileptic psychosis develops following an exacerbation of seizure activity. Because of this close temporal relationship the instrumental role of epilepsy in the aetiology of the psychosis is not open to question. The salient characteristics have been described.[14] The psychosis usually occurs following a cluster of complex partial seizures usually followed by secondary generalization. Characteristically, the subject appears to make a complete recovery, but 1 to 2 days later, the so-called lucid interval, becomes floridly psychotic. Affective, schizophrenic, and confusional elements may be present. An electroencephalogram recorded at the time shows increased focal discharge activity, though less than would be seen in partial status. Spontaneous recovery is to be expected, usually within a week of onset. The first episode is usually delayed until early adult life, a decade and a half after the first seizure. Half of those affected will have further similar episodes. Fifteen to 20 per cent will progress to develop a chronic interictal psychosis. Bilateral EEG discharges are seen more commonly in those patients who develop postictal psychosis. Functional neuroimaging at the time of the psychosis demonstrates relative mesial temporal hyperperfusion suggestive of an active process, either continuous seizure discharge or seizure inhibition.

Rarely, the introduction of certain anticonvulsant drugs may seem to precipitate psychotic episodes. This may be associated with rapid seizure control and give rise to the term 'forced normalization'.[15] In recent years vigabatrin has seemed to be the drug most responsible.

Sexual function

A diminution in sexual interest, a decrease in activity, and impaired performance are the most common aspects of sexual dysfunction in epilepsy. Men have been studied more thoroughly than women. In patients receiving antiepilepsy drugs libido may be diminished and erectile potency impaired. Levels of free testosterone, the biologically active hormone, may be diminished. Sperm concentrations may be reduced, morphological abnormalities may occur more commonly and mobility may be reduced. Menstrual irregularities are increased in women with epilepsy and are related to seizure frequency, polytherapy with antiepilepsy drugs, and the use of sodium valproate. Infertility, ovulation, and the polycystic ovarian syndrome occur more commonly. Hyposexuality may be more pronounced in patients with partial epilepsy, but this may simply reflect the refractory nature of partial epilepsy and the greater amount of drugs prescribed.[16,17]

Epilepsy and crime

There is an association between epilepsy and criminal activity. Male epileptics are three times more likely to receive a criminal conviction,[18] in England and Wales between 0.7 and 0.8 per cent of the

prison population suffers from epilepsy, a figure considerably higher than in the general population,[19] but the pattern of offence does not differ. The reasons for this are unclear. Low intelligence and low socioeconomic class are common to both epilepsy and prison populations; the role of brain damage as distinct from epilepsy has not been fully evaluated. Crimes of violence in the context of disturbed ictal or postictal behaviour do occur, but are extremely rare.[20]

Neurotic illness

Neurotic illness, more especially anxiety and depression, largely account for the increased psychiatric morbidity that is to be found in patients with epilepsy. These disorders have few distinctive characteristics. They may be explained by the adverse social, educational, and economic disadvantages that confront people with epilepsy. A phobic anxiety akin to agoraphobia may be seen in some individuals who fear the onset of a seizure in public places. Obsessive–compulsive disorder does not seem to occur more commonly in epilepsy.

Epilepsy and suicide

Suicide is increased fivefold among patients with epilepsy, but is considerably higher among those with temporal lobe epilepsy.[21] Among patients presenting with self-harm, epileptic subjects are over-represented from five- to sevenfold.[22]

Treatment

Seizure control is most effectively achieved through the appropriate use of anticonvulsant drugs. The use of behavioural techniques to inhibit seizure activity holds promise, but is still in its infancy. Surgical treatment is increasingly available, but should only be considered for those patients who have failed repeatedly to respond to drug therapy and who have resectable lesions. Drug treatment should aim to achieve seizure control through the use of a single anticonvulsant drug, thus minimizing unwanted side-effects. This should be possible in the great majority of patients. If a first-choice drug fails, a second-choice drug should be substituted. Polytherapy may be necessary, notably in the management of partial seizures, but should be avoided wherever possible. Most first-line drugs, except phenytoin, are described in Chapter 6.2.6. Phenytoin, although relatively toxic, especially to the cerebellum, is an effective anticonvulsant and still widely prescribed. Serum monitoring is particularly important. More recently introduced drugs include topiramate and levetiracetam. The benzodiazepines, clobazam and clonazepam, may be used in adjunctive therapy. Lamotrigine and levetiracetam appear to be as efficacious as the longer established drugs and have less side-effects. There is little place for either phenobarbitone, which is unduly sedative and may cause depression and behavioural disturbance especially in children and adolescents, or vigabatrin, which may cause visual field constrictions. Vigabatrin, and to a lesser extent topiramate may cause psychotic episodes. The need for continuing anticonvulsant therapy should be reviewed by a specialist neurologist once the patient has been free of seizures for 2 years. For a more detailed account of the management of epilepsy and of status epilepticus the reader is referred to Shorvon *et al.*[23]

The treatment and outcome for psychogenic seizures have received increasing attention. The importance of early diagnosis is emphasized.[24] Psychological treatment, particularly cognitive–behavioural therapy, can be effective. Reduction or cessation of symptoms can be achieved in at least half of the cases within a 6–12 month period.

5.3.4 Medical conditions associated with psychiatric disorder

James R. Rundell

Introduction

Seven out of 10 office visits to a primary care practitioner are related to a chronic illness.[1] There are high levels of association of many of these chronic conditions with psychiatric disorders.[1] Comorbid medical and psychiatric conditions increase use of medical resources and costs, as well as amplify functional impairment.[2] For example, depression is associated with an approximately 50 per cent increase in medical costs of chronic medical illness, even after controlling for severity of physical illness.[2, 3] Dementia is associated with hospital costs up to 75 per cent higher than for non-demented patients.[4]

As important as a comprehensive knowledge of psychiatric diagnosis and psychosocial formulation is to a consulting psychiatrist, it is also vital to understand the pathophysiology and clinical characteristics of the medical and surgical conditions that frequently coexist with psychiatric disorders. It is also important to know the behavioural and psychiatric side effects of medications and substances. Lacking this data permits only a partial and inadequate approach to diagnosis and treatment.

This section describes general medical disorders associated with psychiatric syndromes. The pathophysiology and clinical characteristics of the medical disorder are described first, followed by psychiatric syndromes often seen with that diagnosis.

Cardiovascular disorders

Ventricular dysrhythmias

Sudden cardiac death is responsible for 300 000 deaths annually in the United States.[5,6] Sympathetic nervous system activity increases the likelihood of ventricular dysrhythmias[6] especially when there is prior ischaemic damage. Sympathetic nervous system stimulation, which increases heart rate, can trigger ectopic sites in the myocardium, which override normal conductive pathways, producing potentially fatal dysrhythmias. Either the peripheral sympathetic nervous system or the central nervous system can generate stimuli leading to this phenomenon. Therefore, anxiety and stress may increase the risk of dysrhythmia.[7] Among individuals with pre-existing heart disease or dysrhythmias, activities which precipitate adrenergic discharge may produce ventricular dysrhythmias—for example, public speaking, road rage, and recall of emotionally charged events.[8] In one series of patients, psychological stressors were more reliable triggers of dysrhythmias than physical manoeuvres such as carotid sinus massage, hyperventilation, and the Valsalva manoeuvre.[8] Simple and inexpensive non-pharmacological techniques such as relaxation training, hypnosis, and medication have been shown to improve ventricular dysrhythmias.[8, 9]

Depression has also been associated with lower threshold for ventricular dysrhythmias.[10] Patients with depression exhibit dysregulation of the sympathoadrenal system—hypothalamic corticotropin releasing factor-containing neurons appear to stimulate several autonomic centres involved in regulating sympathetic activity.[11] Smith *et al.*[8] found that deaths within 18 months of a myocardial infarction were concentrated among depressed patients with 10 or more premature ventricular contractions per hour. In this group of patients, 83 per cent of mortality was due to 'arrhythmic deaths'.

Hypertension

More than 60 million Americans have hypertension. The prevalence among whites is about 15 per cent, but is over 25 per cent in the African–American population. 95 per cent of people with hypertension have primary, or idiopathic, hypertension. The remaining 5 per cent have secondary hypertension, due to conditions or substances such as renal disease, steroids, or oral contraceptives. Managing hypertension reduces the morbidity and mortality of the condition. Constitutional and stress-related factors contribute to hypertension. Patients with hypertension, in general, have a more prolonged vasoconstrictive response to psychological stress than patients with normotension,[12] which may result in both short-term and long-term blood pressure elevation due to this interplay of environmental and constitutional factors.[13]

Myocardial infarction

Myocardial ischaemia often leads to myocardial infarction. Acute myocardial infarction can develop at rest or with normal activity. Deaths associated with acute myocardial infarction occur during the first few hours after the onset of symptoms, and are the result of ventricular fibrillation. It is important that patients know the warning signs and seek care promptly when symptoms develop. Unfortunately, as many as 20 per cent of myocardial infarctions are unrecognized. Denial of acute myocardial infarction symptoms and warning signs by individuals, particularly men, are a frequent source of mortality and morbidity. The roles of gender-specific differences in terms of establishing predictors for clinical outcomes is understudied.[14]

The most common precipitant of myocardial ischaemia among patients with pre-existing coronary artery disease is stress.[15] Stress-induced ischaemia is more common than ischaemia induced by physical stressors. Recovery from a myocardial infarction is also highly dependent on psychosocial factors. Ruberman *et al.*[16] demonstrated that postmyocardial infarction patients, who are socially isolated and have high stress levels, have at least four times

the risk of death, compared to their counterparts who have lower levels of stress and isolation. Particularly, lack of a close confidant predicts negative outcomes after myocardial infarction, including further cardiac events.[17] In addition, emotional distress after myocardial infarction is associated with poorer outcomes in terms of quality of life and psychological adjustment.[18]

Depression may occur in 31 per cent of patients admitted for acute myocardial infarction.[19] Presence of major depressive disorder in a patient with cardiac disease has a significant association with morbidity and mortality. Carney *et al.*[20] found that major depressive disorder was the best single predictor of myocardial infarction, angioplasty, and death during the 12 months following cardiac catheterization. Patients with a history of myocardial infarction and major depressive disorder are up to three to five times more likely to die within 6 months of discharge than non-depressed patients following infarction.[19] As to how depression increases risk include hypothalamic–pituitary–adrenocortical and/or sympathoadrenal hyperactivity, diminished heart rate responsivity, ventricular instability, myocardial ischaemia due to stress, and alterations in platelet receptors and reactivity.[21, 22] The data are limited, antidepressant treatment, stress management, and relaxation training in patients with coronary artery disease or myocardial infarction and major depression probably reduces mortality.[23]

Type A and type D personality

Assessment of the patient's personality and behavioural style is important because type A behavioural patterns increase the risk of a myocardial infarction.[24] The type A behaviour pattern includes ambitiousness, aggressiveness, competitiveness, impatience, muscle tenseness, alertness, rapid and emphatic vocal style, irritation, cynicism, hostility, and an increased potential for anger. Very frequently, such individuals are also hard-working 'workaholics' who deny physical or emotional vulnerability. Their self-esteem is often dependent on constant achievement. Unstable cardiac function poses an immediate and ongoing threat to them, and challenges their need to be in control of their environment and bodies. Many clinicians believe that modifying a type A behaviour pattern is an integral part of preventing future myocardial infarctions.[24] Group or individual psychotherapy that reduces type A behaviour and other behavioural risks has been shown to lower the incidence of recurrent infarction and cardiac death in patients with a previous myocardial infarction.[25]

There has been recent attention to the type D personality construct.[26, 27] D behaviour is characterized by inhibition of negative emotions and avoiding social contacts with others. D personality patients may be at increased risk for cardiovascular morbidity and mortality.[26] Cortisol may be a mediating factor for this increased risk. D personality predicts cardiac events after controlling for concurrent stress and anxiety.[27] Studies are needed to validate this personality construct, further define associations with cardiac outcome, and develop treatment approaches for patients with this personality style.

Respiratory disorders

Asthma

Asthma affects between 3 and 5 per cent of the population of the United States. The three hallmarks of the disease are airway inflammation, airway hyperresponsiveness, and a partially reversible airway obstruction. It is one of the classic 'psychosomatic diseases'. Emotional arousal causes changes in airway tone. The severity of an asthma attack is highly correlated with presence of major depressive disorder, panic attacks, general anxiety, and level of fear among children, adolescents, and adults.[28] Asthma patients with psychiatric disorders have worse asthma control, more frequent exacerbations, and worse quality of life than asthma patients without psychiatric disorders.[29] Education, relaxation, biofeedback, and family therapy have each shown efficacy in the management of asthma.[30] Important in the management of asthma is education about the adverse effects of antiasthma medications, which include jitteriness, palpitations, and insomnia. These side effects may require treatment with behavioural and/or psychopharmacological therapies.

Chronic obstructive pulmonary disease

Patients with chronic obstructive pulmonary disease (COPD) have slowly progressive airway obstruction. The course of the disease is punctuated by exacerbations due to pulmonary infection, heart failure, and poor compliance with prescribed therapy. Generally affects middle-aged and older patients. They present with dyspnoea, exercise intolerance, cough, and sputum production. Physical examination reveals lung overinflation, prominent use of accessory muscles to augment respiration, diminished breath sounds, and diffuse wheezing. As with asthma, pharmacological treatments for COPD can cause psychiatric symptoms, especially higher doses of steroid medications. Patients with COPD must stop smoking; pulmonary function declines faster in smokers who develop COPD than non-smokers who develop COPD.

The chronic hypoxia caused by COPD compromises cognition and mood, which, in turn, can produce delirium, mood lability, mood disorders, and restriction in daily activities. Depression is present in 20–60 per cent of COPD patients.[31] Depression adversely affects treatment adherence and may increase risk for poor outcomes. There is considerable evidence that supplemental oxygen improves cognitive function and quality of life.[30] Unfortunately, mood improvement with supplemental oxygen has not been conclusively demonstrated.

Panic attacks are reported in up to 38 per cent of patients with COPD.[32] Benzodiazepines, which are highly effective for controlling panic attacks, have limited usefulness in patients with COPD because they can suppress respiratory function and if used chronically result in tolerance and dependence. Carbon dioxide likely plays a role in promoting panic attacks; carbon dioxide levels increase with COPD disease progression. Antidepressants are useful in patients with COPD who develop panic attacks. Low-dose neuroleptic medications (e.g. 0.5–1.0 mg risperidone orally two to three times daily) are also sometimes used for severe fear and panic, especially in intensive care unit settings (e.g. when weaning the patient from a respirator). Neuroleptics do not directly suppress respiration, though caution must be exercised so that the sedation induced by neuroleptics—potentially combined with other sedating agents—does not reduce respiratory effort beyond that required to maintain adequate oxygenation. Function must also be monitored to ensure that neuroleptic use does not affect cardiac conduction or cause dysrhythmias.

Pulmonary embolism

Patients with psychiatric disorders, including bipolar disorder, anxiety disorder, and schizophrenia, are at increased risk for pulmonary embolism.[33] Embolism may account for a portion of the

excess risk of death among people with schizophrenia, even after controlling for blood pressure, cholesterol, body mass index, smoking, exercise, alcohol intake, and education level.[34] Most thromboemboli originate in the deep veins of the thigh. The diagnosis of pulmonary embolus is often missed because the clinical findings are non-specific. They include dyspnoea, pleuritic chest pain, haemoptysis, tachypnoea, and wheezing or crackles on pulmonary examination. Number of factors predispose to pulmonary thromboemboli: cancer, stroke, myocardial infarction, congestive heart failure, sepsis, pregnancy, lower extremity fractures, major surgical procedures, polycythaemia vera, and paroxysmal nocturnal haemoglobinuria. Pulmonary emboli are treated with heparin and warfarin. Fibrinolytic drugs and acute embolectomy are used in certain situations. The differential diagnosis of sudden anxiety or a panic attack includes pulmonary embolus.

Sleep apnoea

Apnoea is defined as the complete cessation of respiratory airflow for 10 or more seconds.[35] Apnoea can occur during any sleep stage, but is particularly likely to occur during the period of rapid eye movement sleep. It is important to remember that normal people have apnoeic episodes during sleep. When apnoeic events are frequent and prolonged, they lead to chronically disrupted sleep and excessive daytime somnolence. This defines the condition known as sleep apnoea. Sleep apnoea can be central, obstructive, or a mixture of the two. Central sleep apnoea is caused by an abnormal central drive to the respiratory muscles. Congestive heart failure is the most common cause, followed by neurological disorders involving the brainstem and respiratory centres. Obstructive sleep apnoea is more common; obesity is a major risk factor, but is not always present. Aside from disrupted sleep and daytime somnolence, associated symptoms include an inability to concentrate, depressed mood, irritability, and personality changes. The sleeping partner often sleeps in another room because of the individual's very loud snoring, snorting, gasping, and restlessness. Treatment with continuous positive airway pressure is often effective. Patients should avoid sedatives and alcohol. If obese, they should lose weight.

Gastrointestinal disorders

Oesophageal dysmotility

Oesophageal dysmotility can be demonstrated in 30 per cent of patients with non-cardiac chest pain;[36] a significant number of non-cardiac chest pain patients lack any evidence of oesophageal reflux and have reduced perception thresholds for pain. Cases of oesophageal dysmotility often lead to psychiatric consultation. Situational stress has not been conclusively linked to oesophageal dysmotility, but major psychiatric illness has.[37] The majority of patients with oesophageal motility disorders have an Axis I psychiatric illness, especially major depressive disorder (52 per cent), generalized anxiety disorder (36 per cent), somatization disorder (20 per cent), and substance-related disorders (20 per cent).[38] Smooth muscle relaxants, such as calcium-channel blockers, are superior to psychiatric treatments in improving physiological measures (such as oesophageal motility testing), antidepressants, and behavioural therapies produce more impressive changes in patients' subjective oesophageal complaints and level of psychological well-being.[39]

Irritable bowel syndrome

Irritable bowel syndrome (IBS) ranks second only to the common cold as a cause of absenteeism from work,[40, 41] affecting between 8 and 17 per cent of the general population in the United States.[40] Symptoms include abdominal pain (relieved by defecation), and various forms of disturbed defecation such as altered stool frequency, altered stool form, altered stool passage, passage of mucus, and bloating. Symptoms must be continuous or recur within 3 months to meet the criteria for a diagnosis of irritable bowel syndrome. The severity of this syndrome frequently correlates with periods of emotional stress; the sympathetic nervous system inhibits gastric motility.

The enteric nervous system contains approximately 100 million neurons, close to the same number found in the spinal cord,[41] and more than those distributed to any other organ or physiological system. It therefore, makes sense that the gastrointestinal tract is uniquely sensitive to the neurophysiological aspects of the stress response. With IBS who seek medical care exhibit high rates of psychiatric disorders. The most frequently occurring are panic disorder (26 per cent), generalized anxiety disorder (26 per cent), social phobia (26 per cent), and major depressive disorder (23 per cent).[42] Patients with irritable bowel syndrome who are depressed and complain of diarrhoea may benefit from tricyclic antidepressant treatment, at least partially because of their anticholinergic effects. Anxious patients may also benefit from, and well-tolerate buspirone. At least one in eight IBS patients are offered an antidepressant,[43] though data suggest that antidepressants are more consistent in improving global measures than specific gastrointestinal symptoms. A group of patients with treatment-refractory irritable bowel syndrome—nearly half had no psychiatric disorder—more than 90 per cent benefited from low-dose antidepressant or antianxiety medications: 92 per cent of patients improved, and 56 per cent experienced complete remission of irritable bowel symptoms.

Inflammatory bowel disease

Inflammatory bowel disease is the collective term for patients who have ulcerative colitis or Crohn's disease. The aetiology of inflammatory bowel disease is unknown, but it may involve immunological, infectious, or environmental factors.[44] The primary manifestations of acute ulcerative colitis are rectal bleeding, diarrhoea, urgency, fever, weight loss, and, sometimes, abdominal pain. Crohn's disease presents with malaise, fever, abdominal pain, and frequently rectal bleeding. Surgical treatment (colectomy) cures ulcerative colitis but not Crohn's disease. However, surgery is usually a last resort in ulcerative colitis.

Despite the strong beliefs of early psychosomatic theorists, there is no objective evidence that psychiatric disorders cause inflammatory bowel disease. However, patients with this disease and who have psychiatric disorders are more likely to have unexplained physical symptoms in other organ systems, more disability than patients with similar disease severity and no psychiatric disorder, and prior histories of physical and sexual abuse.[45] Exacerbations of inflammatory bowel disease symptoms are positively associated with major life events and major stressors.[41,46] Stress-induced alterations in gastrointestinal inflammation may be mediated through changes in hypothalamic–pituitary–adrenal axis function and alterations in bacterial-mucosal interactions, and via mucosal mast cells and mediators such as corticotrophin releasing factor.[47] Treatment focuses on the identification and treatment of

psychiatric disorders, if found, and on stress management and quality of life issues. Walker *et al.*[44] treated inflammatory bowel disease patients who had major depression with an antidepressant and found marked improvement in depression and ability to function. Relaxation, stress management,[45, 48] and hypnotherapy were found to reduce abdominal pain and diarrhoea.

Gastroesophageal reflux and peptic ulcer disease

Acid reflux and peptic ulcer disease are common causes of non-cardiac chest pain.[49] Ulcer disease occurs when the balance between stomach acid and mucosal defence factors is disrupted. Gastric acid, *Helicobacter pylori*, and non-steroidal antiinflammatory drugs are the most important risk factors in the development of peptic ulcers.[50] The majority of patients with peptic ulcer disease are present with epigastric pain that begins 1 to 3 h after eating. Treatment is aimed at reducing gastric acid (e.g. using cimetidine and ranitidine), improving mucosal defences (with, for instance, sucralfate), and/or eradicating *H. pylori* (antibiotics).

On examination, at least half of the patients initially suspected of having peptic ulcer disease do not have evidence of an ulcer.[51] Among patients with non-ulcer dyspepsia, psychiatric comorbidity is high. Magni reported that 87 per cent of patients with non-ulcer dyspepsia have one or more anxiety disorders compared with 25 per cent of those with dyspepsia where there is endoscopic evidence of ulcer.[52] Ang *et al.* reported that a majority of patients who have typical symptoms of gastroesophageal reflux do not have erosions on examination; those patients with non-erosive reflux disease have a higher prevalence of psychiatric morbidity.[53]

Metabolic disorders

Obesity

Obesity is becoming an epidemic throughout the developed world. Existing standard treatments in university settings, only 20 per cent of obese patients lose around 9 kg (about 20 lbs) at 2-year follow-up and only 5 per cent of patients lose about 18 kg (40 lbs).[54] The majority of people who lose weight on a diet gain it all back. Weight loss and weight maintenance after loss is associated with more initial weight loss, reaching a self-determined goal weight, having a physically active lifestyle, a regular meal rhythm including breakfast and healthier eating, control of overeating, and self-monitoring of behaviours.[55] Associated with weight regain after significant weight loss include a history of weight cycling, disinhibited eating, binge eating, more hunger, eating in response to negative emotions and stress, and more passive reactions to problems.

There is no ideal treatment for weight loss. Weight-loss programmes vary considerably in terms of risk, cost, and efficacy. For most patients with mild to moderate obesity, a multidimensional approach is best, combining diet, exercise, behaviour modification, and social support. Motivated patients with morbid obesity (more than 100 per cent overdesired body weight) may be considered for very low calorie diets, with the emphasis on long-term diet, behavioural change, exercise, and social support. Increasingly, surgical approaches are being used; patient selection procedures have been developed to address motivations, psychological resilience, dietary education, potentially complicating psychiatric or substance-related factors, and ensuring patients are aware these procedures are not without risk—there are many structural and metabolic complications, including death. It is important to treat comorbid psychiatric illnesses. It is associated with excessive intake of carbohydrate-rich foods and with resistance to engaging in physical activity.[56] With mood disorders and schizophrenia have a high prevalence of risk factors for cardiovascular disease, diabetes, and obesity, which are on the order of 1.5 to 2.5 times higher than in the general population.[56] On the other hand, it is also important to be mindful of metabolic effects of psychopharmacological agents, especially second generation antidepressants. The latter are associated with weight gain, dyslipidemia, and abnormal glucose homeostasis, especially with olanzapine.[56]

Wilson's disease

Wilson's disease, or hepatolenticular degeneration, is an autosomal recessive disorder affecting between one and three persons per 100 000 of the population. The abnormality in Wilson's disease is defective hepatic excretion of copper. The consequence is copper deposition and injury to many organs, particularly the liver and the brain, including diffuse white matter lesions seen on MRI in many patients.[57] The genetic defect occurs on chromosome 13, and the gene product is probably a transmembrane copper transporter.[58] Because copper accumulation is slow, signs and symptoms do not appear before the age of 6 years. Most patients present with manifestations of organ damage between the ages of 8 and 20. Prolonged extrahepatic release of copper not bound to ceruloplasmin causes basal ganglion destruction, and sometimes cerebral cortex destruction. Prominent neuropsychiatric symptoms include irritability, aggression, disinhibition, and recklessness. Depressive features are also common. The severity of psychiatric symptoms correlates with the severity of neurological symptoms, especially dystonic and bulbar manifestations.[58]

Disorders of lipid metabolism

Intervention studies have shown that cholesterol reduction using diet, drugs, or surgery reduces the risk of developing or worsening coronary disease. In general, a 1 per cent reduction in low-density lipoprotein-cholesterol has been associated with roughly a 2 per cent reduction in disease end-points.[59] General agreement exists that eating less saturated fat and cholesterol, and adopting a diet and exercise habits to reduce obesity will benefit the health of most people. Exercise has a much greater effect in reducing triglyceride levels than in reducing low-density lipoprotein-cholesterol concentrations. Triglyceride levels are reduced after even a single exercise session. The efficacy of regular aerobic exercise in mild to moderate hypertriglyceridaemia has been repeatedly demonstrated.[60]

Hepatic encephalopathy

The pathogenesis of hepatic encephalopathy is related to widespread hepatic necrosis, commonly due to an acute viral infection, such as hepatitis B, or exposure to hepatotoxins. Common hepatotoxins that lead to liver failure include acetaminophen, isoniazid, halothane, valproic acid, mushroom toxin, and carbon tetrachloride. Hepatic encephalopathy that accompanies acute fulminant liver failure is frequently associated with cerebral oedema, which might be reversible and a treatable factor. Oedema is the leading cause of death in acute hepatic failure. It may respond to the administration of mannitol and measures to control agitation.[61] For patients with acute hepatic failure who have significant hepatic encephalopathy, liver transplantation increases survival from 20 to 80 per cent, making rapid and accurate diagnosis vital. Survival of

liver transplant patients with neuropsychiatric involvement is significantly lower if there is liver disease alone.[61] There is also an increased incidence of liver disease among patients with primary psychiatric disorders, including substance use disorders.[62] B virus carriers are almost three times more likely to have psychiatric disorders than comparison subjects.[63]

Endocrine disorders

Diabetes mellitus

Type I diabetes (insulin-dependent diabetes mellitus) occurs when the pancreas' ability to secrete insulin is clinically impaired. Hyperglycaemic symptoms emerge when 80 to 90 per cent of islet cells fail to produce insulin. Around 90 per cent of diabetics have type II diabetes (non-insulin-dependent diabetes mellitus). Type II diabetes is characterized by peripheral resistance to the action of insulin and decreased insulin secretion, in spite of the presence of elevated serum glucose levels. Patients with type II diabetes can often avoid or postpone the need for insulin treatment with appropriate diet and exercise. Both type I and II diabetes are associated with a genetic predisposition.[64]

The most frequent psychiatric disorders in patients with diabetes are anxiety and depressive disorders. Among general populations of diabetics, anxiety disorders occurred in up to 45 per cent and depressive disorders in up to 33 per cent.[65] Rosenthal *et al.*[66] in a 3-year prospective study of hospitalizations and mortality in older patients with diabetes, found that the combined presence of retinopathy and a high depression score on the Geriatric Depression scale had the strongest relationship with mortality. Patients with diabetes are twice as likely to experience depression as those without diabetes; this holds true for both type I and II diabetes.[66] Patients with schizophrenia are at increased risk for developing type II diabetes[67] is growing interest in the possibility that there are shared inherited risk factors for the two disorders,[68] though the evidence is weak and largely circumstantial. In addition, second generation antipsychotic medications, especially olanzapine, are associated with type II diabetes mellitus and abnormal glucose metabolism.

Diabetic patients who have psychiatric disorders can have less disease morbidity when their psychiatric disorders are appropriately treated, highlighting the importance of monitoring diabetic patients for psychiatric disorders and monitoring psychiatric patients for excess weight and diabetes.[69] Independent of the level of physical illness present in type I or II diabetes, the presence of anxiety and/or depression is important in determining the quality of a patient's life.[70] Treatment adherence problems complicate care, particularly in children and adolescents with type I diabetes. A great deal of patience, family support, and education is necessary to minimize passive and active non-compliance.

Hypothyroidism

Hypothyroidism is usually the result of primary failure or ablation of the thyroid gland, hypothalamic dysfunction, pituitary dysfunction, autoimmune thyroiditis, or lithium therapy. Clinical manifestations of hypothyroidism include fatigue, cold intolerance, lethargy, weakness, weight gain, constipation, menstrual irregularities, hair loss, slow reaction time, oedema, delayed reflexes, and bradycardia. Hypothyroidism occurs in as many as 10 per cent of patients taking lithium; lithium-induced hypothyroidism is more likely to occur in women.[70]

The association between clinical hypothyroidism and depression is well known. Gold *et al.*[71] found that 5 per cent of a series of 250 patients with major depressive syndromes had at least subclinical hypothyroidism. In many patients with hypothyroidism, the depression responds to thyroid hormone replacement alone,[72] but the response may take a long time. When that is the case, antidepressants are indicated and efficacious.[71]

Hyperthyroidism

The most frequent clinical manifestations of hyperthyroidism are nervousness, diaphoresis, hypersensitivity to heat, palpitations, fatigue, weight loss, tachycardia, dyspnoea, and weakness. The most common causes include Graves' disease, toxic adenoma, and toxic multinodular goitre. Less common causes include Hashimoto's thyroiditis, postpartum hyperthyroidism, and factitious hyperthyroid state.

As with hypothyroidism, depressive and anxiety syndromes are the most common psychiatric conditions seen among patients with hyperthyroid states; there is a three-fold increased risk for development of mood disorder following hospitalization with hyperthyroidism.[73,74] When patients have depressive or anxiety syndromes in the context of hyperthyroidism, and have no past histories of psychiatric disorders, the psychiatric symptoms resolve more than 90 per cent of the time when the hyperthyroidism resolves. This obviates the need for other psychiatric interventions unless antithyroid medication, radioactive iodine, or thyroid surgery has not been successful.[74] Anxiety symptoms will disappear in direct relation to the reduction of thyroid hormone levels. Depressive symptoms are not quite so linearly related and may resolve at a slower pace as thyroid hormone level normalize.

Hypoparathyroidism

Parathyroid hormone mobilizes calcium from bone, induces renal reabsorption of calcium, increases renal clearance of inorganic phosphate, and promotes intestinal reabsorption of calcium. Hypoparathyroidism would be expected to result in hypocalcaemia, which can cause delirium. Hypoparathyroidism can result from autoimmune destruction of the parathyroid glands, removal of the parathyroids, disruption of the glands' blood supply, tumour, or neck irradiation. Medical and neuropsychiatric symptoms and signs are related to the level of serum calcium and the rate at which hypocalcaemia develops. Faster the hypocalcaemia develops, the more likely delirium and other neuropsychiatric symptoms are to occur. The most frequent symptoms are caused by neuromuscular irritability and include paraesthesias, carpal pedal spasm, laryngospasm, blepharospasm, and bronchospasm.[75] Cardiovascular manifestations include prolonged Q–T interval, heart block, and congestive heart failure. The most common neuropsychiatric symptoms and signs are seizures, EEG abnormalities, increased intracranial pressure, disorientation, confusion, and extrapyramidal symptoms. The mainstays of treatment are calcium and vitamin D. Neuropsychiatric syndromes should resolve with the normalization of serum calcium.

Hyperparathyroidism

Typically, hypercalcaemia is discovered by routine laboratory testing in patients without obvious illness. Primary hyperparathyroidism is the most common cause of hypercalcaemia among adult patients; among hospitalized patients, malignancy is the most

common cause.[75] Reversible hyperparathyroidism and hypercalcaemia are also associated with lithium therapy.[76] In primary hyperparathyroidism, parathyroid hormone is secreted inappropriately, despite an elevation in the ionized calcium level. Signs and symptoms of hyperparathyroidism include nausea, vomiting, anorexia, constipation, proximal muscle weakness, polyuria, polydipsia, impaired renal function, hypertension, short Q–T interval, bradycardia, and a number of neuropsychiatric symptoms. The latter include lethargy, drowsiness, impaired concentration ability, and confusion. In severe cases, there may be stupor or coma, psychosis, and cognitive impairment are common in patients who have serum calcium levels above 16 mg/dl. Depressive symptoms, but not cognitive symptoms, tend to resolve with treatment.[77] Cognitive symptoms may improve, but residual symptoms usually remain.

Cushing's syndrome

Hypersecretion of cortisol by the adrenal gland can result in Cushing's syndrome. Cushing's syndrome can also be due to exogenous ACTH or glucocorticoid administration, or endogenous hyperproduction of these hormones. Because a physiological release of cortisol occurs during periods of stress or duress, it is common to see elevations of serum cortisol during the courses of many psychiatric disorders, including major depressive disorder, alcoholism, anorexia nervosa, panic disorder, and psychoactive substance-withdrawal syndromes. The more common clinical signs and symptoms of Cushing's syndrome, whether endogenous or exogenous, include fat redistribution, menstrual irregularities, dysphoria, thin skin, moon facies, increased appetite, sleep disturbances, hypertension, hypercholesterolaemia, hypertriglyceridaemia, poor concentration, impaired memory, euphoria, glucose intolerance, striae, and hirsutism.

At least half of all patients with Cushing's syndrome will experience depressive or manic symptoms[78]; the symptoms will be moderate to severe in half of these patients. Many will also experience psychotic symptoms. Symptoms are dose-related when due to exogenous steroids. Depression or mania due to Cushing's syndrome will eventually remit when the hypercortisolaemia is corrected, the return to euthymia is usually gradual. When depression or mania is slow to remit, treatment with antidepressants or mood stabilizers is warranted.

Addison's disease

Addison's disease is the result of an autoimmune process that destroys the adrenal glands; it is the most common cause of primary adrenal insufficiency in the industrialized world, accounting for about 65 per cent of cases.[70] Both glucocorticoid and mineralocorticoid secretion are diminished in this condition. Clinical manifestations of adrenal insufficiency include weight loss, fatigue, vomiting, diarrhoea, anorexia, and salt-craving. Patients with Addison's disease will require lifelong replacement of both glucocorticoids and mineralocorticoids. Patients may be misdiagnosed with major depressive disorder, personality disorder, dementia, or somatoform disorders. It is not uncommon for the diagnosis to be delayed for many months; Addison's disease is a disorder to be continually mindful about in a patient with treatment-resistant depression.

Hyperprolactinaemia

Prolactin is synthesized in the pituitary gland; its secretion is increased during pregnancy, enhancing breast development. Prolactin secretion is inhibited by glucocorticoids and thyroid hormone, it is predominantly under the inhibitory control of dopamine.[70] Dopamine is, in fact, prolactin inhibiting factor. This is why dopamine blocking medications such as neuroleptics can cause hyperprolactinaemia. Symptoms of hyperprolactinaemia include breast development and lactation. These bothersome side effects of neuroleptics, particularly in men, can be modulated by changing to a more favourable neuroleptic medication, such as a second generation antipsychotic.

Hypopituitarism

Hypopituitarism occurs when multiple pituitary hormones exhibit decreased secretion. It can be due to either gland destruction or inadequate stimulation by factors that regulate pituitary functioning. Common causes of hypopituitarism are pituitary adenomas, hypothalamic tumours, metastatic carcinoma (especially breast and bronchus), and cerebral trauma and haemorrhage.[70] Other causes include vascular disorders, immunological conditions, and a variety of congenital anomalies. Clinical manifestations depend on which hormones are deficient; signs and symptoms are those of the individual deficiency states. Other signs that may be present when there is hypopituitarism include headache, visual loss, and radiographically discovered sella enlargement. Treatment of patients with hypopituitarism involves hormone replacement therapy and surgery when accessible lesions are present.[70]

Autoimmune disorders

Systemic lupus erythematosus

Systemic lupus erythematosus is characterized by the production of autoantibodies that injure tissue in several organ systems, most frequently the skin, central nervous system, kidney, and lungs. In addition, non-specific symptoms occur in a large majority of patients, including fatigue, fever, weight loss, arthralgias, and myalgias.[79] The most common presenting symptoms are fever, arthralgias, butterfly rash, photosensitivity, Raynaud's phenomenon, and mucous ulcers. The laboratory diagnostic hallmark of systemic lupus erythematosus is the production of high-titre autoantibodies directed against a variety of cell nucleus components (antinuclear antibodies). Systemic lupus erythematosus has no known cure, so treatment is based on symptom relief, suppression of inflammation, and preventing future pathology.

The most common psychiatric presentations of active systemic lupus erythematosus are psychosis, delirium, seizures, and cognitive dysfunction.[80] Autoantibodies to neuronal membranes, which interfere with the ability of neurones to respond to stimuli, may account for most neuropsychiatric deficits and symptoms,[81] though CNS vasculitis during the course of this disease may also play a role in some patients. Symptoms in lupus patients are likely to be related to unique sets of autoantigens,[82] and are related to antibodies against N-methyl-D-aspartate (NMDA) receptors.[83] Antibodies may be partially responsible for depression, short-term memory problems, and new learning difficulties in lupus patients. Significantly associated with declining cognitive function are consistently positive antiphospholipid antibodies, consistent steroid use, diabetes, and higher depression scores.[83] Mood syndromes are probably the most common psychiatric presentation of patients with systemic lupus erythematosus,[84] but mood change is not

always due to involvement of the central nervous system. Patients are frequently treated with steroids, which raise the possibility of steroid-induced neuropsychiatric syndromes. However, in many cases, addition of steroids to treatment may improve psychiatric syndromes.

Renal disorders

Acute renal failure

Acute renal failure is an abrupt decrease in renal function sufficient to result in azotaemia—retention of nitrogenous waste in the body.[85] Acute renal failure can result from a decrease of renal blood flow (prerenal azotaemia), intrinsic renal disease (renal azotaemia), or obstruction of urine flow (postrenal azotaemia). Prerenal azotaemia can be caused by renal arterial occlusion or a decrease in the effective blood volume (e.g. haemorrhage, congestive heart failure, diarrhoea). Intrinsic renal azotaemia is most commonly caused by acute tubular necrosis due to an acute ischaemic or nephrotoxic insult. Azotaemia is due to obstruction of the urine collecting system; this may occur when there is bladder outlet obstruction or ureteral obstruction.

Medical complications of acute renal failure include hyperkalaemia, hyperuricaemia, arrhythmias, anaemia, coagulopathies, vomiting, nausea, and urinary tract infections. Metabolic perturbations can lead to delirium. Neuropsychiatric manifestations include somnolence, asterixis (flapping tremor), neuromuscular irritability, and seizures. Mental status abnormalities in acute (but not chronic) renal failure begin to occur for most adults when the serum creatinine level acutely rises to about 4.0 mg/dl. In oliguric renal failure, serum blood urea nitrogen levels can be expected to rise by about 10 to 20 mg/dl per day. Serum creatinine levels can be expected to rise by about 1 mg/dl per day. Neuropsychiatric complications of acute renal failure are best treated by correcting the underlying cause of the renal failure. Dialysis may be used to manage acute manifestations. While awaiting reversal of neuropsychiatric manifestations, symptomatic management with antiseizure medications and neuroleptics may be necessary.

Chronic renal failure and end stage renal disease

Chronic renal failure is a progressive and irreversible loss of renal function.[86] The most common aetiologies of renal insufficiency ultimately leading to end stage renal disease are diabetes, hypertension, and glomerulonephritis. Loss of up to 75 per cent of glomerular filtration rate does not usually result in pronounced clinical symptoms, as the remaining glomeruli adapt with hyperfiltration. Serum creatinine is a sensitive indicator of early, subclinical, chronic renal failure. For example, the doubling of serum creatinine from 0.7 to 1.4 mg/dl signifies a loss of approximately 50 per cent of glomerular filtration rate, emphasizing the importance of early detection and prevention.

Patients with chronic renal failure usually become symptomatic when glomerular filtration rate is less than 10 ml/min. Uraemia affects every organ system, including the central nervous system. Neuropsychiatric manifestations of chronic renal failure include irritability, insomnia, lethargy, anorexia, seizures, and restless legs syndrome.[86] In contrast to acute renal failure—where neuropsychiatric signs and symptoms may appear with a creatinine level as low as 4 mg/dl—in chronic renal failure, patients may have a normal mental status examination with a serum creatinine level as high as 9 to 10 mg/dl. Symptomatic treatments with low-dose neuroleptics, antiseizure medications, or benzodiazepines are sometimes necessary in chronic renal failure.

Kimmel *et al.*[86] studied the prevalence of hospitalizations for psychiatric illness in patients with end stage renal disease and compared that rate with four other chronic medical conditions (diabetes, ischaemic heart disease, cerebrovascular disease, and peptic ulcer disease). Hospitalizations for mental disorders were 1.5 to 3.0 times higher in these patients than in patients with the four other chronic diseases. Dementias and depression were the most common reasons for hospitalization. With end stage renal disease are almost twice as likely to die by suicides as the general populations, after controlling for other potential demographic and clinical contributors to suicide risk.[87]

Sexual dysfunction is very common in patients with end stage renal disease. Abrams *et al.*[88] found that 75 per cent of his sample of men with this disease reported a decrease in frequency of sexual intercourse of at least 50 per cent. Disruptions in sexual function, which may be physiological (e.g. vascular complications of diabetes, fatigue following dialysis treatments) or psychological or both, account for at least a portion of the dysphoria experienced by patients with end stage renal disease.

The definitive treatments for most patients with chronic renal failure are transplantation or haemodialysis. In general, transplantation is encouraged because of a better quality of life and a greater chance for rehabilitation and symptom resolution. Researchers in three separate prospective studies found that patients who received renal transplants experienced better physical and psychological outcomes than patients who remained on dialysis.[89] Neuropsychiatric signs and symptoms resolve much more completely with transplantation than with haemodialysis. Psychiatric aspects of organ transplantation are discussed later. The psychiatric aspects of haemodialysis are discussed next.

Haemodialysis

The average patient on haemodialysis requires 3.5 h of dialysis three times per week to achieve adequate creatinine clearance.[86] Haemodialysis has enabled the survival of countless thousands of patients with chronic renal failure and provides a temporary management tool for patients on transplantation waiting lists. However, it is not a benign procedure, and has a number of potential neuropsychiatric complications. Patients on haemodialysis are at high risk for developing volume overload, pulmonary oedema, hyperkalaemia, hyperphosphataemia, and metabolic bone disease if compliance with restricted diet and fluid intake is not optimal. Patient adherence to these diet and fluid-intake protocols are used as one of the criteria for making decisions about appropriateness for transplantation. Psychiatric reasons for non-adherence should be addressed and are usually reversible, with the exception of personality disorders. These include mood disorders, phobias, panic disorder, substance-related disorders, adjustment disorder, and cognitive disorders.

Haematological disorders

Anaemia due to vitamin deficiency

Both folic acid and cobalamin (vitamin B12) are necessary for the production of DNA; in their absence, the nucleus of the cell cannot

undergo normal mitosis. The main cause of folic acid deficiency is dietary insufficiency.(90) This commonly occurs in severe alcoholics. The main cause of cobalamin deficiency is malabsorption. The major clinical manifestations of folate or vitamin B12 deficiency include fatigue, pallor, and for cobalamin deficiency, neuropsychiatric manifestations. The latter include loss of proprioception in the lower extremities, loss of vibratory perception, anosmial, forgetfulness, and even dementia. Diagnosis is based on measurement of serum levels of vitamin B12 and folate. Treatment is replacement of folate (1 mg/day or improved diet) and vitamin B12 (administered parenterally).

In cobalamin deficiency, neuropsychiatric findings can occur even when megaloblasts and anaemia are absent.(91) Patients with cobalamin levels between 100 and 200 pg/ml, and especially those with levels less than 100 pg/ml, may have cobalamin-reversible neuropsychiatric deficits.(138) Even dementia due to chronic cobalamin deficiency may be partially reversible when diagnosed and aggressively treated. It is also associated with a higher risk of depression, especially in older adults; anaemia severity and depression severity scores are highly correlated.(92) Treatment of the anaemia may result in resolution of depressive symptoms; in some cases depressive symptoms are slower to resolve and may require extended treatment with antidepressant medication, particularly for patients predisposed to mood disorders.

Iron-deficiency anaemia

When erythrocyte-cytoplasm production is abnormally low due to the reduced production or availability of one of the three components of haemoglobin (iron, globin, or haem), the ratio of cytoplasm to the contents of the rest of the cell declines. This results in a microcytic anaemia. In most cases, microcytic anaemia is due to iron-deficient haemopoiesis.(92) Deficiency is usually due to an iron-poor diet or defective iron utilization by the body. Clinical manifestations of iron-deficiency anaemia are related to the severity of the iron deficiency and include severe fatigue, pallor, changes in nail curvature ('spoon nails'), and, at times, pica and cheilosis at the corners of the mouth. A diminished haematocrit and mean corpuscular volume, and low serum iron are the cornerstones of the diagnosis. The severe fatigue associated with iron deficiency can be misdiagnosed as major depressive disorder; treatment with an antidepressant will not help unless there is also clinical major depression apart from the iron deficiency. Iron replenishment to correct the underlying deficiency is the specific. With iron replenishment, the haemoglobin should correct to normal, and symptoms should resolve, within 4 to 6 weeks.

Conclusions

There is increasing recognition that patients with psychiatric signs and symptoms frequently have associated medical disorders. Interactions between the disorders can be quite complex and may involve neuropsychiatric manifestations of medical illness, medical effects of psychiatric treatments, psychiatric effects of medical treatment, increased medical illness related to factors inherent in the psychiatric condition, and maladaptive personality styles or disorders that affect outcomes of medical and psychiatric illness. Psychiatric disorders in patients with other medical illnesses increase mortality, morbidity, health care costs, and decrease adherence to medical therapies. Appropriate and cost-effective management must integrate knowledge from psychiatry and primary care to assure maximal therapeutic gains for the patient. Those involved in consultation to primary care providers must understand both the basic pathophysiology and clinical characteristics of the medical disorders and their treatments, as well as possess the psychiatric knowledge necessary to ensure that the patient with medical illness is adequately managed.

5.3.5 Psychiatric aspects of infections

José Luis Ayuso-Mateos

Neuropsychiatric disturbances stemming from infectious diseases are widespread in both the industrialized world and developing countries. Such neuropsychiatric syndromes are not necessarily the result of infectious processes directly involving the central nervous system, they may also be complications of systemic infections. There are many microbial, viral, and parasitic agents, as well as other types of infectious substances, which can affect the central nervous system, leading to the appearance of neurological and psychiatric symptoms that may cause suffering to the patient, and even be disabling.

When considering the psychiatric manifestations of infectious illness, it is important to consider clinical manifestations derived

from a possible systemic infection, which can be less obvious than a direct involvement of the central nervous system. Acute organic reactions may accompany many systemic infections, especially at the extremes of life. A clear example is the delirium that frequently occurs with pneumonia in the elderly. In these clinical syndromes, several factors could be responsible for the alterations in cerebral metabolism. The mere fact of having a fever could be involved. Cerebral anoxia often appears to be responsible, or the influence of toxins derived from the infecting micro-organism. More complex metabolic disturbances or the accumulation of toxic intermediate products can also be implicated.

Likewise, infections that course as chronic or subacute illnesses are frequently accompanied by the onset of depressive syndromes. One of the factors implied in clinical depression that occurs within the context of systemic infectious illnesses (e.g. tuberculosis and infectious mononucleosis), is a sense of physical vulnerability, possibly heightened by a loss of strength and negative changes in the patient's appearance. Patients are often afraid of losing their earning capacity or even their jobs, as well as other social and occupational problems associated with the illness.

Another very important factor, above all with the human immunodeficiency virus (**HIV**) and other sexually transmitted disease (**STD**), is the social stigma that these patients may suffer.[1] Sexually transmitted disease infection implies sexual activity that historically carries connotations of illicit, casual, sexual encounters, and acquiring an STD is frequently associated with embarrassment and social stigma.

In addition to the disease itself, the medications commonly used to treat infectious illnesses can have side-effects that alter patients' behaviour, as well as their cognitive and affective functioning (Table 5.3.5.1).

In this chapter we consider infections of clinical interest in the practice of psychiatry. These conditions will be dealt with briefly, and textbooks of general medicine should be consulted for further details. Prion diseases and chronic fatigue syndromes, which are also related to the subject of the present chapter, are discussed in Chapters 4.1.4 and 5.2.7, respectively.

Table 5.3.5.1 Neuropsychiatric adverse effects of drugs frequently used in the treatment of infectious diseases

Drug	Adverse effect
Aciclovir	Headache, somnolence, tremor, confusion, lethargy, seizures, agitation, major depression with psychotic symptoms
Amphotericin B	Delirium
Chloramphenicol	Memory impairment, confusion, depersonalization, hallucinations
Cycloserine	Depression, anxiety, confusion, hallucinations, paranoia, agoraphobia
Didanosine (ddI)	Headache, asthenia, polyneuropathy
Efavirenz	Dizziness, headache, insomnia, inappropriate behaviour, depression, concentration impairment, agitation, abnormal dreaming, and somnolence
Foscarnet	Asthenia
Gentamicin	Confusion, hallucinations
Interferon	Depression, anxiety, irritability, delirium
Isoniazid (INH)	Headaches, vertigo, hyper-reflexia, neuritis, convulsions, ataxia, toxic, encephalopathy, confusion, psychosis, antidepressant effect
Ketoconazole	Somnolence, delirium
Para-aminosalicylate (PAS)	Toxic psychosis
Penicillin G (procaine)	Hallucinations, seizures, agitation, confusion
Rifampicin (rifampin)	Myopathy, headache if hypersensitivity
Streptomycin	Toxic effects on cranial nerve VIII (vestibular), vertigo, nystagmus, ataxia, neuromuscular junction blockade
Sulphonamide	Anxiety, depression, insomnia, hallucinations
Trimethoprim-sulphamethoxazole	Vertigo and confusion
Zalcitabine (ddC)	Polyneuropathy
Zidovudine (AZT)	Headache, myalgia, insomnia, asthenia, somnolence, anxiety, depression, mania, restlessness

HIV infection

Patients infected with HIV are at an increased risk for a variety of mental disorders. Those encountered most frequently in psychiatric practice are discussed below. HIV dementia is discussed in Chapter 4.1.9.

Nature of neuropsychiatric disorders in HIV-infected patients

Neuropsychiatric disorders are common in HIV-infected patients, and they can be either primary or secondary. **Primary** complications are those that can be attributed directly to the infection of the central nervous system by the virus, or to immunopathological events precipitated by HIV infection. Primary HIV-related brain disorders include HIV-related dementia and minor cognitive disorder.[2] Immune suppression can lead to a variety of secondary complications affecting the brain, including opportunistic infections (e.g. cerebral toxoplasmosis and progressive multifocal leucoencephalopathy) and tumours (e.g. cerebral lymphoma). **Secondary** complications in the form of acute and subacute syndromes (e.g. delirium) often occur as a result of cerebrovascular complications and toxic states induced by various therapeutic agents.

HIV-associated acute stress reaction

This transitory syndrome appears in some individuals after they are notified of their seropositivity. It is equally frequent among those who, after a period as an asymptomatic carrier, are informed that the infection has progressed towards full-blown AIDS. The appearance of these symptoms is closely linked in time to the stressful circumstance, and generally remits in hours or days.

The symptoms are highly varied. Some patients suffer from intrusive thoughts or brooding related to their uncertainties regarding health, the future, the risk of contagion to others (especially loved ones), and the idea of death. The vegetative symptoms of panic attacks are also usually present. In more severe cases, the patient may also present social isolation, verbal expressions of rage or feelings of desperation, and other forms of altered behaviour.

Depression

(a) Clinical features

Depression is one of the most common psychiatric disorders found among HIV-infected individuals. Symptomatic stages of HIV infection are associated with an increased prevalence of depressive symptoms and a syndromal diagnosis of major depression.[3]

There are several factors behind the increased morbidity for affective disorders found in this population. First of all, the patient's discovery of the infection has a dramatic **psychological impact**, as does the disease's relentless progression. Second, the **neurotropism of the virus** itself produces neuropathological changes in deep grey structures whose dysfunction is known to cause mood disturbances and changes in the neurotransmission systems, which may contribute to the development of depression. Finally, the groups that in Western countries are at the highest risk for HIV infection (intravenous drug users and male homosexuals/bisexuals) are also known to be at a **high risk for depressive syndromes**, independently of having the virus. The risk factors for depression appear to be similar to those for HIV-seronegative patients and include, besides advanced HIV infection: loss of social support; personal and family history of depression; drug use; and lack of confidants.

When severe physical disease is present the diagnosis of major depression can be difficult to make, because the disease itself may be the real source of many depressive symptoms, for example insomnia, loss of appetite and weight, fatigue, lack of energy, retardation, and concentration difficulties. To avoid misdiagnosing depression, it is important to focus on the more psychological, as opposed to somatic, symptoms associated with low mood. These include **persistent low mood**, **loss of enjoyment** of usually pleasurable activities, **suicidal thoughts** and marked **feelings of hopelessness**, **guilt**, and **self-reproach**. Suicidal ideation may not be expressed directly, but may be expressed more passively, for example poor adherence to medical treatment. Assessment of depressed mood also requires evaluation of the probable contributing factors.

(b) Management

(i) Pharmacological treatment

Antidepressants are the treatment of choice in major depression, as well as in less severe depressive syndromes that are unresponsive to psychological and social intervention. Tricyclic antidepressants have been shown to be effective in treating depressed HIV-positive patients.[4] AIDS patients can respond to lower dosages of tricyclics (25–100 mg), but they may also suffer severe anticholinergic effects at reduced dosages. Therefore, the choice of an antidepressant for these patients should be guided by its side-effect profile.

Several studies have been published showing therapeutic response to selective serotonin reuptake inhibitors in seropositive patients with major depression.[5] Many clinicians prefer the newer drugs in the medically ill, not only because of their higher acceptance among patients, but also because of their greater overdose safety margin.

(ii) Psychotherapy

Psychosocial interventions derived from a wide variety of theoretical orientations are effective in treating depression among individuals infected with HIV. There is good evidence for the value of psychological intervention in the management of HIV patients. Both interpersonal psychotherapy[6] and cognitive–behavioural group therapy[7] may be particularly beneficial for HIV patients with depressive symptoms.

Psychosis

Psychotic disorders sometimes occur in people with HIV infection. While their prevalence is not high, such a development can lead to complicated diagnostic and management problems. The fact that psychosis can be related to HIV infection does not imply that a new disease entity or diagnostic category has been identified. When seropositive individuals present with psychotic symptoms, efforts should be made to clarify the clinical features and to establish their aetiology, which could well be unrelated to HIV. While in some cases the psychotic symptoms may be the result of subtle or gross brain pathology associated with HIV infection, in others it may be iatrogenic or secondary to substance misuse. Psychiatric patients per se may be considered a group at risk for contracting HIV infection.[8]

Neuroleptics are the treatment of choice for controlling psychotic symptoms. The risk of developing antipsychotic-induced extrapyramidal symptoms is higher in psychotic patients with AIDS than in psychotic patients without AIDS. AIDS patients may have an increased risk of developing tardive dyskinesia, neuroleptic malignant syndrome, and severe dystonic reactions.[9] The presence of organic cerebral deterioration, in particular HIV-associated dementia, is a risk factor for the development of neuroleptic malignant syndrome. In general, when using neuroleptics in this population, the best course is to start off with low doses, and increase the dosage slowly and progressively. The new antipsychotic risperidone has been associated with fewer extrapyramidal side-effects and used successfully in this group of patients.[10]

Mania

HIV seems to increase the risk of manic episodes, and mania is a frequent reason for psychiatric hospitalization among people with the virus.[11] In some cases illicit drug use or iatrogenic causes are implicated, for example the chance association of HIV infection and bipolar affective disorders, but generally no obvious aetiological factors can be identified. Mania has been found to be a side-effect of medication frequently used for HIV/AIDS, including **didanosine (ddI)**, **ganciclovir**, **procarbazine**, **estavudine** (d4T), steroids, and **zidovudine** (**AZT**). Most cases of new-onset mania occur in advanced HIV disease and they are often associated with the presence of substantial cognitive impairment. New-onset mania in severe symptomatic disease is predictive of reduced survival.

Standard pharmacotherapy with neuroleptics and lithium are effective, but the usefulness of these drugs may be restricted by the development of severe adverse effects in immunosuppressed HIV-infected patients. Most psychiatrists choose atypical neuroleptics for HIV. However, these agents are not without risk for extrapyramidal side-effects in HIV patients, including the risk for metabolic inhibition of some agents by protease inhibitors. Potent antiretroviral therapy has been documented to protect against the development of HIV-associated mania.[12]

Delirium

Delirium is one of the organic mental disorders observed most frequently in hospitalized HIV-infected patients. The exact prevalence of delirium or acute organic brain syndrome in HIV is unknown.

Table 5.3.5.2 Aetiology of delirium in HIV-infected patients

Infections	Encephalitis due to HIV, syphilis, toxoplasmosis, cryptococcosis, coccidioidomycosis, progressive multifocal leucoencephalopathy, herpesvirus
Abstinence	Alcohol, opiates
Metabolic	Depletion of volume, hydro-electrolytic alterations, transfusions
Hypoxia	Pneumonia with respiratory, compromise
Deficiencies	B-complex vitamins
Cerebral vascular event	
Medication	Anticholinergics, central nervous system depressors
Intracranial mass	Haematoma, neoplasias
Toxic	Drugs of abuse

Patients with advanced systemic disease and dementia are at a high risk for delirium, the cause of which is often multifactorial. The precipitant organic factors involved are listed in Table 5.3.5.2.

A conservative attitude has been recommended for the management of these conditions, with the use of low oral or intramuscular doses of neuroleptics, and correction of the organic disorders responsible for the development of disturbances in the level of consciousness.[13] However, other authors have postulated that patients suffering from delirium and agitation should be given high doses of neuroleptics—alone or in combination with lorazepam—in cases where quick control of the symptoms is vital.[14] The efficacy of pharmacological interventions in patients with delirium is heightened if treatment is begun as soon as the first symptoms appear.

Other central nervous infections in HIV-related illness

In the advanced phases of AIDS, opportunistic infections are highly varied, as are the neoplasias that can develop in immunodepressed individuals, which affect the central nervous system. The more frequents are:

- **Progressive multifocal leucoencephalopathy.** This is a grave neurological complication, linked to papovavirus infection. Dementia can develop rapidly, with focal neurological alterations such as blindness, ataxia, and hemiparesia. Death follows very quickly thereafter, and there is no known treatment. Computerized brain images taken from these patients show a characteristic involvement of the white matter.
- **Cerebral toxoplasmosis.** It is linked to the reactivation of a latent cerebral infection by *Toxoplasma gondii,* an opportunistic intracellular protozoan. The clinical presentation can vary greatly, but it is characterized by the rapid development of a marked alteration in the mental state. The focal involvement can produce headache and lateralized neurological effects. The lesions tend to be located in basal ganglia. Diagnosis is based on structural neuroimaging tests, and treatment is with pyrimethamine and sulphadiazine.
- **Cryptococcal meningitis (torulosis).** This form of meningitis, caused by infestation with the yeast-like fungus *Cryptococcus neoformans,* is characterized by headache, meningism (although it sometimes courses without this symptom), photophobia, nausea, fever, and delirium. The diagnosis is made after a lumbar puncture, and analysis of the culture and antibodies.

Syphilis

A century ago, patients with general paresis due to cerebral syphilitic infections constituted a high proportion of mental hospital admissions, and accounted for an appreciable part of the chronic population of such institutions. With the identification in the early twentieth century of the causative agent, *Treponema pallidum*, and the development of effective methods of treating syphilis, this condition has become relatively rare. Historically, the study of syphilis of the central nervous system has been of great interest to psychiatrists due to the light it sheds on the nature of the relationship between cerebral and mental disease. It was one of the first mental disorders for which a specific organic aetiology was demonstrated, and the first to respond to a medical treatment.

Syphilis remains a major problem in certain areas of the world. Because during its early stages it is a genital ulcerative disease, syphilis facilitates the transmission of HIV and may be particularly important in contributing to HIV transmission in those regions where the rates of both infections are high.

Clinical features

Syphilis is a complex STD with an extremely variable clinical course. Neurosyphilis presents 5 years or more after the initial infection. It affects 10 per cent of non-treated cases, and can take several clinical forms.[15]

- **Asymptomatic neurosyphilis**. Infected subjects have abnormalities in the cerebrospinal fluid (pleocytosis, elevated protein, and reactive VDRL score), but no symptoms or signs of central nervous system disorder. It can evolve into a symptomatic form or remit on its own.
- **Meningovascular syphilis.** Appears within 1 to 5 years of primary infection, although it can occur as early as 6 months and as late as 12 years.[16] In the clinical picture, the patient may develop stroke syndromes of subacute onset with a preceding encephalic picture, including psychiatric disturbances such as lability or personality changes. The patient may complain of headache, lethargy, and malaise, and may experience difficulty in concentration and exhibit faulty judgement. Emotional instability and irritability are common. Mental deterioration may progress to dementia, which can be accompanied by delusional symptomatology and episodes of excitation.[16]
- **General paresis.** This form of parenchymal neurosyphilis is also known as *dementia paralytica* or *general paralysis of the insane.* It usually first appears some 20 years after the initial infection. Its initial symptoms are memory disturbance, dysarthria, and hyper-reflexia, which may be accompanied by personality changes and irritability—in many cases the latter are the presenting abnormalities. The symptoms progress to dementia with abnormal motor function and psychotic symptoms. These organic psychoses were frequent in the pre-penicillin era and are known for their florid clinical picture—prominent euphoric mood, expansive demeanour, and delusions of power, wealth, or social position. Other cases may resemble depressive psychosis with somatic delusions.
- **Tabes dorsalis.** This condition is a degeneration of the ascending fibres from the dorsal root ganglia, resulting in atrophy of the dorsal roots and demyelinization in the posterior columns of the

cord. It can develop from 3 to 20 years after the initial infection. Main symptoms are the loss of position reflexes, ataxia, vibration sense, incontinence, and lacinating pains involving many areas of the body.

Diagnosis and management

The clinical picture of neurosyphilis is so variable that routine serological testing upon admission to psychiatric inpatient units has been recommended. In clinical practice, a rise in atypical syndromes with minor symptomatology has been attributed to partial suppression of the infection during its early stages by antibiotics taken for other reasons.[16] The diagnosis of neurosyphilis should be considered on the basis of the patient's symptoms and clinical signs, and confirmed by serology and analysis of the cerebrospinal fluid.

Penicillin is the drug of choice for *T. pallidum* infections, and in the treatment of neurosyphilis, but the dosage must achieve treponemicidal levels within the cerebrospinal fluid. In untreated cases, death usually occurs within 4 to 5 years. If treatment is given early, the condition usually remits; in already established cases, the progression of the disease can be halted. Antipsychotics are indicated for the symptomatic management of the excitement and psychotic symptoms that these patients may present. Clinicians should have in mind that all patients who have syphilis should be tested for HIV.

Other sexually transmitted diseases

A diverse range of psychological symptomatology is associated with STDs, in which maladaptive or pathological responses to infection (or fear of infection) may occur. Most of the studies that evaluated the psychological effects of having a STD have been carried out in patients attending genitourinary clinics, and focused on genital herpes, a common, recurrent, and painful infection. The response to diagnosis of a STD can include depression, anxiety, anger, social withdrawal, feelings of loneliness, and sexual dysfunction.[17,18] Also, high rates of hypochondriasis and veneroneurosis (a strong but unfounded conviction of having a venereal disease) are found in STD clinics and are frequently associated with psychiatric morbidity. Psychological interventions can effectively reduce the distress associated with STDs, contribute to the control of the infection, increase compliance with medication regimens, and reduce somatic symptoms misattributed to a STD.

Tuberculosis

Clinical picture

In spite of pharmacological advances, tuberculosis continues to be a serious public health problem in many parts of the world, especially due to the increased tuberculosis rate in HIV-infected patients and the appearance of multidrug-resistant tuberculosis.

Tuberculosis patients may present with vegetative signs suggestive of depression, especially the elderly and those in the symptomatic stages of HIV infection. The initial depressive symptoms are weight loss, lethargy, lack of interest, and mental confusion. They may also develop sleep disturbances due to night sweats and nocturnal coughing.

Tuberculosis patients quite frequently present with neuropsychiatric symptoms, which can be related to very different circumstances. First, clinicians should bear in mind that tuberculosis infection often develops in patients who previously had a severe psychiatric pathology, such as alcoholism or intravenous drug abuse, or in the chronic mentally ill. Also, the most common psychiatric symptoms, such as emotional lability and depression, could be related, among other factors, to the feeling of invalidity that accompanies the illness, and its social stigma. In addition, the preventive treatment of those in contact with the patient can trigger feelings of guilt. In some cases, tuberculosis leads to chronic respiratory disease, which is also associated with depressive symptoms, suicidal ideation, and cognitive impairment, particularly in debilitated patients.

Neuropsychiatric disorders in patients with tuberculosis can also be related to cerebral infections: tuberculous meningitis, potentially a very serious complication, develops in 5 per cent of all cases. Since these patients frequently present with mental symptoms that can figure prominently from the outset and even precede overt signs of meningeal infection, the correct diagnosis should be established urgently, in order to institute specific therapy as soon as possible.

Diagnosis and management

Sputum tests, cultures, and chest radiographs, as well as a tuberculin skin test, are standard diagnostic tools. In cases of suspected tuberculous meningitis, a spinal puncture is necessary to determine whether the patient has lymphocytosis and a moderate increase in protein. The diagnosis is confirmed when tubercle bacilli can be identified or cultured from the fluid; however, since irreversible brain damage may result from waiting for cultural confirmation, it is often necessary to begin therapy on the basis of a presumptive clinical diagnosis. The brain scan may show hydrocephalus, focal infarcts, and exudate in basal brain cisterns.[19]

It is important in psychiatric settings that suspected tuberculosis patients receive a proper diagnostic evaluation, not only for the sake of their own health but also for that of other patients who may be exposed to the infection in the unit. It may be necessary to transfer psychiatric inpatients with tuberculosis to a ward where isolation can be assured. The Centres for Disease Control recommend routine tuberculosis screening for patients in HIV risk groups, and for residents of mental health facilities.[20]

The most commonly used drugs for the treatment of tuberculosis are isoniazid, rifampicin, pyrazinamide, ethambutol, and streptomycin. Compliance is vital to achieve effective treatment.

Lyme disease

First described in the United States in 1975, this infection has also been reported in Europe, Australia, and other parts of the world. It is caused by the spirochaete *Borrelia burgdorferi*, which is carried and transmitted by the deer tick. The somatic symptomatology features a characteristic skin lesion, an expanding erythematous annular lesion which usually first appears 3 to 32 days after the initial transmission and may last for several weeks. In 15 per cent of the patients, the disease progresses to a secondary phase marked by neurological symptoms, for example meningoencephalitis, radiculitis, central and peripheral neuropathy, and myelitis.

The neuropsychiatric symptomatology consists in difficulties involving memory, orientation, and calculation. Even years after the first infection, patients can present with violent and impulsive

behaviour, labile affect, and depression. Cases of psychotic or catatonic syndromes and chronic dementia have been described. Many patients with Lyme disease, who suffer from neurological symptoms, present with signs of encephalopathy with alterations in their sleep, affect, and memory. The diagnosis can be established from a serological analysis.

Encephalitis

Encephalitis may be caused primarily by a viral disease affecting the brain or can be a complication of bacterial meningitis, septicaemia, or brain abscesses. It can occur after influenza, herpes simplex, measles, rubella infections, and also after vaccination. In the acute stage, the patient may present with headache, vomiting, and seizures. Patients may develop a confusional syndrome. In rare cases, the encephalitis may present with predominantly psychiatric symptoms. That is the case of herpesvirus encephalitis, which due to its damage to temporal lobes can cause a serious amnestic syndrome.

In clinical practice, the psychiatrist is more likely to see the complications that appear after the acute episode in the form of anxiety and depressive syndromes, personality change, and dementia. In the early years of life, encephalitis may be followed by behavioural disorders.[16]

Infectious mononucleosis

The Epstein–Barr virus causes 90 per cent of all cases of infectious mononucleosis. It can appear at any age, but the illness tends to manifest itself clinically in adolescents and young adults.

The most important symptoms are fever, general malaise, diffuse lymphadenopathies, and laryngitis. However, complications can lead to encephalitis and paralysis of the cranial nerves. In the case of encephalitic compromise, delirium can result. Depressive syndromes have also been observed after an acute infectious episode, accompanied by fatigue.

Brucellosis

This infection is produced by micro-organisms of the genus *Brucella*, and is transmitted by exposure to or ingestion of contaminated animal products, especially unpasteurized milk products, or contact with infected animal tissues. Onset can be insidious, since it mimics other more common illnesses, with low fever, fatigue, and sweating, but 10 to 20 per cent of cases present with splenomegaly. The psychiatric manifestations of the disease can include depressive or anxious syndromes. Diagnosis can be confirmed by blood or lymph cultures or bone marrow biopsy, although the majority of diagnoses are made serologically.

5.3.6 Psychiatric aspects of surgery (including transplantation)

S. A. Hales, S. E. Abbey, and G. M. Rodin

Attention to psychiatric disturbances and to emotional distress is important in the surgical setting, from the time of the initial diagnostic assessment, to the perioperative period and the phase of subsequent recovery and rehabilitation. Psychiatric illness and psychological factors, which are not taken into account prior to surgery, may contribute to inaccurate diagnoses, unrealistic assessment of the surgical risk, unnecessary surgery, and complications that could have been avoided or minimized. This chapter will address these factors and provide an approach to the consideration of psychiatric factors and interventions in this setting.

Preoperative assessment and intervention

The assessment of all patients being considered for surgery should include a brief evaluation of their current emotional state, cognitive functioning, personal circumstances, present or past history of psychiatric illness, and personality and coping style, as these factors may affect their adjustment to surgery. Psychiatric consultation may be indicated for a number of specific reasons discussed below.

Psychological contributors to the patient's physical symptoms

The most common psychological factor that complicates the surgical assessment is a low pain threshold and a tendency to somatize, i.e. to experience and communicate emotional distress in physical terms. When emotional factors amplify somatic symptoms, it is more difficult to distinguish organic from functional disorders on the basis of the clinical history. At the extreme end of the continuum of somatization is the dramatic presentation of physical symptoms, which may mimic a surgical condition, in the absence of organic disease. This syndrome may fulfil criteria for a somatoform disorder, such as a somatization disorder, conversion disorder, or somatoform pain disorder.[1] In such cases, careful attention to the objective indications for surgery is required. Individuals with a body dysmorphic disorder, a syndrome of perceived or imagined ugliness, may present with repeated requests for cosmetic surgery.[2] However, cosmetic surgery is unlikely to relieve the body dissatisfaction of such patients, whose condition has much in common with obsessive–compulsive disorder. Dissatisfaction with the results of surgery is common in patients with body dysmorphic disorder, and litigiousness and threats towards the treating surgeon may occur in a small proportion of cases. In general, the failure of clinicians to consider the contribution of somatization to the clinical presentation may lead to unnecessary or inappropriate surgery. When this occurs, postsurgical complications may interfere with the subsequent evaluation of persistent physical symptoms. Somatoform disorders are discussed further in Chapter 5.2.2.

Although physicians commonly consider that emotional factors may amplify physical symptoms, the possibility that disease has been intentionally simulated or fabricated is usually not entertained. Factitious disorder refers to a syndrome in which such behaviour is enacted for no apparent reason, other than to assume the patient role. This is in contrast with malingering, in which there may be reports of physical symptoms motivated by the desire for some specific secondary gain, which may be financial or compensation-related. While relatively rare, factitious disorder poses particular challenges, in both detection and treatment, to psychiatric and surgical teams. Individuals with this disorder may produce or simulate disease in various ways, such as by self-inflicting wounds that require surgical intervention or by surreptitiously contaminating themselves to produce infection. Patients with this condition may also communicate plausible symptoms of a surgical condition. Such patients are at risk to receive unnecessary surgery and should be regarded as suffering from a serious and potentially life-threatening condition. The majority of such patients are unwilling to accept psychological or psychiatric assistance, but an ongoing, supportive relationship with a medical caregiver may diminish this symptom pattern. Factitious disorder is discussed further in Chapter 5.2.9.

Capacity to consent to surgery

Providing information and obtaining informed consent are routine and essential aspects of preoperative care provided by the surgical team. Informed consent to a surgical procedure requires disclosure of pertinent information by the treating physician, and understanding of the information, decisional capacity, and voluntary choice on the part of the patient.[3] The decisional capacity of patients depends on their ability not only to understand information relevant to the decision, but also to apply it to their own situation and to express a consistent voluntary choice.[4] Information required by patients to make an informed surgical decision includes the rationale, risks, and benefits of the surgery, the potential alternative treatments, and the risk of not proceeding with surgery. In most jurisdictions, the emergency treatment of incapable persons is permitted, when substitute consent is not available, unless the clinician has reason to believe that the person would refuse such treatment if he or she were capable.[3] When it is not an emergency, substitute consent must be obtained on behalf of individuals who are incapable of providing informed consent. The legal requirements for substitute consent vary in different jurisdictions.

The capacity to provide informed consent may be impaired by cognitive dysfunction, by psychiatric illness, or by contextual factors, such as the clarity and relevance of the information disclosed or the manner of disclosure. If screening by the treating surgeon indicates that the patient may be incapable, a psychiatric consultation may be requested to evaluate the patient's decisional capacity.[5] Patients with cognitive impairment or a major psychiatric disorder, such as schizophrenia, are not necessarily incapable of making treatment decisions, unless these conditions affect their understanding and appreciation of information relevant to the decision. Numerous tools have been developed to assess decisional capacity but there is no current gold standard.[6]

Obtaining informed consent for surgery is not only a legal and ethical requirement, but also a crucial dimension of the surgeon–patient relationship. In some cases, treatment refusal reflects a breakdown in the relationship between the surgeon and the patient more than it does an informed decision of the patient to reject a

recommendation for surgery. When this occurs, attention to the physician–patient relationship, and the provision of additional information, may help to relieve the impasse so that an informed decision can be made. In other cases, treatment of a major psychiatric illness, such as a psychotic episode in a patient with schizophrenia, is necessary to restore the patient's capacity to provide consent.

Assessment of the response to surgery

Surgical patients face numerous stressors, including the fear of pain, disfigurement, and the loss of control, as well as the possibility of major medical complications and death. The response to these stressors may be affected by the nature of the illness and the surgical procedure, its personal meaning, the prior history of trauma, the support which is anticipated and perceived from medical caregivers and significant others, and the prior experience of the individual with medical or surgical procedures. The age and life stage of the individual, the risk associated with the procedure, and the prognosis of the underlying or associated medical conditions may also affect the psychological response in the perioperative period. Apprehension and mistrust are more common in those who have previously suffered from the adverse effects of missed or delayed diagnosis or treatment. Attitudinal factors, including positive expectations and the desire to participate actively in the recovery process, may also affect clinical outcomes. The desire to maintain a sense of control may be adaptive during the preparation and rehabilitation phases but may be associated with greater distress immediately following surgery, when there is an inescapable and predominant requirement to depend on others.[7] Those with more attachment anxiety, i.e. concern about the availability of support from others, may benefit from predictability and reliability in relation to caregivers, whereas those who tend to be more self-sufficient may benefit most from strategies which promote self-reliance and self-care.[8, 9]

There has been particular interest in psychosocial issues in the setting of transplantation surgery. This occurred, in part, because of the desire of transplant programmes to select optimal candidates for organ transplants, which were experimental and/or in scarce supply. However, the psychiatric and psychosocial selection criteria for transplant surgery have become less stringent, as the transplantation of particular organs has become more routine.[10] At present, psychosocial evaluation of transplant candidates by a multidisciplinary team allows for the identification, treatment, and monitoring of factors that may affect compliance, morbidity, and psychosocial outcomes. Organ transplants from living donors, such as for bone marrow, kidney, and liver transplantation, are unlike most other surgical interventions in that they necessitate surgery for individuals without pre-existing disease. Psychosocial evaluation of such donors includes consideration of the process of decision-making and informed consent, the adaptive capacities of the individual, the degree of social support, and the relationship of the donor to the recipient.[11] Although there has been concern about the psychological consequences of such surgery, the available evidence suggests that organ donation is usually well tolerated and experienced in positive terms by the donor, particularly when the surgical and medical outcomes are favourable.[12]

There is now increasing evidence that the systematic preoperative education of patients and their family caregivers in a therapeutic context may enhance adjustment to surgical procedures.[13] Postoperative education may also improve subsequent rehabilitation following surgical procedures. Such approaches are consistent with modern Western trends towards consumerism and patient empowerment, in which greater emphasis is placed on assisting patients to assume more responsibility for their medical course and treatment outcome. This approach has also been necessitated by the trend towards earlier hospital discharge of surgical patients into the community where much more self-care is required.

Anxiety

Preoperative anxiety is common and may be particularly problematic in patients awaiting procedures such as transplantation, which usually occur in the course of a life-threatening condition, and are associated with long and unpredictable waiting periods for surgery. Anxiety has been reported to be more common in younger patients, in females, and in those who are unmarried or who have less perceived social support.[14] Research suggests that preoperative anxiety may complicate postoperative recovery through behavioural and physiological mechanisms.[15] Symptoms of anxiety can usually be managed with education and reassurance, but when they are persistent and problematic, interventions such as progressive relaxation and guided imagery may be helpful both to reduce symptoms of anxiety and to enhance feelings of self-control.[16] Some patients benefit from a benzodiazepine to reduce preoperative anxiety, but those with antecedent anxiety disorders may require more intensive intervention, as outlined in Chapter 4.6.1. Prior to elective procedures, patients with specific blood or needle phobias may benefit from systematic desensitization. Those with comorbid panic disorder may require a higher dose of anxiolytic medication in the preoperative period. The surgical team should be aware of such treatment so that the medication can be restarted promptly after surgery, to avoid symptoms of withdrawal and anxiety. If oral medications cannot be reinstituted for a prolonged period of time after surgery, intramuscular lorazepam or intravenous lorazepam or diazepam may be used.

Mood disorders

It is important to detect and treat mood disorders prior to surgery because they are associated with increased surgical morbidity and mortality, and with reduced treatment compliance in the postoperative period.[17] Anaesthetists must be aware of any drugs taken to treat and prevent bipolar and depressive disorders, because some can significantly prolong muscle paralysis secondary to neuromuscular blockade. Furthermore, attention should be paid to serum lithium levels and signs of lithium toxicity since they may be affected by the patient's fluid and volume status. Conventional heterocyclic antidepressants and selective serotonin reuptake inhibitors can be continued until the time of surgery, and then restarted postoperatively, when oral medications can be tolerated. Selective serotonin reuptake inhibitors are known to affect platelet serotonin levels and platelet aggregation and to be occasionally associated with prolonged bleeding times, increased perioperative blood loss, and an increased subsequent need for transfusion.[18] Patients receiving monoamine oxidase inhibitors (MAOIs) are usually advised to discontinue this medication for 1 to 2 weeks prior to their surgery, although this recommendation must be weighed against the risk of withdrawal symptoms and of precipitating

a current depression. The medical charts of patients receiving MAOIs should be clearly labelled to advise that all drugs administered should be screened for their interactions with these drugs and that pethidine (meperidine) and dextromethorphan in particular should not be prescribed due to risk of a serotonin syndrome, which is associated with gastrointestinal, neurological, cardiovascular, and psychiatric symptoms. In addition, hospital charts of patients taking MAOIs should be clearly marked to indicate that they must avoid foods containing tyramine. Patients with bipolar disorder should be monitored for mood alterations since they may be at risk of developing hypomania or mania when steroid medications are used following transplantation surgery.

Psychotic disorders

These disorders, most commonly related to schizophrenia or bipolar disorder, pose challenges which vary depending upon the requirements of the surgery and the patient's mental status. Patients with schizophrenia may be at increased perioperative risk for hypotension, hypothermia, confusion, infection, and for ileus, in those who undergo abdominal surgery. These complications may occur due both to pathology of the endocrine, immune, and cardiovascular systems associated with schizophrenia and to the effects of antipsychotic medications.[19] Those who are being treated with a low-potency antipsychotic may be switched to a high-potency agent to decrease the risk of hypotension, particularly with cardiovascular surgery in the postoperative period. For their own comfort and for that of others, individuals who are actively psychotic may require special arrangements, such as a single room, close or constant observation, and, when feasible, greater family involvement. Such patients require closer monitoring for many reasons, including the increased likelihood that they may misinterpret common ward events as threatening and because they may be at increased risk for exacerbation of their underlying condition and for the occurrence of delirium.

Cognitive disorders

The capacity of patients to understand information and to provide a coherent account of their symptoms is fundamental to the process of diagnosis, informed consent, and assessment of the indications for surgery and the risk of specific postoperative complications. Cognitive impairment prior to surgery may complicate these processes and may be associated with an increased risk of delirium or dementia in the postoperative period. In such cases, neuropsychological testing may be indicated prior to elective surgery to establish a baseline, to assist in the evaluation of decisional capacity, and, to aid in the prediction of postoperative delirium or worsening of dementia.

Personality disorders

Patients with personality disorders are more likely to have greater difficulty than others adapting to the multiple and unpredictable stresses associated with surgery. Those with impulsivity may have difficulty adhering to the preoperative and postoperative regimen and those who are suspicious and mistrustful may be more limited in their ability to form effective treatment relationships and to make treatment decisions, in which an enormous degree of trust is required. Those with a borderline personality disorder may be highly sensitive to feelings of personal injury or neglect and may tend to idealize some caregivers and to denigrate others. These responses may create problematic divisions amongst the treatment team and may adversely affect the care of the patient. A psychiatric consultant may be of help to provide patient support and to educate staff about the underlying psychiatric disorder in such individuals, who may otherwise be viewed negatively by staff who regard their behaviour as simply wilful or manipulative.

Substance abuse disorders

The preoperative assessment should include enquiry about substance use, in order to adjust current medication appropriately and to prevent the occurrence of postoperative withdrawal syndromes. Consultation psychiatrists may play a role in continuing medical education about the value of routine, non-judgemental screening for substance use in medical patients, and about the importance of recording these details in the medical record.

Assessment of psychotropic medications

The pharmacological effects of psychotropic medications must be taken into account in the perioperative period. Important factors that affect the risks and benefits associated with psychotropic medication use perioperatively include:

1 End-organ sensitivity to side effects based on medical comorbidity and organ dysfunction;

2 direct effects of psychotropic medications and their potential interactions with anaesthetic and analgesic agents likely to be prescribed;

3 route of access available (oral, suppository, subcutaneous, intramuscular, intravenous);

4 risk of withdrawal symptoms and recurrence or relapse of a psychiatric disorder if psychotropic medications are to be discontinued.[20]

Information on drug–drug interactions is constantly being updated and current information can be obtained from internet sites such as http://www.drugdigest.org/DD/Home or http://search.medscape.com/drug-reference-search.

Postoperative complications and interventions

Agitation and delirium

Agitation is a common postoperative problem, the frequency of which depends upon the characteristics of the disease, the nature of the surgery and its complications, and the pre-existing vulnerability of the patient. A concerted effort should be made to identify the source of the agitation, which may be a worsening of the medical condition, inadequately controlled pain, or delirium. Delirium, which is described in more detail in Chapter 4.1.1, is a common complication, which develops in more than one-third of cases following surgery.[21] Higher rates of delirium are found following longer procedures, due to intraoperative hypoxemia, following cardiac surgeries, due to hypoperfusion and microemboli formation, following orthopaedic procedures, due to fat emboli, and following cataract surgery, due to the impact of vision loss and of ophthalmic drugs with anticholinergic side effects.[22]

Measures to prevent and ameliorate delirium include the identification and treatment of predisposing risk factors and reversible causes, symptomatic treatment, and environmental interventions to reduce distress and agitation. The latter may include measures to prevent sensory deprivation and disorientation, to monitor safety, and to educate patients and family members about the condition. When distress or agitation associated with delirium threaten the safety and care of the patient, pharmacologic interventions may be necessary. There have been trials of cholinesterase inhibitors[23] and of atypical antipsychotics in those patients who can take oral medications, but haloperidol remains the first-choice medication for management of delirium-associated agitation. It is preferred because it has fewer active metabolites and fewer anticholinergic and sedative effects than other antipsychotic medication and because it can be administered intravenously. This route of administration is usually safe, although arrhythmias with its intravenous use have been reported in patients with histories of alcohol abuse or with cardiomyopathy.[24] Benzodiazepines should be used to treat withdrawal from alcohol and sedative-hypnotics using standard protocols.

Delirium may be highly distressing for both patients and family caregivers.[25] Some patients subsequently retain disturbing memories of their experience during a delirium. Such traumatic recall may also occur, in rare instances, when there has been inadequate anaesthesia. In these cases, patients and their family caregivers typically appreciate a discussion of their concerns and the opportunity to review these events with the surgeon and the anaesthetist. A small number of patients with these disturbing experiences develop symptoms of post-traumatic stress disorder and may benefit from a brief course of psychotherapy or pharmacotherapy to alleviate their symptoms.

Ventilator weaning

Some patients experience difficulty being weaned from the ventilator due to anxiety, depression, delirium, or other psychological factors related to their disease or to the ICU environment. Behavioural approaches to facilitate weaning may include relaxation techniques that do not depend on observation or manipulation of breathing, guided imagery, and/or biofeedback.[26] Weaning problems due to anxiety typically respond to benzodiazepines or to haloperidol, administered in a single dose prior to weaning. Apathetic or depressed patients who have difficulty being weaned may benefit from a psychostimulant.[27] When delirium is the cause of weaning problems, its underlying cause should be identified and treated.

Pain management

Effective pain management is a fundamental aspect of postoperative treatment and may reduce distress, agitation, sleep disturbance, anxiety, mood symptoms, and behavioural disorders. Suboptimal pain management may occur due to inadequate assessment of this symptom, insufficient knowledge of the pharmacokinetic and pharmacodynamic properties of analgesic medication, and unfounded concerns about 'addiction'. Further, some patients refuse to accept adequate analgesia because of misconceptions or personal beliefs regarding the importance of stoicism, vigilance, or personal control. Consultant psychiatrists may help patients to address their concerns about analgesic medication and analgesic adjuvants and may act also as advocates or intermediaries for patients to ensure adequate analgesia.

Sleep disturbance

Sleep disturbances, including reduced total sleep time, fragmentation of sleep, frequent arousals and awakenings, and reduced slow-wave sleep, are common in the immediate postoperative period. These disturbances may be caused by multiple factors, including the noise, temperature and light of the hospital environment, neuroimmunological and other changes associated with the surgical insult, and anaesthetic and analgesic medications.[28] Daytime sleeping, related to prolonged bed rest, lack of intellectual and social stimulation, and reduced circadian cues, may disrupt normal sleep chronobiology and increase difficulty with night-time sleep.

Treatment of sleep disturbances should be directed to the identified cause. In those patients in whom anxiety or the intrusiveness of the hospital environment is the main cause of the sleep disturbance, benzodiazepines may be temporarily used. When there are concerns about substance abuse, newer non-benzodiazepine hypnotics may be preferable, due to the lower risk of tolerance associated with their use.[28] Caution should be exercised with patients for whom benzodiazepine-induced nocturnal respiratory compromise may be problematic or with elderly patients who are susceptible to cognitive compromise or to falls.

Cognitive impairment

Cognitive impairment is a common short-term and long-term complication of major surgery, particularly in those with more advanced age. Gradual recovery of cognitive functions occurs in most patients within 3 months after surgery, although it may take as long as 6 to 12 months.[29] Delirium that is slow to resolve may be an early sign of an associated dementing illness or of a cerebral insult that has occurred during or after surgery. Cognitive impairment may be permanent when there has been irreversible brain damage due to neurosurgery or perioperative complications, such as hypoxia or stroke. Neuropsychological testing may be helpful to document or track changes in cognitive functioning. Education of primary caregivers about the risk and manifestations of cognitive impairment is essential, and institution of home supports and respite care for patients and families facing this complication may be necessary. Some patients with cognitive impairment may also benefit from neurorehabilitation interventions.

Adjustment issues

Longer-term problems in adjustment may occur, particularly following disfiguring surgeries, such as facial surgery, amputations, ostomies, or following procedures such as organ transplantation, which impose complicated postoperative regimens. Sexual difficulties that result from procedures that compromise the neural input or functional integrity of genital structures, or that negatively affect body image or feelings of attractiveness, may be disturbing to patients and spouses who may benefit from specific enquiry and assistance. Patients and their families should be informed about the possibility of adjustment problems with such surgeries and should be given information about available resources. A minority of patients develop clinically significant mood or anxiety disorders or significant compliance problems during the

rehabilitation phase which may necessitate psychiatric consultation and intervention.

Prolonged dysfunction

Prolonged and disproportionate pain and disability occur in a subset of patients. In some of these cases, the surgery was undertaken to relieve refractory symptoms that subsequently proved to be functional or medically unexplained. This may occur with hysterectomies performed to relieve pelvic pain and in surgery to relieve chronic back pain. In other cases, persistent disproportionate symptoms may be perpetuated by secondary gain of a financial or social nature, or by opiate dependence. Undiagnosed and untreated mood, anxiety, and somatoform disorders may also contribute to persistent symptoms. The consultation psychiatrist may be called upon to identify these factors and to help distinguish them from undetected medical/surgical pathology or from the effects of inadequate pain regimens.

5.3.7 Psychiatric aspects of cancer

Jimmie C. Holland and Jessica Stiles

Introduction

Psycho-oncology addresses the two major psychiatric and psychological dimensions of cancer: first, the responses of patients and their families at all stages of disease and the psychological stresses on health professionals delivering their care. The patient and physician relationship, dependent on effective communication, impacts

the care of all patients, at every visit, at all sites and stages of cancer, and during all treatments. The second dimension addresses the psychological, behavioural, and social factors that influence cancer risk, detection, and survival.

Many cancer centres and hospitals now have multi-disciplinary psychosocial teams consisting of clinicians and clinical investigators from psychology, psychiatry, social work, nursing, and clergy. These teams provide consultation for patients and their caregivers, psychosocial education for oncology staff, and collaboration in studies in which quality of life is important. In addition, active research in brain, immune, and endocrine links is occurring, particularly in the mechanism of cytokines in producing 'sickness behaviour' that may provide a biological basis for common symptoms of fatigue, depression, anxiety, weakness, and cognitive chances in cancer patients.[1, 2]

Despite the fact that many cancer centres and oncology divisions now have a psycho-oncology or psychosocial unit, only a few centres have programmes that include both research and training.

This chapter describes the common psychiatric disorders and psychosocial challenges experienced by cancer patients and the range of interventions available.

Psychiatric disorders

A key challenge for the oncologist is the differentiation of expected, tolerable, transient distress associated with cancer, such as fear, worry, and sadness, from excessive, disabling, persistent distress requiring therapeutic intervention. Most psychiatric disturbances in patients with cancer relate to their illness or treatment side effects.[3] One-third of patients will experience distress that requires evaluation and treatment.[3–6] The percentage is greater among younger patients, those with sites of cancer with poorer prognosis, for example, brain, pancreas, lung, and those who are hospitalized with greater level of illness causing confusional states and greater anxiety and depression.[7,8]

Anxiety

Anxiety is the most common form of distress experienced by patients in the oncology setting (Table 5.3.7.1). It occurs with abnormal metabolic states: hypoxia, pulmonary embolus, sepsis, delirium, bleeding, cardiac arrhythmia, and hypoglycemia. Hormone-secreting neoplasms that produce psychiatric symptoms consistent with mood or anxiety disorder are pheochromocytoma, thyroid tumour, carcinoid, parathyroid adenoma, adrenocorticotropic hormone-producing tumour, insulinoma, and paraneoplastic syndrome, an immunologic non-metastatic central nervous system complications of several tumours (particularly, lung and ovary) that may present with mood or cognitive changes.

Numerous medications produce symptoms of anxiety: corticosteroids, neuroleptics, bronchodilators, thyroxine, and psychostimulants. The antiemetics, including metoclopramide and prochlorperazine, which are widely used for chemotherapy-related nausea and vomiting, produce restlessness, akathisias, and dystonias. Benzodiazepines promptly reduce the restless movements, anxiety, and agitation. Withdrawal states from alcohol, benzodiazepines, sedative-hypnotics, and opioids produce anxiety as prominent symptoms.

Some patients undergoing cyclic chemotherapy receiving highly emetogenic regimens develop anticipatory anxiety, nausea, and vomiting days to hours in advance of receiving the next cycle of treatment.[9–11] More effective antiemetic regimens have significantly reduced the frequency and severity of this problem. However, behavioural interventions paired with antianxiety medications continue to assist in providing relief from this distress.

Table 5.3.7.1 Causes of anxiety in patients with cancer

Situational
Diagnosis of cancer, prognosis discussion
Crisis, illness/treatment
Conflicts with family or staff
Anticipating a frightening procedure
Awaiting results of tests
Fears of recurrence after completing treatment
Disease-related
Poorly controlled pain
Abnormal metabolic states
Hormone secreting tumors
Paraneoplastic syndromes (remote CNS effects)
Treatment-related
Frightening or painful procedures (MRI, scans, wound debridement)
Anxiety-producing drugs (antiemetic neuroleptics, bronchodilators)
Withdrawal states (opioids, benzodiazepines, alcohol)
Conditioned (anticipatory) anxiety, nausea, and vomiting with cyclic chemotherapy
Exacerbation of preexisting anxiety disorder
Phobias (needles, claustrophobia)
Panic or generalized anxiety disorder
Posttraumatic stress disorder (Holocaust survivors, Vietnam veterans, recall of the death of a relative with cancer)
Obsessive compulsive disorder

Patients who have pre-existing phobias, panic attacks, generalized anxiety disorder, or obsessive–compulsive disorder are at risk of experiencing symptom exacerbations during treatment (Table 5.3.7.1).[12] Phobias of needles, blood, hospitals, magnetic resonance imaging machines, or radiation simulators complicate a patient's ability to tolerate hospital procedures or adhere to recommended treatments. Panic attacks superimposed on physical symptoms of dyspnea and tachycardia may be partially alarming to patients.[3,13] Patients with previous traumatic experiences may suffer a recurrence of intrusive re-experiences of painful memories, maladaptive avoidant behaviour or withdrawal, and hypervigilance.[14,15]

Cancer patients with OCD may have increased difficulty during treatment. Intrusive fears may lead to indecisiveness regarding treatment options and reluctance to accept interventions with known therapeutic efficacy. Excessively time-consuming rituals may interfere with a patient's adherence to medical appointments. Inflexibility of thought, hostility, overwhelming distress, and occasionally poor insight contribute to the challenge of engaging these patients and assisting them in accepting interventions.

Management. Anticipatory anxiety prior to medical interventions responds to empathic validation of the fear, adequate preparation to set realistic expectations for the encounter, and rehearsal of the dreaded event.

Significant disabling anxiety symptoms are frequently treated pharmacologically with benzodiazepines, selective serotonin-reuptake inhibitors (SSRIs), mirtazapine, venlafaxine, buspirone, antihistamines, beta-blockers, or neuroleptics. Table 5.3.7.2 outlines the benzodiazepines commonly used and their initial and

Table 5.3.7.2 Common anxiolytic agents

Drug	Brand name	Starting dose/day	Theraputic dose/day
SSRIs			
Sertraline	Zoloft	25–50 mg AM	50–150 mg
Fluoxetine	Prozac	10–20 mg AM	20–60 mg
Paroxetine	Paxil	10–20 mg	20–60 mg
Citalopram	Celexa	10–20 mg	20–60 mg
Escitalopram	Lexapro	5–10 mg	10–30 mg
Benzodiazepines			
Alprazolam, XR	Xanax	0.25–0.5 mg	0.5–2.0 mg
Clonazepam, wafers	Klonopin	0.25–0.5 mg	0.5–2.0 mg
*Lorazepam	Ativan	0.25–0.5 mg	0.5–2.0 mg
*Diazepam	Valium	2 mg	5–20 mg
Hypnotics			
Temazepam	Restoril	15 mg	15–45 mg
Zolpidem	Ambien	5 mg	5–20 mg
Zaleplon	Sonata	5 mg	5–20 mg
Eszopiclone	Lunesta	2 mg	2–3 mg

* Also IV, IM

therapeutic doses. A shorter half-life enhances control during the upward titration process and decreases the risk of accumulation and intoxications.

Mood disorders

Depression in cancer patients requires early recognition and therapeutic intervention. Depression is more challenging to diagnose in patients with cancer because illness produces many neurovegetative symptoms: sleep disturbances, appetite reduction and weight loss, psychomotor retardation, fatigue, apathy, and poor concentration.[16] Focusing the assessment on the psychological symptoms of dysphoria, anhedonia, hopelessness, worthlessness, excessive guilt, and suicidal ideation helps distinguish depression in the context of medical illness.[17]

Table 5.3.7.3 outlines the medically related risk factors for developing depression: increasing levels of debilitation, advanced disease, and concurrent presence of other chronic illnesses or disabilities. Medications frequently encountered in the oncology setting that contribute to depressive symptoms are corticosteroids (dexamethasone and prednisone), chemotherapeutics (interferon, interleukin-2, vincristine, procarbazine, l-asparaginase), and supportive care medications.[17] Depression may relate to organ failure or nutritional, endocrine, and neurologic complications of cancer. Depression is a common symptom of pancreatic cancer, which led to speculation about a tumour-induced mood disturbance mediated by alteration of brain serotonergic function through the effect of proinflammatory cytokines.[18–21]

Management. Psychotropic medications are effective in reducing depressive symptoms present in cancer patients.[22] Table 5.3.7.4 lists the most frequently used antidepressant medications in patients with cancer and their initial and maintenance doses. The antidepressants commonly used today are SSRIs, mirtazapine, venlafaxine, or buproprion. Tricyclic antidepressants and duloxetine are beneficial for patients with depressive symptoms and neuropathic pain. Psychostimulants treat depressive symptoms, and counter fatigue related to advanced illness and the somnolence

Table 5.3.7.3 Medical-related risk factors for depression in patients with cancer

Poorly controlled pain
Other chronic disease/disability; advanced stage
Medications
Corticosteroids
Prednisone, dexamethasone
Inteferon and Interleukin-2
Chemotherapeutic agents
Vincristine, vinblastine, procarbazine, L-asparaginase
Other medications
Cimetidine
Indomethacin
Levodopa
Methyldopa
Pentazocine
Phenmetrazine
Phenobarbital
Propranolol
Rauwolfia alkaloids
Tamoxifen
Antibiotics
(Amphotericin B)
Other medical conditions
Metabolic (anemia; hypercalcemia)
Nutritional (B_{12} or folate)
Endocrine (hyper-hypothyroidism; adrenal insufficiency)
Neurologic (paraneoplastic syndrome)
Sites of cancer
Pancreatic, small cell lung, breast cancer, lymphoma (producing remote CNS effects)

associated with opioids. For depressed cancer patients not expected to survive weeks to months, psychostimulants provide more rapid relief from distressing depressive symptoms. Initiating antidepressants at low doses for elderly and debilitated patients and titration upward as tolerated provides similar benefits, but over a longer period of time.

Suicide and cancer

The incidence of suicide is increased in patients with cancer compared with the general population, but it is not as high as is often assumed. Suicide is more likely to occur in advanced disease as depression, hopelessness, and the presence of poorly controlled symptoms (especially pain) escalate.

Evaluation of suicidal thoughts should take into account disease stage and prognosis. Almost all patients who receive a diagnosis of cancer, even if the prognosis is optimistic, consider or contemplate suicide in the event of developing unbearable or intolerable distress. Some patients maintain supplies of medications for this purpose. This practice allows the patient to maintain a perception of control over progressive disease and feared intolerable pain and inevitable distress. Maintaining this option sometimes allows patients to tolerate difficult treatments.

Morbid preoccupation with suicide or ruminative plans to commit suicide in cancer patients for whom the disease is in remission or in whom a good prognosis exists require careful evaluation.[23] Patients with a poor prognosis, advanced disease, and poorly controlled symptoms often have thoughts of suicide that are more

Table 5.3.7.4 Commonly used antidepressants in cancer

Drug	Brand name	Starting daily dosage PO (mg)	Therapeutic daily dosage PO (mg)
Selective serotonin-reuptake inhibitors			
Sertraline	(Zoloft)	25–50 mg AM	50–150 mg
Fluoxetine	(Prozac)	10–20 mg AM	20–60 mg
Paroxetine	(Paxil)	10–20 mg AM	20–60 mg
Citalopram	(Celexa)	10–20 mg AM	20–60 mg
Escitalopram	(Lexapro)	5–10 mg	10–20 mg
Tricyclics (neuropathic pain management primarily)			
Nortriptyline	(Pamelor)	25–50 mg	50–200 mg
Amitriptyline	(Elavil)	25–50 mg	50–200 mg
Desipramine	(Norpramin)	25–50 mg	50–200 mg
Other agents			
Venlafaxine	(Effexor)	18.75–37.5 mg	75–225 mg
Trazodone	(Desyrel)	50–100 mg	100–200 mg
Bupropion (XL, SR)	(Wellbutrin, Zyban)	50–75 mg	150–400 mg
Mirtazapine	(Remeron)	15 mg HS	15–45 mg
Psychostimulants			
Methylphenidate	(Ritalin)	5–10 mg (8AM & Noon)	10–30 mg
Modafinil	(Provigil)	50–100 mg (8AM & Noon)	100–400 mg
Dextroamphetamine	(Dexedrine)	5–10 mg (8AM &Noon)	10–20 mg

Lithium and mood stabilizers only for bipolar disorder;

likely to be viewed as rational by physicians.[24] These patients may request assistance from a physician in obtaining a prescription for medications to use to commit suicide. A treatable major depressive episode may precipitate their suicidal ideation, so it is particularly important to evaluate for the presence of hopelessness, which is a better predictor of suicidal risk than depression itself.[23]

Management. Attentiveness to uncontrolled physical symptoms, especially pain, is crucial. Adequate pain control may have a dual effect of hastening death, while ameliorating suffering. Most physicians feel comfortable providing comfort and relieving distress. Increasing numbers of physicians do not consider this practice to be assisted suicide but as best medical care geared to maximal comfort.[25]

Poorly controlled pain in patients with organ failure and metabolic encephalopathy may result in poor judgement and impulse control leading to unpredictable suicide attempts.[26] These patients benefit from a 24 h companion, nurse, or family member who understands the patient's compromised state and treatment for delirium.

Delirium

Delirium is a global cerebral dysfunction characterized by a fluctuating level of arousal and cognitive disturbances. Symptoms include disorientation and confusion, inattention and poor concentration, perceptual disturbances, disordered thought process, psychomotor agitation or retardation, and an altered sleep–wake cycle. Delirium is distinguished from dementia in part by its reversibility. However, in advanced cancer, as organ failure progresses and results in refractory metabolic derangements, delirium may be irreversible. The primary goal is ensuring the safety of the patient and caregivers. Protecting others from aggressive or combative behaviour is essential. Family members should be told that the cause of the behaviour is brain dysfunction, not a mental aberration, and a given guidance in understanding the patient's states.

In patients with cancer, especially those in advanced stages, an abrupt shift in mood or behaviour is most often related to a change in neurologic, vascular, or metabolic status; a psychological basis is far less likely. In fact, up to three-fourths of terminally ill patients may develop a delirium before death. Common causes of delirium in cancer are outlined in Table 5.3.7.5.

Management begins with attention to the patient's safety. It is important to have constant 1:1 observation, preferably by a person who can correct the patient's misinterpretations of reality. Providing

Table 5.3.7.5 Common causes of delirium in cancer

Causes	Examples
Metabolic encephalopathy because of vital organ failure	Liver, kidney, lung (hypoxia), thyroid, adrenal
Electrolyte imbalance	Sodium, potassium, calcium, glucose
Treatment side effects	Narcotic/analgesics Anticholinergics Phenothiazines Antihistamines Chemotherapuetic agents Steroids Radiation therapy to brain
Infection	Septicemia
Hematologic abnormalities	Microcytic and macrocytic anemias, coagulopathies
Nutritional	General malnutrition, thiamine, folic acid, vitamin B_{12}
Paraneoplastic syndromes	Remote effects of tumors
Metastatic or primary brain tumor	Glioblastoma multiforme, primary CNS lymphoma

Table 5.3.7.6 Behavioral symptoms of delirium in patients with cancer

State	Symptom
Early, mild	Alteration of sleep-wake cycle, transient periods of disorientation Unexplained anxiety and sense of dread Increased irritability, anger, temper outbursts Withdrawal, refusal to talk to staff or relatives New onset of forgetfulness
Late, severe with behavioral changes	Refusal to cooperate with reasonable requests; pulling out tubes and lines Angry, swearing, shouting, abusive Demanding to go home, pacing corridor Illusions (misidentifies staff, visual and sensory clues) Delusions (misinterprets events, usually paranoid, fears of being harmed) Hallucinations (visual and auditory)

consistent caregivers, structured interactions with others, and frequent reorientation may limit the distress experienced by the patient. Elderly patients are more vulnerable to developing delirium, and those with cognitive impairment or dementia are at even higher risk. It is preferable to avoid physical restraints. However, containment of severe agitation may temporarily require restraints to prevent removal of endotracheal tubes, intravenous access, and loss of indwelling catheters, and also to avert falls. Behavioural symptoms of delirium in patients with cancer are outlined in Table 5.3.7.6.

Medications commonly used in managing delirium are summarized in Table 5.3.7.7. Identification and corrections of the underlying aetiology of the delirium is not always possible and in these circumstances, neuroleptics providing relief for the patient from distressing symptoms should be the primary intervention. While haloperidol and lorazepam administered in conjunction provide additional sedative effects for patients with sever agitation,[27] patients with hypoactive subtype of delirium will benefit from the administration of neuroleptics for symptomatic relief.[26,28] In the terminal stage of cancer, delirium may be irreversible and refractory to neuroleptics. Additional sedation with alternative agents may be required to provide comfort and safety for the patient and family.

Table 5.3.7.7 Medications for managing delirium in cancer patients

Drug	Brand name	Approximate daily dosage
Neuroleptics		
Haloperidol	Haldol	0.5–5 mg every 2–12 h, PO, IV, SC, IM
Chlorpromazine	Thorazine	12.5–50 mg every 4–12 h, PO, IV, IM
Risperidone	Risperdal	1–3 mg every 12 h, PO
Olanzapine	Zyprexa	2.5–5 mg every 6–8 h, PO
Quetiapine	Seroquel	12.5–50 mg every 12 h, PO
Benzodiazepines		
Lorazepam	Ativan	0.5–2.0 mg every 1–4 h, PO, IV, IM
Midazolam*		30–100 mg every 24 h, IV, SC
Anesthetics		
Propofol*		10–50 mg every h, IV

PO, orally; IV, intravenously; SC, subcutaneously; IM, intramuscularly.

* Usually IV continuous infusion in intensive care setting.

5.3.8 Psychiatric aspects of accidents, burns, and other physical trauma

Ulrik Fredrik Malt

Epidemiology of accidents and injury

The one-year prevalence of accidents is about 15–20 per cent with highest prevalence in the younger age groups. About 80 per cent of accidents cause personal injury, and 1/3 to 1/2 of these injuries result in medical attention. About 10 per cent of medically attended injured victims require hospitalization.[1] In the UK (population about 60 million) 31 845 people were killed or seriously injured in 2006 due to road accidents and there were 2 58 404 road casualties.

Accident occurrence and psychiatric disorders

On a group basis, lower social classes, subjects with less education and lower intelligence tend to sustain more accidents and injuries (and have higher morbidity and mortality in general). The ratio of males to females for both fatal and non-fatal accidents is about 2:1 in subjects below 60 years of age. Individual variables associated with increased liability of being involved in an accident include antisocial tendencies, aggressiveness, impulsiveness, thrill and adventure-seeking behaviour. Conscious or unconscious intention is not an important explanation of the overall prevalence of accidents or injuries in the society.

Patients with significant psychological problems (psychopathology including substance abuse) sustain more severe injuries than healthy subjects and the prevalence of psychiatric disorders is increased among hospitalized injured adults compared to surgical patients admitted for other reasons. At least 15–20 per cent of persons brought to hospital emergency rooms due to accidental injury have clinical significant blood concentrations of alcohol. Furthermore, patients with schizophrenia, affective illness and post-traumatic stress disorder have more accidental *deaths* (and suicides) compared to the general population.

Physical injuries

Most non-fatal injuries treated in hospitals are minor head concussion and lacerations, strains/sprains, contusions/abrasions and fractures to body parts such as limbs. More severe injuries are mostly related to high energy accidents (e.g. motor vehicle accidents) and often involve both the head and limbs. Injuries to the inner organs are less frequent, but mostly more severe. The anatomical based Abbreviated Injury Scale (AIS) and Injury Severity Score (ISS) are the most widely used classification system of physical injury. Other classification systems based on physiological impact of trauma (e.g. Revised Trauma Score, Glasgow Coma Score) and combinations of anatomical injury and physiological impact (e.g. Trauma and Injury Severity Score) exist as well. See: http://www.trauma.org/archive/scores/ais.html;

Physical injury as psychological trauma

Accidental injury implies several important sources of threat, loss or conflict which may cause psychological distress or psychiatric disorders. The most important accident related variables associated with subsequent psychological problems include,

- Severity of the accident (e.g. real degree of threat to life of one self and others)
- Degree of helplessness
- Duration of the stressor
- Presence and type of actual physical injury
- Exposure to dead and mutilated bodies.

Nevertheless, pre-accident adjustment, personality and the personal meaning of the accident or injury are the strongest predictors

of both acute psychological responses and long-term psychiatric outcome. This observation holds even in the presence of a severe injury,[2] although the type of injury *per se* may influence the short- and long-term outcome. The relative contribution of 'objective' accident related compared to 'subjective' appraisal related variables in shaping the acute response varies. A rule of thumb is that the less severe the accident, the more important are variables not directly related to the accident *per se* (i.e. the personal meaning of the accident and its consequences for the individual.[3] Important individual variables include,[4–6]

- Pre-injury mental health and adjustment problems
- Personality traits (e.g. neuroticism, quality of attachment)
- Trauma history

The accident *per se* may represent a blow to the person's feeling of invulnerability (narcissistic loss). In some, the accident situation may provoke conflictual feelings (e.g. self-blame, survivor guilt) or shame (e.g. own actions or fantasies prior to the situation). Injury to the body may threaten self-esteem and body image; or represent a loss of function. In some cases, the injury may even serve as a primary gain in a psychodynamic sense. The immediate responses will also be influenced by psychological issues like fear of losing control, or the effect of that phenomenon if it occurs. Conflicts related to secondary gains may also influence the clinical response observed by others.

Clinical features and assessment of trauma at the accident scene

The ABC rule of assessment (Airway, Blood pressure, Circulation) should always be the first step in any medical assessment of acute injury followed by physical examination of the thorax, abdomen, head and finally the extremities. However, except for head injuries associated with impaired cognitive function and injuries that significantly interfere with ventilation or cardiovascular function (e.g. agitation due to hypoxia or apathy due to cardiovascular hypotension), the injury it self plays a minor role for the immediate *psychological* responses to trauma.

Early and marked psychophysiological arousal symptoms like (in decreasing frequency) heartbeat, tremor, dry mouth, restlessness, shaking/trembling, weakness in legs, and sweating are common responses to an acute accident. However, the majority of accident victims appear reasonably calm[5] although many have some degree of inner turmoil that may impair the ability to receive, retrieve, and handle information. If behavioural disturbances are seen during the first seconds to minutes, they mimic phylogenetic responses known from all mammals exposed to acute and severe stressful events: flight, freeze, or fight.

(a) Flight response (anxiety, panic)

The patient appears frightened, may scream or cry. Clear cut panic (e.g. overt confusion, bewildered or aimless behaviour or running away), is rather infrequent even during disasters (<1 per cent). Although lowering of blood pressure is not part of the clinical features of panic, panic is often included in the concept of 'shock' used by lay people and media.

Physiological response to physical injury may be misunderstood as flight response. Patients with injury to the thorax hyperventilate and may appear anxious and scared. Cyanosis is not a sign of emotional distress in adults, and hyperventilation should always be considered as sign of respiratory problems needing urgent medical attention (e.g. pneumothorax). Patients with head injury may be confused and bewildered, but they seldom display the open anxiety seen in patients who panic.

Panic with severe behavioural disturbances may threaten the safety of the subject and provoke anxiety in bystanders and other victims who may themselves be afraid to lose control. Thus, whenever possible, patients with strong anxiety or panic should be offered immediate psychological support. Establishing physical (e.g. hand around the shoulder) and verbal contact is important to reduce panic and provide a sense of security and control. Verbal contact may also reveal the subject's real or imagined fears and provide the subject with an alternative way to express their inner turmoil and despair and thus pave the way for more optimal coping and subsequent behavioural control. The subject should be removed from the accident scene, but not left alone. These subjects need to move around and should not be forcefully immobilized. A helper may walk with the patient until he calms down. The exception to this rule is rare instances where the subject's behaviour is completely out of control representing an immediate threat to the physical safety of self or others.

Reuniting family members may reduce anxiety and worries.

Hyperventilation is treated as usual (breathing into a bag to increase the CO_2 -level) combined with physical and verbal contact as described above. It is crucial that somatic causes (e.g. pneumothorax, intoxication) have been ruled out.

(b) Freeze response (apathy)

Freeze responses include halted surprise or in more extreme cases emotional numbness (apathy). Apathy causing lack of appropriate lifesaving activities occur rather infrequently among random samples of accidentally injured adults (less than 10 per cent). In less than 1 per cent, significant parasympathetic (vagus) responses with lowering of blood pressure occurs ('emotional shock'). These patients appear pale and silent. The look of their eyes gives an impression of detached distance, if they were looking onto their own personal world somewhere far away from the actual accident scene. Rarely, an atypical freeze response characterized by blank denial of having sustained an injury when one, in fact, exists may be seen. These subjects may continue to behave as if nothing had happened and not take appropriate precautions at the accident scene.

Several physical injuries may mimic freeze-response. Patients with internal bleedings (e.g. liver, spleen) may appear pale and silent as if in emotional shock ('freeze response'). The pulse is weak and fast (tachycardia), however, in contrast to the vagus tonus induced bradycardia of the freeze response.

If there is a risk of further injury associated with remaining at the accident scene, patients with freeze responses must be removed to a safe place. They should not be left alone, but covered with a jacket or a blanket over their shoulders and attended to in a calm and gentle way, encouraging them to express some of their thoughts and emotions. If the freeze response is severe and prolonged, the patient should be brought to an emergency room for renewed and extended medical evaluation and basic psychological care. Cases of complete denial of having sustained an injury despite evidence for the opposite, should clinically be handled as a freeze response.

(c) Dissociative symptoms

Dissociative symptoms occur in about 15 per cent during the 1st second to minutes after an accident and may be associated with

flight or freeze responses. Brief symptoms of derealization are most common, even in relatively minor accidents (e.g. 'unreal', like a 'dream' or 'slow movie'). Symptoms of depersonalization (e.g. 'I watched my body burn from a distance') are less common and usually signal a more severe psychological response. Brief symptoms of dissociation do not predict later psychiatric problems,[5,7,8] but marked and prolonged dissociative symptoms still present weeks after the accident.[7]

(d) Fight response (aggression)

Fight responses include irritability, anger and more rarely, open aggression. This response is most often seen among bystanders or helpers who feel threatened by the exposure of dead and mutilated bodies. They may quarrel with the rescue team, and sometimes even interfere with the work of police or helpers. Open aggression is rare among victims themselves with the exception of intoxicated victims with severe personality disorders and a few who have sustained severe head injuries (e.g. subdural hematoma, frontal brain contusion).

Irritability and aggressive comments should not be taken personally by the helpers, but interpreted a symptom of helplessness. In most cases, this response is psychological, but impaired behavioural control due to drug or alcohol may be contributing factors. The patient should be treated as being extremely anxious and under high emotional distress. Reuniting with family or significant others if possible may be helpful. Physical activity may reduce aggression. If suitable, simple tasks which require physical movements may be therapeutic ('Can you give me a hand with . . . . .'), but subjects under stress should never be involved in important rescue tasks due to their impaired judgement ability and tendency to act irrationally.

(e) Acute stress reaction

Marked or severe flight, freeze or fight reponses are included in the ICD-10 (F43.0) definition of acute stress reaction (ASR). ASR is defined as immediate onset of marked psychological symptoms (within 1 hour) following exposure to an exceptional mental or physical stressor. The symptoms must begin to decrease after 8 hours if the stressor is transient (e.g. accident). If exposure to the stress continues (e.g. combat zone, hostage situation) the symptoms must begin to diminish after 48 hours. In contrast, the DSM-IV concept 'acute stress disorder' (ASD) describes development of symptoms not earlier than 2 days after the trauma but within one month after exposure.

Psychotropic drugs are seldom needed to treat acute psychological responses at the accident scene if proper medical care including emotional contact from skilled, empathic helpers is offered. Violence towards victims having lost behavioural control may increase the anxiety among other victims and bystanders, and in fact, increase the risk for more behavioural disturbance within the group, and should thus be avoided.

(f) Acute pain

Some injured persons do not report pain complaints during the 1st second to minutes after even severe physical injury, and some may even continue to perform tasks as usual. This response occurs particularly in situations with continous threat to others or own life (e.g. wounded soldiers). This is part of a brief dissociative response which may be life saving and does not reflect psychopathology. However, a few accident victims respond differently. They may report the most painful physical sensations ever experienced. In the absence of severe physical injury, this response most often reflects catastrophic cognitions associated with severe anxiety[5] and should be treated accordingly. Most injured patients report some degree of pain as minutes pass, however.

Severe pain should be treated at the accident scene and will contribute to psychological and physical recovery from the injury.[9] Anxiety and fear may lead to increased pain complaints, so may imagined (!) severe injuries. For those reasons, it is important not only to examine the presence of actual injury, but also explicitly ask the victim if he or she *believes* or *fears* having sustained serious or life-threatening injuries not detected by the medical personnel. If yes, factual information combined with additional proper medical examination if needed, should be provided to reduce the subject's fears and worries. Faced with true life-threatening injuries, the helper should admit facts if asked, but nevertheless provide some hope and cautioned optimism. It is often hard to evaluate true prognosis at the accident scene and advanced trauma surgery may save the life of many severely injured subjects who would have died a few decades ago.

Responses seen in the emergency room

In urban areas, most subjects will be brought to emergency rooms within less than an hour. At that time most victims have started the process of working through the accident, the injury and its implications. This process is reflected in a characteristic cluster of emotions, cognitions and physiological symptoms observed in humans exposed to all types of stressful situations.[10–12]

- Intrusion includes images of the accident popping into the victims mind, and thinking about the accident even when the person do not want to do so. The main load of intrusive symptoms are related to the severity of the accident and the personal meaning. Intrusive symptoms are common both in post-traumatic depression and anxiety.[5]
- Avoidance includes trying not to talk about the accident or avoiding any cognitive or behavioural activities which reminds the person about the accident. Such symptoms and signs are strongly related to accident-independent variables such as personality traits (e.g. coping style) and more often associated with anxiety than depression.[5]
- Hyperarousal includes startle response, strongly increased heart rate, shivering and trembling, irritability, difficulty in concentrating, hypervigilance and disturbed sleep. With the exception of difficulty to sleep, clinically significant hyperarousal is rather infrequent in randomly selected accidentally injured subjects (less than 10 per cent). However, severe hyperarousal signifies a strong physiological and emotional response and is increased among injured compared to non-injured accident victims and is in some studies associated with later post-traumatic distress problems.[13]

The three most common types of behavioural problems seen in the emergency room are,

- Uncontrolled crying or screaming
- Strong anxiety which may include excessive pain complaints
- Aggression and dyssocial behaviour

Crying and anxiety are associated with high levels of intrusion and avoidance, and may be part of ASR. Systematic and carefully

conducted medical examinations accompanied by supporting questions about the patients emotions, thoughts, and fantasies are the most effective way to put the patient at ease. Sedating drugs are seldom needed if the necessary psychological support is provided. Separation from family members or significant others may increase anxiety and despair, and family reunion may be helpful. If symptoms of high arousal persist, prazosin, a central nervous system (CNS) active alpha-1 adrenoreceptor antagonist or a beta-blocker (e.g. 40–60 mg propranolol) or alfa—may be given to attenuate extreme adrenergic tonus.[14]

Aggressive behaviour occurs in about 5 per cent of injured persons brought to hospital, mostly among intoxicated subjects. The presence of head injury must be ruled out. Most cases can be brought under control with the help of significant others and firm, but calm attitude, addressing the fear or helplessness. In a few cases, acute administration of benzodiazepines or a sedating neuroleptic may be necessary. If the patient is intoxicated or suffer from respiration difficulties, neuroleptics may be the safest option. In cases of armed patients, the necessary precautions must be taken.

Psychotic forms of ASR are seldom seen in injured adults and even patients with schizophrenia or other psychotic disorder prior to the accident appear remarkably calm and collected upon arrival in the hospital. If psychosis is present at arrival in the emergency room, influence of psychoactive substances, severe injury (e.g. brain injury, respiratory failure) or a concurrent psychotic disorder must be ruled out.

(a) Whiplash injury

Rear end collision may cause a whiplash like movement of the neck. Biomechanical studies suggest overstretch of cervical facet-joint capsules as a possible source of pain. Neck pain, stiffness or tenderness may occur minutes to hours after the accident. A medical examination including an X-ray of the cervical columna seldom reveals pathological findings (Quebec classification grade I). In more severe cases, distortion and minor bleeding in capsules, ligaments, tendons or muscles (grade II) may lead to additional musculoskeletal signs such as decreased range of motion and point tenderness. In severe injuries, neurological findings (impaired myostatic reflexes, pareses, loss of sensibility, grade III) or even fractures (grade IV) may be present. In patients with whiplash related injury grade I or II, acute psychological distress and associated neck pain is the most important predictor of long-term outcome.

In the emergency room, treatment should aim at providing the subject with adequate information about the good prognosis. Pain after whiplash-injury usually lasts for four-to-six weeks (!), but gradually disappears. In cases of pain without somatic findings, pain killers or antiflogistic medication have uncertain effect and should not be prescribed for more than a week. Sick leave should be avoided or be as short as possible. Mobilization and early return to work is recommended. Overtreatment by physicians or physiotherapists (e.g. application of stiff collar despite no findings of injury to the cervical columna) may lead to permanent illness behaviour and pain-fixation.[15] The optimal physical treatment of whiplash injury is still unsettled,[16] but premorbid pain and psychiatric disorders represent a risk for development of chronic disabling symptoms and should be treated.

(b) Significant others' needs

Relatives or survivors may want to see dead significant others brought to hospital, and touch them. This process helps the relatives to work through the traumatic event and should be encouraged. If the dead body is grotesquely disfigured, the most horrifying parts should be covered prior to exposure. In any case, a physician or a skilled nurse should accompany the relatives during exposure. Small childrens' emotional response to dead bodies mirror the adults' response. Accordingly, reducing the anxiety and fear of the adults is the best way to help children cope with dead ones. Correspondingly, in cases of severe anxiety in accompanying small children, addressing the helplessness and anxiety of the parents is important. If dead bodies are stored in hospital chapels, care must be taken to cover the presence of religious symbols incongruent to the religious status of the dead one and his family (e.g. Christian crosses should be covered in case of a Jew or a Muslim). The reader is referred to chapter 4.16 for more information on culture specific responses to stress and trauma.

In disaster situations, the need for information varies among relatives, depending on whether their loved ones are missing, injured, or dead (survivor status). Those who have lost loved ones often want to talk to rescuers or get information with regard to any hint about the emotional status of the dead one at the time of death. Accordingly, in situations with several hundred relatives come to the hospital, information is provided in separate groups according to the significant other survivor status. The logistics of such procedures should be outlined in the hospital's disaster plan.

Psychiatric treatment during hospital stay

Most studies indicate that risk factors, emotional, and behavioural responses correspond to that of medically ill patients and identifying those who are at increased risk can follow the same guidelines as for medicine in general.[17] Some patients may complain about physical symptoms suggesting undetected injury. Such complaints may in fact be true. If not addressed and attended to, psychological distress presented by means of somatic complaints or symptoms is the rule.

Clinical syndromes requiring psychiatric attention during hospital stay are listed in Table 5.3.8.1. Complete denial of severity of injury or avoidant coping is maladaptive and should be counteracted.[18] Relatives or significant others should be contacted. They may convey unrealistic fears—or hopes (e.g. 'you will be able to walk'—attitudes in patients with permanent paralysis of legs)—which strongly influence the behaviour and emotional well-being of the patient. They may also provide information which may be helpful to understand current behaviour (e.g. previous dysfunction, 'silent' delirium undetected by staff).

(a) Anxiety and acute stress reaction

Worrying and compulsive thoughts about the accident or the injury (intrusion) is seen both in anxiety and depression. Extreme anxiety may infrequently lead to cardiovascular complications (e.g. pulmonary embolia) in subjects with cardiovascular risk factors (e.g. elderly subjects often smokers with hypertension and arterosclerosis).

Sleep problems may be present or related to physical pain and treatment procedures. The aetiology of nightmares following traumatic injury is complex.[19] They mostly emerge a couple of days after the accident and disappear gradually. Persisting nightmares for more than two weeks without any signs of mastery in the dream content, suggest development of post-traumatic stress disorder and should thus be treated.

Table 5.3.8.1 The most frequently seen psychiatric syndromes during hospital stay following accidental injury

Type of syndrome or clinical problem	Clinical symptoms and signs	Comment
Delirium	Confused, strange behaviour; episodic disorientation; irritability; episodic fearful look	May occur without obvious signs of agitation if sedated; Relatives may detect it and be upset. Diagnosis: 'Draw a clock test' helpful
Abstinence from drug or alcohol	increased pulse; sweating; tremor; insomnia; agitation; anxiety; nausea; abdominal pain; dysphoric.	May be interpreted falsely as accident-provoked anxiety
Antisocial personality, histrionic or borderline personality disorder	Aggressive behaviour; poor compliance with treatment; abusive language; high demand for analgesics	Undetected brain dysfunction must be ruled out; Relatives may provide important pre-injury information
Hypomanic or manic responses	Elated mood; emotions do not correspond to the situation; uncritical behaviour	Undetected brain dysfunction; bipolar disorder or hypomanic response as a defence against survivor guilt
Anxiety	Tense, anxious, restless, worrying, increased startle reflexes; insomnia; dissociative symptoms may occur.	Prolonged or delayed stress response or disorder; imagined or real threat from accident or injury; physical complication (e.g. hypoxia, delirium); abstinent or side effects of drug. Obsessive-compulsive traits and high inner tension with fear of losing emotional control. If unexplained, consult relatives for psychological clues.
Depression	Withdrawn, loss of appetite; inability to feel; sad; worrying; passive; lassitude; anxiety symptoms frequent	Grief; survivor guilt; psychological response to disfigurement or loss (real or imagined) of function or self-esteem; reactivating of previous painful memories
Medically unexplained physiological events including delayed healing of wounds	Rare phenomena; typical senior physicians statement 'I've never seen something like it before'	Secondary gain by extended hospital stay (e.g. alternative prison); factitious disorder; extreme stress (psychophysiological activation)
Excessive pain	Complaints of pain; poor sleep and appetite; poor performance; do not reveal emotions.	Undetected physical complication; insufficient pain treatment; anxiety or depression response in past with obsessive-compulsive traits; withdrawal syndrome; drug abuser.
Partial or complete denial of actual injury	As-if-nothing-has-happened behaviour; refuse treatment; request early dismissal from hospital	Undetected brain dysfunction; psychotic disorder. If male and partial denial, consider obsessive-compulsive traits and high inner tension with fear of passivity

Psychological interventions should be based on clear indication and be brief, distress focused and time limited. Symptoms of intrusion including nightmares may be treated by simple psychological techniques. If one specific traumatic event which can be delineated (e.g. visual image of a traumatic moment), psychological video replay techniques (VRT) may be useful. The subject is taught how to relax. Subsequently, the subject reviews the pre-accident and accident situation on an imagined (i.e. mental) video screen. When the anxiety rises to unacceptable levels, the subject is asked to push the (imagined) stop button and press fast replay until a pre-accident situation where the subjects is at ease is reached. When calm, the procedure is repeated, until the subject can view the whole accident without strong anxiety.

If the anxiety level is high or the traumatic event is more complex, more comprehensive interventions are needed, e.g. Eye Movement Desensitization and Reprocessing (EMDR) or Trauma-Focused Cognitive Behavioural Therapy (TF-CBT).[20] If strong anxiety is not brought under control by means of psychotherapy or other behavioural techniques (e.g. applied relaxation), psychoactive drugs can be added. In injured patients with childhood trauma or other traumatic events in the past, a selective serotonin reuptake inhibitor (SSRI) probably should be the first choice. Sleep problems are best dealt with by environmental adjustment whenever possible, or by optimal pain control if appropiate. Sedative drugs are secondary option. Mianserin or mirtazapine combine sedative and antidepressant effects and may be alternative to benzodiazepines.

Acute stress disorder (ASD) may be conceptualized as an acute form of PTSD and may predict chronic PTSD.[21] The main treatment is psychotherapy (i.e. EMDR, TF-CBT). In PTSD, prazosin reduces nightmares and sleep disturbance in placebo-controlled studies, and may thus be an option also during the first days to weeks after trauma. Some studies have reported propranolol given within days following a traumatic event to be useful for mitigating PTSD symptoms or perhaps even preventing the development of PTSD. The mechanism is thought to be explained by reduced consolidation of emotional memory. Small doses of glucocorticoids may reduce traumatic memories in ASD as well,[22] but larger controlled studies are needed to verify this finding. Benzodiazepines may also reduce acute distress, but may not reduce the risk of 6-month psychiatric anxiety problems. In conclusion, all psychopharmacological treatments must be provided together with psychological interventions addressing the key psychological sources of distress and worry.

(b) Depression

Depressed mood during the first days to weeks following an accident are mostly due to guilt, shame, or grief due to real or

imagined losses. The key to understanding the response is the meaning of the accident or the injury for the patient. Guilt, shame or rumination over real or imagined losses is associated with long-term problems[23] and may require specific therapy.[24] Premorbid causes of depression (e.g. bereavement, mood disorder at the time of the accident), must be kept in mind. In patients with immobilizing injuries staying in hospital for an extended period, some degree of depressive symptoms is the rule. If the symptomatology is severe and persistent, antidepressants are indicated.

Persisting depression has been found to be highly predictive of a long-term psychiatric consequence, and moderate to severe depression predicts less likeliness of returning to preaccident functional level. Thus, depression should always be taken seriously. If marked depression presist for more then 2–3 weeks, an antidepressant should be given. Due to lower incidence of side effects, the newer low-toxic antidepressants are preferred. Delirinm and abstinence are treated as usual. Detailed presentations of the psychopharmacology of the injured or medically ill are available.[34–36]

(c) Pain

Both the injury itself (e.g. burn injuries, injuries to the pelvis, penetrating traumas) or medical treatment (e.g. physiotherapy to prevent contractures, ICU) may be associated with psychological distress and pain.[25,26] Pre-accident psychopathology increases the prevalence and severity of pain complaints. Pain or fear of bringing about pain leads to diminished movement, which can engender contractures, muscle atrophy, and bed ulcers. Traumatic amputation may be associated with phantom pain and exacerbation of pain in response to imagined movements has been reported in subjects with spinal cord injury.[27] Poorly treated pain can be demoralizing to patients and provoke psychological regression, giving-up responses and long-term psychiatric problems[28] including increased risk for suicide.[29] Thus active pain control is crucial and may reduce the prevalence of long-term suffering.[30] Comprehensive reviews of the psychological care of burned subjects are available.[31]

Concerns that trauma patients with injury related pain will become addicted if treated properly with analgesics is neither supported by clinical experience nor by empirical data.[32] However, co-morbid psychiatric disoders must be taken into account when treating injury-associated pain. Patients with a history of substance abuse may have greater tolerance to analgesics and will have to be titrated to higher doses.[33]

(d) Confusion and psychoses

In civilian life situations, confusion or psychotic responses appearing for the first time days after being admitted to hospital are almost exclusively due to a central nervous system dysfunction. Risk factors are severe injuries (ISS >15; third degree burn injury) and major head injuries (e.g. contusion). Impaired cognitive functions or drug or alcohol abuse prior to accident and age >50 increase the risk of organic mental dysfunction.

In a few cases, psychotic-like confusional and agitated responses occurring during the hospital stay may be due to abrupt disruption of intake of psychotropic medication taken for long periods prior to the accident. If in doubt about the aetiology of a psychotic response seen during the first days to weeks (including severe manic episodes), the psychiatrist should consider the response to be of organic origin and explore the pathophysiological processes as done in cases of delirium. Asking the patient to draw a clock, may be a simple and effective way of detecting organic dysfunction.[37]

(e) Alcohol and drug abuse

A significant number of accident victims brought to hospital have an alcohol or drug problem, and symptoms of abstinence may be misinterpreted as psychological anxiety.[38] In cases of grossly deviant behaviour, the presence of co-morbid severe personality disorder should be considered. Alternative explanations include delirium or side effects to drugs (e.g. steroids).

(f) Psychological needs of rescue personnel and staff

Debriefing is a psychological treatment intended to reduce the psychological morbidity that may arise after exposure to accident or injury. Debriefing involves promoting emotional processing/ catharsis or ventilation by systematically encouraging recollection/ ventilation/ reworking of the traumatic event. There is no evidence that this method reduces the incidence of post-accident problems in civilian life.[20,39] Accordingly, psychiatric intervention in the emergency room should be limited to those who display acute and severe psychiatric disorders.

Rescue personnel and medical staff may be psychologically affected by sudden exposure to grotesquely mutilated bodies.[40] The same individual vulnerability found in injured subjects apply. Group debriefing has been recommended if the rescue operation was extremely difficult; there were many dead or there was explicit harsh critique of the rescue operation from the media. Debriefing offered and conducted by a respected senior member of the rescue team is probably more appropriate than debriefing offered by psychologists or psychiatrists. However, empirical data regarding efficacy of emotionally focused group debriefing is scarce.

Long-term behavioural and psychiatric consequences of physical trauma

Physical injury may cause permanent physical change including neurological dysfunction,[41] impaired physical function, changes in perceived somatic health including pain,[30] decreased capacity to work (in children: play), decreased social contact and decreased leisure pleasure.[42] In an unselected population of hospitalized accidentally injured adults, about half will report some complaints three years later. Among those with most severe injuries (ISS >15), only 1/3 will have made full recovery after three years, and about half will report at least moderate disabilities.[43]

The prevalence of non-organic mental disorders among hospitalized adults is about 20 per cent after six months and 10 per cent after two years.[29, 44–49] Depressive symptoms and disorder are most frequently seen followed by specific accident-related phobia and PTSD. Subsyndromal PTSD-cases must be added to these numbers. PTSD is associated with several physical health problems including cardiovascular diseases, respiratory diseases, chronic pain conditions, gastrointestinal illnesses, and cancer.[12] The prevalence of alcohol and drug abuse is increased as well.

The prevalence of long-term psychiatric is increased in injuries associated with visual disfigurement, loss of body parts or physical function (e.g. spinal cord injury), neck injuries and injuries to the pelvis and genital areas.[42] Chronic pain following accidental injury is often associated with concommittant mental disorders, in particular mood disorders or PTSD.[50] Man-made accidental injury

(e.g. assault, combat, rape, terrorism) cause more long-term mental problems than other types of accidental injury (e.g. natural disasters). Studies comparing outcomes in *men versus women* have been mixed. Current evidence suggests that women are at higher risk for anxiety and depression, and men are more at risk for substance abuse and antisocial behaviour.

Following extreme psychological and physical trauma (e.g. torture, concentration camp survivors, hostage situations), permanent change in the person's pattern of perceiving, relating to, and thinking about the environment and the self may occur (ICD-10 F62.0: Enduring personality change after catastrophic experience). The changes should not fully be explained by the presence of PTSD. This diagnostic category does not exist in the DSM-IV.

Assessment of long-term psychiatric consequences of traumatic injury

The following key-points need to be explored when evaluating long-term effects of traumatic injury

- Social and cognitive resources (including social support)
- History of mental disorder, social dysfunction or trauma in the past
- Overlooked physical injury (increased risk if high energy accident or severe injury, e.g. undetected frontal brain damage or other neurological injury)
- Deviant behaviour or accident-related psychiatric disorders following the accident (including ASR or ASD)
- Painful treatment procedures
- Accident-independent traumatic life-events during the post-injury period
- Current psychiatric disorders

Patients, relatives and physicians may evaluate long-term problems differently[51] and psychiatric co-morbidity is prevalent. Thus the clinical assessment should be supplemented by a systematic screening for the most common psychiatric disorders (e.g. MINI neuropsychiatric interview) and cognitive, behavioural and quality-of-life issues (e.g. Impact of Event scale, General Health Questionnaire). Questionnaires specifically designed to address physical, emotional and social outcome of accidental injury are available.[42] A proper, complaint-focused medical examination is often necessary as well.[52] The psychiatrist may improve the quality of the medical examination by providing the examining physician with specific diagnostic questions based on information of the patient's trauma history and symptom complaints.

Treatment of long-term problems

Psychiatric disorders occurring in the aftermath of injury are treated according to general treatment guidelines of mental disorders with some modifications. EMDR and TF-CBT are the best validated psychotherapeutic interventions for trauma related PTSD.[20] If the psychological themes are related to conflicts, family issues or secondary events, short-term psychotherapy as outlined by Horowitz and his group[10] may be conducted. Body-focused treatments may be helpful in some subjects with chronic pain problems after trauma.[53] Randomized controlled treatment trials of accidentally injured adults with post-injury psychosomatic and psychiatric problems are few, however. Comprehensive treatment of patients may provide better results than intervention performed by one single professional only.[54]

Antidepressants should be given in cases of mood disorders or PTSD not responding to psychotherapeutic interventions alone. SSRIs and related drugs are first choice. Drugs acting on nor-adrenalin reuptake alone (e.g. atomoxetine, reboxetin) may increase anxiety and should be avoided. Psychopharmacological treatment of somatoform pain disorders should target both serotonin and nor-adrenalin (e.g. amitryptyline, chlomipramine, duloxetine, venlafaxine). In cases of chronic PTSD with high level of intrusive symptoms, prazosin or propranolol may be added. Betablockers may be valuable as a supplement to anxiety provoking exposure therapy. Benzodiazepines may reduce PTSD-related anxiety, but differences in modulation of skin conductance compared to patients with panic disorder support clinical experience that drug treatment should be supplemented with psychological interventions in order to achieve optimal results. Guidelines for psychopharmacological treatment in patients with co-morbid physical disorders exist (e.g.[36]).

Compensation claims and litigation

Most accidentally injured subjects do not exaggerate their loss,[55] and in non-litigant situations malingering is an unlikely explanation in most cases of chronic disturbances after accidents. Neither is economical settlement followed by significant change in clinical situation in most cases. However, in litigation situations, the patient's problem report may sometimes be exaggerated or even invalid. Studies of personal injury plaintiffs indicate that a significant number report pre-injury functioning superior to that of controls, and malingering has been estimated to 20–30 per cent.

Studies consistently show that delayed-onset PTSD in the absence of any prior symptoms is rare, whereas delayed onsets that represent exacerbations or reactivations of prior symptoms may occur.[56] Untrained subjects are able to endorse symptoms on checklists to meet criteria for diagnoses of major depression, PTSD and GAD, and PTSD self-report measures cannot be used for diagnosis.[57] Furthermore, intrusive symptoms are not PTSD-specific and may be significant in depression as well.[5] This fact is often neglected which explains why some expert testimonies misinterpret depression as being PTSD.

The physician should always try to get patient-independent information from reliable sources (e.g. medical records, general practitioners) also related to pre-injury function[58] before concluding about long-term problems due to physical injury. The possibility that clinically significant brain injury or non-injury related illnesses or psychiatric disorders occurring after the injury, have been overlooked during the medical evaluation part of litigation and compensation cases must be kept in mind.

There is no evidence that physical injury provoke *de novo* bipolar disorder or disorganized schizophrenia, even among severely maltreated subjects.[59] However, permanent injury to frontal and temporal lobes of the brain may provoke manic episodes, paranoid psychoses with schizophrenic-like symptomatology and chronic depression. Both in clinical and court settings, such brain dysfunctions may be overlooked due to lack of classical neurological signs.

Expert testimony should be based on the best available evidence and standards of care, which requires that experts stay current in their field of expertise, and revise old opinions as new information is published. Personal experience alone is rarely sufficient. The psychological difficulties and challenges faced by an expert witness is discussed elsewhere.[60]

5.4

Obstetric and gynaecological conditions associated with psychiatric disorder

Ian Brockington

Introduction

This chapter covers the psychiatry of menstruation, various manifestations of the desire for children (such as surrogate pregnancy and pseudocyesis), pregnancy and mental health, the psychopathology of parturition, infant loss, postpartum psychiatric disorders, the mother–infant relationship and infanticide.

The psychiatry of menstruation

It has long been realized that menstruation and mental illness are linked. As early as 1827 menstrual mood disorder was used as a defence in filicide.[1] In the 1850s, Brière de Boismont[2] and Schlager[3] carried out the first surveys showing that 20–30 per cent of women suffered a mood disorder before or during the menses—usually irritability or depression, occasionally euphoria. There are descriptions of a wide variety of deviant behaviours, including nymphomania, food cravings, binge drinking, pathological lying, shoplifting, and fire-setting, as well as suicide, violence, homicide, and morbid jealousy. There are other nervous diseases associated with menstruation, including epilepsy, migraine, and hypersomnia.

Recently, there has been much research into the biological basis and treatment of 'premenstrual tension' (or its synonyms). A number of daily rating schedules have been published, but self-devised rating scales, tailored to an individual patient's symptoms, can be used, provided that they are carefully completed every day. Scientific studies are bedevilled by difficulties in defining the disorders.[4] It is not known whether this is one syndrome or many. Irritability is striking, but otherwise the symptoms are common to many other disorders.

Although little is known about the aetiology, progress has been made in treatment. There may be a response to serotonin-reuptake-inhibiting antidepressants (e.g. fluoxetine, chlomipramine). In so far as a luteal-phase defect may be a factor, ovulation-promoting drugs such as clomiphene can be tried. The synthetic steroid danazol, and the gonadorelin agonists (which suppress menstruation), are draconian treatments for severe cases. All interventions should be prescribed in the context of a long-term study using daily ratings.

Rarely, menstruation is linked to a psychosis with acute onset, brief duration, and full recovery. Premenstrual, catamenial, paramenstrual, mid-cycle, and 'epochal' variants have been described.[5] Menstrual psychosis is rare, but perhaps not excessively so. There is a clustering of episodes around puberty and after childbirth, although only a small proportion of menstrual cycles are involved. There are sufficient case reports from Japan, India, and Islamic countries to suggest a worldwide disorder. This is not a specific entity, and most typical examples manifest non-menstrual bipolar disorder at another stage of life. Clinically, it resembles puerperal psychosis. The close relationship between these two psychoses is emphasized by women who develop puerperal and menstrual psychosis at different times.[6] A Japanese investigation showed an association with anovulatory cycles.[7] Pregnancy has a beneficial effect, and there are claims of successful treatment with oral contraceptives, progesterone, clomiphene, danazol, and gonadorelins. The basis for intervention is a long-term study, with a good baseline and exact timing of events in relation to the menstrual cycle.

Infertility

Motherhood is among the strongest and most universal of motivations. For many infertile women, childlessness is the most upsetting experience of their lives, and the yearning for children dominates everything. Infertility is stigmatizing, especially in some cultures. Infertile couples often suffer from self-reproach over sexual indiscretions, abortions, or contraception. They envy fertile couples, and contacts with other people's children, family celebrations, and friends' pregnancies are problematic. The security of the marriage may be threatened by the fear that the spouse will desert to a fertile partner; nevertheless, the marriages themselves are often happy.

Infertility differs from other stresses in its duration. The psychological reaction unfolds over years. When treatment begins, there is a cycle of optimism and hope, with a build-up of tension towards the end of the cycle, followed by disappointment and despair. Sexual functioning comes under strain during the investigation, and the discovery of azoospermia is especially stressful. There is some evidence that stress affects conception, though more prospective studies are needed.

Assisted reproduction

Artificial insemination (using the husband's or partner's semen) has been available from the late eighteenth century, and donor insemination since 1884. Its psychological effects on marriage seem minimal; husbands or partners rarely react with jealousy to the

baby, any more than to an adopted child. The proof that the experience is acceptable is that it is often repeated. One of the principles is privacy, ensuring that donor and couple never meet and remain ignorant of each other's identity. It is felt that violating anonymity might compromise the marriage, since donor and mother are too deeply involved in procreation to regard their relationship with detachment; but times may be changing. The interests of the children have to be considered; donor insemination obscures the genetic lineage, and the child cannot benefit from advances in genetics.

In vitro fertilization (IVF) was first performed in 1978, and was achieved with a donated oocyte in 1984; it is now widely used—in Holland, 1/60 babies are born by IVF. The procedure is harrowing, and counselling is mandatory. There is an increase in multiple births, which are more stressful. But the quality of parenting may be superior to that of families with naturally conceived children.

Surrogate motherhood

This has two meanings:

- A woman is inseminated (artificially or naturally) with the husband's or partner's semen, and surrenders the child to the genetic father and adoptive mother. The surrogate provides oocyte and womb, and is a substitute spouse.
- The wife donates a fertilized oocyte to the surrogate gestational mother. This method, involving *in vitro* fertilization and embryo transfer, is the only way a woman without a uterus can have a child that is genetically her own.

A considerable number of women apply to become surrogate mothers, for motives of financial gain, altruism, pleasure in being pregnant, or atonement.[8] A child can now have 3 mothers—genetic, gestational, and rearing.

Surrogate pregnancy has stirred up an ethical debate. Apart from religious objections, there is concern about the physical and psychological consequences for the gestational mother, and there are endless opportunities for custody disputes and other legal complications. It has been found that the gestational mother does not bond strongly to the foetus, and most surrogate and commissioning mothers do not suffer from psychological problems.

Pseudocyesis

When a woman believes herself to be pregnant and develops symptoms and signs of pregnancy, this is called pseudocyesis. In a classic monograph, Bivin and Klinger[9] collected 444 cases from the literature. Many sufferers were parous, including women with as many as 10 children, and as many as six episodes of pseudocyesis.

The differential diagnosis includes delusions of pregnancy, in which there are no somatic changes. This is a common delusion and can also occur in men. There is also pregnancy simulated for social, mercenary, or legal purposes (e.g. to escape the death penalty).

The clinical features include:

- a firm belief in the pregnancy, usually lasting until the onset of a false labour at 9 months, after which the disorder usually resolves
- amenorrhoea
- morning sickness and/or pica
- enlargement of the breasts and nipples, and even a discharge of colostrum
- abdominal enlargement, caused by muscular contraction, tympanites, fat, or pathological lesions, but without effacement of the navel
- an illusion of foetal movements
- enlargement of the uterus to the size of a 6-week pregnancy.

Modern diagnostic tests have greatly reduced the frequency. The diagnosis should be made on ultrasound examination. Where radiology or ultrasound are unavailable, an examination under anaesthetic is recommended—in the presence of a family member to avoid accusations of abortion.

The psychological basis is usually an intense desire for children, especially in older childless women. In some cases, however, a guilty fear of pregnancy has been the background; this has occasionally led to dangerous attempts at abortion by non-pregnant women. Pseudocyesis is a demonstration of the influence of psyche over soma, mediated by hormonal secretion. It occurs in dogs, cattle, and rodents. Persistence of the corpus luteum would explain breast changes, moderate uterine enlargement, and secretory endometrium; but it is not the only basis: hormonal measurements have been made in at least 30 patients, some of whom had chronic anovulatory states, hyperprolactinaemia, or androgen excess.

These women require psychotherapy. Simply revealing the diagnosis is unsatisfactory because the patient may consult another doctor with the same symptoms, or develop a recurrence. The underlying conflicts must be explored, helping the patient to accept that she is not pregnant.

Sterilization

Women can be prevented from bearing children by various operations on the uterus and Fallopian tubes, indications for which are contraceptive, medical, eugenic, or psychiatric. Sterilization is the most effective and widespread contraceptive method. A large number of studies have looked at its effect on mental health, but many had methodological weaknesses. Ekblad, however, published two thorough studies in 1950s—a general study of 225 women, of whom 99 per cent were interviewed 5 to 6 years later, and a unique study of 60 sterilized women with no living children.[10]

There have been two modern prospective studies. Cooper and colleagues in Oxford[11] interviewed 201 women 4 weeks before non-puerperal tubal sterilization for contraceptive reasons; 190 were re-interviewed 6 months later, and 193 at 18 months after sterilization: the number with psychiatric illness fell from 21 before the operation to 9 at 6 months, and rose to 18 at 18 months. Not surprisingly, the presence of psychiatric disorder before the operation was a predictor of its continued presence; only two who were in good psychological health before the operation developed psychiatric illness 6 months later. A WHO collaborative study, involving five countries (India, Colombia, Nigeria, Philippines, and England), compared 926 sterilized women with 924 who used other methods of contraception: those who chose sterilization had more preoperative psychiatric disorder. The results from the Nottingham field centre[12] were published separately, and found that 9/138 sterilized women had psychiatric disorder before the operation; after surgery there were only three new cases at 6 weeks, and four more at 6 months, less than the control group.

A small minority of sterilized women are troubled by frigidity or severe regret. The most concrete evidence is a request for reversal, several studies of which have been published. Regret is more common in the following groups of women:

- Younger women or those with fewer children: Ekblad[10] found that none of his 60 childless women required hospitalization for depression, but 16 were seriously distressed and 29 expressed a longing for children of their own.
- Those in whom sterilization was the condition for a termination—a barbaric and punitive practice that used to be the rule in some countries.
- Those sterilized at a time of crisis—after parturition, or during a psychiatric illness—when it is difficult to make a balanced judgement.
- Those under external pressure.
- Those with learning difficulties: the issue of sterilization, which has from time to time been practised in various countries, is becoming more important. With a policy of community care and a greater tolerance of sexual activity, there is an increased risk of pregnancy in women with severe learning difficulties, with the spectre of inherited disorders and problems in mothering. Yet these women greatly desire children, and do not have the same resources to compensate for their lack.
- Those sterilized for medical reasons such as inherited disorders, for which medical advances have later provided alternative solutions (e.g. amniocentesis).
- Those who seek sterilization in a context of marital disharmony: after the marriage has failed, the wife may remarry and change her mind about further children.
- Those with religious scruples.

Hysterectomy

This is one of the commonest operations, and is performed in about 10 per cent of women. There have been claims that it leads to 'post-hysterectomy depression'. But this idea has been thoroughly and systematically refuted. Several prospective investigations have shown that mental health improves after hysterectomy. Three comparable Oxford studies, conducted between 1975 and 1990, have addressed this problem: all showed that psychiatric morbidity fell below its preoperative level, or remained low.[13] The ranks of women with 'post-hysterectomy' depression are swollen by those seeking a surgical remedy for psychosomatic complaints.

In younger women, infertility can be a source of discontent. It would not be surprising if the loss of the womb affected feminine identity and libido; but this is probably also a myth. Prospective studies from Oxford,[13] St Louis,[14] and Aberdeen showed an increase in the frequency of intercourse, and of enjoyment. Concomitant oöphorectomy does not adversely affect psychiatric well-being.[15]

The psychiatry of pregnancy

Pregnancy adjustment

The psychopathology of pregnancy needs to be understood in terms of the adjustment all women must make when they conceive. Pregnancy is not only a biological event, but also an adaptive process.[16] A pregnant woman must carry the baby safely through to delivery, and adjust to the sacrifices that motherhood demands. She must ensure the acceptance of the child by the family, develop an attachment to the baby within, and prepare for the birth. She must adjust to the alteration in her physical appearance, and develop a somewhat different relationship with the child's father.

Many pregnancies are unplanned and not initially welcomed. Many women react to conception with grief and anger. A random sample of English mothers showed that 44 per cent of pregnancies were unintentional, including 17 per cent that ended by legal abortion. In married women aged 25 to 29 years with one child, 80 to 84 per cent of pregnancies were planned, compared with 26 per cent in the unmarried.[17] The planning of pregnancy and its acceptance are two different things. The fact of planning does not guarantee acceptance; 6 to 12 per cent of those who plan their pregnancies subsequently regret them. Most unplanned pregnancies are immediately accepted; even if the initial response is negative, gradual acceptance usually follows. In a small proportion of cases, rejection continues to the end of the pregnancy.

Pregnancy has a profound effect on the relationship with the child's father. At every stage this relationship is of the highest importance. A pregnant woman needs increased attention and care and is sensitive to perceived rejection. Pregnancy alters other relationships as well—with the wider family and friends. Many women become closer to their families-of-origin and in-laws.

The change in appearance and shape is sometimes distressing. Some take pride and pleasure in these changes, enjoy the extra attention, and feel an enhanced sense of womanliness. Others are concerned about their loss of figure and facial bloom, weight gain, and stretch marks. Dysmorphophobia, with ideas of reference and social avoidance can ensue.

Pregnancy may be accompanied by medical disorders, and in all there is an interaction between physical and psychological factors. Pica is common, especially geophagia (eating earth or clay), which can lead to iron deficiency anaemia, bowel obstruction, and roundworm infection; other forms of pica can lead to lead poisoning or hypokalaemia. Rarely, hyperemesis can cause Wernicke's encephalopathy, and delirium can complicate chorea gravidarum.[18]

Denial of pregnancy

In women who do not realize they are pregnant, one must distinguish between three different phenomena: unnoticed pregnancy, deliberate concealment, and dissociative denial. A German survey of 29 000 births found 62 women who failed to recognize pregnancy until the 20th week (1/475 births); 12 were not diagnosed until they were in labour with a viable infant (1/2455).[19] A Welsh study obtained similar figures.[20]

The late discovery of an unwelcome pregnancy carries a small risk of suicide. The mother is also at risk of all those complications of delivery that, with modern antenatal care, have become rare. For the child there are increased hazards, including prematurity and neonaticide.

Prenatal attachment

The mother 'bonds' or 'affiliates' to the unborn child in a way analogous to the formation of the mother–infant relationship after birth. Prepartum bonding is catalysed by quickening and probably by ultrasound examination. The mother begins to have fantasies

about the baby and talks affectionately to it. She may engage the husband or partner and other children in 'playing' with the baby. At the same time she prepares for the birth and motherhood ('nesting behaviour').

There is a pathology of the affiliative stage. In some mothers there is minimal attachment even at term. The foetus is viewed as an intrusion, whose movements annoy the mother and disturb her sleep. A poor mother–foetus relationship is one of the predictors of impaired mother–infant bonding. When the mother's attitude to the pregnancy is obstinately rejecting, therapists can direct her attention to the relationship with the child within. Stroking the abdomen and identifying foetal body parts, or telling stories about the baby's future life, have been suggested.

Foetal abuse

When a mother deeply resents her pregnancy, she may try to harm the foetus. This occurs, with determined intent, in self-induced abortion. It may also occur as a manifestation of rage against the baby;[21] a pregnant woman may pound on her abdomen, even to the point of causing bruising.

It is not only the mother who may 'batter' the foetus. Domestic violence is common and may increase during pregnancy, when kicks and blows are directed at the abdomen, rather than the face. The main factors are sexual frustration, substance abuse, jealousy, the mother's irritability, and unreadiness for fatherhood.

The foetus is cushioned from external violence by the amniotic fluid, but can still be damaged by severe abdominal or pelvic injuries. Domestic violence can lead to miscarriage, foetal death, and premature birth. Infants can be damaged by penetrating wounds, and there are over 100 instances of gunshot wounds to the gravid uterus—the result of murderous assaults, attempts to induce a late abortion, or suicide attempts.

Mental illness during pregnancy

(a) Anxiety

For many mothers, pregnancy is a time of considerable anxiety. The first trimester may involve an anguished decision whether to continue or terminate the pregnancy. Those who have previously suffered from prolonged infertility, multiple miscarriages or foetal loss are especially prone to prepartum anxiety. In the third trimester anxiety is centred on three main themes: fears of parturition (tocophobia), of foetal abnormality, and of failure to cope with motherhood.

These anxieties will usually be managed by ventilation and support, but anxiolytic medication can be used cautiously. Of the anxiolytic agents, phenothiazines are relatively safe. Benzodiazepines are contraindicated in the last stages of pregnancy because of foetal intoxication ('the floppy infant syndrome'). Propranolol is best avoided, because of reports of intrauterine growth retardation, and neonatal cardiac and respiratory symptoms.

(b) Depression

Although prepartum depression has not aroused the same interest as postpartum depression, it is no less common. Depression is common in all women in the reproductive age group, and pregnancy is not protective. Depression can be recurrent, and there is an association with puerperal mania.

The frequency of suicide is a vexed question. There are problems about the accuracy of the data since not all suicides are reported to the coroner, not all have necropsies, and not all necropsies include an examination of the uterus. In addition, both suicide and pregnancy are often concealed. One must therefore treat with scepticism those enquiries which do not scrutinize the primary records. Nevertheless, there is evidence that the suicide rate has declined throughout this century; in the first quarter, about 13 per cent of women who committed suicide were pregnant—a rather high figure, suggesting that pregnancy was a risk factor at a time when illegitimate pregnancy was stigmatized. This was confirmed by the thorough mid-twentieth century study of Weir.[22] More recent studies show rates below those in the general population.

Severe prepartum depression is sometimes left untreated, because of fears about the effect of drugs on the foetus. These fears have been exaggerated. No antidepressive drug is known to have teratogenic effects. Most have no effect on the foetus, though fluoxetine may reduce uterine blood flow and paroxetine may cause neonatal pulmonary hypertension. There are reports of toxic effects or withdrawal symptoms in neonates, so that medication is more to be avoided during the last trimester. Electroconvulsive therapy is safe, provided that the mother is competently oxygenated during anaesthesia; pregnant women should be screened for rare syndromes of pseudocholinesterase deficiency before receiving this treatment.

(c) Alcoholism

Pregnancy has a beneficial effect on alcohol addiction, but, if heavy abuse continues, there are severe effects on the foetus. The main effect is retardation of intrauterine growth[23]; although ethanol shortens gestation, the low birth weight is not explained by prematurity, rather the infants are small for gestational age. The infant becomes addicted and may suffer neonatal withdrawal symptoms. Ethanol is also teratogenic, causing 'the foetal alcohol syndrome' (or 'spectrum disorder'), first described in France in 1968.[24] The features include facial dysmorphism due to maxillary hypoplasia, and brain damage, resulting in long-term cognitive impairment and behavioural disorders (see also Chapters 9.2.7 and 10.4). In the detection of these severe complications, systematic prenatal screening for alcohol abuse is useful.

(d) Other addictions

Cannabis is commonly abused by pregnant women; it affects foetal growth, and may lead to long-term neurobehavioural and cognitive deficits. **Lysergic acid diethylamide** may have teratogenic or mutagenic effects. **Phencyclidine** addiction leads to withdrawal symptoms.

Narcotic addicts, like alcoholics, have multiple emotional and social problems, and many do not seek antenatal care. The infants may be affected by maternal malnutrition and infections such as venereal disease, hepatitis, endocarditis, and AIDS. Narcotics are not teratogenic, but a high proportion of the infants are of low birth weight, partly explained by prematurity, and partly by intrauterine growth retardation. A withdrawal syndrome develops in most babies. The perinatal mortality rate and frequency of sudden infant death, are increased. There is an increased incidence of microcephaly, and there may be impaired mental development, although other factors in the maternal life style may account for this. Methadone maintenance reduces the effect on birth weight; but it may depress respiration in the newborn, and lead to a more severe and prolonged withdrawal syndrome, with a greater frequency of seizures. Buprenorphine may be a more suitable maintenance therapy, with milder withdrawal effects. If it is decided to withdraw heroin, this should be done in the second trimester,

replacing it by methadone. Naloxone, which can be given by implant, has been used, although there are concerns about foetal abstinence syndromes. After birth, the infants should be kept in hospital for at least 14 days. Respiratory depression can be treated by naloxone, and seizures and withdrawal symptoms by sedatives such as diazepam, or by tincture of opium.

Cocaine may be teratogenic, causing genitourinary and cardiac abnormalities, but the evidence is conflicting. Its main effects are cardiovascular: it causes uterine vasoconstriction, and this can lead to placental abruption. The infants may suffer cerebral infarction. There is intrauterine growth reduction and an increased incidence of microcephaly. Premature labour is common. There is a withdrawal syndrome, but this is less severe than with narcotics. There is some evidence of an increased risk of sudden infant death. Long-term effects on language development and behaviour are controversial, and may be due to confounding factors such as maternal depression, other drugs, and the environment.

All these mothers should receive close psychiatric supervision and social casework. Hair and meconium analysis improves the diagnosis of opiate and cocaine abuse in mothers who present unexpectedly in labour.

(e) Eating disorders

There are psychological and somatic reasons for an antagonism between pregnancy and anorexia nervosa; nonetheless, most anorexic women recover, and menstruate when their weight reaches about 80 per cent of the standard weight. Ovulation can be induced by clomiphene or menopausal gonadotrophin in those who fail to menstruate. There are numerous case reports and several long-term studies showing that many women with a history of anorexia nervosa give birth to children in the normal way. The overall effect on fertility has been quantified by a 12-year Danish study; the average number of children (0.6) was about one-third the usual figure.[25] The desire for children is shown by the frequency of infertility treatment, planned pregnancy, and breast feeding.

A minority become pregnant while in the throes of the disease. Anorexic amenorrhoea may delay the diagnosis. Pregnancy usually has a beneficial effect; but if the mother continues to restrict her diet, the foetus may suffer from malnutrition. Occasionally it has been necessary to rescue the infant by elective Caesarean section. There is a tendency to relapse in the puerperium. When mothers are actively anorexic, there is often conflict at mealtimes; occasionally children may become involved in their mother's asceticism, and suffer stunted growth.

Bulimia nervosa is often improved by pregnancy. The pressure of the enlarging uterus on the stomach makes bingeing more difficult. About half relapse after delivery.[26] Pregnancy is not much affected by bulimia, but low birth weight has been reported. Bulimic mothers sometimes show deviant mothering, ignoring or excluding their children while overeating or vomiting, or restricting food supplies.

(f) Obstetric factitious disorder

Self-induced illness behaviour can extend into the obstetric domain.[27] Women may induce bleeding to simulate threatened miscarriage, placenta praevia, or postpartum haemorrhage. They may stimulate rupture of the membranes to precipitate an early delivery. Others have been caught manipulating instruments, for example an external tachodynamometer. Two patients even attempted to simulate hydatidiform mole, by adding human chorionic gonadotrophin to blood samples.

(g) Psychosis

Numerous asylum surveys have testified to the lower frequency of psychosis during pregnancy than after delivery. This was confirmed by Kendell and colleagues, in their linkage of Edinburgh obstetric and psychiatric case registers[28]: in a study of 54 087 births, they found rates of 2.1 per month before conception and 2.0 per month during pregnancy, much lower than after childbirth (51 in the first month).

Pregnancy probably has no effect on chronic delusional states, but it does have a beneficial effect on menstrual, bipolar, and possibly cycloid (acute polymorphic) psychoses.[29] Nonetheless, acute manic and cycloid episodes occur during pregnancy, and some seem remarkably similar to puerperal psychosis. They would be regarded as sporadic or random, except that they have been observed in women with a history of puerperal psychosis (at least 13 in the literature).[30] There is an association with multiparity, with the postpartum episode occurring first.

Neuroleptic agents appear to be safe during pregnancy. Phenothiazines and butyrophenones are not teratogenic. The main (but infrequent) hazard is sedation and extrapyramidal symptoms in the newborn. Lithium is relatively dangerous; at least 12 cases of the rare Ebstein's anomaly have been reported. As delivery approaches, reduced renal clearance can result in toxicity with normal doses; eight cases of alarming blood levels (up to 5 mmol/l) have been reported, with coma and convulsions in the mother. Even at normal blood levels, babies exposed to lithium have suffered lethargy, hypotonicity, and other effects. Carbamazepine has been associated with rather high rates of congenital abnormality, and sodium valproate is particularly dangerous, with major abnormalities especially spina bifida, and a foetal valproate syndrome.

(h) Obstetric liaison services

In view of the complexity of the psychological response to pregnancy, and the frequency of anxiety, depression, and other psychiatric disorders, there should be good liaison between obstetric and psychiatric services. In addition to the need to diagnose and treat prepartum psychiatric disorders, the high level of supervision in the antenatal clinics offers an opportunity for preventive psychiatry, by screening for vulnerable women, including those with unwanted pregnancies, severe social problems, or a history of psychosis, addictions, or depression.

The psychopathology of parturition

Childbirth can be one of the severest of human ordeals, and in spite of its brevity, is a time of risk for psychopathology.[18] In advanced countries, all these complications are rare, but may still be common where obstetrics is primitive, or pregnancy denied. Acts of desperation, such as auto-Caesarean section or suicide, and rage attacks, endangering the foetus, are fully described in the older literature. Delirium is well documented; in most cases, it lasts a few hours, starting shortly before delivery and disappearing after the birth, with amnesia for the event; but it can continue into the puerperium, or start immediately after the birth. Engelhard[31] gave the best estimate of its frequency: in a 10-year survey, there were five cases of transitory confusional states in 19 910 births. The existence of this phenomenon aggravates the jurisprudential problem of neonaticide, because, in an unattended delivery, it is impossible

to know whether or not the mother was temporarily confused. Unexplained stupor or coma has also been described during and immediately after delivery.

Infant loss

The child may be lost for a variety of reasons:

- termination of pregnancy at the behest of the mother
- miscarriage, ectopic pregnancy, and late termination of a wanted child for medical reasons
- foetal death *in utero*, stillbirth, neonatal death, and sudden infant death ('cot death', SIDS)
- relinquishment to adoption.

(a) Termination of pregnancy

The indications for abortion include the following:

- medical—to preserve the health and life of the mother
- humanitarian—when pregnancy has resulted from rape or incest
- eugenic—where there is a risk of congenital abnormality
- psychiatric
- social—because pregnancy is untimely and disruptive
- on demand—in the belief that women should be free to decide when to have children.

There has been a debate on the validity of the psychiatric indications; this turns on the psychiatric consequences of a refusal to terminate. Suicide threats are common, but are rarely carried out; nevertheless there can be no doubt that unwanted pregnancy is a factor in completed suicide. A history of puerperal psychosis is not an indication, because it is equally likely to follow abortion; but there are other, arguably more serious, puerperal complications such as mother–infant relationship disorders, which are more common and severe after unwanted pregnancy. These can be avoided by adoption, but the psychological effects of relinquishment are not negligible.

The psychological effects of termination have been thoroughly explored. Most who voluntarily abort suffer no adverse effects, either in the short or long-term. There is often relief, even euphoria, and a reduction in anxiety, depression, anger, guilt, and shame. A minority experience regret and self-reproach over the 'murder' of the baby. Some feel like criminals and worry about punishment, a nemesis of sterility or future congenital malformations. A few develop clinical depression. A Finnish study showed that the suicide rate was increased from $11/10^5$ to $35/10^5$.[32]

There is a literature on 'postabortion psychosis', but both parts of the term have multiple meanings; 'abortion' refers to miscarriage, termination, criminal abortion, and even stillbirth after short gestation, and 'psychosis' includes delirium, Wernicke–Korsakow syndrome, melancholia, and psychogenic paranoid disorders. Manic or cycloid episodes, similar to puerperal psychosis, occur after abortion: apart from epidemiological evidence[33] and individual cases, the association of postabortion and postpartum psychosis in the same woman has been reported on at least 14 occasions.[30] Some episodes occurred after miscarriage, but several followed termination, in most cases performed to prevent a recurrence of puerperal psychosis.

To minimize the psychological risk, prudent decision taking is of the essence, and counselling has a valuable role. The most difficult part of the experience is the loneliness and isolation. Many do not inform their parents, and, when they do, face censure and unwelcome pressure. The attitude of the child's father is crucial. Attempts should be made to involve him in all aspects of the experience; unfortunately his reaction is often unhelpful. It is axiomatic that a woman should make her own decision—one of the most difficult she will ever take. It often has to be taken hastily, in an atmosphere of conflict and turmoil. The best outcomes are found when a woman makes her decision in a context of respect and support from partner, parents, friends, or counsellor.

(b) Miscarriage

This is a common event, perhaps 40 per cent of all conceptions, but only 10 per cent occur after pregnancy is recognized by amenorrhoea or other signs. An ectopic pregnancy is gynaecologically more serious, but has the same psychological effects. The emotional consequences of miscarriage are not trivial, and can be compared to perinatal death—less severe, because there has been little time for attachment to the newly conceived, but still the loss of a greatly desired child. The event itself, with foetal tissue passed suddenly and painfully, may be disturbing. Some of the psychological symptoms may resemble post-traumatic stress disorder, with intrusive re-experiencing ('flashbacks') and nightmares. There is a sense of failure, guilt, and anger. The incidence of depression is four times the rate found in the general population. There may be depressive episodes at the time of the expected delivery, anniversary reactions, and an increased risk of postpartum emotional disorder after a later normal delivery.

Helping a mother who has suffered a miscarriage is a variant of grief therapy, in which her intense distress is shared, and sadness, guilt, and anger ventilated.

Late termination for medical reasons, although a deliberate intervention, is psychologically similar to miscarriage and to foetal death *in utero*. Some wish to continue the pregnancy in the full knowledge that the baby will be abnormal. Depression is common, and grief long-lasting. All these women require counselling, before and after the termination.

(c) Foetal death *in utero*, stillbirth, neonatal death, and sudden infant death

Reactions to these events are generally more severe than to miscarriage, and each has its special characteristics. When the baby dies in late pregnancy, the mother carries a corpse within her, and must undergo a futile labour. If it dies during labour, the loss is sudden and shock pronounced, with a strong sense of unreality. When the child dies in the first week, the parents have to endure great anxiety, with dwindling hope; they may be involved in the decision to switch off the respirator, and witness the child dying. The later death of an infant, when the maternal emotional response is fully developed, especially sudden infant death, is at the very top of the catalogue of calamities; there is no warning or preparation, and the death is followed by a forensic investigation.

(d) Grief after infant loss

This is similar to other grieving, but has its own special character. There is shock, followed by emotional numbness and emptiness, then long-lasting and agonizing sadness. Grief hallucinations (of foetal movements, the baby's face, the infant crying or playing in the cot) may be experienced. There is guilt, anger, and recrimination. There are various crises, especially the disposal of toys, baby

clothes, and nursery furniture, as well as meeting friends and relatives; some, floundering in their embarrassment, are evasive and unable to comfort or sympathize ('wall of silence'). Especially after SIDS, there may be shame, stigma, and even ostracism or malicious speculation. Envy of successful mothers is a problem; there may even be a temptation to steal babies. Surviving children may be confused by their parents' grief, upset by family turmoil, and deprived of attention and care; they are also grieving and preoccupied with their own search for the meaning of death.[34]

When helping the parents,[35] the principles are as follows:

- **Honesty and openness in communication**. The admission of errors is delicate, but the parents' guilt should not be reinforced by the obstetric team's refusal to accept responsibility. Recrimination, litigation, or querulant reactions are common. Staff should accept this as normal, and try not to be defensive. After a stillbirth, most mothers prefer to be segregated, and discharged early. One or more interviews with the consultant obstetrician are indicated. It is essential that the mother is visited by a member of the primary care team. A lactating mother may need bromocriptine, or to donate milk to a milk bank. Hypnotics may help mothers troubled by insomnia. The doctor should be alert for secondary depression.
- **All parents want to know why the baby died**. The necropsy can help, but parents should be warned that often no explanation is found. Necropsies in SIDS are specialized; the pathologist can play a vital psychological role, and should be available for discussion.
- **Mementoes** should be kept, including a photograph. The dignity of naming and a burial ceremony is helpful. The value of seeing and holding the dead baby has been challenged.[36]
- **The bereaved mother needs to share her distress**. A sensitive and sympathetic person, with the time and interest to listen, can help her grieve and accept her loss. This support will often come from the husband or partner, family, or friends. If not, professionals, especially chaplains or nurses, should step in. Self-help groups and voluntary agencies are invaluable for some mothers.
- **The next pregnancy**. No doctrinaire advice can be given about the timing of the next pregnancy. Increased anxiety during pregnancy and the puerperium can be expected.
- **The grieving sibling**. The routine and rhythm of family life should be disturbed as little as possible. The parents should not be afraid to show their emotions—it is best to acknowledge their sadness, and how much they will miss the baby. They should try to give a factual account of what happened, avoiding euphemisms. It is important to reassure the children: they are not responsible and will not lose the love of the parents; neither they nor their parents are in imminent danger of death. The child can be helped to grieve by looking at pictures of the dead sibling, attending the funeral, and visiting the graveyard. (see Chapter 9.3.7 for further information about bereavement in childhood.)

(e) Relinquishment

Adoption used to be the main way to satisfy the longing to rear children and to handle accidental pregnancy, but there has been a great social change in Europe and North America. Since 1950, the number of children born to single mothers has climbed steeply, and is still climbing, but, despite this increase, the number of adoptions is falling steadily. This is not due to spectacular improvements in the infertility treatment, reducing the demand, nor to the relaxation in the abortion laws, reducing the supply, but a new tolerance of single motherhood. In partial compensation for the scarcity of relinquished babies, the practice of adopting foreign-born children has arisen.

Although adoption is on the wane, attention has been focused on the psychological effects of relinquishment.[37] For some relinquishing mothers, giving up the child is a painful, loving act of selfless courage. In others it is the enforced loss of a living child, with a charade of informed consent. Relinquishment is among the most stressful of events. Instead of understanding and support, there is often loneliness and ostracism. Time is no healer; the child continues to exist and can be seen again, and there is often a fantasy of reunion or restitution. As time goes on, there is a new component; the adult child may seek its biological mother, and there is the hope that this event, which she cannot influence, may happen. There has been a growth in the number of organizations to help relinquishing parents find their offspring. Many countries are grappling with the problems of legislating for reunions.

To avoid these severe and prolonged psychological effects, a relinquishing mother needs counselling during the pregnancy. The aim is to emerge from the experience with self-respect and dignity. After delivery the mother should be encouraged to see the infant and photographs should be filed. Follow-up counselling should be continued for at least 6 months. The mother may wish to join a society for relinquishing parents. There is also the relationship with the adopting family to consider. Adoptive parents should accept any gift or token of the natural mother's love. Information on the outcome of the child should be available. Some birth-mothers wish to provide up-to-date information, so that the child knows they are now respected citizens. A recent innovation is the practice of 'open adoption', in which both sets of parents meet. There is even 'continuing open adoption', which means that they remain in contact over the course of the child's development.

The psychiatry of the postpartum period

The normal puerperium

For many or most mothers, giving birth is a supreme moment, and euphoria or elation is common. Some may be too excited to sleep. These feelings of peace, fulfilment, and accomplishment help to sustain mothers during the weeks of strain that follow. Prolonged euphoric reactions, lasting a week or more, are probably mild puerperal mania, and are often followed by depression.

Newly delivered mothers have to face a number of challenges, including the following.

- **Physical exhaustion**. This can be coupled with the painful sequelae of pelvic trauma.
- **Breast feeding**. Although this has many advantages, it is often difficult to establish.
- **Insomnia**. Sleep deprivation, especially during the first month, is a cause of irritability, and should be borne in mind when mothers present 'at the end of their tether'.
- **Recovery of normal figure and attractiveness**. This may be threatened by weight gain and stretch marks. Mothers may occasionally develop a state similar to dysmorphophobia.[38]

- **Loss of libido**. Episiotomy and vaginal trauma often cause dyspareunia; fatigue may depress sexual activity. Nevertheless sexual relations are usually resumed within 1 to 3 months, though reduced in frequency, and with a delayed return of orgasm. For this and other reasons (e.g. jealousy) the marriage may come under strain.
- **Social privation**. The loss of employment, income, and leisure, as well as confinement to the house, are all contributory factors.

With this background of rapid biological, social, and emotional transition, it is not surprising that a wide variety of psychiatric disorders occur; indeed the psychiatric complications of childbirth are more numerous and complex than in any other human situation.

The **maternity 'blues'** is so common as to be almost normal. Usually between the third and fifth days, many mothers experience a sudden, fleeting, and unexpected period of sensitivity and uncharacteristic weeping. In the great majority this passes off within a few hours, or a day or two. There is some evidence for an association between this brief dysphoric reaction and postpartum depression.

Reactions to severe labours

(a) Post-traumatic stress disorder

After excessively painful labours, some women suffer nightmares, and repetitive daytime intrusion of images and memories, similar to those that occur after the harrowing experiences of war and natural disaster. Since the original description,[39] over 40 papers have been published on this subject, including 10 quantitative studies showing rates of up to 5.9 per cent of deliveries. Many of these women avoid further pregnancy (secondary tocophobia), and those who become pregnant again may experience a return of symptoms, especially in the last trimester.

This disorder can be treated by counselling and by specific psychological therapies. Tocophobia is an indication for elective Caesarean section.

(b) Querulant reactions

Another reaction to a severe labour experience is pathological complaining (*Querulantenwahn*). These women complain bitterly about perceived mismanagement, and their angry rumination may continue for weeks or months, interfering with infant care. Some confine themselves to vengeful fantasies and verbal or written criticism, but others proceed to litigation. Careful assessment is needed to distinguish these reactions from reasonable complaining.

This disorder can be treated by a psychotherapeutic approach, which distracts the mother from her grievances and reinforces productive child-centred activity.

Postpartum anxiety disorders

Recent research has shown that postpartum anxiety disorders are just as common as postpartum depression.[38,40] A review of eight studies of 'panic disorder' showed that 44 per cent of anxious women had an exacerbation, and 10 per cent a new onset, in the puerperium.[41] It is important to identify the focus, as well as the form, of anxiety, because there are several themes that indicate specific psychological therapies. Benzodiazepines should be used with caution in lactating mothers. They are well absorbed from the gut, and more slowly metabolized in the neonatal liver, and occasionally cause lethargy and weight loss in breast-fed infants.

(a) Puerperal panic, and phobic avoidance of the infant

Some mothers, especially *primiparae* in isolated 'nuclear' families, are overwhelmed by the responsibility of caring for the newborn.[42] The panic and agitation seen in extreme examples is an exaggeration of the anxiety that many women experience when they first confront this awesome task. If no help is available, a mother can develop a phobic avoidance of the infant,[43] and risks losing her mothering role.

These disorders can often be handled by the wider family, without invoking professional help. The mother needs sedation, especially at night. During waking hours, she should remain with the baby, but must be supported at all times. Treatment is by desensitization. Gradually the mother takes over, at her own pace, undertaking the easiest tasks first, and involved in all decisions. In severe cases, conjoint admission may be the only way to rescue the situation. With correct diagnosis and management the prognosis is excellent.

(b) Anxieties about infant health and survival

The care of an infant involves ceaseless vigilance. In women prone to anxiety and excessive worrying, or in those who have suffered years of infertility or recurrent miscarriage, motherhood can lead to excessive solicitude about banal tasks that put the baby at risk (e.g. bathing) and sensitivity to the slightest indication of illness. In some, the anxiety is focused on the possibility of sudden infant death.[44] These mothers lie awake listening to the baby's breathing; sleep with their hand on the infant's chest, check the infant many times each night, or even wake the baby to ensure that he or she is still alive. This results in excruciating tension, insomnia, and exhaustion.

These mothers require anxiety management. Day-hospital attendance, with relaxation therapy and group support is ideal. A mother with 'fear of cot death syndrome' may be helped by explanations about the rarity of SIDS, and the infant's resistance to asphyxia, as well as devices to monitor the infant's breathing. The vicious cycle of insomnia and hypervigilance can be interrupted periodically by involving relatives or friends, so that she can sleep under sedation. Ventilation, and the support of mothers who have recovered from similar problems, is helpful. However, these are only palliatives, because the underlying cause is an event, which, albeit uncommon, remains possible during a period of several months.

Puerperal obsessional disorders

There is evidence that the puerperium is one of the main precipitants of obsessive–compulsive disorders.[45,46] In addition to obsessional rituals, the disorder may present with thoughts, images, or impulses of child harm. These impulses to attack the child must be distinguished from the pathological anger that precedes child abuse. The mother is gentle and devoted. She experiences extravagant infanticidal images, such as stabbing, decapitation, or strangulation. She fears being left alone with her infant, and may take extraordinary precautions.[47] The obsessional content may be of child sexual abuse, for instance masturbating or castrating their sons.

Ventilation, explanation, and psychotropic medication are part of the treatment, but are rarely sufficient. It is important to discourage avoidance of the child, and encourage cuddling and play, thus strengthening positive maternal feelings. Cognitive–behavioural treatment can help her to achieve mastery over

irrational impulses. (For the treatment of obsessive–compulsive disorder, see Chapter 6.3.2.1.)

Depression

Puerperal melancholia was one of the first postpartum psychiatric disorders to be identified. During the asylum era, only the most severe cases were admitted, and the occurrence was underestimated when compared with 'puerperal mania'. When, in the 1950s, attention turned to milder disorders, postpartum depression was found to be common in the general population. The pioneering work of the Gordons in New Jersey[48] was soon widely confirmed. In the last 10 years there has been a flood of papers from all over the world. Surveys have shown rates of at least 10–20 per cent, or even higher in the 'Third-World'.[49] 'Postnatal depression' has become a household word. It is an important lay concept, which has legitimized maternal depression in the minds of the public, providing a valid explanation for role failure, diminishing stigma, enabling mothers to accept that they are ill, and to come forward for treatment. It is a slogan that can be wielded in the political struggle to obtain better services for mothers of young families. There is a need for such concepts, which have social influence.

However, one must examine the scientific value of this concept with scepticism. Depression after childbirth is clinically similar to any other depression, and the association of depression with the puerperium is not striking. Whatever the prevalence in surveys, only about 5 per cent consult their general practitioners. The epidemiological evidence is weak. The suicide rate in the first postpartum year is below the female rate.[32] Depression is common in women during the reproductive years, whether they are infertile, pregnant, puerperal, menopausal, or involved in child rearing. The term 'postnatal depression' has the danger of introducing into the minds of the unwary the mirage of a homogeneous disorder with a single cause. Rather, it is a rubric for a heterogeneous group of disorders. Many mothers with anxiety, obsessional, or post-traumatic disorders, or with a disturbed infant relationship, are depressed, but the setting, causes, and treatment are different. Not surprisingly, research into its causes has found that they are the same as those that cause depression at all ages—heredity, a history of previous or prepartum depression, 'neuroticism', adverse events or social conditions, difficult relationships, and social isolation. It has been suggested that the burden of child rearing, rather than child bearing, is a factor, but this has been challenged by a Swedish twin study[50] and a Norwegian suicide study[51] showing that parous women have a lower risk of depression than nulliparous women. In mothers with recurrent puerperal depression one would expect to find specific factors. Adjustment to motherhood has received much less emphasis than it deserves; unwanted pregnancy has been found to be a predictor of antepartum and postpartum depression.

Whatever its frequency, the effects of depression on family life, and the emotional climate in which children are reared, is of great concern. A growing child needs emotional support, attention, approbation, and stimulation. The mother is the child's primary environment, and her mood dominates his or her world. Even very young infants are disturbed by deviant social behaviour in the mother. Although deficits are not universal,[52] her depression can lead to inattention through anergia or brooding, reduced quantity, quality, and variety of interaction, and loss of the reinforcement of the mother's gaiety and tenderness. Her anger may be misdirected at the children. Frequent irritability, impatience, and criticism induce social withdrawal, anxiety, and reciprocal anger. There may be educational deficits. These effects depend on the degree and duration of maternal depression, and the extent to which it involves interactions with the child. (See Chapter 9.3.6 for further information on the effects of maternal depression on child development.) In extreme cases, maternal depression can lead to the tragedy of combined suicide and filicide.

Treatment begins with effective diagnosis. Many more mothers are depressed than ever make their way to the surgery. The reasons for the failure to seek help are not fully understood: some recover early, some do not realize they are ill, and some are ashamed of confessing their symptoms, suffering in silence because of ignorance, stigma, and fears of losing their baby. Screening procedures help the primary care services to identify cases; an example is the Edinburgh Postnatal Depression Scale,[53] which has high sensitivity and specificity. Patients identified by screening, or self-referral, require a full psychiatric examination, in order to identify vulnerability factors and the specific components of postpartum disorders. This initial interview is best held at home, because clinic attendance is an obstacle for mothers fettered with the care of young children, and because domiciliary assessment has a quality that cannot be achieved in the office. The interview should explore the symptoms and course of the illness, study its context in the mother's life history, personality, and circumstances, review the events of this pregnancy, explore the mother's relationships with her spouse, baby, other children, and family of origin, and establish the available supports.

Treatment is focused on depression and any underlying vulnerability. It will always involve psychotherapy, if only in the form of a single interview; it will usually include medication or other specific treatments; a few require electroconvulsive therapy. Working with the baby's father, potentially the main supporter, is important; fathers can come under strain, either because their wife's intimacy with the baby disturbs conjugal dynamics, or because her depression has a domino effect on him. Home visits by community nurses are an ideal method of delivering continuing care and psychotherapy. An extensive literature has accumulated demonstrating the efficacy of psychological treatments by double-blind randomized controlled trials. As for drug treatment, there is no evidence that any drug is superior to others. There are at least 50 reviews of drug treatment in lactating mothers. The suckling infant has little body fat, less plasma protein-binding, an immature liver and kidney and an undeveloped blood-brain barrier. But the risks are minor. Only a minute dose is delivered to the infant: Epperson and colleagues demonstrated that serotonin re-uptake blocking agents do not affect serotonin levels in breast fed infants.[54] Occasionally, babies have been over sedated. It is not recommended that antidepressant agents be withheld, or that breast-feeding be stopped; but it is wise to use these drugs cautiously, and it may be helpful to take the drug after breast feeding (see also Chapter 6.2.3).

Prevention is important in mothers with a history of severe or prolonged postpartum depression. They often present during the next pregnancy, requesting advice or prophylaxis. If they are already symptomatic, or have obvious risk factors such as marital friction or social isolation, they need support from community psychiatric nurses, voluntary agencies, or other groups. If they are well, it is only necessary to establish contact, so that a recurrence is diagnosed and treated promptly. Prophylactic antidepressant medication can be considered.

Mother–infant relationship disorders

Just as the emerging relationship with the foetus is important during pregnancy, so also the growth of the mother–infant relationship is the key psychological process in the puerperium. 'Bonding' is a popular lay term; some professionals prefer 'attachment', but one must not confuse this with infant–mother attachment. The mother–infant relationship consists essentially of ideas and emotions aroused by the infant, which find their expression in affectionate and protective behaviour. Its immense power is revealed in self-sacrifice, and the pains of separation. Its inner presence is betrayed by external signs—touching and fondling, kissing, cuddling and comforting, prolonged gazing and smiling, baby talk and cooing, recognizing signals, tolerating demands, and resisting separation; but it is hard to select a single activity that lies at the core. Particular behaviours wax and wane, but the relationship endures, even when the child is absent, even when it is gone for ever. This emotional response enables the mother to maintain the never ending vigilance, and endure the exhausting toil of the nurture of the newborn.

There is no 'critical period' in the development of the maternal response. Close proximity from the start ('rooming-in') gives confidence in mothering skills, and breast-feeding may help. The infant plays an important part. At an early stage, it can discriminate speech, and reacts preferentially to the human face and voice. Eye-to-eye contact mediates the interaction, and gazing becomes an absorbing activity on both sides. The baby's smile is another catalyst. Videotape studies have shown the infant contributing to a dialogue with its caregiver. Sometimes the maternal response is immediate, primed by affiliation to the foetus, but sometimes there is a worrying delay. For the first 3 to 4 weeks many mothers feel bruised, tired, and insecure, and their babies seem strange and distanced. As the baby begins to respond socially, a normal relationship develops rapidly.

The term 'mother–infant relationship (or bonding) disorders' covers a spectrum of clinical states, which has two main dimensions:

- An absent or negative emotional response. In severe cases, the mother regrets the pregnancy and expresses dislike or hatred of her baby. She may try to persuade her own mother, or another relative to take over, and may demand that the infant be fostered or adopted. The most poignant manifestation is a secret wish that the baby 'disappear'—be stolen, or die.
- Pathological anger. The infant's demands anger the mother and provoke aggressive impulses, which may lead to shouting, cursing, screaming, or assaults.

There is at present little data on the frequency of these disorders in the general community. At the level of 'threatened rejection'—where the mother has an aversion to her child and seeks temporary escape from child care (the threshold for active intervention)— the frequency of these disorders in the general community is probably about 1 per cent. It is much higher in mothers who seek help for 'postnatal depression'—about 10 per cent at the level of established rejection, and another 15 per cent for threatened rejection.[55]

These disorders are usually accompanied by depression, but there are many reasons to reject the euphemism 'postpartum depression with impaired mother–infant interaction'.

- A disturbed relationship is different from a mood disorder.
- When depression is associated with phobias, obsessions, or deviant behaviour, these co-morbid phenomena are still considered worthy of study and treatment in their own right.
- Impaired interaction, although it can be recorded and measured, is not the essence of the phenomenon, but merely its behavioural manifestation; it has other causes, especially infant-centred anxiety.
- Aversion to the infant is not confined to depressed mothers;[56,57]
- When they coexist, their severity and course often differ.
- Only a minority of depressed mothers have this problem. It is important to select them for treatment and not to stigmatize the others.
- The risks—including child abuse and neglect—are higher. It is these disorders, rather than uncomplicated depression, that have serious and long-term effects on the child's development.[58] These mothers are a high-risk group that can contribute to the vital task of preventing child abuse and neglect.
- The treatment is different and specific (see below). Assessment and treatment of this relationship forms an important part of the work of mother–infant mental health teams.
- Management must be aware of the need for training and service provision.
- The aetiology is different, with more emphasis on unwanted pregnancy and challenging infant behaviour.

The diagnosis can be facilitated by self-rating questionnaires, but the main clinical resource is an interview probing the mother's emotional response and behaviour. In severe cases and in research, the 'gold standard' is direct observation, preferably over a substantial length of time.

The treatment proceeds in stages:

- Where there is a delay in the maternal emotional response, explanation and reassurance are usually sufficient.
- When hostility, rejection, and anger are prominent, the primary decision is whether to attempt treatment or not. The mother must be given freedom of choice; it is dangerous for her to feel trapped in unwelcome motherhood. At the same time, the father has his rights. The option of relinquishing the infant must be openly acknowledged, and fully discussed with both parents.
- If it is decided to embark on treatment (as in most cases), depression should be treated with psychotherapy, drugs, or (occasionally) electroconvulsive therapy.
- The specific element of therapy is working on the dyadic relationship. This relationship, like others, grows through shared pleasure. The baby alone has the power to awaken its mother's feelings, so the aim is to create circumstances in which mother and child can enjoy each other. It is a mistake to separate the mother and baby completely, which merely compounds the problem by adding an element of avoidance. If there is any hint of abuse or aggressive impulses, the mother must never be left alone with her infant. She must be relieved of irksome burdens of infant care. When mother and baby are calm, she is encouraged and helped to interact with him—to cuddle, talk, play, and bring out his smile and laughter. Participant play therapy and baby massage may assist.

Treatment can take place in various settings. Home treatment can be successful, provided there is enough support to relieve the mother of night care and stressful duties: the maternal grandmother,

an understanding husband or partner or a family group can sometimes achieve this. Day-hospital treatment provides individual support and group discussion, as well as specific therapies. In the most severe and refractory cases, the proper setting is an inpatient mother-and-baby unit, where an experienced team of psychiatric and nursery nurses, available 24 h a day and 7 days a week, can provide full support. Even in the most severe cases, one can feel optimistic about a successful outcome. (For further information about child abuse see Chapter 9.3.3.)

Postpartum psychoses

These fall into two main groups—organic psychoses and bipolar disorders; a third group—reactive or psychogenic psychosis—is most convincingly seen in adoptive mothers and fathers. There are many causes of delirium after childbirth.[18] Organic psychoses are hardly ever seen in Europe or North America, but may still be important in Africa,[59] India, South-East Asia, and Latin America, where the majority of children are born. Historically the most important causes have been infection and eclampsia psychosis, but cerebral venous thrombosis is common in India.[60]

The form of psychosis still seen in Europe and North America was described by Osiander,[61] and illuminated by the case studies of Esquirol.[62] The long-standing controversy about its nosology has been resolved in favour of a relationship with the bipolar group; but there is also a connection with acute polymorphic (cycloid) psychosis, which may also belong to the bipolar rubric. These are biological brain disorders, with high heritability and an inborn tendency to develop episodes throughout life. The problem of causation can be broken down into three subsidiary questions: the nature of the diathesis, the determinants of clinical polarity (mania, depression, or cycloid), and the trigger that provokes the episode. The first two questions belong to the wider study of bipolar disorder. The third is specific to puerperal psychosis. The clinical facts suggest not one, but several triggers related to the female reproductive process—abortion, pregnancy itself (especially the last trimester), the early puerperium (especially the first 10 days), postpartum menstruation, menstruation in general (see menstrual psychosis above), and weaning. These triggers can be added to the list of other biological events that trigger bipolar episodes, including surgery, adrenocortical steroid treatment, and seasonal climatic changes. Instances can be given of the combination of all these triggers in the life history of individual women, and there may be a shared pathway in these diverse precipitants. The incidence is somewhat less than 1 in 1000 pregnancies.[28,63] The Edinburgh study showed no link with twin pregnancies, breast feeding, single parenthood, or stillbirth. The miscarriage rate has been low in two studies. This psychosis has high heritability—not just for bipolar disorder, but also the puerperal trigger.[64]

Postpartum bipolar psychoses are acute, rapidly reaching a climax of severity. The onset is usually between 2 and 14 days after delivery. Mania is severe, often with 'schizoaffective' symptoms or extreme excitement. Almost every psychotic symptom may be seen—the whole gamut of delusions, verbal hallucinations, disorders of the will and self, and catatonic features. There is often an apparent confusion or perplexity. Since the advent of electroconvulsive therapy and neuroleptic medication, the duration has fallen to a few weeks. A minority of patients show a tendency to relapse in rhythm with menstruation. Puerperal recurrences occur after 20 to 25 per cent of subsequent pregnancies. Non-puerperal recurrences are also common.

There are no specific treatments. The first resource is sedation by neuroleptic agents, but these should be used with caution because of the risk of severe extrapyramidal side effects, which include neuroleptic malignant syndrome. It is usual to stop breast-feeding, although this may not be necessary, because the infant receives only a minute dose of the neuroleptic and adverse effects have not been noted; Clozapine may, however, accumulate in breast milk. Lithium has been used increasingly since the link with manic-depressive psychosis was recognized. There is also evidence for its prophylactic value in women at high-risk. However, it may have adverse effects on breast-fed infants. Electroconvulsive therapy is highly effective in all varieties of puerperal psychosis, including puerperal mania. The location of treatment is an important issue. Since hospitalization can be disruptive to the family, this disorder should for preference be treated at home, where the patient can maintain her role as wife, homemaker, and mother, and her relationship with the newborn; but its severity and the lack of community resources make this a counsel of perfection. If hospital admission is necessary, there are great advantages in conjoint mother and baby admission.

Services for mothers with mental illness

An outline of the services required for this area of psychiatry is slowly emerging. Its aims are prevention in those who are vulnerable, early and accurate diagnosis, and rapid effective intervention, with minimal disruption of family life. These aims require the following:

- **A multi-disciplinary specialist team** This team, a key resource whatever the cultural background, should consist of psychiatrists, nursing staff of various kinds, psychologists and social workers; it can serve a population of several million inhabitants, handle severe and intractable illness, train all staff, develop services, and conduct research.
- **A community service** Domiciliary assessment and home treatment are appropriate for mothers.
- **Day care** A day hospital can provide a full range of interventions, including groups, play therapy, motherhood classes, anxiety management, and occupational therapy, with minimal family disruption. The presence of mothers with similar disorders is an additional support. The children are cared for in a crèche.
- **Inpatient facilities** Conjoint admission of mother and infant is superior to the admission of the mother alone.[65] Wards dedicated to conjoint admission also have advantages over admissions to general psychiatric wards, although they are more expensive.
- **An obstetric liaison service** Apart from treating prepartum mental illness, this provides an opportunity for preventive psychiatry, by detecting vulnerability during pregnancy.
- **Links with other agencies providing services for mothers** The social services have a key role. Their family centres fulfil a similar function to mother-and-baby day hospitals. They can relieve the burden on the mother, and safeguard the child, by providing emergency foster care. Other agencies include the National Society for the Prevention of Cruelty to Children (in the United Kingdom), midwifery services, primary care teams, and child psychiatry services.

- **A network of voluntary organizations** These are independent organizations, but can have close cordial ties with the professional service. There is no one better suited to support a depressed mother than another mother who has suffered a similar problem and is now well—she knows the stratagems or words of comfort that were helpful, and is living proof of the hope of recovery. For each disorder, a panel of recovered mothers is an important resource.
- **Medico-legal expertise** Expert advice is often required in cases of child abuse or infanticide, and where a mother with mental illness is seeking custody of, or access to, her children.

The psychiatry of parental children-killing

The term 'infanticide' covers the killing of infants and children by their mother or father in a wide variety of circumstances, broadly divided into 'neonaticide' (killing the newborn) and 'filicide' (the later murder of a child).

Neonaticide

Killing neonates (especially female infants) has been customary in certain societies as an official policy or 'grass-roots' custom for controlling population growth. This is completely different from criminal neonaticide, in which a mother, who has concealed her pregnancy and given birth in secret, kills the infant immediately after parturition. This was a major public health problem in Europe during the nineteenth century. Its frequency has dwindled as a result of contraception, a relaxation of the abortion laws, and changed attitudes to single motherhood; but it still occurs.

The mental state of mothers who kill the newborn can be deduced from the methods used. Suffocation is by far the most common,[66] and this testifies to the mother's panic, faced by a crying baby. In a minority, brutal head injuries, stabbing, or decapitation testify to rage and hatred.

In Europe, starting in Russia in 1647, the public has gradually taken a humane view of this felony. By 1881, all European states, with the exception of England and Wales, made a distinction between infanticide and other forms of murder, and assigned a more lenient penalty. England and Wales at last came into line with the Infanticide Act 1922. In some American states no distinction is made between this and other forms of murder.

There has been much debate whether the defence of insanity can be invoked. Most of these babies die when the mother is in the grip of an emotional crisis—seized by fear or fury. This is not generally acceptable in law as evidence of insanity, which is defined as a defect of reason. However, impairment of consciousness undoubtedly occurs during labour (see above); it is rare in hospital practice, but may be more common in clandestine deliveries, and is hard to exclude. If the defence is burdened with the proof of insanity, there can be no valid evidence in unwitnessed deliveries; but there is the possibility of a miscarriage of justice—that a mother, who killed her baby when her consciousness was clouded, is wrongly condemned.

Filicide

The majority of murdered children are killed by their parents, and the majority of female murderers kill their own child. A survey in Queensland gave an estimate of the frequency: of 49 infanticides between 1969 and 1978, there were 11 neonaticides and 38 filicides; this is about 3 in 100 000 per year of children under 5 years of age.[67] In Sweden, between 1971 and 1980, there were 79 cases involving 96 children—an annual rate of 2 in 100 000 children under the age of 5 years.[68] There are a variety of causes.

- **Depression** This is the most common cause. Studies of convicted mothers underestimate the frequency of depressive filicide, because many complete suicide. Melancholic filicide is committed in the belief that the child's best interests are being served (delusional mercy-killing). Mothers surviving depressive filicide usually make no attempt to conceal the crime; they confess and seek punishment. Mothers may kill more than one child, but family murder seems more common in men.
- **Child abuse** This is the other relatively common cause. Death results from ill-tempered assaults or overzealous punishment, without homicidal intent. Fathers are often involved.
- **Psychosis** In non-affective psychosis, filicide may occur if delusions involve the child, or as a result of command hallucinations.
- **Trance states** A few filicides have occurred during epileptic automatism or somnambulism.

Not all parental child killing occurs as a complication of mental illness. Unwanted infants are occasionally murdered in cold blood. Euthanasia of an incurably ill and suffering child can also occur.

Further information

5.5

Management of psychiatric disorders in medically ill patients, including emergencies

Pier Maria Furlan and Luca Ostacoli

The coexistence of psychiatric disorders in patients with medical illnesses may influence both the diagnosis and the course of the illness by their effects on pathophysiological, diagnostic, and therapeutic processes. There may also be effects on patients' collaboration with treatment and on their relationships with health care staff. Several factors change the management of, medical illnesses and psychiatric disorders, and their inter-relation

- increased life-expectancy and increasing survival of people with-severe illness alter the risk of other medical and psychiatric disorders;
- social changes affecting family structure can affect care giving. Other social factors include changes in the role of women (work, delayed maternity); increased immigration with consequent cultural diversity including different concepts of medical and psychiatric disorders (see Chapter 1.3.2);
- increased use of medication in medical and in psychiatric treatment, and changes in the organization of health care and social assistance from hospital-based to community-based.

This chapter describes how to recognize, treat and manage psychiatric disorders in medical illnesses.

The frequency of psychiatric disorders among the medically ill

The prevalence of psychiatric disorders in medical illnesses ranges from 16–60 per cent depending on the research methodology (self-reports or interviews; inclusion or exclusion of somatic items), the setting (out-patient or hospitalized), and the sample. In general, the frequency of psychiatric disorders in patients with heart disease[1] (coronary disease, heart failure), gastrointestinal diseases (irritable bowel syndrome), lung diseases (asthma, chronic bronchitis), and diabetes is 15–20 per cent. In patients with cancer and chronic pain it is 30–40 per cent; and in neurological diseases (Parkinson's, multiple sclerosis, epilepsy) and dialysis it is 50 per cent. Ten to 20 per cent of patients have sub-threshold symptoms that nevertheless influence psychosocial functioning. The prevalence of psychiatric disorders among family members of people with chronic disabling conditions is only slightly lower. The most frequent are organic mental disorders (5–44 per cent), followed by substance abuse (10–25 per cent), anxiety disorders (10–30 per cent), mood disorders (9–13 per cent), personality disorders (6–9 per cent), somatoform disorders (5–9 per cent), mania and psychosis (1 per cent). Recognition by medical doctors is below 50 per cent and the referral rate to liaison services is approximately 1–3 per cent.

The frequency of medical illnesses among psychiatric patients

The most severe psychiatric disorders are frequently associated with social isolation, difficult relations with health-care providers, poor adherence to treatment, unhealthy lifestyle[2] (nutrition, smoking, hygiene), side-effects of medication and substance dependence. The presence of psychiatric symptoms can also lead to failure to recognize physical symptoms. And yet some medical illnesses are more frequent in people with schizophrenia than in the general population.[3] These conditions are cardiovascular risk (9.4 per cent in men, 7 per cent in women), diabetes (13 per cent), hypertension (27 per cent) and chronic conditions in general (41 per cent).[4]

Table 5.5.1 Prevalence of medical illnesses in patients with mood disorders

Disease	%
Hypertension	18.1–34.8
Stroke	1.7–1.9
Headache	19.3
Chronic pulmonary disease	10.6–12.9
Hypothyroidism	9.6
Obesity	4.6
Alcohol abuse	12.2–24.7
Nicotine	9.1–12.6
Illicit drug abuse	9.7

The diagnosis of psychiatric disorder in medically-ill patients

Anxiety, fear, demoralization, a sense of loss, decreased pleasure, and thoughts of death are frequent in advanced debilitating physical disease even when there is no coexisting anxiety or depressive disorder.

Physical disease and its treatment may cause somatic symptoms similar to those of psychiatric disorders. And the 'aetiological' criterion of the DSM-IV-TR that requires exclusion of a physical cause is often difficult to apply in advanced medical illness, as are the criteria for depression. Endicott[5] proposed replacing the four somatic items for depression (fatigue, insomnia, weight-loss, and difficulty in concentrating) with four psychological symptoms: depressed appearance, social withdrawal, brooding, non-reactive mood. However, this proposal risks excluding somatic symptoms which are a core manifestation of more severe forms of depressive disorder. In doubtful cases, an inclusive approach to somatic symptoms is preferable, and the risk of severe psychiatric disorders should not be underestimated.

Self-abasement and guilt are less frequent in medically ill patients. In assessing guilt, ethnic and cultural factors must be taken into account, for example, feelings of guilt are uncommon in depressed Arabs, whereas somatization is common.

Some syndromes in medically ill patients do not correspond to standard diagnostic categories but nevertheless influence functioning and the course of disease. The Diagnostic Criteria for Psychosomatic Research[6] mention illness denial, thanatophobia, demoralization, and alexithymia. In medical illness, psychiatric disorders may manifest with somatic symptoms (see Chapter 5.2.3).

Table 5.5.2 gives some broad indications for the differential diagnosis of psychiatric disorders in the presence of medical illness.[7]

To be classed as a psychological reaction, the psychiatric disorder must develop at the same time as the onset of the medical illness or the treatment. In some conditions such as, pancreatic cancer, multiple sclerosis, the onset of psychiatric disorder may precede the recognition of the medical illness (e.g. Multidimensional evaluation of the care requirements is essential and codified approaches exist).[8]

Atypical symptoms occur in psychiatric disorders due to medical conditions. Drium is often complex with auditory hallucinations prevailing, whereas tactile, olfactory, and gustatory hallucinations are rare.

Causes of psychiatric illness among medical patients

These are both psychological (see Chapter 5.6). and medical (see Chapter 5.3. 4.

Course and prognosis

If properly treated, psychiatric disorders in medically ill patients have the same prognosis as those occurring without medical illness, except in some very advanced and debilitating cases, and in these, the few reported studies give contrasting results. Psychiatric disorders may significantly influence the outcome of the medical condition. Depression is associated with an increased risk for subsequent development of ischaemic heart disease, Parkinson's disease, Alzheimer's disease (and other dementias) and medical diseases in general. It is an independent predictor of severe complications in diabetes and of mortality in ischaemic heart disease, heart failure,[9] stroke, dementia, cancer and HIV. Anxiety may exacerbate angina, arrhythmia, asthma, movement disorders, hypertension and irritable bowel syndrome and is associated with increased health-seeking behaviour and prescription of inappropriate drugs.

Delirium is reversible in 70–80 per cent of cases, but in terminally ill patients may be progressive and intractable, and is associated with increased short-term mortality.[10] Mania and psychosis may worsen the medical outcome due to behavioural alterations, poor adherence and increased drug adverse effects.

Table 5.5.2 Differential diagnosis among psychiatric disorders (PD) in medical illnesses (MI)

	Comorbidity (MI – PD)	Latent (PD)	Psychological Reaction	Psychoorganic PD
Onset with mi	-	+	+	+/-

Family history for psychic symptoms	+	+/-	-	-
Empathy of doctor	-/+	+/-	+	-
Response to psychiatric treatment	+/-	+	+	-

Treatment

In specific populations of patients such as those with diabetes, asthma, myocardial infarction, irritable bowel syndrome, cancer, Parkinson's disease, multiple sclerosis, and rheumatic diseases, psychosocial interventions and a variety of psychological treatments have a positive effect on psychiatric disorders, and the quality of life and relationships.[11] In medical conditions requiring active patient participation, psychological treatments improve adherence to the therapeutic programmes. In diabetes they reduce glycosylated haemoglobin, in Parkinson's they produce cognitive and motor improvement. Such treatments can reduce physical symptoms including pain, nausea, dyspnoea and disability. For other indices such as mortality in heart attack, longevity in cancer, severity of hypertension and peptic ulcer, and inflammatory activity in rheumatoid arthritis, there are psychological benefits and improvements in quality of life but poor effects on medical outcome. Indeed, in the more severe psychiatric disorders, combined treatment with psychopharmacological drugs is more effective. Studies of cost-effectiveness and length of hospitalization have reported conflicting results.[12]

Management

The consultation process

(a) Forming an alliance with the medical team

The psychiatrist should initially aim to work with medical staff on their clinical rounds, and interview patients who have no psychiatric disorder to learn what it means to have the medical condition and to undergo its treatment. The psychiatrist should be present at informal discussions, such as those during coffee breaks,and share the clinical team's emotional experiences.

(b) Interview with medical team

The aim is to evaluate the clinical situation, review the medical records; identify the most significant reason for referral and why the consultation has been made at this time; identify the team's approach to the patient, clarify whether the patient has been informed of the consultation and in what way. If the referral seems inappropriate for the patient, does this reflect a problem within the medical team such as burn out?

(c) Interview with the patient

The interview should move dynamically between the 'objective' position (clinical data, psychosocial information) and the 'subjective' position. Feelings evoked in the psychiatrist frequently mirror perceptions of the patient and the medical team. To recognize them helps empathetic relations and emotional containment. A protocol for the interview is shown below. [13]

(d) Reporting back to the medical team

Reporting should be clear and concise with both a verbal and a written report. The focus should be on the reason for referral. Risk factors and points of strength should be identified. A verbal report of an 'image' such as an episode fom the patient's experience, a memory or even a dream can sometimes aid empathetic understanding by the medical team. Practical advice on management should be provided.

(e) Psychopharmacological treatment

The psychopharmacological treatment of medically ill patients may be difficult for several reasons including the stigma associated with psychiatric disorders, weariness with the many medical treatments already undergone, increased sensitivity to side-effects due to pharmacokinetic changes produced by interactions with medical drugs and any underlying liver or renal disease.[14] However when adherence is adequate, the therapeutic response is similar to that of patients without medical illnesses. Nevertheless, the prescription of medication must not replace receptiveness to the patients problems and emotional support, which are frequently the most effective intervention.

It is often useful to offer the patient a drug not for symptoms such as depression when these arise in a discouraging physical situation because this may be seen as disparaging—but for other

Goal	Approach
Overcome stigma	The medical team: present the psychiatrist to the patient as a team member and motivate consultation The psychiatrist: explores any ambivalence or negative feelings empathetically (it may not be clear to the patient why a psychiatrist is discussing his/her disorder)
Open questions: background and information	Why is the patient hospitalized? What does he/she think of the illness?
Principal emotions and fears	What does the patient feel? What is he/she most afraid of?
Consider constructive ways of coping; and discuss dysfunction	What and who most help the patient to overcome difficulties; who is important, what other resources are available
Completing the information	Medical history and current quality of life
Develop a shared understanding of the situation in which medical and psychological aspects are linked and not viewed as alternatives.	"Normalize" emotional disorders as reactions to illness that may amplify symptoms and influence course. Describe physical mechanisms of symptom production such as muscular contraction, vasodilation/constriction, hyperventilation, asthenia, inactivity, immune defences. Use clear, descriptive language with imagery: e.g. tension is like a tight shoe.
Defining goals and reducing unrealistic expectations	Discuss the main problems Aim to improve problems, not solve them. Set realistic goals
Propose a treatment plan	What interventions, "first steps" Practical advice about day-to-day matters such as interpersonal relations, how to reduce tension

realistic goals. The specific contribution that the drug can make to achieving these goals should be explained and a clear description provided of its somatic effects. The psychiatrist should also:

- Aim to simplify treatment as far as possible. The distinction between 'psychiatric' and 'medical' drugs is arbitrary since many drugs have both physical and psychological effects.
- Rationalize treatment using the fewest possible drugs. First choice should be drugs that act on more than one symptom, psychological or medical (e.g. reduce agitation and nausea, insomnia and hyporexia, depression and headache, pain and anxiety).
- Consider side-effects and interactions before deciding treatment including their time of onset. Thus, SSRI should be prescribed at least one week apart from any treatment with significant gastrointestinal side-effects. Investigate complementary drug use: e.g. 20–40 per cent of oncology patients take herbal remedies, many of which have significant pharmacological interactions (see Chapter 6.2.9).
- Prefer drugs that were effective for the patient in the past; starting with low doses and increasing them gradually.
- Sometimes the best action is to discontinue a drug.

Psychosocial treatments

Differences from traditional psychotherapy

The major aims are to control distress, maintain self-respect, maintain significant relations and doctor-patient communication, work through information, and develop adaptive coping mechanisms.

Timing: At times of crisis (e.g. immediately after the communication of a serious diagnosis), the need for control is paramount. At the onset of complex diseases, short cycles of interviews may prevent subsequent psychiatric disorder.

Flexibility: This is needed due to variations over time in the conditions of treatment (in hospital, or as a day patient or outpatient), the symptoms, and the motivation of the patient, who may alternate between the need for emotional sharing and moments of self-withdrawal. Existential uncertainty is reflected in relations with the psychiatrist and each interview is an entity in itself.

Eclecticism: The complexity of the situation often requires integration of different approaches at different times: expressive, cognitive, body-mediated or psycho educational. The intervention may focus on the patient, on family members or on the medical team. Flexibility and eclecticism must originate from the integration of the patient's needs and the psychiatrist's empathic and comprehensive evaluation of these needs.

Regression: Illness, hospitalization, fear, and the 'invalid role' may make a patient, who would otherwise refuse it, become receptive to the psychiatrist's intervention. During medical illness, emotional defences are more fluid, the relationship with the psychiatrist may form more rapidly and short interventions can be effective. After discharge the psychiatrist must be ready to change approach.

Existential context: A severe disease often casts doubt on the meaning of existence. Patients may fall into despair or ask themselves what really matters. They may want to reorganize their lives around new priorities. In these circumstances, interviews should focus on the present, abandoning the 'past-future' approach, and define the psychiatric disorder as an accentuation of natural human emotions. Fear should be dealt with directly, including fear of dying, and the patient's relatives, including their doctors, should be helped to provide support since fear is greater when experienced alone.

Physical contact: Faced with severe disease, some patients 'speak' only after having been touched. Sometimes bodily contact, for example through simple massage, may keep open communication with family members and staff, even without the use of words. A glance, a voice, the sense of touch, or other bodily sensations may form an intense dialogue between patient and therapist and be the most effective way to understand how aware the patient is of his/her condition.

Treatment of urgent situations

Prevention

- Medical treatment should address the overall quality of life, including the gap between expectations and reality. Many medical interviews target practical matters but place less emphasis on working through expectations. A doctor-patient relationship capable of offering relief while gradually reducing the gap between hope and reality is fundamental.
- The patient's chief supports are family members and caregivers. Improving their psychological skills through simple psychoeducational programmes may be more cost-effective than generally increasing psychiatric consultations.
- Psychosocial and biological risk factors should be identified early, including both current factors and those in the medical history.

Acute anxiety

Treatment of acute anxiety should maximize the beneficial effects of the doctor-patient relationship as well as providing specific psychosocial and pharmacological interventions. At times of crisis, one-on-one companionship is useful, sometimes with simple relaxation or massage that family members can provide. When a serious medical diagnosis is communicated, it is helpful to listen, and for medical staff to be receptive to emotional reactions in the subsequent 24 hours; solitude should be alleviated, if necessary with the help of voluntary workers. Benzodiazepines should be prescribed only when really necessary and for short periods to reduce the risk of tolerance and addiction. Benzodiazepines may reduce respiratory function further in patients who retain CO_2, thereby worsening their asthenia. If prolonged pharmacological therapy is necessary, sedative antidepressants may be an alternative to benzodiazepines.

Panic attacks: Somatic symptoms of a panic attack may be confused with an excacerbation of medical conditions such as chest pain, irritable bowel syndrome, and asthma. Treatment with a selective serotonin reuptake inhibitor is usually effective but half of these patients require long-term treatment since relapse is common after discontinuation. Psychological treatment[15] (see Chapter 4.7.3) can be effective.

Post-traumatic stress disorder: Stress factors in medical contexts may cause and prolong this disorder. Such factors include acute medical events, intensive care, post-confusional reactions, communication of a serious diagnosis, and presence at unexpected deaths. Pharmacological therapy has limited results but psychological treatments may be effective (see Chapter 4.6.2), Risk prevention is important.

Depression

Treatment should be based on prevention, and psycho education, psychosocial and pharmacological interventions.

Antidepressants: The choice of drug should be based on the side-effect profile and interactions (see Chapter 6.2.3). The somatic effect of treating depression can be important. Cognitive and motor functions can improve in stroke patients, glycaemic control can improve in diabetics, as can chronic pain, and dyspnoea in lung-disease. SSRIs may produce gastrointestinal side effects, bleeding due to platelet dysfunction, so that monitoring is essential in patients on anticoagulants. Venlafaxine in high doses may increase blood pressure. Mirtazapine has no sexual side-effects, has anti-nausea activity and stimulates the appetite, but may cause weight gain and sedation. TCAs, being anticholinergic, affecting heart conduction and the peripheral autonomic nervous system, are contraindicated in heart disease, cognitive impairment, orthostatic hypotension, hypertrophic prostate, glaucoma and epilepsy. Secondary amines, such as nortriptyline and desipramine, are preferable.

Methylphenidate may be useful in particular medical situations, such as palliative care or advanced cancer, to alleviate fatigue, increase appetite, and reduce opiate-induced sedation. It may elevate mood and has rapid onset. Agitation and insomnia are the main problems.

Personality disorders

Personality disorders, particularly antisocial and borderline disorders, may create emergencies due either to aggressive behaviour towards self or others or to conflict within the team. Screening for substance abuse and depression is necessary since these increase impulsiveness. Patients can become aggressive when their demands are not met, e.g. for increased painkillers, or interviews with their doctors. Staff require support to manage conflicts and frustration, and to maintain a caring approach.[16]

Staff must be empathetic but at the same time act as a team. Limits and rules should be established at admission treatment to prevent escalation of aggression. Interviews must be in conditions of safety; if necessary with other staff or even police present. The agreed plan must be respected by all staff, avoiding the extremes of excessive permissiveness and excessive rigidity, which may be induced by the patient's disorder. Patients with personality disorders often use truth-based observations pathologically to exploit the therapist's and institution's weak points. Recognizing what is true in their criticisms may improve patient management.

Delirium and dementia (see Chapters 4.1.1 and 4.1.13)

Mania

A manic crisis affects the care of the medical condition dramatically both through excessive activity, weight-loss, reduction of sleep, and through non-compliance with treatment and conflict with staff. The medical history should be evaluated for disease-related stress factors which may trigger crises. Manic symptoms recognized early together with possible causes of insomnia such as pain, nocturia, dyspnoea, or environmental factors including noise, unsuitable temperature, frequent entrance of night-staff for other patients. Where possible, precipitating factors should be removed. When this is impossible (e.g. a requirement for high-dose cortisone), treatment is as that of mania in other situations (see Chapter 4.5.8) taking medication side-effects into account (see Chapter 6.2.4). Antipsychotic drugs are generally faster acting at lower doses than in primary mania. More potent antipsychotics are preferable since they have lower anticholinergic and alpha-blocking effects. It is useful to focus on symptoms the patient finds disturbing rather than ego-syntonic symptoms. Restraint or hospitalization in a psychiatric ward is necessary when hyperactivity could compromise physical safety or the underlying condition.

Psychosis

Close collaboration between the psychiatrist and the medical team is necessary, with the most appropriate environment for treatment, medical or psychiatric unit, being decided case-by-case. Medical investigations and interviews should be simplified and clear basic information provided. Continuity of care among medical professionals is important. The psychological effect of medical treatment should be assessed. When there are hallucinations, medical staff should be educated about their nature and supported, so that they do not criticize any content expressed by the patient, but are able to empathize with the patient's distress. Management may require constant observation and in some cases restraint and involuntary treatment. Medically ill patients are especially sensitive to the side-effects of antipsychotic drugs but generally respond to lower doses. The choice of drug and dose are based on the side-effects and the underlying disease (see Chapter 6.2.2)). Cardiac pathology and QTc enlargement require ECG monitoring and ziprasidone, haloperidol, chlorpromazine, and thioridazine are contraindicated. Caution is also necessary in alcoholics, and patients with hypokalemia and hypomagnesemia.[17]

Extra-pyramidal effects of high doses of typical neuroleptics may cause laryngospasm and affect the diaphragm, worsening any respiratory insufficiency. For chronic treatment, newer drugs are preferable. Caution is required in hepatic and renal diseases and where there is a risk of epileptic fits. Fluid intake should be monitored carefully because dehydration increases the risk of neuroleptic malignant syndrome. In secondary psychosis, the family should be informed and supported and, after the psychotic episode has been resolved, the patient must be helped to work through the disorientating experience.

Aggression and restraint

Aggression should be assessed, thoroughly defining the sequence of events that preceded it and the role of medical and psychiatric factors, stressful events and environmental factors. Major predictors related to the patient include a history of violence, difficulty in communication, and the psychological condition. Predictors related to the environment include: crowding, and a medical team unreceptive to the patient's discomfort. The best strategy is prevention through providing information in a clear and empathetic way, recognizing risk situations and early signs of agitation, and using de-escalation techniques if necessary with pharmacological support (see also Chapter 11.14).

Environmental measures to limit psychomotor agitation include: making the patient as comfortable as possible, reducing background noise, removing potentially harmful objects, and identifying situations of which the patients is intolerant. Patients can be

distracted by walking or occupational activities, avoiding a forced stay in bed and making the timetable flexible. If possible, family members can be asked to collaboration.

Where permitted under national law, restraint may become necessary during unmanageable agitation and aggression in the course of an acute psychiatric disorder, in confusional states, especially in the elderly and aftersurgery, with metabolic diseases or during abstinence from alcohol and drugs (seen especially during the first few days of hospitalization).

If restraint is permissible, staff training is necessary because improper use may cause injury to patients or staff. Restraint should be used only when strictly necessary and for the shortest possible time, with constant monitoring of its continuing necessity and the patient's condition.

In medically ill patients restraint may increase the risk of thromboembolism, reduce respiratory function with increased risk of infection, increase cognitive deficit, pressure ulcers, urinary and intestinal incontinence. When restraint is removed there is an increased risk of falls.

Deliberate self-harm and suicidality (see also Chapter 4.15.4)

In advanced medical illness, suicidal ideation is frequent as an expression of the wish for release from suffering, to regain control over a condition that is perceived as unstoppable, and is wearing the patient down. The actual risk of suicide is slightly above that of the general population. Specific risk factors are: chronic disease, uncontrolled physical symptoms such as pain or dyspnoea, disfiguring surgery, unrecognized psychiatric disorder (delirium, depression, personality disorder), substance abuse, and lack of social support. The most frequent form of self-harm is drug overdose, particularly of analgesics and psychopharmacological drugs. Most lethal suicidal acts are of the impulsive type, in particular jumping. [18] The doctor-patient relationship is often the best help against loss of hope. Safety of the environment is crucial since medical contexts facilitate access to potentially lethal objects and to the possibility of jumping. In cancer, the risk is higher in the first year, decreasing with time after diagnosis. In the end stage of illness e.g. in renal failure, treatment withdrawal may have to be considered, with the: clinical and ethical problems of distinguishing a rational decision by the patient from one affected by a psychiatric disorder or another potentially modifiable factor.

Patients refusing treatment (see also Chapter 1.5.1)

Background culture should be taken into account as some 'overall rejections' are actually related to this rather than to factors in the individual. An alliance with family members is necessary. Factors in the doctor-patient relationship should be evaluated, together with the information that the patient has received. In some cases refusal relates to fear, anger or despair. If it seems that the patient would feel belittled by a psychiatric consultation it is better to support medical staff who are receptive to the patient's emotional sate. This is done patients often then accept psychiatric support more readily. In complex cases, the history of the patient's attitude to treatment should be evaluated on admission to treatment. Aa history of interrupted treatment, changes of doctor or diffidence towards caregivers, may indicate a need for greater efforts to develop good doctor-patient relationships. When obtaining items of medical history from family members, it is important to identify whom the patient trusts most. In relations with the medical team, the most appropriate figure for dialogue should be identified. In some cases, informal conversations, for example in the evening, are more useful than formal medical interviews.

5.6

Health psychology

John Weinman and Keith J. Petrie

Introduction

Health psychology is concerned with understanding human behaviour in the context of health, illness, and health care. It is the study of the psychological factors, which determine how people stay healthy, why they become ill, and how they respond to illness and health care.

Health psychology has emerged as a separate discipline in the past 30 years and there are many reasons for its rapid development. An important background factor is the major change in the nature of health problems in industrialized societies during the twentieth century. Chronic illnesses such as heart disease and cancer have become the leading causes of death, and behavioural factors such as smoking, diet, and stress are now recognized as playing a major role in the aetiology and progression of these diseases.[1] The provision of health care has grown enormously and there is an increased awareness of good communication as a central ingredient of medical care and of the importance of such factors as patient satisfaction and quality of life as key outcomes in evaluating the efficacy of medical interventions.

Although health psychology has developed over a similar time period to general hospital/liaison psychiatry and shares some common areas of interest, there are some clear differences between these two fields. Liaison psychiatry has a primary focus on hospital patients, particularly those experiencing psychological difficulties in the face of a physical health problem. In contrast, health psychology has a much broader focus on both healthy and ill populations and on the psychological processes that influence their level of health or their degree of adaptation to disease. Whereas health psychology has been mainly concerned with developing explanations based on theory, for health-related[2] and illness-related behaviour,[3] liaison psychiatry has concentrated on the diagnosis and treatment of either unexplained symptoms or psychiatric disorders occurring in people with medical conditions (see the other chapters in Part 5 of this volume).

In this chapter we provide an overview of the main themes and areas in health psychology. Four broad areas of behaviour will be reviewed, namely behavioural factors influencing health, symptom and illness behaviour, health care behaviour, and treatment behaviour. Inevitably such an overview is selective and the interested reader should seek out a more comprehensive introductory text[4,5] or more in-depth accounts of specific areas.[2,3]

Behavioural factors influencing health

A wide range of behavioural factors can influence health. In the following section there is a focus on stress, personality, and the main theories that have been developed to explain the variation in health-related behaviours.

Stress and health

The term 'stress' is usually used to describe situations, in which individuals are faced with demands that exceed their immediate ability to cope. Stressful situations are typically those that are novel, unpredictable, and uncontrollable as well as those involving change or negative events such as a loss. These situations can give rise to adverse psychological and physiological changes which, in turn, may result in disease.[6]

Stress may have indirect effects on health by increasing levels of risk behaviour (e.g. smoking, alcohol consumption), or may have direct effects on specific physiological mechanisms (e.g. increase in blood pressure) as well as affecting the individual's resistance to disease through suppression of the immune system, or by exacerbating or triggering a disease process in an already vulnerable individual.

A range of behavioural and emotional responses are shown by individuals as they attempt to cope with stressful situations and these are accompanied by autonomic, neuroendocrine, and immunological changes. During stressful episodes, releasing factors from the brain cause the pituitary to release ACTH which gives rise to the release of corticosteroids from the cortex of the adrenal glands. In addition to producing a number of well-known changes associated with the mobilization of both short- and longer-term physical resources (e.g. release of adrenaline (epinephrine) or noradrenaline (norepinephrine), release of glucose, activation of endorphins/encephalins, etc.), these steroids can also have effects on the immune system.[7]

The effects of stress on immunity have sparked the development of the new multi-disciplinary field of psychoneuroimmunology which focuses on the links between psychological, endocrine, and immunological processes (see Chapter 2.3.10). A large amount of work in this area has concentrated on the links between stress and immune function, but less work has focused on impaired immunity and the later development of disease. Acute stressors, such as examinations, or more chronic stressors, such as caring for

a dependent elderly relative, have been shown to lead to deleterious immunological changes. Work has also associated stress with a greater susceptibility to viral infection[8] as well as longer healing times for experimental puncture wounds[9] and wounds from surgical operations.[10] A recent meta-analysis of studies of stress and immunity shows substantial evidence for a relationship between stress and impaired immune system effectiveness, particularly for chronic uncontrollable sources of stress.[7]

Personality and health

Although there is no consistent empirical support for the older idea that different diseases are linked with specific personality types, there is evidence from different, more credible sources that personality factors can influence health and play a role in determining illness in other ways.[11]

Probably the best known work in this area concerns the link between the so-called 'type A' personality and coronary heart disease. The *type A personality* was originally characterized by competitiveness, time urgency, hostility, and related behavioural factors, which were associated with a significantly increased risk of coronary heart disease (CHD). However, it is now thought that only certain components (e.g. anger and hostility) of the original type A formulation are 'pathogenic'.[12]

Type A individuals show a greater physiological reactivity (e.g. in blood pressure and heart rate) to environmental demands and may even generate more demands by their style of behaviour. The more frequent elevations in blood pressure and higher levels of hormonal change, characteristic of this behavioural style, may eventually cause adverse physical changes to the heart and blood vessels. Also, type A individuals are more likely to engage in unhealthy behaviours since they drink more alcohol than type B individuals and, if they smoke, they inhale their cigarette smoke for a longer time.

Type A behaviour is probably the most extensively investigated personality factor in current health psychology research, and there have been interventions developed to change the behaviour pattern, with positive health outcomes.[13] More recently the concept of the *type D personality* has been described as another major psychological risk factor for CHD. Type D refers to the tendency to experience negative emotional states and to inhibit the expression of these emotions in social settings. Type D patients with CHD have been found to have a significantly higher risk of further cardiac morbidity in the short- and longer-term.[14]

More generally, patterns of positive or negative emotional responses, associated with personality, can influence various aspects of health.[11,15] Individuals who are high in negative affect (i.e. experience more negative emotions, particularly anxiety) do not seem to be more prone to disease, but they are more likely to notice bodily changes and symptoms and consequently seek medical help more frequently (see Wiebe and Smith[15] for a more detailed account of negative affect and the links between personality and health).

Another aspect of personality which has been shown to be health protective is optimism, which describes a tendency towards positive expectations in life and which enables individuals to cope better with stressors and engage in healthier lifestyles. There is emerging evidence that optimistic individuals not only cope more effectively with illness and other life crises but also show better health outcomes than those with lower levels of optimism.[16]

Lifestyle and health

The effects on health of behaviours such as smoking and high alcohol use are well documented.[1] There is overwhelming evidence that smokers not only are much more likely to die from lung cancer and other cancers but also have much higher rates of cardiovascular disease and chronic respiratory disorders, particularly emphysema and chronic bronchitis. Moreover, the disease risk is dose related in that higher levels of smoking are more strongly associated with all these diseases. With sustained high levels of alcohol use a different but equally unpleasant spectrum of health problems can be seen. Drinking is a major cause of accidents particularly motoring accidents and can cause liver damage as well as having detrimental effects on brain functioning.[1]

For health psychologists, the key questions about health-risk behaviours concern their origin, their maintenance, and their prevention or treatment. There are diverse determinants of these behaviours since they may start as ways of coping with stress, in response to peer pressure, for pleasure or for a number of other reasons. Similarly, they will be maintained by a variety of psychological, social, and biological factors.

There are many other risky behaviours that cannot be discussed in detail in an overview; these include drug abuse, poor diet, and accidents, and the health effects of all these are also well documented.[1] Although health psychology has an important role to play in describing, explaining, and intervening in all risk behaviours, these problems should not be conceptualized exclusively in individual behavioural terms since they often reflect adverse social circumstances or particular cultural contexts.[17]

The same caveats about the influence of social and cultural factors must also be applied to the understanding of health-protective or health-enhancing behaviours. Prospective cohort studies have confirmed that various daily behaviours (e.g. patterns of eating, sleeping, and exercise) can have significant long-term effects on health.[18] For example, there is now a growing body of evidence to indicate that regular exercise has a beneficial effect on both physical and psychological health.[19] Exercise can reduce the incidence of physical health problems in elderly people and facilitate recovery from heart attack. However, there can be significant problems in ensuring that exercise and other health-promoting activities are adhered to. Interventions need to be planned carefully, because it has been shown that it is usually very difficult to make and maintain changes in health-related behaviour. Information provision is rarely sufficient to promote behaviour change since it is also necessary to elicit and modify beliefs (see below) as well as influencing social networks in order to ensure success.

Beliefs and health-related behaviour

Even though health psychologists acknowledge the importance of situational, dispositional, and socio-cultural factors as determinants of health-related behaviour, most current research has a primary focus on the role of beliefs in explaining variance in health-related behaviour. The most widely used explanatory approaches have been described generically as 'social cognition models' (see Conner and Norman[2] for an excellent overview of these models). These models are based on the premise that, when a person is faced with having to make a decision about a particular health behaviour (e.g. attend for a screening test; wear a seat belt, etc.), their decision-making and behaviour can be best understood in terms of their perceptions or beliefs about the health issue and the behaviour in

question. The best known models here are the Health Belief Model, Theory of Reasoned Action/Theory of Planned Behaviour, and Protection-Motivation Theory. Broadly these models locate the strength of certain beliefs or evaluations of the health threat (e.g. 'is it serious? Is it likely to affect me?') and/or the associated health behaviour ('Is it an acceptable or worthwhile thing for me to do?') as the key determinants of an individual's motivation or intention to carry out the behaviour. More recent models incorporate other beliefs, such as self-efficacy, which reflect the individual's belief about their ability to implement or carry out the health-related behaviour.

For habitual and addictive health-related behaviours (e.g. dietary behaviour; substance abuse) there have also been attempts to develop stage-based models, such as the Precaution Adoption model and the Transtheoretical model[2] as ways of describing the stages which people may go through in evaluating the health issue through to thinking about, planning, and maintaining behaviour change. Although these stage models provide a framework for identifying the patient's state of readiness for a health behaviour change intervention as well as an immediate target for an intervention, the evidence for them is weak and there are now a number of serious critiques of their validity and applicability.[20]

Symptoms and illness behaviour

The psychology of physical symptoms

Understanding how symptoms are perceived is critical to explaining variation in illness behaviour. Psychological factors play an important role in the appraisal of symptoms. There is considerable evidence that bodily symptoms and functions are not perceived with a high degree of accuracy and individuals vary widely in what symptoms are noticed and whether medical help is sought for symptoms.[21]

The probability that individuals will attend to somatic information will depend on the competition for attention from other sources of available stimuli. When the environment is lacking in stimulation individuals tend to pay more attention to bodily symptoms. Conversely, when an individual's attention is drawn to the external environment, bodily symptoms are less likely to be noticed. This finding has wide day-to-day applications ranging from why people cough in the boring parts of movies and lectures to explaining demographic differences in symptoms reports, such as increased symptom reporting among the socially isolated and the unemployed. It also has clinical applications in chronic pain and other chronic medical conditions where patients' isolation may exacerbate the condition by increasing preoccupation with symptoms.

Cognitive schemas can also strongly influence the reporting of physical symptoms by guiding the way individuals pay attention to their body. Schemas determine the organization of incoming information and guide health directed behaviour. There is a strong tendency for individuals to search for information that is consistent with existing schemas and disregard information that does not fit. Individuals also attach more importance to symptoms consistent with a current cognitive schema than other symptoms. Schemas may develop through personal experience with the condition or by having come across the illness through family, friends, or in the media. Illness schemas can vary from vague ideas about the types of symptoms that represent an illness to more elaborate and detailed conceptions of individual illnesses. Medical students' disease, where students studying a particular illness notice they also have the symptoms of the condition, and episodes of mass psychogenic illness are more dramatic demonstrations of this phenomenon, but the process is seen on a more subtle level with response to placebos (see below). Here, following treatment, a new cognitive schema may shift attention towards symptoms that indicate recovery rather than those of the illness.

Patient delay

There is growing research to suggest that patients' interpretation of their symptoms can influence help-seeking behaviour.[22] One medical condition where delay can have serious consequences is myocardial infarction, as early arrival at hospital is strongly associated with improved chances of survival. There is a large variation in how long patients delay before seeking help, and a strong predictor of early arrival at hospital is the belief that the symptoms are a heart attack.[23] Heart attacks are generally seen as sudden and dramatic events that involve severe chest pain and collapse. In the case of myocardial infarction patients, the mismatch between these expectations and the symptoms experienced gives rise to patient delay.

Research investigating the stages of patient delay for medical conditions has generally found three main stages prior to entering treatment, with each stage influenced by a different set of factors and decisional processes. The first interval is generally referred to as appraisal delay, which is the time period from when the individual first detects symptoms to when an illness is inferred. The main influences on this period are factors related to interpretation of symptoms. The second interval is called illness delay—the period from the time the individual decides he or she is ill until the decision is made to seek medical help. The final period called utilization delay is the time until the individual enters hospital or has contact with medical personnel. This first period of appraisal delay has been generally found to cause the largest contribution to overall delay.[24]

High health service users

A large percentage of medical consultations are made for non-medical complaints. This is particularly so for primary health care services. A number of studies have found that a small percentage of individuals without significant medical illness use a disproportionately large amount of medical services and at considerable cost.[25] These individuals have been variously labelled as somatizers, hypochondriacs, the worried well, patients with medically unexplained symptoms, and multiple attenders.

Research on high health service users suggests they are higher in trait anxiety. This is consistent with research showing a strong relationship between the somatic complaints and high levels of psychological distress or neuroticism. Individuals high in anxiety tend to be more introspective, watchful for any unusual symptoms, and develop more negative interpretations of symptoms they experience.[26] Symptoms of anxiety, such as tachycardia, can also be misinterpreted as signs of a physical illness by some patients.

Some individuals also seem to have a tendency to make catastrophic interpretations about physical symptoms and this may influence frequency of presentation to medical services and recovery from illness. Catastrophizing in pain patients has been associated with disability, and drop-out from pain-management programmes.[27] It has also been associated with higher levels of fatigue and disability in chronic fatigue syndrome patients.

Catastrophizing is also seen in 'cardiac invalidism'. Here patients adopt an extremely passive, dependent, and helpless role in the belief that any form of overly vigorous activity will bring on another myocardial infarction. A hypersensitivity to bodily symptoms means that normal sensations may be misconstrued to indicate overexertion or an impending fatal myocardial infarction. This pattern often results in a cycle of inactivity and loss of physical condition, which in turn can support these beliefs when patients exert themselves. Many patients who develop highly negative illness beliefs overuse medical services mainly for reassurance about symptoms.

The issue of reassurance in medical consultations is relevant here. One of the common patient expectations in primary care consultations is to have a better understanding of current symptoms. For many patients, being told there is no serious medical problem underlying their symptoms is effective in reducing concern about their condition, but for a significant number there remains worry about their health status. Continued anxiety in this group often results in further needless consultations and investigations. Evidence suggests that patients' existing beliefs about their condition are predictive of reassurance failure and that for reassurance to be effective, patients' concerns need to be elicited and appropriate information provided to explain either the patient's symptoms or why serious pathology has been ruled out.[28]

Recent work on improving reassurance following medical testing has suggested providing information to patients about the meaning of normal test results before testing, may weaken patients' preconceived beliefs about their condition and provide a context to help understand the test result. In this study, providing patients with information about normal test results prior to testing, improved their reassurance, reduced their symptoms, and lessened their use of unnecessary medication.[29]

If patients' ideas and beliefs about their symptoms are not addressed when symptoms persist or recur it is likely that health worry will also be reactivated as the patient still lacks a satisfactory cognitive model or explanation that enables them to interpret their symptoms as benign. A practical consequence of these findings is the need for clinicians to elicit the patient's own attributions and concerns about their symptoms and to use these as the basis for dealing with misconceptions and providing the patient with a more benign explanation of their symptoms.[29]

Cognitive models of illness

Research suggests patients cluster their ideas about an illness around five coherent themes or components, which health psychologists have called illness perceptions.[30] These provide a framework for patients to make sense of their symptoms, assess health risk, and direct action in the recovery phase. The major cognitive components are as follows.

- Identity: the label of the illness and the symptoms the patient views as being part of the disease.
- Cause: personal ideas about aetiology, which may include simple single causes or more complex multiple causal models.
- Time-line: the patient's belief about the likely time course of the illness (e.g. acute, chronic, or episodic).
- Consequences: expected impact of the illness on the patient's life.
- Cure/control: the patient's beliefs about the extent to which the illness is amenable to cure or control either through personal actions or by treatment.

These components show logical interrelationships. For example, a strong belief that the illness can be cured or controlled is typically associated with short perceived illness duration and relatively minor consequences.

The theoretical framework for this research is derived from the self-regulatory model developed by Leventhal *et al.*[30] This model views illness perceptions as critical in guiding the patient's coping efforts to deal with symptoms, illness, and threats to health. It consists of four components: the cognitive representation of the illness, the emotional response to the illness and treatment, the coping directed by the illness representation, and the individual's appraisal of the coping outcome.

Patient cognitive models of their illness are, by their nature, private. Patients' are often reluctant to discuss their beliefs about their illness in medical consultations because they fear being seen as ignorant or misinformed. Until recently, assessment of illness perceptions has been by open-ended interviews designed to encourage patients to elaborate their own ideas on the illness. However, questionnaires have been developed to measure illness perceptions in a variety of illnesses[31,32] as well as specific beliefs about medication.[33]

The illness perception approach has recently been applied to a large number of health conditions (see Hagger and Orbell[34] for a meta-analysis). Current research in this area is building on these findings to develop cognitive–behavioural interventions designed to modify dysfunctional illness perceptions and provide better recovery. A good example of this is a study showing that the early elicitation and modification of dysfunctional illness beliefs can improve recovery and return to function in patients with a recent myocardial infarction.[35]

Health care behaviour

In this section we examine the role of psychological processes in the delivery of health care by focusing on two broad areas: doctor–patient communication and health care in hospital.

Doctor–patient communication

There is now considerable evidence not only of patient dissatisfaction with medical communication but also of widespread non-compliance with subsequent treatment recommendations. Early research revealed that patient dissatisfaction was often associated with receiving insufficient information, poor understanding of the medical advice, and subsequent reluctance or inability to follow recommended treatment or advice. Another source of patients' dissatisfaction is the perception that the doctor lacks interest and empathy, and is unwilling to involve them in decision-making during the consultation. Thus, an overview of research in this area[36] revealed that patient satisfaction was higher following consultations in which the doctor engaged in more social conversation, positive verbal and non-verbal behaviour, and partnership building.

A range of frameworks have been developed for describing the process of the consultation. Similarly various methods have been devised for analysing the interactional processes which occur during the consultation[36] and Roter *et al.*[37] have used these

analyses to propose five distinct patterns of communication in doctors:

- narrowly biomedical, characterized by closed-ended medical questions and biomedical talk
- expanded biomedical, similar to the narrowly biomedical but with moderate levels of psychosocial discussion
- biopsychosocial, reflecting a balance of psychosocial and biomedical topics
- psychosocial, characterized by psychosocial exchange
- consumerist, characterized by patient questions and information giving by the doctor.

The highest levels of patient satisfaction were found with those who had seen doctors using the psychosocial communication pattern, whereas the lowest satisfaction scores were recorded in those who had experienced either of the two biomedical patterns.

An alternative and broader distinction has been made between consultations which are described as patient centred and those which are doctor centred, reflecting the extent to which the doctor or patient determines what is discussed. Doctor-centred consultations are ones in which closed questions are used more often and the direction is determined by the doctor, typically with a primary focus on medical problems. In contrast, patient-centred encounters involve more open-ended questions with greater scope for patients to raise their own concerns and agendas.

Patient satisfaction and understanding of their illness following the medical consultation can play a major role in influencing adherence with treatment or advice as well as other outcomes including health and well-being. A number of studies have demonstrated beneficial effects on patients' health and well-being arising from positive experiences in medical consultations.[38] These have focused on psychological states such as anxiety as well as changes in specific physical variables such as blood pressure and blood glucose control. Some of the most impressive findings here have been found in the patient-intervention studies, which are described below.

One important spin-off from the findings in this area has been the development of communication skills training packages for medical undergraduates and for experienced clinicians, particularly for improving skills in difficult areas of communication such as giving 'bad news'. There have also been a number of specific interventions aimed at patients. Generally, these have involved interventions for patients prior to a consultation in order to increase their level of participation, particularly to ensure that their own concerns are dealt with and that information provided by the doctor is clearly understood.

Health care in hospital

Patients experience many stressors in hospital and these arise from a range of factors including enforced lifestyle changes and the demands involved in developing good relations with hospital staff.[39] Other hospital stressors include worries about aspects of communication with staff, as well as concerns about investigations and treatment. Even such factors as the layout and colour of the ward, and the view from the patient's bed have been found to affect recovery. Not surprisingly, studies that have compared home-treated and hospitalized patients with the same condition have shown less psychosocial distress in those remaining at home.

In addition to these general psychological impacts of hospitalization, there may be specific problems or demands which occur either as a result of the particular health problem or the type of treatment which the patient has to undergo. An example of the way in which patients' health problems may influence their experience of hospital care can be seen in some of the studies of patients with HIV/AIDS who may experience negative or blaming attitudes from staff or other patients. For example, with AIDS patients being treated in either special care units or integrated in more general hospital settings, the latter group reported higher levels of stress associated with feelings of abandonment, and impersonal or discriminatory treatment. Where staff perceive patients as instrumental in having brought about their own condition through their own behaviour or neglect, they may be less committed, motivated, and sympathetic towards them.

A number of studies have been made of the psychological effects of specific treatment settings such as intensive care units (ICU) and haemodialysis units. Studies of patients in intensive care reveal high levels of psychological distress both during and for some time after their stay.[40] A range of factors seem to be involved, including being intubated and not being able to communicate. Even physical aspects of the ICU can have significant effects. Thus comparisons of patients in intensive care units with and without windows found that those in the windowless units were less well oriented during their stay and had a less accurate recall of their length of stay afterwards. In addition to these general problems associated with the intensive care units, other studies have assessed the degree of stress experienced by staff and visitors. For patients' relatives there is evidence that they find the time spent by the patient on life support in the intensive care unit particularly worrying. During this time they experience considerable fear and uncertainty but this can be improved by seeking information and the use of other resources.

In contrast with the acute psychological restrictions and demands of intensive care, some patients such as those on renal dialysis are subject to much more chronic restrictions. Dialysis can have major effects on an individual's psychological and social functioning, particularly giving rise to vocational impairment, reduced sexual activity, and mood changes.[41] In addition to the physical limitations and demands of dialysis, patients are also faced with the need to adhere to strict recommendations regarding diet and fluid consumption, as well as complex medication regimens. A number of aspects of dialysis can give rise to psychological distress, including the constant threat of death, dependence on the dialysis machine and medical staff. The stringent dietary and liquid restrictions are also important factors in patients' feelings of helplessness and lack of control. The ways in which patients cope can have important influences on their well-being and outcome. For example, problem-focused types of coping have been shown to be associated with better adherence to fluid intake restrictions, when these coping strategies were used in response to stressors arising from a relatively controllable aspect of dialysis. For those stressors, which patients perceived as less controllable, emotion-focused coping strategies provide better levels of adherence.

Many medical procedures in hospital can give rise to considerable discomfort and anxiety. These include certain treatments such as surgery, and specific investigative procedures such as barium radiography, endoscopy, and cardiac catheterization, which may not only be uncomfortable and sometimes physically distressing but which also carry the threat of uncovering a serious medical

condition.[42] Consequently a number of psychological interventions have been developed to prepare patients for surgery or other stressful procedures in the hospital setting. In broad terms they can help by providing the patient with information to reduce the uncertainty of the event, or with specific behavioural or cognitive skills to help with some of the discomfort or pain.[43]

These interventions have been found to improve a range of post-surgical outcomes, including anxiety, pain and use of pain medication, length of stay in hospital, and various indicators of recovery. All the interventions have been found to be successful in improving at least one aspect of outcome, and the majority of them have a positive impact on many of the outcomes. A meta-analysis by Johnston and Vogele[43] revealed that the largest recovery effects were obtained for pain, negative affect, and physiological indices of recovery but there was considerable variation in the magnitude of these effects. Smaller but more consistent advantages of psychological preparation were found on pain medication and length of hospital stay. The interventions, which had the most widespread overall effects on all the outcomes, were found to be procedural information provision and behavioural instructions. In addition to these specific psychological preparations, there is now evidence that the pre- and post-surgical social setting can have a significant effect on recovery. Studies have also revealed clear beneficial effects of sharing a room with someone who was recovering from surgery. Patients who had post-surgical room-mates, who had undergone the same type of surgery, have been shown to be less anxious prior to surgery, engaged in more post-surgical physical activity, and were discharged home sooner.

Treatment behaviour

Patients respond to their treatment in a range of ways and these can have very significant effects on clinical outcomes. Two major areas of patient behavioural variation are seen in the extent to which patients adhere to their prescribed treatment and in the non-specific or placebo effects of the treatment on clinical outcome. An overview of research on these two areas is now presented.

Adherence

The extent to which the patient adheres to the advice or treatment offered in health care consultations has been widely studied. Most medical consultations result in the prescription of treatment or advice, and the use of medicines is a key aspect to the self-management of most chronic illnesses. However, many patients fail to do this and low rates of adherence to recommended treatment are seen as problematic in chronic physical and psychiatric illnesses.[44]

The incidence of reported medication non-adherence varies greatly from 4 to 92 per cent across studies, converging at 30 to 50 per cent in chronic illness. In primary prevention studies, it has been found that many participants drop out of lifestyle change programmes, designed to improve diet or reduce health-risk behaviours. Even patients who have experienced major health problems, such as heart attacks, may show low levels of uptake of rehabilitation programmes as well as considerable variation in the adoption of recommended lifestyle change. In the area of mental health, there is also evidence of significant rates of non-adherence to various recommendations from health care providers.

Non-adherence behaviours may be categorized as either intentional or unintentional. Intentional non-adherence arises when the patient makes a strategic decision not to take the treatment as instructed. An example of this type of behaviour has been found among hypertensive patients who believed that they could judge when their blood pressure was high by the presence of symptoms such as stress or headache and thus took antihypertensive medication only when these symptoms were experienced. From a self-regulatory perspective, the level of treatment adherence may be indicative of a strategic coping response, which is entirely consistent with the patient's view of their problem. Thus, patients who believe that their problem will not last for long have been found to be less likely than those with a more chronic time-line representation to adhere to their medication over a long period of time.

Non-adherence may be unintentional when the patient's intentions to follow treatment recommendations are thwarted by barriers such as forgetting, and inability to follow treatment instructions because of a lack of understanding or physical problems such as poor eyesight or impaired manual dexterity. Thus, if the quality of communication is poor and patients receive information, which is difficult to understand or recall, as has been outlined above, then this makes it less likely that treatment will be adhered to.

The determinants of non-adherence

One very obvious explanation for non-adherence arises from poor understanding and recall of information presented in the medical consultation. Many patients lack basic knowledge about their medication but there is no simple relationship between this and their adherence. Reviews of adherence research fail to demonstrate a consistent positive association between knowledge and adherence. Moreover, interventions that enhance knowledge do not necessarily improve adherence. Patient satisfaction can act as a mediator between information provision, recall, and adherence since patient surveys reveal that many patients wanted more information than they were given. Dissatisfaction with attributes of the practitioner or the amount of information and explanation provided may act as a barrier to adherence by making the patient less motivated towards treatment.

The emphasis of adherence research over the last decade or so has moved away from attempts to identify stable trait factors which characterize the non-adherent patient to achieving a greater understanding of how and why patients decide to take some treatments and not others. Much of this research is informed by psychological theories, which conceptualize behaviour as the product of cognition which occurs within a social framework.

The application of the social cognition models, described earlier in this chapter, indicates that medication non-adherence may arise from a rational decision on the part of the patient and identifies some of the cognitions which are salient to these decisions. The types of beliefs and attitudes specified by such theories as the Health Belief Model, the Theory of Planned Behaviour and the Self-Regulatory Model (SRM) have all been used to explain aspects of treatment adherence. The SRM also acknowledges the importance of symptom perception in influencing illness representations and adherence as a coping behaviour. Confirmatory evidence for this is provided by findings from studies of patients with hypertension and with diabetes, both of whom commonly use perceived symptoms to indicate their blood pressure and glucose levels respectively, and to guide self-treatment. However, patients' beliefs about their symptoms and estimations of their own blood pressure

and glucose levels are often erroneous, and this can result in poor control of symptoms and illness.

More recent research has begun to focus on the role of people's beliefs about medicines and the ways in which these could influence adherence.[45] This research has revealed two broad factors describing people's beliefs about their prescribed medicines: their perceived necessity for maintaining health (specific-necessity) and concerns based on beliefs about the potential for dependence or harmful long-term effects and that medication taking is disruptive (specific-concerns). Two factors were also found to describe people's beliefs about medicines in general. The first relates to the intrinsic properties of medicines and the extent to which they are harmful addictive substances (general-harm) and the second factor comprises concerns that medicines are overused by doctors (general-overuse).

People's views about the specific medication regimen prescribed for them were found to be much more strongly related to adherence reports than are more general views about medicines as a whole. Moreover, interplay was found between concerns and necessity beliefs, which suggests that people engage in a risk–benefit analysis and consequently attempt to moderate the perceived potential for harm by taking less. Patients with stronger concerns based on beliefs about the potential for long-term effects and dependence reported lower adherence rates, whilst those with stronger beliefs in the necessity of their medication reported greater adherence to medication regimen.[45] This work points to the importance of accessing patients' beliefs as a prerequisite of any intervention designed to increase medication adherence. In particular, it would seem important to identify specific concerns about treatment and to allay these in ways which make sense to the patient.

The placebo response

The term 'placebo' is used to describe a treatment that gains a response due to its therapeutic intent rather than the specific ingredients of the treatment itself. Placebo responses have been shown for a wide variety of medical treatments including surgery, psychotherapy, medication, therapeutic ultrasound, injections, and aerosol sprays. Placebos have also been demonstrated to have effects in countless medical conditions and also on a number of physiological functions such as blood pressure, heart rate, gastric motility, lung function, and postoperative swelling. Adverse effects from placebos or so-called 'nocebo' effects have also been noted in the literature.

Characteristics of the treatment itself and the setting it is administered in can have a strong influence on the magnitude of the placebo response. In general, treatments that involve more serious rituals and sophisticated equipment such as surgery have stronger placebo effects. Likewise, other treatments imparting a powerful impression to the patient such as foul- or strong-tasting medicine, injections, and precise instructions also enhance the placebo response. The colour of medication has been shown to have some effect depending on the condition, and known brand names seem to have an edge in placebo response over unknown drug companies.

A similar theme runs through the clinician characteristics that increase the placebo response. Clinicians and clinics seen as having high status and having high levels of credibility have an improved placebo response. At the same time, the doctor–patient interaction is also important. If the doctor shows high levels of concern and empathy for the patient then the response increased. High confidence shown by the doctor in the treatment administered to the patient along with a clear indication of the expected response of the treatment is also likely to improve the likelihood of placebo response.

In contrast, isolating characteristics of patients who are placebo responders has yielded inconclusive results. Much of the evidence for the role of demographic, intellectual, or personality characteristics of patients likely to respond to placebos is mixed and inconsistent. Studies have found individuals who responded to placebos in one setting to be unresponsive in another. Likewise, conditioning studies have shown individuals who have been unresponsive can later respond. These findings point to the fact that individual characteristics probably play a less significant role than situational factors and the doctor–patient interaction in influencing the placebo response.

Treatment response has been divided into specific and non-specific components, with the non-specific component encompassing factors such as clinician attention, expectation, reputation, treatment setting, etc. Determining the magnitude of the specific and non-specific components of medical treatment is a difficult and probably impossible task. In an attempt to determine how powerful non-specific effects are under ideal circumstances, Roberts *et al.*[46] chose to look at the effect of a number of medical treatments later shown to be ineffective but where clinician faith in the treatment was initially positive. Pooling the data from diverse treatments such as gastric freezing for duodenal ulcer and glomectomy for asthma, this study found 40 per cent of patients had an excellent response to the treatments, 30 per cent good, and 30 per cent poor. This suggests that under ideal circumstances where clinician and patient expectations are high and the treatment is administered in a credible way, non-specific factors can by themselves exert a powerful effect.

The role of compliance with placebos also appears to be important. In a review of five placebo-controlled studies measuring both compliance with medication and outcome, Epstein[47] found that subjects who were more compliant did better on outcome measures, regardless of whether they were on placebo or active treatment. Outcomes included prevention of relapse in schizophrenia, reduction of fever or infection in cancer patients, alcohol abstinence, reduction of weight, and prevention of mortality in patients with heart disease. In a later study, Horwitz *et al.*[48] also found the risk of death was substantially less in patients who took more than 75 per cent of their medication regardless of whether the medication was placebo or β-blocker. This suggests the act of compliance may have some effects of other health-promoting behaviours or cause cognitive or emotional changes that may influence health in the long-term.

There have been a number of theories proposed to explain the placebo response but no one theory yet provides an adequate integrated theoretical framework. The reduction of anxiety following treatment and consequent effect on symptoms has been proposed as one mechanism by which the placebo effect may operate, but changes in anxiety states have not reliably been associated with placebo responses. The role of the medical situation and its accoutrements being associated through classical conditioning with symptom relief is likely to play some role. There is, however, little direct research on this proposed mechanism, although

classical conditioning of drug responses has been shown in certain situations.

Two other theories proposed have been the role of cognitive dissonance and patient expectations. The cognitive dissonance argument proposes that the placebo effect may be due to the pressure on individuals to show consistency in their views and actions. Therefore, for some individuals, having treatment is inconsistent with not showing any change in symptoms and this may encourage the person to reduce this inconsistency. The role of patient expectations and placebo effects is an area that has not received a great deal of systematic research. It is suggested that patient expectations may cause changes in cognitive schemas that influence the types and nature of symptoms that patients pay attention to following treatment. New developments in research on illness perception and beliefs about treatment, outlined above, as well as in the fields of neurobiology and neuroimaging[49] hold considerable promise for increasing our understanding of the nature of the placebo effect and its determinants.

Conclusions

This selective overview of health psychology has demonstrated the range of psychological processes in health, illness, and health care. At the present time it is primarily a disciplinary area of psychology with an emphasis on research into health and illness behaviour. However, many interventions have been developed for healthy individuals, patients, and health care staff. This practitioner aspect of health psychology is now being accompanied by specific professional developments, and formal postgraduate training in health psychology is now available in many countries.[50]

Health psychology has established itself rapidly but it is still very much an emerging discipline. Greater insights are needed into the ways in which psychological processes can influence health and illness, and more comprehensive models are required for explaining all aspects of health and illness behaviour. In the long term this will result in the increasing use of psychological interventions for preventing and managing health problems and for the effective delivery of health care.

The organization of psychiatric services for general hospital departments

Frits J. Huyse, Roger G. Kathol, Wolfgang Söllner, and Lawson Wulsin

Introduction

The organization of psychiatric services for general hospital departments might change in far-reaching ways in the coming decades. Whereas the focus was primarily on reactive services for inpatients on medical and surgical wards, the future should focus on more proactive integrated service delivery for the complex medically ill. The essential difference from other psychiatric services is that the population served is taken care of by medical specialists in the general health setting. Consequently services are delivered in the context of the medical-psychiatric interface. Consult requests are always formulated in this perspective: the patient is treated for a medical illness or physical complaints and there are signs of an interfering psychiatric disorder.[1] Nowadays these patients are referred to as the 'complex medically ill'.[1] Therefore triage and treatment integrated in the medical context is the area of expertise of consultation-liaison (CL) psychiatrists.

The development of this area of psychiatry has been hampered by dysfunctional splits in health care, such as between general and mental health care, both on the level of its organization as well as its reimbursement.[2, 3] Recent reports, such as the report of the joint working group of the United Kingdom Royal College of Physicians and the Royal College of Psychiatrists, which describe the psychological needs of the medically and surgically ill, provide guidance to counteract these dysfunctional splits.[4] As the delivery of care-trajectories for comorbid patients becomes more and more an issue on the health care agenda, CL psychiatrists should seize this opportunity and become advocates for integrated service delivery for the complex medically ill.

[1] Whereas in mental health comorbidity refers to making more than one criteria based psychiatric diagnosis, in the CL literature the term 'comorbidity' is generally used to describe the combination of physical diseases and psychiatric disorders.

Current levels of service delivery

Around 1990 the extent of inpatient CL psychiatric service delivery was evaluated, based on the records of a representative national sample of hospitals (United States)[5] and based on a prospective multicentred study (Europe).[6] Both studies reported an average consult rate of 1 per cent, ranging up to 4–5 per cent in some university settings. This rate is much lower than the prevalence of psychiatric disorders in medical populations.[6] Taking this underutilization into account, the most striking finding was still the large variation in departments served and types of patients seen. The European Consultation-Liaison Workgroup's (ECLW) Collaborative Study made clear that CL psychiatric service delivery is primarily an emergency service. Most referrals were late, as reflected by an average time of 11 days after admission before patients were referred. In addition one-third was emergency referrals: 'See the patient the same day'.[6, 7] Exceptions were the German psychosomatic services driven by their primary interest in patients with unexplained physical complaints and problems of coping with somatic illness using a more integrated liaison approach. These services showed higher consultation rates (between 2 and 4 per cent), provided more follow-up visits, and communication with aftercare providers.[6, 7–9]

It is now evident that mental disorders and physical diseases cluster in vulnerable patients. The prevalence of mental disorders in the general hospital population is on average twice as high compared to that of the general population. However, when focusing on specific populations such as cardiac, diabetes, or transplantation, the rates of major depression may reach up to 30 per cent[10, 11] (see other chapters of this section). Patients in the general hospital setting are primarily treated for their physical diseases. However, the multiple interactions between the comorbid medical and psychiatric disorders make them complex. This justifies an integrated approach and requires individualized multimodal and multidisciplinary care.[12,13] These complex patients are the target population for CL psychiatrists. They are in need of integrated services.

Table 5.7.1 Types of service delivery

1 Emergency services
• Attempted suicide
• Acute behavioural disturbances and their prevention
  • Deliria
  • Withdrawal

2 Regular consults for patients with possible interfering psychiatric complications, such as anorexia, factitious disorder, anxiety- or depressive disorders, adjustment disorders, somatization and organic mental disorders.
3 Integrated services • Participation in multidisciplinary clinics, such as pain, memory, or transplant • Participation in multi-disciplinary rounds on 'liaison-wards' or of disease management programmes, such as for patients with Parkinson disease, diabetes, cancer, or chronic heart failure • Screening for depression or complexity in at risk populations, including the development of related care trajectories • Clinical services for highly complex patients with both medical and psychiatric acuity, such as the medical psychiatric unit

Types of service delivery

Here several models of service delivery are described (Table 5.7.1). The models have an increasing level of sophistication determined by their level of integration and the related procedural collaborative activities. Service delivery requires by definition, negotiations with health plans for their reimbursement. This is especially true for the integrated models of service delivery.[7,13,14]

Consultations

Consultations are the classical mechanism for doctors to involve other medical specialists in the treatment of patients with additional medical problems. Patients are referred if the treating physician recognizes psychiatric comorbidity or a psychological problem and if he or she thinks that psychiatric evaluation and/or intervention may be helpful. The problem linked with this type of service delivery is that physicians often do not recognize psychiatric disturbance in medical patients.[15] In some cases, this problem is avoided by organizing a 'contract type' of consultation where every patient with a defined clinical problem is referred, for instance patients with attempted suicide.

Liaison[2]

Whereas in the consultation function psychiatrists wait for the referral, the liaison function is proactive. A preventive approach is implemented through weekly multidisciplinary rounds. In orderto establish such a role the consultant and a departmental head formulate a liaison arrangement for the provision of psychiatric services for a certain population, clinic or ward. An important additional aspect of the liaison model is its educational focus. Though every consult offers an educational opportunity, in the liaison function the consultant is better equipped to enhance the skills of the teams through weekly attendance of clinical rounds. Currently, the liaison model is restricted to tertiary care hospitals with more extensive CL psychiatric services. In the European collaborative study only 5 per cent of the consults came from a liaison arrangement.[6,8]

Psychiatric-medical, medical-psychiatric units, or psychosomatic units

The 'Psych-Med unit' is an integrated clinical service for high complex patients with unstable medical disease, such as diabetes, and psychiatric disorders. Due to their mutual interactions such patients require not sequential but integrated assessment and treatment, including both intensive medical and psychiatric nursing. Depending on the required acuity levels of physical and psychiatric nursing, different types of Psych-Med units can be described.[14] Dual-trained or combined staffs are selected to provide these levels of integrated care. Organizational prototypes of this function are the US-initiated psychiatric-medical clinics and the Germfan psychosomatic wards, which focus on adjustment disorders in medical patients and complex somatization.[14] During the last years, the efforts to improve integration between inpatient and outpatient care for complex patients led to the implementation of multidisciplinary, and specialized integrated treatment programmes for specific patient groups in day hospitals (e.g. for chronic pain patients and geriatric patients).

Screening

As the selection criteria for patients in the liaison function are not operationalized, referrals are intuitively generated on the basis of clinical expertise.[15] Nowadays instruments are available to support both clinical work and research. The liaison function can be seen as a precursor of screening. It will gradually merge into more structured preventive functions, defined by the needs of a target population and guided by screening.[16] Currently, two lines of screening are in its development. First of all there is a model with a primary focus on psychopathology and primarily depression, using the patient health questionnaire (PHQ) as an indicator of psychiatric comorbidity. It is used in (elderly) patients with physical disorders, such diabetes, or physical complaints of unknown origin.[11,17] Until now this is mainly used in an outpatient setting. The other approach taken is screening for 'complexity'. A European group has taken the approach to operationalize complexity and to develop a screener and an assessment tool to detect and analyse the complex medically ill.[12,16] The Complexity Prediction Instrument (COMPRI)—the screener—is to be applied at admission on an internal medicine ward to detect patients at risk for negative outcomes of care. At the same time a comparable instrument has been developed for the elderly population to detect patients who are frail and are or have an increased risk of becoming complex.[18] Other indicators of complexity such as administrative and clinical are discussed elsewhere.[12] The INTERMED-method has been developed for complexity assessment and the design of related integrated interventions.[19] It starts with a structured interview evaluating 16 health risk variables (Table 5.7.2). The fitting of these 16 risks with 4 prognostic variables in a biopsychosocial schema and the uniform-scoring system providing different levels of action visualized in different colours, supports decision-making and facilitates interdisciplinary communication. The integrated multidisciplinary interventions designed might require case-management.

[2] Here the term 'liaison' is only used to describe the specific 'liaison function' in addition to the basic consultation function.

Table 5.7.2 Health risks evaluated for complexity assessment with INTERMED-method

Chronicity	Is patient known with physical illness/disease
Diagnostic dilemma	Were physical symptoms clarified
Severity of symptoms	Physical functioning
Diagnostic challenge	Complexity of current medical problem
Restrictions in coping	Interferences of coping with medical problems
Psychiatric dysfunctioning	Psychiatric history
Resistance to treatment	Capacity to collaborate with treatment
Psychiatric symptoms	Severity of symptoms
Restrictions in integration	Social integration reflected by work and leisure
Social dysfunctioning	Quality of relations
Residential instability	Stability of housing
Restrictions of network	Availability of help
Intensity of treatment	Utilization
Treatment experience	Trust in health professionals
Organization of care	Participating health professionals
Appropriateness of referral	Capacity to deliver appropriate care

Until now this is an area of health care in which mental health care is not formally integrated. It is to be expected that screening for psychopathology or complexity in the chronically ill will be become important future tools to initiate integrated care and allow CL psychiatric teams to actively contribute to the care of complex patients.

The organization of a consultation-liaison psychiatric service

It is unrealistic to assume that in the future the needs of general hospital patients with psychiatric morbidity can be met simply by increasing staff. To see all patients with psychiatric comorbidity would require many times the present staffing levels. Consequently, CL psychiatrists should plan their services carefully together with their medical colleagues. The following points should be considered.

The population to be seen

Every consultant working in a general hospital, in primary care, or in a nursing-home setting needs to define what patients have to be seen and what services are to be delivered. In a general hospital, emergency services will be required for patients who attend for psychological reasons, including attempted suicide, and for patients with substance abuse withdrawal and acute deliria (Table 5.7.1). In addition consults should be done for patients with unexplained physical problems and other complex illness behaviour. The consult capacity beyond these two consult categories should be used for the development of more preventive consults integrated in existing forms of multidisciplinary service delivery. Selection of areas of interest depends on several factors, such as service delivery or research priorities of the hospital (for instance transplant or oncology) or an own research agenda. In primary care the target population in addition to the chronically ill will be patients with somatization problems including affective and anxiety disorders (see Chapter 5.2.3).

Psychiatric assessment

As in other settings, the formal psychiatric assessment is a crucial part of the services delivered. Specific to the setting is the differential diagnosis with physical disorders, the role and the meaning of physical deregulations, effects of pharmaca, the effects of the psychiatric disturbance on compliance with the treatment of the physical disease, the consequences of the assessment for the integrated prognosis, and the subsequent long-term integrated management of the patient. As the outcome of psychiatric disorders is clearly related to the interfering problems, which contribute to the complexity of patients, inclusion of the assessment of potential risks for such problems should be considered.[19]

Disciplines and staffing

The size and composition of the CL team needs to be defined depending on the size and type of the hospital and of the target group of patients (Table 5.7.1) as well on the financial possibilities and other available services. For the basic function, the assessment and treatment of patients seen for attempted suicide, one is referred to Chapter 4.15.4. In a European study (ECLW Collaborative Study) it became clear that there was a variation in team composition from monodisciplinary (medical model) to multidisciplinary (mental health model) depending on the size of the service as well as the country.[8] In addition to individual psychotherapeutic treatment, mutual adjustment with and instructions of other caretakers is a key aspect of CL work. Consequently, nowadays CL psychiatry cannot provide optimal care without team members focusing on psychological treatment and the organization of case-management required for long-term individualized care-trajectories. Good evidence is becoming available that psychological interventions (cognitive–behavioural, problem solving, and interpersonal psychotherapies) are effective in patients with physical illness and depression as well as unexplained physical complaints;[20,21] (see also Chapter 5.2.3). The effectiveness of interventions of CL psychiatric nurses depends on their roles. For the effectiveness of case-management in these patients is less evidence according to a recent systematic review.[22] Turning it another way around, as CL psychiatric nurses will often work in the chronic medically ill, a recent review has provided an overview to assess the effective elements of chronic disease management (Table 5.7.3).[23] To be able to contribute to integrated care programmes, such as for diabetes or for haemodialysis, tertiary care hospitals should have teams with, on average, one full-time equivalent of psychiatric staff per 300 beds and a secretary, in addition to psychiatric residents, nurses, and psychologists.[24] Both psychiatric and complexity screening functions need to be supported by manpower to translate the findings into clinical action, such as the design and implementation of a long-term individualized care trajectory and prevent decompensation in those who are vulnerable.

Relationship between medical staff, hospital board, and regional mental health facilities

For the development of more integrated services beyond emergency consultations good working relationships are required. The psychiatrist should be a formal member of the medical staff. Negotiations on the size and focus of CL psychiatric service delivery

Table 5.7.3 Evidence for effective chronic care management

There is evidence to support the following initiatives
- Broad chronic care management models
- Integrated community and hospital care
- Greater reliance on primary care
- Identifying people at greatest risk of complications and hospitalizations
- Involving people with long-term conditions in decision-making
- Providing accessible structured information for people with long-term conditions and their families
- Self-management education
- Self-monitoring and referral systems
- Electronic monitoring and telemonitoring
- Using nurse-led strategies, where appropriate

There is less evidence to support the following initiatives
- Case-management
- Evidence-based care pathways
- Shared learning among health professionals

There is limited information about
- New models of commissioning services
- Appropriate data collection and monitoring
- Linking health services with voluntary and community services

(From D. Singh (2006), *Transforming chronic care*, NHS Surrey and Suffolk UK. © Crown copyright.)

should be organized with representatives of the general hospital board, the regional mental health provider, and the health plan. They should decide on functions, budgets, and facilities. The lack of medical facilities in mental health institutions is a good reason to include the need to develop a psychiatric medical unit in the general hospital to serve the more serious medically ill from mental health institutions. Wards with both a psychiatric and medical function can solve the problems created by the artificial division between general and mental health care.

Audit

Both for financial purposes as well as for strategic planning practice audit is required. It does not make much sense to have an extensive audit system such as used in studies, unless this is used for projects. Otherwise an audit system integrated in the hospital mainframe seems the most appropriate, including the basic patient documentation, the reason for referral, the referring department, their diagnoses, and treatment.[25]

Training

In the 'western' world CL psychiatry is becoming more and more an area of special interest, which is reflected in a subspecialty-status in several countries, such as the United States, the United Kingdom, and Australia. Training should include specific medicopsychiatric aspects of the work, including psychopharmacology in the medically ill. Guidelines have been formulated by several associations and have been published.[26, 27]

Further information

Associations for consultation-liaison psychiatry exist, which organizational format differs by country. Since the first decade of the twenty-first century there is an increasing international exchange between leading organizations as well as among leaders in the field. Leading associations are

- The Academy of Psychosomatic Medicine in the USA: www.apm.org. This organization has an international membership and focus and
- The European Association of Consultation and Liaison Psychiatry and Psychosomatics: www.eaclpp.org

SECTION 6

Treatment Methods in Psychiatry

6.1

The evaluation of treatments

Contents

6.1.1 The evaluation of physical treatments

Clive E. Adams

The strengths and weakness of the single trial

Strengths

New treatments, or variations of older therapies, rarely represent a revolutionary departure from what has gone before. As progress is usually made in modest steps, evaluation in prospective randomized trials is needed. These studies, comparing a new treatment with a relevant control, may be able to highlight and quantify relatively subtle but important differences in outcome.

Randomization controls for selection biases. If undertaken carefully, it should ensure that both known and unknown confounding variables, such as age, sex, and additional medications, are evenly distributed between groups. Any differences in outcome should then be due to the treatment, or the intention to give the treatment (see below). In 1991, the World Health Organization stated that the randomized controlled trial, if ethical and feasible, is the most objective means of evaluating mental health interventions.[1]

Certainly, large well-conducted trials, with participants, interventions, and outcomes recognizable to those working in health services, are potent guides to clinical practice. Nevertheless, even when such trials exist, it is important to view them alongside all other comparable evidence. Should the large study affirm the findings of smaller trials the clinician can proceed with confidence. If there is a discrepancy then debate will be generated, which should clarify important issues relating to the participants, interventions, or outcomes measured or to the methods by which the trial was conducted.[2]

Power

As numbers within a study increase so does the precision of results, enabling important but subtle differences to be detected, if they do indeed exist. Should a new treatment be considerably better than its predecessors few people would have to be randomized in order to demonstrate clearly the advantage of the innovative approach. As the advantage expected of new treatments is usually modest, reasonably large studies are often needed.

The power calculation is an important prerequisite for any randomized trial. For example, if clinical observation suggests that a new treatment can help 20 per cent more people avoid admission than the standard care, this can form the basis for a power calculation for a trial. Using a simple formula[3] the trialist can work out how many people would have to be randomized in order to have a known probability of highlighting such a difference, should one really exist. In this case, about 150 people would have to be allocated to each arm of the trial to be reasonably confident of detecting a true 20 per cent difference ($\alpha = 0.05$, $\beta = 0.8$). Most mental health trials are far too small to show up anything but very gross differences between treatments. For example, the average number of participants in schizophrenia trials is about 100 with only a slow increase over time.[4]

A single small trial should not greatly influence the clinician, but the combined results of several studies may begin to have the power to inform practice.

Biases

Randomization attempts to control for the biases that would influence treatment allocation (selection biases). Blinding at outcome attempts to control for biases that would result from participants or raters knowing which treatment had been allocated to whom (observer bias). Inadequate randomization leads to an overestimate of effect in the region of 31 to 40 per cent, and poor blinding at outcome to that of about 17 per cent.[5] Further overestimate results from the use of unpublished or modified scales, commonly seen in mental health studies, and a financial or academic investment in the therapy by the trialists.[6,7]

There are many threats to the validity of a single trial. Viewing all relevant studies, each of which was subject to different degrees of bias, should give a more balanced picture. Of course, the reader of a review should be vigilant for the systematic bias, across all trials, that may consistently sway results one particular direction.

Generalizability

Even if a study is adequately powered and undertaken with due regard for bias, a single trial may be difficult to apply to everyday practice.

(a) Participants

Most studies involve unusual participants. Frequently those eligible for trials have to give informed consent, their problems are well defined and do not involve multiple pathologies, and they are expected to tolerate the demands of a study.

(b) Interventions

Applying the results of a single study is made even more difficult because study interventions are often impractical. For example, drug trials may use rigid dose regimens impossible to apply to routine care. Psychosocial therapies tested within a trial are often of such high quality that they bear little resemblance to what an overstretched clinical service can provide.

(c) Outcomes

Measurement of outcome may also limit the value of a single trial. In a survey of 2000 schizophrenia trials, 640 different scales were used to record outcomes such as mental state, behaviour, global impression, and adverse effects.[4] Specific subspecialties within psychiatry may have an even greater propensity to create scales for trials.[8] Even within poorly powered trials, these sensitive tools may be able to detect real differences between treatments that may be statistically if not clinically significant. However, few clinicians use such scales in everyday practice and interpreting results becomes a matter of conjecture.

Trials that involve carefully defined groups of participants receiving meticulously controlled treatments and having outcomes measured on sensitive scales are called 'explanatory' studies.[9] Such trials dominate the literature, although calls for more pragmatic or 'real world' methodology are increasing[4,10] and there are now examples of this broader approach.[11,12,13,14] Currently, generalizing from the results of a single trial to day-to-day practice is inadvisable. If, however, several explanatory studies, all undertaken with constrained, but different, methodologies are giving a similar result, the clinician can feel a little more comfortable when acting on their findings.

The rogue result

Even the well-conducted generalizable trial can produce a rogue result. Currently, the acceptable level of chance is one in 20. A statistically significant result, often denoted as $p<0.05$, suggests that the finding, if the experiment was to be replicated, should occur 19 out of 20 times. One time in 20, however, a different result will appear simply because of chance. This can lead to an interesting paradox. A single trial may not provide the best evidence of how to manage people, even in the locality that the study was undertaken. The play of chance may result in an erroneous result and unless that trial is viewed in the company of all relevant evidence, clinicians will be mislead.

Time

It is inadvisable to act on the results of a single trial because of issues of power, biases, generalizability, and the possibility of chance erroneous results. There is, however, also the issue of time. Clinicians may often prefer to read the results of a single review rather than spending time assimilating information from several similar trials. Most practitioners have very little time to keep up with research relevant to their practice. Clinicians admit to having half an hour of reading time per week,[15] and much of that may not be retained.[16] Reading reviews is time efficient.

Reviews

There are two main approaches to the reviewing process—the traditional and the systematic.

The traditional review

The traditional review is often undertaken by a person well respected in the relevant field who uses knowledge and acumen, supplemented by research, to produce a synopsis of the literature. This approach still dominates the current texts, journals, and lecture tours. For example, in 1987 in four major North American medical journals, 86 per cent of review articles depended on qualitative synthesis and contained no 'methods' section whatsoever.[17] In only 6 per cent of the reviews was quantification attempted in order to support opinion and the situation did not improve much across the next decade.[18] Therefore, the clinician is left in a situation where it is difficult not to operate under a double standard. On the one hand, a large relevant trial providing objective evaluation would be desirable, but frequently, a traditional subjective review is all that is available.

Systematic reviews

The form of a systematic review encourages the introduction of basic epidemiological principles and quantification into the process of reviewing. Gene Glass, an educational psychologist, was the first to add the results of similar studies in the hope of quantifying the effects of a treatment.[19] Glass defined 'meta-analysis' as 'the statistical analysis of a large collection of analyses results from individual studies for the purpose of integrating the findings'.[20] Unsurprisingly, in the sensitive area of the psychotherapies, their first and flawed attempts in the new discipline generated controversy.[21] Critics were quick to point out that drawing conclusions from summation of very different types of therapies, undertaken by practitioners of varied experience, was likely to be inadvisable. These pioneers, who even years later are still being criticized for adding 'apples and oranges',[22] are nevertheless owed a great debt by the rest of medicine. After all, it depends on the question being asked. It is fine to mix apples and oranges, if your question is about fruit.[23]

Systematic reviews attempt to minimize bias in the identification, extraction, and summation of relevant data by applying good survey methods to the process of literature reviewing. An analogy may help. In a community survey of the prevalence of mental disorders, a researcher stands on the doorstep of the hospital and suggests that 5 per cent of the population suffers from serious mental illness. By chance, the final estimate may even be correct, but the work could not be seen as methodologically rigorous. The researcher should have written a study protocol, clearly defined an

unbiased sample of individuals to interview, and specified *a priori* the analyses to be undertaken. A systematic review should do this for a survey of a 'population' of relevant literature. Within such a review, the objectives, criteria for selection of relevant studies, search strategy, methods of study selection, data extraction, and assimilation are all made explicit.

The advantages of the systematic approach

As is suggested above, a systematic review may, by adding the results of similar studies together, at least begin to address the issue of the underpowered study, single trials of biased methodology, poor generalizability, and idiosyncratic results. Although often longer than most traditional reviews, the systematic review is still a time-efficient way to appraise research. Additional advantages are both intuitive and practical.

(a) Objectivity

Medicine remains a scientific discipline and the attempt at objective quantification must be an integral part of this approach. However, the systematic review and meta-analysis should never become a source of clinical tyranny. Individual clinicians will always have to use wisdom and judgement in their day-to-day decision-making, but to exclude objective appraisal from this process is foolhardy.

(b) Clinical empowerment

Systematic reviews can provide clear information to clinicians, policy makers, and recipients of care, and so help inform the decision-making process. For example, a systematic review of family therapy suggests that this educational, psychosocial package can help those with schizophrenia avoid or postpone relapse.[24] This finding is very much in line with the suggestions of traditional reviews.[25] However, the systematic review is able to illustrate how seven families have to undergo regular therapy, for up to a year, in order for a single relapse to be postponed. Such data, of course, mean different things to different people. Clinicians may find this an acceptable degree of effort, whereas managers of services, or even families of those with schizophrenia, may not. Although the findings may not decrease controversy, at least debate can be informed.

The quantification of trial data can sometimes provide information quite at odds with the advice of traditional reviewers. The best example comes from outside mental health care. In 1992, Antman *et al.* undertook a meta-analysis of randomized trials evaluating the care of those with acute myocardial infarction.[26] As the reviewers added trial data, they found that by 1973 enough studies existed to show clearly that thrombolytic treatment saved lives. Subsequent trials added precision to the result but did not change the finding. Antman and colleagues also showed how traditional reviews continued to fail to mention thrombolytic therapy up to 15 years after the summated trial data could have shown its value.[26] These traditional reviews recommended treatments for myocardial infarction that were positively harmful. Examples have emerged from mental health. Sometimes, traditional reviews make bold claims or recommendations which are not supported by the evidence in quantitative, systematic reviews. For example, some claims made for cognitive therapy for schizophrenia[27] go well beyond objectively summarized evidence.[28,29] Conversely, even when evidence is of high quality and readily accessible, traditional reviewers can be blind. For example, both the strengths and the limitations of new generation antipsychotic drugs have been evident for years[30,31,32] but traditional reviews and texts have encouraged uncritical enthusiasm for their use[33,34] and even guilt for failing to prescribe.[35]

(c) Gaps in research

Often a systematic review will highlight unsuspected gaps in research. The trial-base of much routine practice is not strong, and systematic reviews can help shape questions to be tested in well-planned and conducted trials.[36] Certainly, some research funders are now requiring that a systematic review be undertaken before a randomized trial is funded. This also avoids wasting resources on questions that have already been answered.

The limitations of the systematic approach

(a) Qualitative information

Systematic reviews focusing on the value of treatments given to those with mental health problems usually involves quantitative synthesis of data from randomized trials. Incorporating the great wealth of information from more qualitative approaches in an unbiased way is problematic.

(b) Trial content and quality

Systematic reviews are limited by trial content and quality. For example, it is feasible that, on average, those taking a new drug may have a statistically significant 10-point-greater decrease in a modified Brief Psychiatric Rating Scale[37] score than those taking the comparison treatment. First, this finding is difficult to put into clinically meaningful terms. Second, most scales do not provide 'interval' data. A 10-point change for someone who started with a very high score may not mean the same as the same change for a person entering the study with a lower rating. Third, more problems stem from the modification of the scale. This may well not be published and so validity is questionable. The use of such data is associated with an overestimate of effect.

Undertaking a systematic review of poor-quality trials is an important prerequisite for the design of good studies, but clinical interpretation can be problematic.[38]

(c) Rare outcomes

Randomized trials are not a powerful means of identifying rare but important outcomes. For example, large cohorts of those taking the 'atypical' antipsychotic drug, clozapine, suggest a rate of about 1 per cent for agranulocytosis, a serious adverse effect.[39] However, a systematic review of all relevant randomized trials finds a much lower incidence.[40] As the most vulnerable period for the occurrence of agranulocytosis is from weeks 6 to 18 of treatment,[39] and most studies in the systematic review were of shorter duration, the incidence was underestimated.

Trials have limited power to identify rare outcomes and, although systematic reviews may increase this power, reviews of studies of different methodologies may be needed to quantify these important effects.

(d) Limited statistical methods

The statistics used to summate data within meta-analyses are still evolving. For example, much of the continuous scale data, seen so frequently in mental health trials, is not normally distributed. How robust the commonly used methods of meta-analysis are for these non-parametric data is not clear. In addition, as mental health begins to evaluate preventive interventions then cluster randomization, where communities or institutions are randomized rather

than individuals, will become more common. The statistics for a meta-analysis of these studies is still a matter of debate.[41] Frequently, a systematic review of mental health trials must present, but not summate, relevant data.

The methods of systematic reviews

Setting the question

Clinical questions regarding the effects of treatments have three parts: the participants (who are the people of interest to the questioner?), the interventions (what are the specific treatments that are to be the focus of the review?), and the outcomes (what are the outcomes of interest to the reviewers?) . Although the reviewers may have knowledge of existing trials and their limitations, it is important that the questions set are relevant to the review's readership. If the review is to service clinicians then clinically relevant outcomes must be a priority and not necessarily those anticipated by foreknowledge of the trials. If all studies then provide data on mean change in the Brief Psychiatric Rating Scale and fail to mention the outcome of 'clinically important improvement', the review can highlight this important gap in knowledge.

Developing an answerable question. The next stage for formulating the question is to decide on the type of study that is best suited to answering the question. For questions related to the efficacy of treatments this is usually the randomized trial. At first glance, this may seem straightforward, but it is important to state *a priori* whether studies that implied, but did not state, randomization should be included. No other methodological parameter is so consistently linked with exaggerated estimations of effect than poor description of randomization.[5] Studies that describe themselves as 'prospective, double-blind, evaluative controlled trials' would be excluded from a review if the entry criteria demanded an explicit description of randomization.

Identifying studies

Studies are usually identified by searching bibliographic databases such as EMBASE, MEDLINE, or PsycINFO. Hand-searching relevant journals, conference proceedings, and references is also often undertaken.

A systematic review would be a misnomer if the researchers did not make the means of identification of studies clear and reproducible. The exact source of trials, and the search strategies, must be explicit. It is at this poin`t that the advice of an information specialist is important. The coverage of mental health journals in many bibliographic databases is poor and often limited by region or language[42] so that searching several sources is advisable. For example, the last decade China has become highly productive of mental health trials[43] but few are reported in mainstream bibliographic databases.[44]

In recent years, however, the situation for those wishing to identify all treatment trials relevant to a particular topic has become easier. The Cochrane Controlled Trials Register within the Cochrane Library,[45] is the largest and most comprehensive bibliographic database of published and unpublished randomized trials, and controlled clinical studies, in existence. For citations of trials, this specialist register has eclipsed databases such as EMBASE, Medline, and PsycINFO. Searching the Cochrane Controlled Trials Register also avoids the problem of the numerous 'false' positive citations produced by searches of unspecialized biomedical databases.

Identifying every possible study is important. Potent biases operate in this area. Trials that have statistically significant results are more likely to be published than those reporting equivocal findings,[46] and they are more likely to be published in English.[47] Systematic reviews incorporating only Anglophone published data or trials from one region are likely to produce, at best, imprecise, and at worse, overoptimistic views of efficacy.

Selecting studies

Once a search is completed, relevant studies must then be selected without bias. Reviewers usually work independently and document the outcome of all disputed decisions. Some feel that those selecting the trials should be blind to the study's author, source (usually a journal), and the institution where the trial was undertaken. All have potential to bias the study selection. However, such blinding would often involve prohibitive effort. In any event, a systematic review should make explicit the degree of effort made to avoid selection bias at this crucial stage.

Quality assessment of trials

Once studies are identified and prespecified entry criteria met, a last set of quality criteria may be applied. Scales are available, but essentially they rate selection and observation bias (see above). The description of concealment of allocation is central, as this methodological parameter has consistently been shown to be linked with an estimate of effect. If this is poorly reported, the trial is likely to overestimate the effect of the experimental intervention.[5] For trials that describe allocation with nothing more than 'randomized', this single parameter may not be a sensitive measure of quality. A scale addressing both selection and observation bias by rating the description of randomization, blinding, and reasons for people withdrawing, may be more appropriate.[48]

A systematic review should prestate the level of quality that is acceptable, or, at the very least, how the data from poor-quality studies are to be managed.

Data extraction

Reliable data extraction is important. Just as studies must be selected with due regard for the inclusion of bias, so data must be extracted carefully and reproducibly. Often reviewers ensure maximum reliability by organizing double data extraction by an independent reviewer.

Data management

(a) *A priori* primary analysis

As with any quantitative research, a systematic review will generate the potential for multiple analyses. As one in 20 will be statistically significant by chance, it is important to state *a priori* the primary analyses to be undertaken. Although multiple secondary analysis are often undertaken, these are only hypothesis-generating as data have been multiply tested.

(b) Unacceptable loss to follow-up

In every study, there must be a certain attrition that renders data meaningless. For example, in a trial of tacrine for those with Alzheimer's disease 68 per cent of people taking the experimental compound were withdrawn or lost to follow-up.[49] Drawing conclusions from the data provided by the 32 per cent of 'completers' is problematic as selection bias, originally addressed by

randomization, is likely to be great. Trial attrition may not be immediately apparent from first glance. For example, a meta-analysis of studies comparing the antipsychotic quetiapine with chlorpromazine and haloperidol for schizophrenia shows considerable loss to follow-up at only a few weeks.[50] The last observation of those leaving was carried forward to the results, so that data presented in the trials were on the numbers originally randomized. The trialists made an assumption that data collected just before leaving the study would reflect the situation at the end of the trial. These assumptions by the trialists may or may not be justified[51] but reviewers must also make judgements. It is crucial to make these important decisions explicit and to make them before seeing the data.

The limit at which data become meaningless may differ depending on the question addressed. For example, in the situation of trialling a new oral drug for schizophrenia, clearly a loss of nearly 60 per cent of people at 6 weeks is clinically untenable. The reviewer may judge that the unfortunate clinician may lose up to 30 per cent of people by 6 weeks but that any greater loss would reflect more than misfortune and render data of little use. In different circumstances, such as the acute care of very disturbed people in closed wards, the loss of even 10 per cent of participants could be seen as a threat to the value of the data presented.

(c) Intention-to-treat analysis

Interventions are not randomized in trials — it is the *intention* to give treatments that is randomly allocated. Once people are lost to follow-up, the property of the randomization to distribute known and unknown confounding variables is under threat. The randomization has, in effect, been broken. The real threat of an introduction of selection bias has led to the phrase — once randomized, always analyze.[3]

Once a limit to trial attrition has been set, reviewers must, before seeing trial data, exercise more judgement in what outcome is to be attributed to those who were lost. It is impossible to avoid assumptions, but these should be based on common sense if not evidence. For example, when presenting data for the outcome of 'clinically improved', reviewers could assume, unless contrary information is provided in the trials, that those who left early did not have an important recovery. If good quality sources of information are available, this assumption can become more evidence-based. Perhaps an exemplary trial within a systematic review managed 100 per cent follow-up even on those who left the study early. If this trial found that 90 per cent of those who had not complied with the study protocol were not 'clinically improved', it would provide a rationale for applying this figure to the other trials in the meta-analysis. Unless individual patient data are available, this process is impossible for continuous outcomes and only 'completer' data must be presented.

(d) Continuous data

Data on continuous outcomes are frequently skewed, with the mean not being the centre of the distribution. The statistics for meta-analysis are thought to be able to cope with some skew, but were formulated for parametric normally distributed data. Reviewers may wish to build in simple rules to avoid the potential pitfall of applying parametric tests to very skewed data. For example, in scale data where a mean endpoint score is provided with a standard deviation, when the latter is multiplied by 2 and is then greater than the mean, data could be stated to be too skewed to summate.[52] This rule cannot be applied for scale data reporting change, rather than endpoint, scores.

A wide range of rating scales are available to measure outcomes in mental health trials. These scales vary in quality and many are poorly validated. It is generally accepted that measuring instruments should have the properties of reliability (the extent to which a test effectively measures anything at all) and validity (the extent to which a test measures that which it is supposed to measure). Before publication of an instrument, most scientific journals insist that both reliability and validity be demonstrated to the satisfaction of referees. Reviewers may well decide, as a minimum standard, to exclude data from unpublished rating scales.[38]

(e) Individual patient data

Most mental health meta-analyses are of aggregate data from published reports. Other specialities have set a 'gold standard' for systematic reviews by acquiring, checking, and reanalyzing each person's data from the original trialists.[53] Collecting individual patient data allows reviewers to undertake time-to-event analyses and subgroup analyses, to ensure the quality of the randomization and data through detailed checking and correction of errors by communication with triallists, and finally to update follow-up information through patient record systems (such as mortality registers).

Limited empirical evidence exists for some of the advantages of individual patient data reviews over other types of review. The former does help to control publication bias, to ensure use of the intention-to-treat principle in the analysis, and to obtain a fuller picture of the effects of different treatments over time. Undertaking individual patient data reviews requires considerable additional skills, time, and effort on the part of the reviewers when compared to meta-analyses of published aggregate data.[54]

Statistics

(a) Inappropriate meta-analyses

Systematic reviews may, or may not, contain meta-analyses. Where participants, interventions, or outcomes are clearly too different to summate, reviewers must resist the temptation to use powerful statistics on inappropriate data.[41]

(b) Summary measures

Much has been written about the statistics for meta-analysis,[55] but if their meaning is not conveyed to the user of the review, they are of little value. Summary measures such as odds ratios or relative risk are frequently employed for dichotomous outcomes and weighted and standard mean difference for continuous data. Where continuous data are presented from different scales measuring similar phenomena then standard mean difference is often calculated and called the effect size. This estimate has statistical integrity, but is even more problematic to interpret clinically than weighted mean difference. In each of these summary measures, an individual trial contributes to the final statistic, inversely proportional to the precision of its result.

Currently, in this new discipline, statistics for meta-analysis are powerful and evolving. In recent years, there has been a much better understanding of how best to summate data from cluster randomized trials and crossover studies. Techniques for these types of analyses are now widely accessible. Further statistical flexibility is available through use of generic inverse variance. This statistical

technique facilitates analyses of properly analyzed cross-over trials, cluster randomized trials and non-randomized studies, as well as outcome data that are ordinal, time-to-event or rates. Better methods for managing non-parametric data can confidently be expected in the next few years.[41]

(c) Sensitivity analyses

This is where an analysis is used to determine how sensitive the results of the review are to changes in how it was undertaken. For example, the reviewers may state, again *a priori*, that they wish to compare the size of effect of industry-sponsored trials versus those undertaken independently of the manufacturer of the experimental drug.[7] The sensitivity of the final result to adding and subtracting sets of trials is then tested. Sensitivity analyses can be proposed on many variables, such as severity of illness, age of participant, means of diagnosis, subtype of intervention, and quality of trial. This can easily lead to the problems of multiple testing, although for meta-analyses of published data the quality and extent of trial reporting severely restricts the numbers of sensitivity analyses that are possible.

(d) Heterogeneity

In systematic reviews heterogeneity refers to variability or differences between studies' estimates of effects and is a function of clinical and/or methodological diversity among the studies. Despite rigorous definition and application of inclusion criteria, the trials eventually selected may not be homogeneous enough to summate. Heterogeneity should be considered, sought, and measured, and, if present, investigated. Statistical tests of heterogeneity are used to assess whether the observed variability in study results (effect sizes) is greater than that expected to occur by chance. These tests, however, have low statistical power and careful inspection of results for outlying findings is just as valuable. Recently, partly because it is more intuitive than previous measures, the I^2 has become widely used. This quantifies inconsistency across studies, moves the focus away from testing whether heterogeneity is present to assessing whether the heterogeneity, that many argue is inevitable, will impact on the meta-analysis. A value greater than 50 per cent is often considered to indicate substantial heterogeneity.[41]

Heterogeneity can be caused by various factors, and its presence generates debate about differences in study design (methodological diversity) and differences between studies in key characteristics of the participants, interventions, or outcome measures (clinical diversity). Heterogeneity can be explored by undertaking subgroup analyses or employing meta-regression. In subgroup analyses, the results of one group of studies with a characteristic thought to be causing heterogeneity is compared to those of another group of trials without that characteristic. For example, trials of a new interpersonal therapy for depression may be heterogeneous. The reviewers may have stated, *a priori*, that the new therapy, targeted at young people, may not be effective for those over 30 years of age. Overall, although the trials may have heterogeneous results, if the two subgroups of studies involving people over and under the age of 30 have homogeneous results, it is feasible that the original hypothesis of the reviews regarding age was correct. Meta-regression, is an extension to subgroup analyses that allows the effect of variables, even several simultaneously, to be investigated. Again these variables should be pre-stated and this technique necessitates much high quality data to be meaningful. Even then, the regression is essentially an observational study with all the dangers of unexplained or residual confounding. In mental health reviews, investigation of heterogeneity often generates valuable debate, rather than providing definitive answers.

(e) Reporting bias

There are several ways to assess whether reporting (publication) bias (see above) is operating within a review. The reviews may use a funnel plot technique[56] where the results of a trial are plotted against its size. Large studies with any result, positive or negative, tend to be published. Small positive studies are also usually easily identified, but it quickly becomes apparent if small 'negative' studies have not been found. This could be due to a variety of reasons, but one of which is a selective reporting of positive outcomes.

Sources of systematic reviews

Journals

Systematic reviews are increasingly seen in major journals. These can be identified by simple or comprehensive methodology-specific searches of bibliographic databases such as EMBASE, Medline, or PsycINFO. Examples of these searches can be readily identified[57] but need to be updated periodically to reflect changes in notation or indexing. These search phrases would then be linked to a subject-specific phrase such as 'depression' or 'cognitive therapy', by the word 'and' to limit and focus the number of identified citations.

DARE database

The Database of Abstracts of Reviews of Effectiveness (DARE) is a specialist database containing thousands of citations of systematic reviews of health care. These reviews are assessed according to explicit criteria, and structured abstracts describing methodology and results, and commenting on quality and clinical implications, are also included.

Cochrane reviews

The Cochrane Database of Systematic Reviews is an electronic publication increasingly favoured by clinicians, researchers and those compiling guidelines. It contains the full text and data of reviews undertaken to the most rigorous systematic standards[58] and is updated quarterly. There is often a considerable lag time for traditional journal publication and this can result in the publication of good-quality but misleading systematic reviews. For example, an important systematic review on the effects of family intervention for schizophrenia was published in August 1994.[59] Just 2 weeks later, the same authors re-summated relevant data in an electronic version and the results were much less favourable than had been previously reported.[60] In the considerable period between completion of the paper version and its publication, less favourable trials appeared. Further updates of this review suggest that the trend is continuing. By using electronic publishing, the Cochrane Database of Systematic Reviews allows trends over time to be highlighted and reviews to be maintained.

The Cochrane Library is a collection of databases supplying high-quality evidence to inform all those interested in the evaluation of health care.[45] It is published quarterly on CD-ROM and the Internet, and includes the Cochrane Database of Systematic Reviews, the source of many of the reviews quoted in this

chapter, the DARE abstracts, and The Cochrane Controlled Trials Register.

Summary publications

There are now several periodically updated, systematically compiled, publications designed primarily for busy clinicians. For example, one such publication, Clinical Evidence,[61] now has a comprehensive mental health subset, and is available in short or very short versions, providing clinical 'bottom lines' of relevant systematic reviews or randomized trials.

Further information

The Cochrane Handbook - http://www.cochrane-handbook.org/ contains up-to-date methodological details of systematic reviews and meta-analysis

Clinical Evidence - http://clinicalevidence.bmj.com/ceweb/index.jsp an on-line, regularly updated compendium of systematic evidence summaries

6.1.2 The evaluation of psychological treatment

Paul Crits-Christoph and
Mary Beth Connolly Gibbons

Introduction

Psychotherapy continues to be a widely practised treatment for psychiatric disorders and other problems in living. Since publication in 1952 of the well-known article by Hans Eysenck,[1] in which he claimed that there was no evidence that psychotherapy was effective, there has been an accelerating literature concerned with methodologies for evaluating psychotherapy, as well as specific studies demonstrating the efficacy, or lack thereof, of various psychotherapies. In more recent years, pressures from the government agencies and insurance companies that bear much of the cost of mental health treatments have added to the call for accountability regarding psychotherapeutic treatment.

Despite a vast literature of over 1000 outcome studies of the effects of psychotherapy, questions remain about the role of psychotherapy as a treatment for mental disorders. Extensive meta-analytical reviews of the psychotherapy outcome literature provided evidence that, generally speaking, psychotherapy appears to be efficacious.[2] While encouraging, this information was not particularly useful. As with any medical problem or disorder, the relevant public health clinical question is whether a treatment is beneficial for the presenting problem or psychiatric disorder for which help is sought. Along these lines, a number of efforts have been made at summarizing the results of the psychotherapy outcome literature in terms of what works for different disorders or problems.[3, 4] For example, these efforts have arrived at conclusions such as 'cognitive therapy is efficacious in the treatment of major depressive disorder'.

The simplicity and clinical appeal of such conclusions, about which psychotherapy treatments work for which patient problems, belies a host of more complex issues regarding how one evaluates psychotherapy and makes a decision about whether treatment 'works' or not. Other treatments within psychiatry, such as pharmacotherapy, lend themselves to rather straightforward designs (namely placebo-controlled randomized clinical trials) that permit clear inferences about the efficacy of a treatment approach. In contrast, research on psychotherapy as a verbal interchange between two or more participants does not have the luxury of such straightforward pharmacotherapy research designs. Instead, psychotherapy outcome research is characterized by the use of a variety of research designs and methods that, while often not without limitations to strong scientific inferences about treatment efficacy, can provide incremental scientific advance in the understanding of the usefulness of psychotherapeutic treatments. The aim of the current chapter is to provide an overview of approaches to the evaluation

of psychological treatments. We begin with a discussion of specific research designs employed in psychotherapy outcome research, with a discussion of some of the broad issues that currently guide the selection among these different experimental designs. This is followed by a selective review of assessment strategies for outcome evaluation, with discussion of examples of instruments.

Issues in planning research evaluating psychotherapy

A number of other sources provide a detailed discussion of issues involved in planning a study on psychotherapy, as well as explication of various research designs. In particular, our presentation draws heavily from Kazdin,[5] supplemented with writings that illustrate more recent trends in both design and methodology.

There are, of course, a wide range of decisions to be made in designing an evaluation study of psychotherapy. These decisions affect the choice of patients, therapists, control groups, data analytical strategies, etc. Table 6.1.2.1 presents a list of the types of questions that need to be asked in designing or evaluating a study of psychotherapy outcome. A discussion of some of the key methodological issues that cut across many of the questions raised in Table 6.1.2.1 follows.

Internal versus external validity

An initial important decision in planning an evaluation of psychotherapy outcome, or any intervention, is the relative emphasis on internal versus external validity of the inferences from the investigation. Internal validity refers to the extent to which inferences can be attributed to the intervention *per se*, as opposed to other factors. In order to maximize internal validity, the investigator attempts to control as many of the extraneous factors as possible through a variety of procedures including, among others, random assignment, the use of control groups, assessing subjects in the same ways and at the same point in time, and careful selection of a relatively homogeneous subject sample. With as many factors as possible held constant across treatment groups except for the nature of the intervention, an outcome difference detected between the experimental and control group(s) can be attributed to the intervention, rather than other factors.

External validity, in contrast, refers to the extent to which the results of a study can be generalized to other subjects, settings, treatment durations, and treatment providers other than those used within the specific study. In regard to the evaluation of psychotherapy outcomes, external validity is often invoked to raise the question of whether study results pertain to the 'real world' in which psychotherapy is practiced—the diverse set of patients, therapists, and settings occurring in the community that may be quite different from the conditions of an investigation conducted in a research setting.

Clearly, both internal and external validity are important, but it is difficult to maximize each within the context of the same study. Studies of homogeneous patient samples, for example, may have high internal validity, but generalize poorly to the mix of heterogeneous patients seen in clinical practice. The relative merits of studies with high internal versus external validity have been a source of ongoing debate among psychotherapy outcome researchers.

Different research designs are more or less appropriate depending upon the scientific question of interest. For example, the process of developing and testing new treatments generally proceeds stepwise, beginning with individual case reports and then progressing to an 'open-label' (a term derived from pharmacotherapy research) trial involving the application of a single treatment to a relatively small group of patients. Following an open-label trial, a promising treatment would then be tested within the context of a controlled, efficacy trial. In this efficacy trial, the treatment would be tested under ideal circumstances (for instance, by highly trained clinicians). If an effect is found in the controlled efficacy trial, a controlled, effectiveness trial is the next step. In this effectiveness trial, the treatment would now be tested under more 'real world' conditions. This line of research is oriented towards understanding whether the treatment *per se* is responsible for change (efficacy trial) and whether the effect generalizes (effectiveness trial).

Naturalistic studies represent an alternative type of effectiveness trial in which the scientific question is usually not a focus of type of treatment. Instead, such studies might examine the relationship of patient characteristics, therapist factors, or length (dose) of treatment to outcome.

Selection criteria for psychotherapy outcome studies

The choice of selection criteria for a psychotherapy outcome study depends, of course, on the nature of the research question to be asked. From a public health perspective, samples are usually chosen based upon the presence of a discrete disorder or problem that has significance to society. The selection of the target disorder, however, is only the beginning of the selection process. For studies of DSM Axis I non-psychotic disorders, it is typical that other major psychotic disorders such as schizophrenia and bipolar disorder are excluded from the study. However, there is wide variability across research studies in the extent to which other Axis I and Axis II disorders are included in a study or not.

This aspect of selection criteria relates primarily to the internal versus external validity distinction discussed above. Studies that emphasize internal validity will probably exclude many comorbid diagnoses, while studies that maximize external validity will tend to be more inclusive. As the comorbidities among Axis I diagnoses can be high, the impact on the nature of the patient sample selected can be considerable.

Naturalistic studies that focus on psychotherapy *per se*, rather than public health concerns, are oriented towards external validity and typically do not have restrictive selection criteria. For these studies, the question is 'how effective is psychotherapy for the types of patients that end up in psychotherapeutic treatment in the community?' Thus, few, if any, selection criteria are specified.

One particular selection problem that affects any type of psychotherapy outcome study is whether or not patients currently treated with psychotropic medication are included in the evaluation study. Once again, from the point of view of internal validity—attempting to attribute the treatment outcome to the psychotherapy treatment *per se*—patients on concurrent medication treatment are usually excluded. In contrast, external validity concerns would lead to the inclusion of patients on medications, since increasing numbers of patients in the community with anxiety and affective

Table 6.1.2.1 Selected questions to raise in planning a study of psychotherapy

Sample characteristics
1 Who are the subjects and how many of them are there in this study?
2 Why was this sample selected in light of the research goals?
3 How was this sample obtained, recruited, and selected?
4 What are the subject and demographic characteristics of the sample (e.g. sex, age, ethnicity, race, socio-economic status)?
5 What, if any, inclusion and exclusion criteria were invoked (i.e. selection rules to obtain participants)?
6 How many of those subjects eligible or recruited actually were selected and participated in the study?
7 With regard to clinical dysfunction or subject and demographic characteristics, is this a relatively homogeneous or heterogeneous sample?
Design
1 How were subjects assigned to groups or conditions?
2 How many groups were included in the design?
3 How are the groups similar and different in how they are treated in the study?
4 Why are these groups critical for addressing the questions of interest?
Procedures
1 Where was the study conducted (setting)?
2 What measures, materials, equipment, and/or apparatus were used in the study?
3 What is the chronological sequence of events to which subjects were exposed?
4 What intervals elapsed between different aspects of the study (assessment, treatment, follow-up)?
5 What variation in administration of conditions emerged over the course of the study that may introduce variation within and between conditions?
6 What procedural checks were completed to avert potential sources of bias in implementing the manipulation and assessment of dependent measures?
7 What checks were made to ensure that the conditions were carried out as intended?
8 What other information does the reader need to know to understand how subjects were treated and what conditions were provided?
Therapists
1 Who are the therapists, and why are these individuals selected?
2 Can the influence of the therapist be evaluated in the design as a 'factor' (as in a factorial design) or can therapist efforts be evaluated within a condition?
3 Are the therapists adequately trained? By what criteria?
4 Can the quantity and quality of their training and implementation of treatment be measured?
Treatment
1 What characteristics of the clinical problem or cases make this particular treatment a reasonable approach?
2 Does the version of treatment represent the treatment as it is usually carried out?
3 Does the investigation provide a strong test of treatment? On what basis has one decided that this is a strong test?
4 Has treatment been specified in manual form or have explicit guidelines been provided?
5 Has the treatment been carried out as intended? (Integrity is examined during the study but evaluated after it is completed.)
6 Can the degree of adherence of therapists to the treatment manual be codified?
7 What defines a completed case (e.g. completion of so many sessions)?
Assessment
1 If specific processes in the clients or their interpersonal environment are hypothesized to change with treatment, are these to be assessed?
2 If therapy is having the intended effect on these processes, how would performance be evident on the measure? How would groups differ on this measure?
3 Are there additional processes in therapy that are essential or facilitative to this treatment, and are these being assessed?
4 Does the outcome assessment battery include a diverse range of measures to reflect different perspectives, methods, and domains of functioning?
5 What data can be brought to bear regarding pertinent types of reliability and validity for these measures?
6 Are treatment effects evident in measures of daily functioning (e.g. work, social activities)?
7 Are outcomes being assessed at different times after treatment?
Data evaluation
1 What are the primary measures and data upon which the predictions depend?
2 What statistical analyses are to be used and how specifically do these address the original hypotheses and purposes?
3 Are the assumptions of the data analyses met?
4 What is the likely effect size that will be found based on other treatment studies or meta-analyses?
5 Given the likely effect size, how large a sample is needed to provide a strong powerful test of treatment (e.g. power ≥ 0.80)?
6 Are there subdivisions of the sample that will be made to reduce the power of tests of interest to the investigator?
7 What is the likely rate of attrition over the course of treatment, and post-treatment and follow-up assessments?
8 With the anticipated loss of cases, is the test likely to be sufficiently powerful to demonstrate differences between groups if all cases complete treatment?
9 If multiple tests are used, what means are provided to control error rates?
10 Prior to the experimental conditions, were groups similar on variables that might otherwise explain the results (e.g. diagnosis, age)?
11 Are data missing due to incomplete measures (not filled out completely by the subject(s) or loss of subjects)? If so, how are these handled in the data analyses?
12 Will the clinical significance of client improvement be evaluated and if so by what method(s)?
13 Are there ancillary analyses that might further inform the primary analyses or exploratory analyses that might stimulate further work?

disorders are receiving psychotropic medications for their problems. Often, a compromise is struck: patients on medications are eligible for the psychotherapy study as long as they (and their prescribing doctor) agree to maintain a stable dosage of the medication for the duration of the psychotherapy study.

Treatment standardization

Psychotherapy efficacy research, like pharmacotherapy research, requires that the treatment be standardized. Such standardization serves two related purposes. First, from a clinical point of view, it is necessary that the treatment be clearly specified, so that any conclusions about differential treatment efficacy can be translated into clear treatment recommendations. From a research point of view, treatment standardization allows studies to be replicated. In addition, by making the delivery of a treatment more standardized, differences between therapists and the statistical problems that result from the non-independence that 'therapist effects' introduce can be avoided.[6]

Standardization of pharmacological interventions is relatively straightforward—a per-day dosage (or range of dosages) is set in advance. But for psychotherapy, how can something so complex as patient–therapist dialogue be standardized? The central ingredient in standardization of a psychosocial treatment is a treatment manual. A psychotherapy manual describes the treatment in detail, with case examples and instruments for psychotherapists. Some treatment manuals, particularly those coming from a cognitive behavioural perspective, present a highly systematized step-by-step programme which therapists follow over the course of therapy. The relative success of treatment manuals in standardizing psychotherapy has been supported by a meta-analysis,[7] which documented that studies employing treatment manuals had fewer outcome differences between therapists compared with studies that did not employ treatment manuals. Thus, when a treatment manual is used, therapists appear to produce relatively more uniform outcomes. In contrast, when no treatment manual is used, therapists differ considerably in their typical outcomes with patients; suggesting that different therapists are likely to be conducting sessions in discrepant ways, with some therapists producing more favourable outcomes and other therapists producing less favourable outcomes.

Treatment standardization, however, does not simply translate to the use of a treatment manual. A variety of steps are needed to ensure that therapists are delivering the intended treatment (Table 6.1.2.2), including: the careful selection of therapists; training of therapists in the intended modality using a treatment manual; certification of therapists based upon their adherence to the treatment model during training; and continuing adherence and competence monitoring of therapists during a clinical trial.

Concerns have been raised about the 'treatment manual' concept applied to less directive treatments such as psychodynamic therapy. The belief is that session-by-session manuals would remove the essence of good psychotherapy, and good dynamic therapy in particular, by making treatment artificially rigid and taking away the necessary clinical flexibility and creativity. Psychodynamic treatment manuals, however, are perhaps better described as 'guides', which specify the principles of treatment but do not overly constrain the necessary clinical flexibility and creativity. The flexibility of treatment is fully retained through the principle of tailoring the treatment intervention to the specific idiosyncratic issues that are salient for each patient. The actual learning of the practice of treatment is accomplished through supervision in the application of the treatment manual. Because dynamic treatment manuals are less like 'cookbooks', there may be a greater reliance on the supervision process compared with perhaps more straightforward behavioural treatments.

Table 6.1.2.2 Steps involved in the standardization of psychotherapy for outcome research

Selection of therapists
Training of therapists using a treatment manual
Certification of therapists based upon adherence to the treatment model
Continued assessment of therapist adherence and competence during a clinical trial

Research designs

Unlike pharmacological research where a single form of research design (placebo-controlled study) dominates the literature, psychotherapy researchers have employed a host of different research designs to understand the effects of psychotherapy. Some of the more common designs are listed in Table 6.1.2.3 and are explicated in the next section.

Single-case designs

Clinical evaluation of the effects of psychotherapy dates back to Freud's descriptions of individual cases in treatment. However, methods to systematically examine the effects of interventions with individual patients were developed by behaviour therapists.[8] These single-case experiments rely on comparing patient responses to differing experimental conditions over time. Typically, such single-case studies begin with an extended baseline period where patient behaviours or symptoms are recorded without any intervention. Then, different intervention phases are introduced, usually followed by more baseline (no intervention) assessment phases.

While experimental, single-case designs lend themselves well to the investigation of behavioural treatments that include a focus on immediate overt behaviour, such designs have rarely been employed with other verbal psychotherapies that emphasize longer term processes such as patient psychological growth and functioning. The generalizability of findings from single-case research is another limitation to this form of research.

Table 6.1.2.3 Common research designs for the evaluation of psychotherapy

Single-case designs
Randomized controlled trials with non-specific or psychological 'placebo' control
Comparative designs
Dismantling or additive designs
Comparisons with medication and pill placebos
Naturalistic designs

Randomized controlled trials

Random assignment of subjects to treatment and control conditions is generally viewed as the preferred method of evaluating the effects of interventions in psychiatry, and in medicine in general. However, perhaps the single most vexing problem in research of psychotherapy outcome is the design of control groups. In pharmacotherapy research, a pill placebo (with 'double blinding', i.e. the patient and the doctor are unaware of treatment assignment) serves to control for all elements of treatment except for the chemical ingredient of interest. Thus, the overall effects of treatment are the sum of the specific effect of the chemical agent plus the effects of 'extraneous' or non-specific factors such as patient expectancy, hope, and aspects of the doctor-patient relationship. With psychotherapeutic treatments, it is less clear which aspects of treatment are specific and which are non-specific. Furthermore, designing a credible control treatment that contains only the non-specific elements of the treatment package is inherently difficult.

(a) Types of control groups

A variety of types of control conditions have been implemented in psychotherapy efficacy studies. One common form of control group is the 'waiting-list' control. Patients are randomly assigned to either the experimental group or to delayed treatment. While such a control condition appears to control for the passage of time (i.e. patients generally improve over time even without treatment), assignment to a waiting-list control condition is likely to immediately change patient hope and expectations about relief of their problem. Patients in the waiting-list condition will not expect to improve until they actually receive treatment, while patients assigned to the experimental condition will likely be more hopeful about change. Thus, the treatment and control conditions are not balanced with regard to expectancy or other non-specific factors such as regular meetings with a competent caring professional. The potential superiority of the experimental condition over the control condition cannot be attributed to the hypothesized active ingredients in the experimental condition. Nevertheless, such waiting-list controls can serve as a useful initial step in evaluating a treatment.

A scientifically stronger type of control group for psychotherapy evaluation studies is one that involves regular meetings with a psychotherapist, but does not contain certain important hypothesized active elements. Some forms of supportive psychotherapy have been used as a control group in this regard. For example, in evaluating the efficacy of cognitive behavioural therapy for posttraumatic stress reactions, a supportive therapy control condition has been successfully used.[9] With some psychotherapy treatments, however, the supportive elements are an important part of the overall treatment model and are hypothesized to be curative in their own right. In this case, a supportive psychotherapy control condition is not appropriate for evaluating the efficacy of the overall package. In fact, sometimes supportive therapy has been found to be superior to other therapies.[10]

Comparative designs

An alternative to attempting to create an adequate psychological 'placebo' control is to only compare active treatments rather than comparing active treatments to 'placebo' control groups. However, rather than solve the problem of how to evaluate the efficacy of a psychotherapeutic intervention, comparative designs simply change the scientific question from 'Is this treatment efficacious?' to 'Which treatment works best?' Comparative designs are generally only informative if one active treatment proves to be more effective than another. If, as is commonly the case in psychotherapy studies, both active treatments produce equivalent results, the investigator is left not knowing whether both treatments are effective, or whether both treatments are non-effective (beyond the effects of non-specific elements).

Dismantling designs

Dismantling designs are an alternative to psychological placebos, waiting lists, or comparative designs. In a dismantling design, the full clinical treatment package is compared with the full package minus one element in order to establish which elements are necessary and sufficient for change. Variations on this theme include 'additive' or constructive designs that examine whether adding a new element enhances the efficacy of a treatment package.

As an example, dismantling designs have been usefully applied in the evaluation of the behavioural treatment of obsessive-compulsive disorder. The full treatment package involving exposure and response prevention techniques has been compared with each of the individual components of the package.[11] Patients were randomly assigned to either the full exposure and response prevention package, exposure alone, or response prevention alone. Those receiving the full package improved significantly more than did the patients in either of the control treatments. At follow-up assessments, 80 per cent of patients receiving the full package remained improved at follow-up, whereas only 27 per cent of those in the single components groups remained 'improved'.

The advantage of dismantling strategies in psychotherapy research is clear. Causal statements about differences in improvement between treatment conditions can be made, since all factors (including non-specific elements) except one are held constant, and the problems involved in other types of control groups are avoided. These designs, in general, should probably be used more often than they are. Some psychotherapies, however, may not easily lend themselves to such dismantling strategies. Moreover, it may be premature to attempt to dismantle a treatment package when questions about the efficacy of the whole package need to be resolved first.

Comparisons with medication

One type of design for the evaluation of psychotherapy that has increased in importance consists of comparisons to medication treatments. An example of this type of study is a recent investigation comparing cognitive therapy, medication (paroxetine), and pill placebo in the treatment of moderate to severe major depressive disorder.[12] The rationale for this design is that the medication group provides the standard reference condition with established efficacy. The pill-placebo group allows for establishing that the particular sample in the study showed the typical medication-placebo difference that would be expected (in other words, the sample was not unusual), and controls for some of the non-specific effects of the psychotherapy (for example, regular visits to a professional, positive expectancies for change). While the pill placebo is clearly not a perfect control condition for psychotherapy, it serves as a practical function—i.e. if a specific psychotherapy is not better than a pill placebo, should the psychotherapy be pursued as a treatment option?

Attribute by treatment interactions

An emerging emphasis in psychotherapy outcome research is the investigation of attribute by treatment interactions. Partly influenced by the common finding of no differences between psychotherapies, as well as the desire to make more specific clinical recommendations, investigators have hypothesized that certain matches of client characteristics and treatment modalities produce superior outcomes. One initial problem with pursuing potential matches of patient characteristics with the type of treatment is that there are a large number of potential variables (for instance, various combinations of diagnosis, therapist, treatment, patient's problem, setting).

The investigation of patient-treatment matches has intuitive clinical appeal, as most therapists believe that some patients seem to 'fit' a form of treatment better than others. Research on patient-treatment matching, however, is inherently difficult, particularly because large sample sizes are generally needed to adequately test interaction effects. Two of the largest randomized clinical trials ever performed with psychotherapeutic treatments have failed to find much support for specified patient-treatment interactions.[13,14] Thus, it remains to be seen whether aptitude by treatment-interaction designs will provide useful information about psychotherapy outcome.

Naturalistic studies

Naturalistic designs are used to examine issues such as the effectiveness of treatments in real-world setting with the types of patients that typically seek treatment. For example, the effectiveness of cognitive behavioural therapy for panic disorder and agoraphobia has been examined in a naturalistic study.[15] The authors report that outcomes were better for patients receiving naturalistic cognitive behaviour therapy, compared to a non-randomized wait-list control group. However, the overall outcomes for cognitive behavioural therapy were not as robust as previously seen in controlled clinical trials. While this form of naturalistic study has several advantages, including the fact that the data are drawn from actual clinical services in the real world, such data do not add to an understanding of which forms of psychotherapy work and which do not, and they do not provide strong causal statements. Hypotheses generated from naturalistic studies can inform the planning of experiments that can make stronger statements about causality. In addition, naturalistic studies provide useful descriptive information about the service delivery system.

Strategies for assessing psychotherapy outcome

Once a particular experimental design has been decided upon, the next crucial question in evaluating psychotherapy pertains to the selection of instruments for the study. Instruments include those needed to adequately select a patient population, such as measures of psychiatric diagnoses and initial symptomatology. Therapeutic change is often evaluated on a broad range of measures including dimensional measures of symptoms, personality, self-esteem, quality of life, and functioning in a variety of areas (for example, social and occupational functioning). In addition, the impact of treatment on specific theoretical constructs (mediators) can be examined. Discussion of each of these domains follows.

Patient selection

(a) Diagnosis

Because the identification of effective therapies for specific disorders is an important research priority from a public health point of view, an accurate and thorough assessment of these disorders is central to the evaluation process. The most widely used instrument for assessing the major DSM-IV Axis I diagnoses in research settings is the Structured Clinical Interview for DSM-IV.[16] The format of this semi-structured interview, with questions grouped by criteria and by diagnosis, allows an experienced clinical evaluator to assign diagnosis as the interview progresses. It is most commonly used to select subjects according to study inclusion or exclusion criteria or to characterize a study population. It can also be used to document change in diagnostic status post-treatment or over the course of a longitudinal study.

(b) Symptom measures

Whereas categorical measures are critical for the selection of a relatively homogeneous patient sample at intake, the evaluation of patient improvement requires the measurement of symptoms and functioning on a continuum. These continuous measures of the amount, timing, and nature of change are typically the primary outcomes of intervention studies. They include ratings of a single construct representing a core feature of the disorder, scales which cover the range of symptoms present in a general diagnostic category (e.g. rating scales of 'depression' or 'anxiety'), and measures that cut across many diagnoses and are indicative of overall psychopathology or symptomatology. At each of these levels of assessment, one can find both clinician-rated and self-report tools; for practical reasons, the self-report method predominates.

Measures of therapeutic change

(a) Dimensional assessment of core symptoms

In general, the more circumscribed and behavioural the problem, the simpler the assessment method. For some disorders, investigators have found that single-item measures of target symptoms suffice. For example, treatment studies of panic disorder and bulimia rely on self-reporting the number of 'episodes' that occur in a well-defined interval, such as the past week or the past month. Daily diaries are often used to facilitate recall and to enhance accuracy. Obsessive-compulsive symptoms can be assessed by Likert-type ratings of the severity of compulsions and obsessions, and the improvement of specific phobias by ratings of fear and avoidance. Severity ratings can be completed by both the patient and an independent evaluator.

For most disorders, core symptom measures of greater psychometric sophistication are needed to supplement simpler methods. The Penn State Worry Questionnaire,[17] for example, assesses the central feature of generalized anxiety disorder, and the Yale-Brown Obsessive-Compulsive Scale[18] measures the various symptoms that occur with obsessive compulsive disorder. In eating disorder research, the self-report EDI-2[19] and the Eating Disorder Examination[20] are commonly used.

In depression research, the Inventory of Depressive Symptomatology[21] is the result of efforts to develop a continuous measure of the nine DSM symptoms for major depressive episode. Other widely used scales include the interview-based Hamilton Rating Scale for Depression[22] and the self-report Beck Depression

Inventory,[23] although these instruments do not map directly on to DSM criteria. The severity of specific manic symptoms can be assessed with either the Bech-Rafaelsen Mania Scale[24] or the Young Mania Rating Scale.[25]

(b) General measures of anxiety, depression, and other symptoms

The Hamilton Rating Scale for Depression and the Beck Depression Inventory are often administered concurrently to provide clinician and patient perspectives on the level of depression, and are used both as primary outcome measures in studies of depression, and as secondary measures in treatment studies of other disorders. Because of the comorbidity of Axis I disorders in general, and the interrelatedness of anxiety and depression in particular, it is useful to include assessments of both depression and anxiety. General measures of anxiety include the Hamilton Anxiety Rating Scale[26] and the Beck Anxiety Inventory.[27] These general measures are used with a variety of diagnostic groups, but it is important to remember that they have varying relevance to different disorders within a given diagnostic group. For example, a score on the Beck Anxiety Inventory might be a good index of the severity of the generalized anxiety disorder, but be less informative about specific phobias or obsessive-compulsive behaviour.

(i) Psychotic symptoms

In psychological treatment studies of severe depression, mania, and psychotic disorders, it is often necessary to assess the level of psychotic symptomatology. The Brief Psychiatric Rating Scale[28] is recommended for this purpose. It has items covering five symptom clusters: thinking disturbance, anxious depression, withdrawal/retardation, hostile/suspiciousness, and agitation/excitement. As with other clinician-rated scales, it should be administered by an experienced clinician who has received standardized training on this instrument.

(ii) Substance use problems

Because of the frequent comorbidity of substance use problems with other Axis I disorders, it is important to evaluate the level of drug and alcohol use when screening patients for study enrollment or when characterizing a sample. The substance use modules of the DSM-IV Structured Clinical Interview are frequently used for this purpose. The Addiction Severity Index[29] has the advantage of providing more comprehensive and detailed information on problem areas associated with abuse, and yields scores that can be compared across patients, and from the beginning to the end of treatment. Because it is a rather time-consuming interview, it is recommended only in instances when the rates of substance use and related problems are expected to be high and their measurement is a research priority.

(c) Measure of global psychological functioning/ psychopathology

The rationale for using measures that cover a broad range of psychopathology is that they characterize the sample in terms of associated symptoms (i.e. symptoms other than those of primary interest) and provide a global measure of subjective distress. They have also proved to be quite useful in detecting treatment-related changes in evaluations of diverse psychotherapies. A popular self-report measure of general psychopathology is the SCL-90-R (and its abbreviated version, the Brief Symptom Inventory).[30] The SCL-90-R is a 90-item scale; the Brief Symptom Inventory is composed of 53 items. Both yield nine symptom dimensions and three global indices of distress. Because correlations between the two instruments are very high, it is recommended that the latter be used when time is an issue or when this measure is included as part of a larger core battery of assessment.

(d) Measures of self

Many psychotherapies explicitly attempt to improve self-esteem, self-concept, and self-confidence, and therefore it is relevant to examine the extent to which treatment successfully impacts on these domains. One of the oldest and most widely used measures of self-esteem is the Rosenberg Self-Esteem Scale,[31] an easily administered 10-item Likert-type scale yielding a uni-dimensional indicator of global self-esteem. More recent work in this area aims to distinguish other self-related constructs (such as self-concept) from self-esteem, develop more theoretically based multifactorial models, and improve upon the psychometrics of earlier measures. Some resulting scales, such as the Beck Self-Concept Test[32] or the Selves Questionnaire,[33] are appropriate for patients with a fairly wide range of psychiatric diagnoses.

(e) Personality assessment

Personality variables typically appear in evaluations of psychological treatment as either primary outcomes (as in the study of psychotherapy for personality pathology), or as prognostic indicators in studies of other Axis I disorders. They might also be included as part of a larger effort to thoroughly describe the patient sample. There are two ways to approach the evaluation of personality within these contexts: determination of the presence or absence of a DSM personality disorder, and dimensional ratings of personality features.

(i) Categorical: DSM-IV Axis II

Treatments that target specific personality disorders tend to rely on the first approach to assessment, namely the use of interviewer-administered instruments which assess criteria for the 10 specific personality disorders listed in the DSM-IV. The Structured Clinical Interview for DSM-IV Axis II[34] was designed for this purpose. A positive feature of this assessment is its efficiency in eliciting the information required to assign Axis II diagnoses, especially when used in conjunction with the self-report Personality Disorder Questionnaire.

(ii) Dimensional

Dimensional methods of assessing personality arise from either theoretical or factor-analytical models of the essential elements of personality structure. The Five Factor Model[35] proposes that personality, in both patient and non-patient samples, can be measured along five dimensions: neuroticism, extraversion, openness to experience, agreeable, and conscientiousness. Extremes of these traits define personality pathology. This model and several instruments used to generate scores on these factors, including the self-report NEO Personality Inventory and NEO-PI-R[36] and a semistructured interview (the Structured Interview of the Five-Factor Model of Personality[37]), have received considerable empirical support in both clinical and non-clinical samples.

Another dimensional measure of personality is the SWAP-200.[38] This instrument consists of a set of 200 personality-descriptive statements designed to be used by a clinician who knows a given patient well. The clinician arranges the 200 statements into eight categories, from those that are not descriptive to those that are highly descriptive of the patient. These scores are then used to generate both individualized, ideographic case descriptions as well as dimensional scores for the 10 personality disorders included in DSM–IV.

The categorical and dimensional methods are not entirely mutually exclusive and both are valuable in ongoing research into the phenomenology, aetiology, correlates, and treatment of personality disorder.

(f) Measures of functioning and quality of life

In recent years, the definition of mental health has been broadened to encompass its more positive, and somewhat paradoxically, its more negative aspects. Mental health is now viewed as more than the absence of illness, but the illness itself is increasingly seen as chronic and quite disabling. This has prompted investigators to turn their attention to outcomes other than symptom change—to evaluate fully the effectiveness of a psychotherapeutic intervention means to document its broad effect on a number of relevant domains including social/interpersonal functioning, work functioning, and quality of life.

(i) Overall functioning

Incorporated into the DSM system as a separate axis (Axis V), the Global Assessment of Functioning scale[39] (GAF) is the most widely used measure of psychosocial impairment. Clinicians rate on a scale of 1 to 100 the current level of functioning, or if desired, the highest or lowest level of functioning within some designated time period. General well being and functioning are also assessed with scales that have been developed for the routine outcome assessment in clinical practice, rather than for efficacy trials. An example is the OQ-45,[40] a self-report measure consisting of three subscales representing broad content areas: (1) symptom distress, (2) interpersonal relations, and (3) social role (dissatisfaction and distress in tasks related to work, family roles, and leisure life).

(ii) Social and occupational functioning

The assessment of role performance has a fairly long history in psychotherapy research. The Social Adjustment Scale (SAS)[41] was developed to document the level in functioning in six areas: work as worker, 'housewife', or student; social activities; relationship with family; relationship with spouse; parental responsibilities; member of a family unit. There is much documentation of its psychometric properties and clinical utility, and it has been used with a wide range of adult outpatients. A unique feature of the Longitudinal Interval Follow-up Evaluation (LIFE)[42] is that it was designed to collect information on psychosocial functioning (as well as on diagnosis and symptoms) over longer periods of time. In the hands of trained evaluators, it is a structured interview that has been shown to have good reliability.

The concern among both scientists and health-care managers about the cost-effectiveness of specific treatments has generated interest in more comprehensive assessments of work functioning and productivity. Endicott and Nee developed the Endicott Work Productivity Scale,[43] a self-report instrument containing 25 items designed to be sensitive to more subtle differences among patients in work attitudes and behaviour.

Two self-report instruments measuring interpersonal difficulties have been used in studies of psychotherapy: The Inventory of Interpersonal Problems[44] and the Dyadic Adjustment Scale.[45] The Inventory of Interpersonal Problems is a 127-item self-report measure with high internal consistency and test-retest reliability of each of the six subscales: assertive, social, intimate, submissive, responsible, and controlling. The Dyadic Adjustment Scale is a 32-item scale designed to assess the severity of relationship discord in married and unmarried cohabiting couples, with higher scores indicating better adjustment. Responses on the Dyadic Adjustment Scale discriminate between distressed and non-distressed couples and yield a total score based on the factors of dyadic consensus, dyadic cohesion, dyadic satisfaction, and affectional expression.

(iii) Quality of life

The most promising of the quality-of-life measures for mental health outcome research are those based on a broad definition of quality of life—covering role functioning and social-material conditions as well as life satisfaction or well being—and which can be applied across disorders and across treatments. However, more widespread use and testing of quality-of-life instruments is needed to establish their utility and to help resolve a number of important measurement issues, including the value of more 'objective' indices of quality of life and the relationship between symptoms and quality-of-life judgments.

(g) Utilization of treatment services

The impact of a treatment on usage of other health-related services is a factor to be considered in determining the cost-effectiveness of that treatment. One broad instrument designed to assess changes in service usage over the course of treatment is the Treatment Services Review.[46] This is a 5-minute interview that documents the number and types of treatment services received during rehabilitation from substance abuse, but it also can be adapted for use with other clinical populations.

(h) Theory-based measures

Evaluation of the hypothesized important psychological constructs of a particular psychotherapy can serve as outcome measures in their own right or as mediators of change in symptoms and functioning. For example, the cognitive model of depression holds that distorted cognitions about the self and world are responsible for generating and maintaining negative emotions. Measures of depressogenic cognitions are therefore included as outcomes and mediators of symptom change in studies of cognitive therapy for depression. The Hopelessness Scale[47] is a 20-item self-report scale that assesses the hopelessness and pessimism associated with suicidal ideation and intent. The Dysfunctional Attitudes Scale[48] is a 40-item index of general attitudes and beliefs hypothesized by Beck and colleagues to underlie a propensity for depressive thinking, whereas the Automatic Thoughts Questionnaire[49] covers 30 negative thoughts proposed to occur during a symptomatic depressed state.

In regard to psychodynamic psychotherapy, theory-specific mediators include measures of core conflicts[50] and self-understanding.[51]

Conclusions

Of all the treatments in medicine and psychiatry in particular, the evaluation of psychotherapy offers some of the greatest challenges to researchers. A wide variety of research designs and instruments have been employed, with distinct advantages and disadvantages to each. No one study of psychotherapy can answer all the important questions that need to be asked. Given the complexity of research on psychotherapy, knowledge accumulates slowly. Despite the problems, complexities, and slow pace of scientific advance,

psychotherapy outcome research now has the tools and emerging findings to begin to influence the practice of psychotherapy and mental health treatments in general. We expect that in the next decade methodological advances in the evaluation of psychotherapy will lead to a stronger link between research and practice.

6.2

Somatic treatments

Contents

6.2.1 General principles of drug therapy in psychiatry

J. K. Aronson

The successful use of psychotropic drugs demands an understanding of their pharmaceutical, pharmacokinetic, and pharmacodynamic properties.

- *Pharmaceutical properties*: Pharmaceutical formulations can be manipulated to produce different durations of action, for example the use of oily emulsions of antipsychotic drugs in depot formulations.
- *Pharmacokinetic properties*: Pharmacokinetics is the mathematical description of the disposition of drugs in the body by absorption, distribution (to plasma proteins and tissues), and elimination (usually by hepatic metabolism and renal excretion). Differences in drug disposition determine differences in dosage regimens and are important for drug interactions.
- *Pharmacodynamic properties*: Pharmacodynamics is the study of the pharmacological actions of drugs and how actions at the molecular level are translated, via actions at cellular, tissue, and organ levels, into therapeutic or adverse effects. The known pharmacological actions of psychotropic drugs are not necessarily the actions that produce their therapeutic or adverse effects.

Dosage regimens

A drug dosage regimen is a recipe for drug administration, intended to produce the desired therapeutic effect with a minimum of unwanted effects. It is described in terms of the pharmaceutical formulation, the dose, and the frequency and route of administration used. The duration of administration is also important.

In treating any condition, it is best to learn initially to use a few drugs, preferably well-established ones, and to expand one's repertoire with increasing experience.

The choice of drug depends firstly on the indication—obviously an antidepressant will be the drug of choice for a patient with depression, if drug therapy is thought to be required. The choice of

antidepressant will depend on features of the disease and other factors. For example, some antidepressants are more sedative and anxiolytic than others, and can be helpful in patients who are agitated. The avoidance of adverse effects or interactions can also dictate the choice; for example, tricyclic antidepressants should be avoided in men with prostatic hyperplasia and selective serotonin reuptake inhibitors (SSRIs) should not be used in children, because of the increased risk of suicidal ideation.

It is usual to start therapy with published dosage recommendations, generally beginning at the lower end of the recommended dosage range and monitoring for a therapeutic effect. A common error is to give a starting dose of a drug and then to add or substitute another drug if the first does not work. This is usually bad practice. If the desired effect does not occur with the initial dosage, increase the dose gradually until the effect occurs or the upper limit of the recommended range is reached (although adverse effects may limit this process). Only then should another drug be tried. Sometimes a poor response is due to poor adherence to therapy; careful explanation of the condition and the need for therapy helps.

Psychotropic drugs can be given orally or parenterally, and as immediate-release or modified-release formulations. Most drug administration is oral, but parenteral therapy can be useful to guarantee administration (e.g. depot formulations in schizophrenia) and for a quicker onset of action (e.g. in the treatment of acute mania). Modified-release products are used for long-term therapy. They can be given less often and produce a smoother profile of blood concentrations (Fig. 6.2.1.1).[1] The advantage of intramuscular modified-release (depot) formulations of antipsychotic drugs is that drug delivery can be ensured by supervised infrequent administration (say every 2 weeks). Different modified-release formulations of the same compounds have different release characteristics and are not interchangeable; for example, when prescribing a modified-release oral formulation of lithium always give the patient the same formulation and specify the brand name on the prescription.

Combination formulations (e.g. a phenothiazine plus a tricyclic antidepressant in a single tablet) do not allow flexibility of prescribing and should generally be avoided. Important exceptions include combination analgesic formulations (e.g. co-codamol, which contains paracetamol plus codeine) and combinations of levodopa with a dopa decarboxylase inhibitor (benserazide or carbidopa).

Treatment of children

There are no uniform rules for determining dosage regimens in children. Pharmacokinetics and pharmacodynamics are different for some drugs but not others.

- Absorption is not greatly different from absorption in adults.
- The distribution of water-soluble drugs is different, but psychotropic drugs are lipid-soluble.
- Protein binding is reduced in neonates; phenytoin is affected.
- Hepatic oxidative metabolism and glucuronide conjugation are deficient in neonates, and mature at variable rates; this is important for psychotropic drugs.
- Glomerular and renal tubular functions are immature in neonates and take about 6 months to reach adult values.

If a child needs a psychotropic drug, consult the manufacturer's literature and always start with a low dosage.

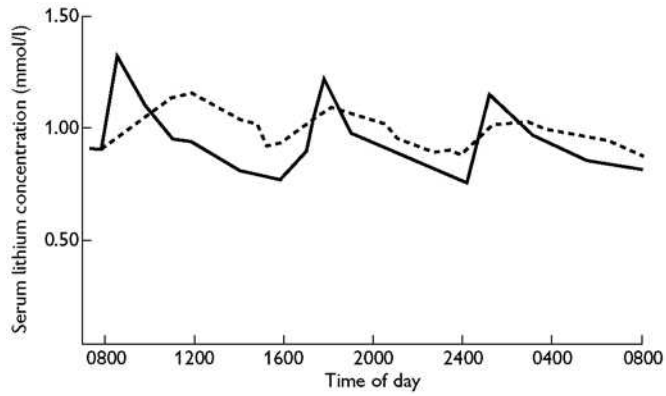

Fig. 6.2.1.1 Administration of lithium in immediate-release and modified-release oral formulations. The immediate-release formulation (solid line) produces rapid peaks of serum concentration and large fluctuations during a dosage interval. In contrast, the modified-release formulation (dotted line) is more slowly absorbed but produces much less fluctuation in serum concentrations. Note also that the apparent half-life of lithium is longer after administration of the modified-release formulation; this is not the true half-life of lithium, but the half-life of its release from the modified-release formulation. (Adapted from A. Amdisen, Variation of serum lithium concentration during the day in relation to treatment control, absorptive side effects and the use of slow-release tablets, *Acta Psychiatrica Scandinavica*, **207**, 55–7, copyright 1969, John Wiley & Sons, Inc.)

Treatment of elderly people

Pharmacokinetic differences in old age are more predictable than in children, but pharmacodynamic changes are variable.

- Absorption is not greatly affected.
- Elderly people have less body fat, and so lipid-soluble drugs may be more highly concentrated in the brain; however, this effect varies unpredictably from drug to drug (e.g. the apparent volume of distribution of diazepam is increased while that of nitrazepam is not).
- Protein binding is reduced in elderly people; phenytoin is affected.
- Hepatic metabolism is reduced in frail but not in fit old people; this effect is proportional to liver size.
- Renal function is impaired with age; use creatinine clearance, measured or estimated (not eGFR), as a guide.
- Inappropriate polypharmacy is common in old people, increasing the risk of drug interactions.

When treating an elderly person with a psychotropic drug always start with a low dosage and increase dosages more slowly.

Pregnancy and breast feeding

Anticonvulsants are teratogenic.[2] For example, sodium valproate has been associated with spina bifida, cardiac malformations, hypospadias, anomalies of the brain and face, coarctation of the aorta, and limb reduction defects.[3]

Few other psychoactive drugs are teratogenic. However, most of them cross the placenta and some can cause withdrawal symptoms in the neonate. The teratogenicity of lithium has been overstated in the past; the main risk is cardiovascular teratogenicity, but although the risk of Ebstein's anomaly is increased, the absolute risk (0.05–0.1 per cent) is still very small;[4] nevertheless, some

advise that it should be avoided or used with caution in the first trimester of pregnancy,[5] and fetal sonography is recommended at 18–20 weeks after first-trimester exposure.[3]

Although most psychoactive drugs are lipid-soluble and therefore enter the breast milk, few do so in high enough amounts to trouble the neonate; if a neonate becomes drowsy while breast feeding, reduce the mother's dosage or stop breast feeding. Lithium appears in the breast milk and can be found in the serum of breast-fed babies in variable concentrations, up to half of those in the mother. Because neonates have immature renal function, some recommend avoiding breast feeding.[6] However, others consider that the benefits of breast feeding to mother and child outweigh the small risk of lithium toxicity.[4] The following advice has been given:[3]

- Educate the mother about the manifestations of toxicity.
- Explain the risks of dehydration.
- Consider partial or total formula supplements during episodes of illness or dehydration.
- Suspend breast feeding if toxicity is suspected.
- Check infant and maternal serum concentrations.

Pharmacokinetics—drug disposition

Most psychotropic drugs are rapidly and well absorbed after oral administration. However, drugs can be removed by various processes before they reach the systemic circulation. The fraction of drug that reaches the systemic circulation is called its systemic availability (or, more commonly, bioavailability).

After oral administration a formulation will generally disintegrate in the stomach and the drug it contains will dissolve in gastric contents. However, drugs are not generally absorbed in the stomach. After gastric emptying they are for the most part absorbed in the jejunum and ileum, and some are absorbed from the colon as well. During transit across the gut wall they may be metabolized by an oxidative isozyme of cytochrome P450, CYP3A4, and can be secreted back into the gut lumen by P glycoprotein. When they enter the portal circulation they may be eliminated by the liver. If hepatic metabolism is extensive, a large amount of drug will be removed during this first passage through the liver. For example, clomethiazole has extensive first-pass metabolism in the liver and its systemic availability is low (about 40 per cent); thus, intravenous doses are considerably lower than oral doses. In severe liver disease, such as cirrhosis, or when there is arteriovenous shunting, this presystemic metabolism is reduced and the systemic availability increases up to 90 per cent; oral doses of clomethiazole should be reduced in liver disease.[7]

In the systemic circulation drugs are bound to plasma proteins and distributed to the tissues. Protein binding is important for drugs that are highly bound (over 90 per cent) and not widely distributed to the body tissues; in those cases protein-binding displacement can result in a large rise in the amount of unbound drug available to the target tissue. This is important for phenytoin, which is 90 per cent bound to plasma albumin and has a low volume of distribution. The binding of phenytoin is reduced when the serum albumin concentration falls (in chronic liver disease, the nephrotic syndrome, protein malnutrition, or the third trimester of pregnancy), when binding to the protein is abnormal (in chronic renal insufficiency), or when another drug (e.g. sodium valproate) causes displacement. Acute displacement causes phenytoin toxicity, but only transiently, because in the case of phenytoin an increase in unbound concentration causes it to be more rapidly eliminated. When measuring plasma phenytoin concentrations in patients in whom protein binding is reduced, the target concentration (and the laboratory will measure total drug, i.e. bound plus unbound) is reduced (see Fig. 6.2.1.2).

In chronic renal insufficiency the protein binding of phenytoin is reduced. This leads to an increase in the unbound plasma (or serum) concentration relative to the total concentration; the target total concentration therefore falls. The shaded area shows the range of plasma phenytoin concentrations that one would generally aim to achieve (the target concentration range) in treating a patient with epilepsy. As renal function deteriorates (indicated here by an increase in serum creatinine concentration), the target range for plasma phenytoin concentration falls from 40–80 μmol/l when renal function is normal to 10–30 μmol/l in severe renal insufficiency.

After absorption and distribution most psychoactive drugs are cleared from the body by hepatic metabolism;[8] impaired liver function, if severe (for the liver has a large capacity), reduces their elimination, and dosages should be reduced.

Lithium is cleared solely by renal elimination and therefore the dosage should be reduced in proportion to the creatinine clearance. Since renal function falls with age, lithium dosages should be lower in older people.[9]

The half-life of a drug is a function of its clearance and its distribution volume: the slower the rate of clearance or the more extensive the distribution the longer the half-life. If a drug is given in a regular maintenance dose, the amount of drug in the body will gradually accumulate; however, as the amount in the body increases, the rate at which it is eliminated also rises, and eventually a plateau (or steady state) is reached when the amount eliminated during a dosage interval equals the dose (the maintenance dose). The time it takes to reach this steady state depends on the half-life

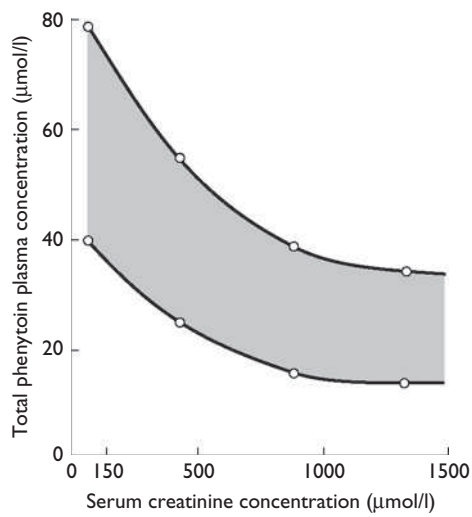

Fig. 6.2.1.2 In chronic renal insufficiency the protein binding of phenytoin is reduced. This leads to an increase in the unbound plasma (or serum) concentration relative to the total concentration; the target total concentration therefore falls. The shaded area shows the range of plasma phenytoin concentrations that one would generally aim to achieve (the target concentration range) in treating a patient with epilepsy. As renal function deteriorates (indicated here by an increase in serum creatinine concentration) the target range for plasma phenytoin concentration falls, from 40–80 μmol/l when renal function is normal to 10–30 μmol/l in severe renal insufficiency (I. Odar-Cederlöf, unpublished data.)

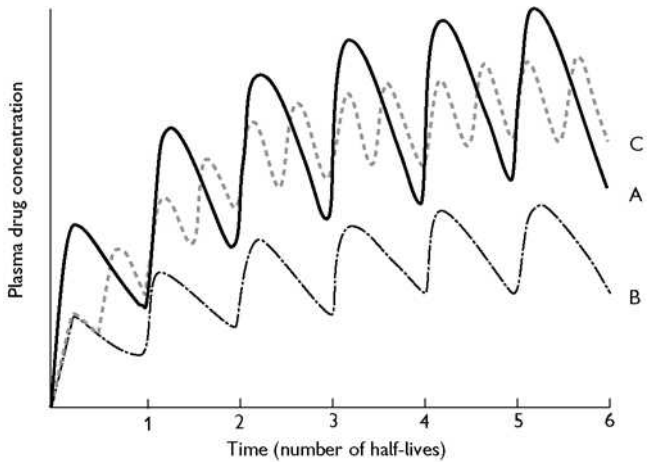

Fig. 6.2.1.3 Curve A—during the regular administration of a maintenance dose of a drug the amount of drug in the body rises after a dose, reaches a peak, and then falls as the drug is distributed to the tissues and eliminated. If another dose is given soon after the first, the plasma concentration will rise by the same amount as before but will fall faster after peaking, since most drugs obey first-order kinetics and the plasma concentration falls exponentially. Thus, when a drug is given repeatedly the mean plasma concentration rises more slowly with each successive dose, until eventually a steady state is reached, when the amount eliminated in a dosage interval is equal to the dose itself. This takes about four half-lives of the drug. Curve B represents the concentrations during administration of half the dose given at the same frequency. The time taken to reach steady state is the same in both cases, but the eventual steady-state concentration in case B is half that in case A, being proportional to the dose. Curve C represents the concentrations during administration of half the dose given twice as often (i.e. the total dose is unchanged). Neither the time taken to reach steady state nor the eventual mean steady-state concentration is affected. However, the fluctuations in plasma concentration during a dosage interval are reduced (cf. Fig. 6.2.1.1). (Adapted from Amdisen, A. Variation of serum lithium concentration during the day in relation to treatment control, absorptive side effects and the use of slow-release tablets, *Acta Psychiatrica Scandinavica*, **207**, 55–57. Copyright 1969, John Wiley & Sons, Inc.)

of the drug; about 94 per cent of the steady-state value will be reached after four half-lives (Fig. 6.2.1.3, curve A). For example, lithium has a half-life of about 24 h; after 4 days of maintenance therapy with the same regular dose a steady state will be reached; this does not depend on the dose or frequency of administration (Fig. 6.2.1.3, curves B and C). If a modified-release formulation is used and the half-life of absorption of the drug from the formulation is longer than the drug's own half-life, the longer (apparent) half-life will determine the time to steady state; for example, the apparent half-life of flupentixol after the administration of flupentixol decanoate is 17 days, compared with 36 h for flupentixol after oral administration. When using depot antipsychotic drugs, which have long half-lives of absorption, steady-state therapy should first be established with an ordinary formulation.

Curve A shows that during the regular administration of a maintenance dose of a drug the amount of drug in the body rises after a dose, reaches a peak, and then falls as the drug is distributed to the tissues and eliminated. If another dose is given soon after the first, the plasma concentration will rise by the same amount as before but will fall faster after peaking, since most drugs obey first-order kinetics and the plasma concentration falls exponentially. Thus, when a drug is given repeatedly the mean plasma concentration rises more slowly with each successive dose, until eventually a steady state is reached, when the amount eliminated in a dosage interval is equal to the dose itself. This takes about four half-lives of the drug. Curve B represents the concentrations during administration of half the dose given at the same frequency. The time taken to reach steady state is the same in both cases, but the eventual steady-state concentration in case B is half that in case A, being proportional to the dose. Curve C represents the concentrations during administration of half the dose given twice as often (i.e. the total dose is unchanged). Neither the time taken to reach steady state nor the eventual mean steady-state concentration is affected. However, the fluctuations in plasma concentration during a dosage interval are reduced (cf. Fig. 6.2.1.1). Kinetic characteristics of some psychotropic drugs are shown in Table 6.2.1.1.

Pharmacological actions of drugs

Psychotropic drugs interfere with neurotransmitter functions in several ways—via actions on neurotransmitter receptors, storage, release, reuptake, and metabolism. Transmembrane neurotransmitter receptors are broadly speaking of two types—ionotropic and metabotropic receptors. Ionotropic receptors (e.g. nicotinic acetylcholine, glycine, GABA, and NMDA, AMPA, and kainate receptors) incorporate ion channels in their structures and mediate rapid responses. Metabotropic receptors (e.g. G protein-coupled receptors such as adrenaline, noradrenaline, cannabinoid, dopamine, opioid, and serotonin receptors other than $5HT_3$ receptors) produce their effects via signal transduction systems, which activate second messengers or ion channels, and produce longer lasting responses.

Agonist action at a receptor

Agonists are substances that act by stimulating the action of a receptor.

Benzodiazepines bind to benzodiazepine receptors in the spinal cord, brainstem, cerebellum, limbic system, and cerebral cortex. These receptors are associated with receptors for the inhibitory neurotransmitter γ-aminobutyric acid (GABA), linked to a chloride channel.[10] The benzodiazepines enhance the action of GABA through its chloride channel, the presumed mechanism whereby they are anxiolytic and hypnotic. Some other hypnotics that have non-benzodiazepine structures also act via benzodiazepine receptors: zopiclone binds to the GABA–benzodiazepine receptor complex, but at a site different from that of benzodiazepines;[11] clomethiazole binds to a binding site distinct from those of benzodiazepines and barbiturates;[12] zolpidem binds to a subtype of binding site called BZ_1, found on GABA neurones in the sensorimotor cortex and extrapyramidal tracts.[10]

The triptans (such as sumatriptan, naratriptan, zolmitriptan), which are used to treat migraine, are agonists at 5-hydroxytryptamine ($5\text{-}HT_{1B/D}$) receptors, causing vasoconstriction. They are therefore contraindicated in patients with cardiovascular disease and in those with hemiplegic or basilar migraine because of the fear of stroke.[13]

Antagonist action at a receptor

Antagonists are substances that have no actions of their own at receptors and act by preventing the action of an agonist, usually an endogenous one.

The antipsychotic (neuroleptic) drugs are all antagonists at receptors for the endogenous neurotransmitter dopamine; this is thought to be the basis of their antipsychotic actions in the mesolimbic system (via D_1 and D_4 receptors) and undoubtedly produces their

Table 6.2.1.1 Pharmacokinetic information about some psychotropic drugs

Drug	Systemic availability (%)	Half-life (h)	Route of hepatic elimination[a]
Benzodiazepines			
Alprazolam	90	12	CYP3A
Chlordiazepoxide[b]	95	15

Droperidol	75	2	
Thioxanthenes			
Flupentixol	40	36	
Zuclopenthixol	50	20	CYP2D6
Others			
Clozapine	50	12	
Risperidone	75	3/20[c]	CYP2D6

[a] CYP refers to isozymes of the cytochrome P-450 family of enzymes.

[b] All these drugs are partly metabolized to active metabolites, Some of the metabolites have long half-lives (e.g. diazepam is metabolized to desmethyldiazepam). Some benzodiazepines (e.g. clorazepate and prazepam) are completely metabolized to active metabolites with long half-lives.

[c] Extensive and poor metabolizers respectively.

adverse effects in the extrapyramidal tracts (via D_2 receptors). The so-called atypical antipsychotic drugs (including clozapine and risperidone) have little effect on D_2 receptors and less commonly cause extrapyramidal adverse effects.[14]

Flumazenil is a competitive antagonist of benzodiazepines at benzodiazepine receptors and is used to reverse their effects.[15]

Partial agonist action at a receptor

Partial agonists are substances that can be agonists or antagonists at receptors, depending on the endogenous tone of the system upon which they are acting. If the degree of endogenous stimulation of the receptor is low, a partial agonist will tend to act as an agonist; if high, it will end to act as an antagonist.

The anxiolytic buspirone is a partial agonist at 5-HT_{1A} autoreceptors and reduces the firing of 5-hydroxytryptamine (5-HT) neurones by stimulating the auto-receptors.[16]

Actions via second messengers and ion channels

Some drugs act directly on second messenger systems and ion channels, without actions at receptors.

Lithium inhibits enzymes involved in the metabolism of inositol phosphates and may deplete cells of phosphoinositides, which are important as second messengers in neurotransmission.[17] However, other mechanisms have been proposed, including effects on the synthesis, turnover, and functional activity of brain 5-HT and effects on neuronal membrane function by effects on sodium and potassium fluxes via the sodium/potassium pump enzyme.[18]

Altered neurotransmitter storage

Reserpine, which causes depression, inhibits the incorporation of neurotransmitters into presynaptic storage vesicles and thus causes depletion of neurotransmitter stores.

Increased neurotransmitter release

Amphetamines cause increased release of noradrenaline (norepinephrine) and dopamine and have mood-enhancing effects.[19]

Inhibition of neurotransmitter reuptake

Most antidepressants inhibit the reuptake of monoamines into the presynaptic nerve ending after their release.[20] The effects of different antidepressants on monoamine reuptake are listed in Table 6.2.1.2. Reduced reuptake of monoamines occurs immediately, but the full therapeutic effects of antidepressants take some weeks to occur. This is explained by the occurrence of adaptive changes in presynaptic and postsynaptic receptors, including down-regulation of β-adrenoceptors, reduced sensitivity of β- and α_2-adrenoceptors, and increased sensitivity of α_1-adrenoceptors and 5-HT receptors. However, it is not known how these actions are translated into the therapeutic effect. The last of these effects has led to the use of 5-HT autoreceptor antagonists, in the hope of producing a quicker onset of antidepressant action by enhancing 5-HT neurotransmission.[21,22] For example, the partial β-adrenoceptor agonist and 5-HT_{1A} receptor antagonist pindolol hastens the response to SSRIs, although it does not affect the extent of the response.[23] Another strategy involves drugs with several actions, which inhibit more than one reuptake system and are antagonists at neurotransmitter receptors.[24]

Table 6.2.1.2 Effects of antidepressants on monoamine reuptake

Drug	Inhibition of uptake		
	Noradrenaline	5-HT	Dopamine
Tricyclics			
Amitriptyline	+++	++	—
Clomipramine	+++	+++	—
Desipramine	+++	++	—
Imipramine[a]	++[a]	+	—
Nortriptyline	++	+	—

Paroxetine	—	+++	—
Sertraline	+	++++	+

[a] Through its metabolite desipramine.

Altered neurotransmitter metabolism

Inhibitors of monoamine oxidase (MAO) enhance monoamine neurotransmission by irreversibly and non-selectively inhibiting the breakdown of monoamines after their release. Moclobemide[25] is a RIMA, a reversible inhibitor of MAO type A, which metabolizes 5-HT and noradrenaline. Moclobemide is therefore less likely to cause hypertension when taken in combination with amine-containing foods, such as cheese, since this reaction requires inhibition of both MAO type A and MAO type B.

Valproate partly acts by inhibiting GABA transaminase, thus enhancing GABA inhibitory transmission. However, it has other actions: it inhibits GABA reuptake, increases the sensitivity of GABA receptors to GABA, reduces the concentrations of the excitatory neurotransmitter aspartate, and may open potassium channels, thus stabilizing neuronal cell membranes.

Adverse effects of drugs

Unwanted effects of drugs are commonly referred to as toxic effects or side effects. However, these are ambiguous terms, for several reasons:

- Toxic effects occur through exaggeration of the desired pharmacological action of the drug, and therefore occur at doses that are above those usually associated with a therapeutic effect. For example, antipsychotic drugs produce some toxic effects by antagonism at dopamine receptors in the extrapyramidal tracts.
- Toxic effects can also occur through exaggeration of actions other than those that are thought to produce the therapeutic action. Paracetamol toxicity occurs because an active metabolite binds covalently to liver proteins, damaging them.
- Side effects occur either through actions that are unrelated to the desired pharmacological effect or through actions that are related to the desired pharmacological effect but occur in another tissue. Tricyclic antidepressants cause dry mouth, glaucoma, and urinary retention by anticholinergic action. Sildenafil causes colour vision disturbances by inhibiting phosphodiesterase type V in the eye, the action by which it has its therapeutic effect in erectile dysfunction. True side effects are more properly called collateral effects.[26]

It is therefore better to use the terms 'unwanted effects' or 'adverse effects/reactions'. Adverse reactions and adverse effects are identical—the former are seen from the point of view of the patient, the latter from the point of view of the drug.

Adverse drug effects are classified according to the scheme known as DoTS (Dose, Time, and Susceptibility).[26]

Classification according to dose-relatedness

1 *Hypersusceptibility reactions*: Here the dose–response curve for harm is far to the left of the dose–response curve for benefit; hypersusceptibility adverse reactions therefore occur at doses below those that are normally beneficial. Penicillin allergy is an example.

2 *Collateral reactions*: Here the dose–response curve for harm is in a region that is bounded by a curve that is just to the left of the dose–response curve for benefit and one that is just to the right; collateral adverse reactions therefore occur at doses within the range of those that are normally beneficial. They can occur (i) through a pharmacological effect that is distinct from that involved in the beneficial effect (for example an anticholinergic effect of a tricyclic antidepressant) or (ii) through the same pharmacological effect as that associated with the beneficial effect, but in a different tissue (for example colour vision disturbance due to sildenafil).

3 *Toxic reactions*: Here the harm occurs through the same mechanism as benefit (i.e. is on the same dose–response curve) but at doses that are above those that are normally beneficial. An example is serotonin syndrome due to fluoxetine.

Classification according to time-relatedness

Adverse drug reactions can be either time-dependent or time-independent (Table 6.2.1.3).

1 Time-independent reactions can occur at any time during therapy and are generally toxic reactions. They occur when the actual concentration of the drug increases or dose response curve shifts to the left, for whatever reason. An example is digoxin toxicity, which can occur for pharmaceutical reasons (for example administration of the wrong tablets), pharmacokinetic reasons (for example renal insufficiency), or pharmacodynamic reasons (for example hypokalemia). In the first two cases the concentration at the site of action increases and in the last the dose–response curve is shifted to the left.

2 Time-dependent adverse drug reactions are of six types; examples are given in Table 6.2.1.3.
   - Immediate or rapid reactions occur when a drug is given too quickly.
   - First-dose reactions occur only after the first dose of a course.
   - Early reactions occur soon after the first administration; they either wear off with time (early tolerant effects) or persist (early persistent effects).

Table 6.2.1.3 Time-related classification of adverse drug reactions in the DoTS method. (Reproduced from *British Medical Journal*, Aronson, J.K. and Ferner, R.E. (2005), **327**, 1222–5, with permission from BMJ Publishing Group Ltd.)

Type of reaction	Examples	Implications
Time independent		
Due to a change in dose or concentration (pharmaceutical effects)	Toxicity due to increased systemic availability	Beware of changing formulations of some drugs (e.g. modified-release formulations of lithium)
Due to a change in dose or concentration (pharmacokinetic effects)	Lithium toxicity due to renal insufficiency	Forewarn the patient; monitor carefully throughout treatment; alter dosage when pharmacokinetics change (e.g. renal insufficiency); avoid interacting drugs
Occurs without a change in dose (pharmacodynamic effects)	Digitalis toxicity due to hypokalaemia	Forewarn the patient; monitor carefully throughout treatment; avoid precipitating (pharmacodynamic) factors; avoid interacting drugs
Time dependent		
Immediate (due to rapid administration)	Red man syndrome (vancomycin) Hypertension (digitalis) Hypotension (iodipamide)	Administer slowly
First dose [of a course]	Hypotension (Ð1 adrenoceptor antagonists and angiotensin converting enzyme inhibitors) Type I hypersensitivity reactions	Take special precautions for the first dose Careful history taking; if a reaction occurs, avoid re-exposure; counsel the patient
Early tolerant	Adverse reactions that involve tolerance (e.g. nitrate-induced headache)	Monitor during the early stages; give appropriate reassurance; expect adverse effects if strategies to avoid tolerance are adopted
Early persistent	Glucocorticoid-induced diabetes mellitus	Monitor during the early stages and treat appropriately or withhold
Intermediate (risk increases at first, then diminishes)	Venous thromboembolism (classical antipsychotic drugs) Neutropenia (clozapine) Hypersensitivity reactions types II, III, and IV	Monitoring not needed after the high-risk period unless susceptibility changes; withdraw drug if a reaction develops
Late (risk increases with time)	Osteoporosis (glucocorticosteroids) Tardive dyskinesia (dopamine receptor antagonists) Retinopathy (chloroquine) Tissue phospholipid deposition (amiodarone)	Assess baseline function; forewarn the patient; monitor periodically during prolonged treatment
	Withdrawal syndromes: opiates, benzodiazepines, hypertension (clonidine and methyldopa), myocardial infarction (beta-blockers)	Withdraw slowly; forewarn the patient; replace with a longer acting drug if withdrawal is not possible
Delayed	Carcinogenesis (ciclosporin, diethylstilbestrol) Teratogenesis (thalidomide)	Avoid or screen; counsel or forewarn the patient

- Intermediate reactions occur within the first few weeks or months of administration but not thereafter; those who are susceptible will suffer the reaction and those who are not will not (healthy survivors); for example, clozapine causes neutropenia predominantly during the first 24 weeks of therapy—thereafter the risk is small.
- Late reactions occur late in the course of administration, the risk increasing with time; this group includes withdrawal reactions.
- Delayed reactions are seen at some distant time after the initial exposure, even if the drug is withdrawn before the reaction appears.

Classification according to susceptibility factors

The risk of an adverse drug reaction differs among members of an exposed population. For some reactions some individuals are susceptible, others are not—for example, prolonged muscle relaxation due to suxamethonium in people with pseudocholinesterase deficiency. In other cases susceptibility follows a continuous distribution—for example, increasing susceptibility with increasing impairment of renal function. Although reasons for increased susceptibility may be unknown, several types are recognized (Table 6.2.1.4).[27–34] These include:

- genetic variation;
- age;
- sex;
- physiological variation (for example pregnancy, body weight);
- exogenous factors (for example drugs and food);
- diseases (for example renal or hepatic impairment).

More than one susceptibility factor can be present in an individual.

Table 6.2.1.4 Sources of susceptibility to adverse drug reactions

Source of susceptibility*	Examples	Implications
Genetic	Porphyria Suxamethonium sensitivity Malignant hyperthermia CYP isozyme polymorphisms	Screen for abnormalities; avoid specific drugs
Age	Neonates (chloramphenicol[27]) Elderly people (hypnotics[28])	Adjust dosages according to age
Sex	Alcohol intoxication Mefloquine, neuropsychiatric effects[29] Lupus-like syndrome[30]	Use different doses in men and women
Physiology altered	Phenytoin in pregnancy[31]	Alter dosage or avoid
Exogenous factors	Drug interactions Interactions with food (e.g. grapefruit juice with drugs cleared by CYP3A4[32]; see Table 6.1)	Alter dosage or avoid co-administration
Diseases	Renal insufficiency (e.g. lithium[33]) Hepatic cirrhosis (e.g. morphine[34])	Screen for abnormalities; avoid specific drugs; use reduced dosages

*Mnemonic GASPED

Factors that increase the risk of an adverse effect

(a) Pharmaceutical factors

Adverse effects can arise from changes in the pharmaceutical formulation. There is a risk of lithium toxicity or loss of action when one modified-release formulation of lithium is replaced by another.

(b) Pharmacokinetic factors

Changes in the pharmacokinetics of a drug can result in toxic or collateral adverse effects. This most commonly occurs through impaired liver function (Table 6.2.1.1) or renal insufficiency (lithium).

(c) Pharmacodynamic factors

Changes in the sensitivity of a tissue to a drug occur during long-term therapy and can result in adverse effects. Tardive dyskinesia with dopamine receptor antagonists may be related to altered sensitivity of dopamine receptors,[35] although there are problems with this hypothesis, and complex interactions with other neurotransmitters may be involved.[36]

When adaptive changes occur during long-term therapy, sudden withdrawal of the drug can result in rebound reactions. Examples include the typical syndromes that occur after the sudden withdrawal of narcotic analgesics[37,38] or of alcohol (delirium tremens).[39] Sudden withdrawal of barbiturates can cause restlessness, sleeplessness, mental confusion, and convulsions; a similar syndrome, in which anxiety features prominently, can occur after the sudden withdrawal of benzodiazepines.[24,40]

Drug interactions

In a drug interaction one drug alters the effects of another, resulting in increased or decreased effects. Fluvoxamine inhibits the hepatic metabolism of warfarin and increases its anticoagulant effect,[41] whereas carbamazepine reduces the anticoagulant effect of warfarin by increasing its metabolism.[42]

1 Pharmaceutical interactions occur when there is a physicochemical interaction between two compounds in solution. Lists of such incompatibilities are too long to remember. To avoid pharmaceutical interactions, do not combine drugs in an infusion solution and use only sodium chloride 0.9% or glucose 5% in drug infusions.

2 Pharmacokinetic interactions occur when one drug interferes with the disposition of another during absorption, distribution, or elimination. Here are examples that are relevant to psychotropic drugs.

- Sucralfate reduces the absorption of amitriptyline by about 50 per cent;[43] this might be of clinical importance, but drug absorption interactions are not usually important.
- Phenytoin is displaced from protein-binding sites by valproate (which also inhibits its metabolism).[44]
- The metabolism of psychotropic drugs can theoretically be inhibited by drugs that inhibit metabolism via cytochrome P450 in the liver (Table 6.2.1.1). Reports of such interactions appear frequently. Inhibitory drugs include cimetidine, antifungal imidazoles (such as fluconazole), and macrolides (such as erythromycin).
- Non-selective MAO inhibitors, such as tranylcypromine, inhibit the metabolism (by MAO type A) of dietary amines in the gut and metabolism (by MAO type B) of the noradrenaline that they release, resulting in hypertension. Avoid this combination.
- Diuretics inhibit the renal excretion of lithium; alter the dosage of lithium and monitor the serum concentration when starting a diuretic or changing the diuretic dosage.

3 Pharmacodynamic interactions occur when two drugs interact at the same site of action. Alcohol potentiates the actions of all psychotropic drugs; patients taking psychotropic drugs should be warned that even one alcoholic drink can impair their ability to drive or operate machinery. The combination of reuptake inhibitors with non-selective irreversible monoamine oxidase inhibitors can cause the serotonin syndrome,[45] which is

sometimes fatal.[46] The combination of lithium with either SSRIs[47] or the SNRI venlafaxine[48] can also cause the serotonin syndrome. Flumazenil reverses the effects of benzodiazepines—a beneficial pharmacodynamic interaction.

Monitoring drug therapy

If possible, monitor drug therapy by observing the clinical outcome. In psychiatric disorders this is difficult, but it can be done by asking patients or their carers to keep diaries of symptoms.

Next best is to monitor some pharmacological effect of the drug, in the way that one measures the international normalized ratio (INR) in patients taking warfarin (thus measuring the effect of the drug on the blood, being unable to monitor its clinical effect of preventing pulmonary embolism). However, there are no comparable routine tests available for monitoring the pharmacological effects of psychotropic drugs.

Because of these difficulties one falls back on measurements of serum concentrations of some drugs. The assumptions in doing this are that the serum concentration reflects the concentration at the site of action and that there is a concentration–effect relationship. Few psychoactive drugs can be monitored in this way, the principal ones being lithium and phenytoin. Some advocate monitoring treatment with some tricyclic antidepressants,[49] but this use is controversial.

Serum concentration measurement can be used to individualize therapy in the early stages of treatment or when the dosage is being changed, to check adherence to therapy, to help diagnose toxicity, and to monitor the effects of drug interactions.

Carbamazepine

The target plasma carbamazepine concentration range is 17–42 mmol/l, but plasma concentrations do not correlate well with effect, since it has an active metabolite, oxcarbazepine; higher concentrations are associated with an increased risk of toxicity.[50] Carbamazepine induces its own metabolism, and its half-life is therefore shortened during long-term therapy. So, after an initial apparent steady state has been reached 3 or 4 days after starting therapy, a new steady state occurs at a lower concentration a few weeks later, and the dose may need to be increased at that time. Blood samples should be taken immediately before a dose.

Lithium

The target serum lithium concentration is 0.4–1.0 mmol/l. Concentrations above 1 mmol/l are associated with an increased risk of toxicity. Take blood samples at a standard time—12 h after the last dose. In my view, routine monitoring is unnecessary, and the serum lithium concentration should be measured at times when toxicity is most likely, for example in patients with changing renal function or with acute alterations in electrolyte balance.[51,52] Many psychiatrists prefer to measure the serum lithium concentration routinely at, say, 3- or 6-monthly intervals. However, although regular monitoring may emphasize the dangers to the patient and give an opportunity for a consultation, it is no substitute for proper monitoring at the appropriate times.

Valproate

The target serum valproate concentration range is 40–80 μmol/1, although this range is based on its use in epilepsy rather than bipolar affective disorder;[53] higher concentrations are associated with an increased risk of toxicity. The blood sample can be taken at any time after the last dose.

6.2.2 Anxiolytics and hypnotics

Malcolm Lader

Introduction

Anxiety is a commonly experienced emotion that becomes a clinical disorder when it is too severe, too protracted, or too pervasive for the subject to bear. Insomnia is a failure to experience satisfying sleep, together with a feeling of tiredness during the day. Many compounds, the anxiolytics and hypnotics, are used to treat these conditions, but the two groups of drugs overlap.

The classical antianxiety drugs (anxiolytics) are alcohol, the opioids, and the barbiturates. For the past 45 years, the benzodiazepines, such as diazepam and lorazepam, have dominated the field. They are effective anxiolytics in the short term but their long-term efficacy remains in dispute. Their disadvantages include cognitive and psychomotor impairment, paradoxical reactions, tolerance, and dependence, and they are major drugs of abuse.

Other anxiolytics act on the 5-hydroxytryptamine (5-HT; serotonin) systems of the brain and include buspirone and the selective serotonin reuptake inhibitors (SSRIs). Newer compounds are still being introduced that lie outside these groups.

The use of benzodiazepine and benzodiazepine-like hypnotics, by contrast, continues apace. Some switching to the shorter-acting benzodiazepines has occurred, together with the introduction of the 'z-compounds', zopiclone, zolpidem, and zaleplon. These drugs tend to have fewer residual effects the next day than the benzodiazepines, and are claimed to be less likely to induce rebound and dependence than equivalent benzodiazepines. Particular care is needed in prescribing such hypnotics to the elderly.

The rational use of both anxiolytics and hypnotics requires minimal dosage, short durations of use, and simultaneous exploitation of non-pharmacological methods.

Definitions

'Sedative' originally meant a substance that has the property of allaying anxiety. However, it has now come to denote feelings of drowsiness or torpor. This state was originally called 'oversedation', and was often noted with the barbiturates and other older drugs such as chloral. Next, the term 'tranquillizer' was introduced 40 or more years ago in an attempt to distinguish between the older sedatives and the newer drugs, supposedly non-sedative, such as the benzodiazepines. But this distinction is artificial as, apart from safety in overdosage, the benzodiazepines closely resemble the barbiturates in pharmacological and clinical properties. The term 'anxiolytic' is now generally favoured.

Anxiolytic drugs

Anxiety-allaying drugs have been used for thousands of years, dating back to the discovery that, among its psychotropic properties, alcohol could induce sedation. The nineteenth century saw the development of inorganic and, later, organic chemical compounds. Bromides were introduced as sedatives and became widely used despite their poor effectiveness, toxicity, and potential abuse. Organic chemists in the second half of the nineteenth century introduced sedatives such as chloral and paraldehyde.

The first barbiturate was introduced over a 100 years ago. This group of drugs is divisible into the ultrashort-acting (e.g. anaesthetic-induction agents such as thiopentone and methohexital), short-acting (e.g. secobarbital), medium-acting (e.g. butobarbital), and long-acting (e.g. phenobarbital) barbiturates. Most of the rest are of medium duration with half-lives of 16 h or so. The disadvantages of the barbiturates include drowsiness, tolerance to their effects, dangers of overdose, and possible physical and psychological dependence with severe withdrawal syndromes.[1] Meprobamate was introduced as the first of the 'tranquillizers', but its advantages over the barbiturates proved minimal.

The benzodiazepines were first synthesized in the 1930s, but not developed until 2 years later. The prototype, chlordiazepoxide, was evaluated in the clinic, found effective, and soon introduced into medical practice. More than 1000 benzodiazepines and related compounds have been synthesized, including diazepam, the most widely used of all. Anxiolytic and hypnotic, as well as muscle-relaxant and anticonvulsant properties are licensed indications. However, the distinction between anxiolytic and hypnotic uses often seems to owe more to commercial expediency than to scientific rationale; some compounds, such as lorazepam, are marketed for both indications.

The benzodiazepines

The main reason for the original popularity of the benzodiazepines was the perceived safety in overdose compared with the quite marked toxicity of the barbiturates. In turn, concern has mounted concerning the benzodiazepines.[2] These drugs are widely prescribed by many physicians for patients with emotional problems, circulatory disorders, tension headaches, and pains in the chest and back as well as digestive disorders, all with the common symptom of anxiety. This widespread use, even overuse and the induction of dependence even at normal therapeutic dose has led to official injunctions for greater caution in prescribing.

Pharmacokinetics

Two aspects of the pharmacokinetics of the benzodiazepines are relevant to the prescriber—speed of onset of action and the duration of that action. The speed of onset depends on the mode of administration and the penetration time to the brain. Given by mouth, most benzodiazepines are rapidly absorbed and exert a prompt anxiolytic effect, for instance in panic states. Diazepam and lorazepam are prime examples. Although temazepam enters the brain more rapidly than, say, oxazepam, it still takes an appreciable time to induce sleep. The redistribution phase can be pronounced and will then largely determine the duration of effect of single doses of benzodiazepines such as diazepam and flunitrazepam.

The metabolic half-lives of the benzodiazepines also vary greatly. *N*-desmethyldiazepam (nordiazepam) is the major and active metabolite of diazepam and several other benzodiazepines. It has a long half-life, about 60 h, and accumulates over the first month of treatment. Metabolism of these drugs is even slower in the elderly and in patients with liver damage.

Benzodiazepines with a 3-hydroxyl grouping, such as lorazepam, oxazepam, and temazepam, have half-lives averaging 12 h or less. Liver damage has to be severe before the metabolism of these drugs

is affected. Alprazolam is a triazolobenzodiazepine with a half-life of 9 to 16 h, and with hydroxy metabolites of low biological activity. Both chlordiazepoxide and diazepam are absorbed erratically after intramuscular injection. Lorazepam, however, is well absorbed after intramuscular injection.

Basic pharmacology

The benzodiazepines potentiate the widespread inhibitory neurotransmitter γ-amino butyric acid (GABA). Benzodiazepines do not act directly on GABA receptors but have their own receptors. Because of this widespread inhibitory effect, benzodiazepines alter the turnover of neurotransmitters such as norepinephrine and serotonin. The main sites of action of the benzodiazepines are in the spinal cord where muscle-relaxant effects are mediated, the brainstem (perhaps accounting for their anticonvulsant properties), the cerebellum (causing ataxia), and the limbic and cortical areas involved in the organization of emotional experience and behaviour.

Clinical pharmacology

The depressant effects of single therapeutic doses of a benzodiazepine can usually be readily detected. However, lower doses may fail to impair psychological functioning and subjective effects are usually absent. In the clinical context with anxious patients and with repeated higher doses, sustained impairment of functioning is more difficult to demonstrate. Some studies have shown decrements in performance after the first dose, but improvements in functioning, in comparison to predrug levels, may become apparent by the end of a week of repeated usage. This suggests that the well-known impairment of performance produced by pathologically high levels of anxiety is first worsened by the sedative effects. Then as the antianxiety effects build-up, the patient's psychological functions may improve.

A second mechanism concerns tolerance, which reflects several biochemical mechanisms including alteration in benzodiazepine-receptor type. Patients who have a high alcohol intake are tolerant to benzodiazepines.

The benzodiazepines have marked and selective effects on memory by interfering with episodic memory, that is to say the system concerned with remembering personal experiences.[3] This effect seems independent of any sedation or attentional impairment. Alcohol adds to the cognitive impairment induced by the benzodiazepines but does not necessarily potentiate it.

The dependence potential of benzodiazepines is seen in drug-preference studies, but these drugs are much less preferred than say the amphetamines. Differences among benzodiazepines have been documented; for example, oxazepam seems to have less abuse liability than diazepam.

The largest gap in our knowledge of these drugs is on their long-term usage, which has been evaluated in relatively few studies.[4] Thus, it is still largely unclear whether therapeutic effects are maintained in most patients for longer than a few weeks and when dependence supervenes in the minority of patients who encounter problems on protracted usage.

Hypnotic drugs

The main groups of drugs used in the modern treatment of insomnia are the benzodiazepines, and the newer compounds, zopiclone, eszopiclone, zolpidem, and zaleplon. The pharmacology of these benzodiazepines is essentially the same as that of the anxiolytic compounds.

Nitrazepam is a long-acting benzodiazepine with an elimination half-life ranging between 25 and 35 h, but it is longer in the elderly. Because of this, it is likely to produce residual effects and to accumulate. Flunitrazepam is more potent, but is somewhat shorter acting with a half-life of 10 to 20 h. It has a rapid redistribution phase, which can result in a short duration of intense action. It has earned an undeserved reputation as the 'date-rape' drug. Flurazepam is still widely used in the United States. It has a very long-acting metabolite, which can produce psychological impairment on regular dosage, especially in the elderly. Of the intermediate-acting compounds, temazepam has a half-life of 10 to 15 h, without active metabolites. At modest dose (10–15 mg daily), it results in few residual effects and is fairly well tolerated by the elderly. Major problems with abuse have limited its popularity, but it is still widely prescribed worldwide. Lormetazepam is slightly shorter acting, loprazolam has a fairly short half-life, but its absorption may be slow and erratic.

Triazolam is the archetypal short-acting benzodiazepine, with a mean half-life of around 3 to 4 h, and no clinically significant metabolites. Daytime sedation is seen after high doses (0.5 mg daily), but not usually with lower ones. These higher doses have also been associated with an increased incidence of anterograde amnesia and unusual behaviours, including depressive reactions and hostility.

Zopiclone is a cyclopyrrolone derivative believed to bind close to, but not exactly at, the benzodiazepine receptor. It has a half-life of about 5 h in younger subjects and about 8 h in the elderly. Its sedative and hypnotic effects are similar to those of the benzodiazepines, but its side effect profile is generally superior with fewer central nervous system effects such as oversedation, confusion, and memory impairment. Rebound and withdrawal problems also seem to be less.

Eszopiclone is the S-enantiomer of zopiclone, which is a racemic mixture. It is licensed for the long-term treatment of insomnia in the United States, following successful clinical trials.

Zolpidem is an imidazopyridine compound that binds selectively to one subtype of the benzodiazepine receptor. It is rapidly absorbed and has a short elimination half-life of 0.7 to 3.5 h (mean 2.4 h). It decreases sleep-onset latency but has less consistent effects on total sleep time.[5] Residual effects are minimal, as are memory disturbances. Rebound and withdrawal are uncommon but have been documented.

Zaleplon is also a selective compound with a very short half-life averaging only 1 h. It shortens sleep onset without usually prolonging total sleep time. Residual effects are absent, and memory is minimally disturbed.

Clinical effects of anxiolytics

Although the usual licensed indications are generalized anxiety and panic disorder,[6,7] the main practical application of the benzodiazepines is to aid in the symptomatic management of anxiety and stress-related conditions.[8] These indications are often so wide as to be difficult to define in terms of recognized disorders. Instead the symptoms of anxiety, in whatever context, are the main indication.

Thousands of comparative trials among the benzodiazepines have been carried out, but few differences with respect to risk–benefit ratios have been found.

Antianxiety medications are difficult to assess. Anxiety disorders are very varied in their natural history; some resolve over a few weeks, whereas others become chronic for no apparent reason, with subsequent acute-on-chronic exacerbations. The patients with chronic, severe unresponsive illnesses tend to be referred to psychiatric outpatient departments. Uncontrolled observations on family practice patients will give a more encouraging impression of antianxiety drugs than will assessment of the more chronic patients attending psychiatric clinics. Even in the latter type of patient, useful symptomatic relief is often obtained without complete resolution of the illness.

Drugs such as diazepam have a long elimination half-life so that once daily or nightly dosage is sufficient. Nevertheless, many patients prefer to take a divided dosage during the day, often claiming that they can detect further antianxiety activity after each dose and are thereby reassured. For episodic anxiety, shorter-acting compounds such as lorazepam can be used, taken 30 min or so before entering the anxiety-provoking situation. If the panic has already started, lorazepam can still be given and will exert a fairly prompt action. Lorazepam is also invaluable in the emergency management of the acutely anxious and disturbed psychotic patient.

Antipanic actions have been claimed for the benzodiazepines, in particular alprazolam, acting to prevent the episodes rather than aborting them. However, although suppression of the panic attack is often quite effective, relapse, and even rebound may occur when the benzodiazepine is discontinued, even if it is tapered off.[9] Because of this SSRI antidepressants are generally preferred.[7]

The short-acting benzodiazepines are also used as adjuncts to relaxation therapy, preoperative medication, and deep sedation for minor operative procedures such as dentistry. The drugs render the patient calm, conscious, and cooperative, with often total anterograde amnesia for the operation.

Unwanted effects

The commonest unwanted effects of the anxiolytic benzodiazepines are tiredness, drowsiness, and torpor, features of 'oversedation'. The effects are dose and time related, being maximal within the first 2 h after large doses. Drowsiness is most noticeable during the first week of treatment, after which it largely disappears probably due to a true tolerance effect. Patients should be warned of the potential side effects of any prescribed benzodiazepine and the initial dosage should be cautious. Both psychomotor skills and intellectual and cognitive skills are affected. In particular, patients should be advised not to drive during the initial adjustment of dosage. Important decisions should be deferred during this period because judgement may be clouded.

Benzodiazepines have major effects on cognitive function in long-term users. A meta-analysis of 13 research studies revealed impairments across all cognitive categories examined.[4] The drugs differ in their ability to produce memory deficits, with lorazepam being especially powerful.[3] However, most benzodiazepines can cause problems, especially in higher dose and in the elderly.

Psychomotor performance is also affected, with elderly drivers particularly at risk. As with other depressant drugs, potentiation of the effects of alcohol can occur. Patients must be warned not to drink alcohol when taking benzodiazepines, either chronically or intermittently. Patients taking benzodiazepines may develop paradoxical behavioural responses such as uncontrollable weeping, increased aggression and hostility, and acute rage reactions or uncharacteristic criminal behaviour such as shoplifting.[10] This phenomenon is by no means confined to the benzodiazepines; alcohol is a cardinal example of a drug whose use may lead to excessive violence or criminal behaviour. Paradoxical reactions, including the release of anxiety or hostility, are most common during the initial week of treatment, and usually resolve spontaneously or respond to dose adjustment. Reports of the induction of depression by the benzodiazepines in patients with apparent generalized anxiety disorder are probably the result of an initial misdiagnosis and a failure to detect the underlying depression.

Other unwanted effects include respiratory depression, excessive weight gain, skin rash, impairment of sexual function, menstrual irregularities, and rarely, blood dyscrasias. The use of benzodiazepines in pregnancy is generally regarded as reasonably safe. However, benzodiazepines pass readily into the foetus and can produce respiratory depression in the neonate. Finally, benzodiazepines pass into the mother's milk and can over sedate the baby, so breastfeeding should be discouraged if benzodiazepines are prescribed, especially in high dose.

Overdosage

Overdosage with benzodiazepines is common; deaths are not. Although fatal-overdose statistics contain deaths ascribed to benzodiazepines alone,[11] many such attributions are suspect. Only in children and the physically frail, especially those with respiratory illness, are the benzodiazepines on their own hazardous. However, they can markedly potentiate other central nervous system depressant drugs such as alcohol. Typically, the person falls into a deep sleep but can be roused the administration of the benzodiazepine antagonist, flumazenil.

Tolerance and dependence

If tolerance occurred regularly, then escalation of dosage would be the norm. This does occur with the benzodiazepines, but is fairly uncommon. Escalation of dose is often stepwise, with each increment following a temporary deterioration in psychosocial circumstances. Most patients later reduce the dose as the stress resolves, but others continue the higher dose to which they presumably have developed some tolerance.

Tolerance to the clinical effects in patients maintaining moderate doses of benzodiazepines is now generally accepted.[12] Few controlled observations concern the long-term efficacy of antianxiety compounds in chronically anxious patients. If medication is withdrawn, the original symptoms may reappear. This is taken as evidence that therapeutic benefit still continues. However, it may reflect 'rebound' rather than long-term clinical benefit. Undoubtedly, many chronically anxious patients are helped by their treatment with benzodiazepines, but this raises the question as to the frequency of psychological and physical dependence on these drugs. Dependence is easily demonstrable in those patients who have attained high doses. Rebound and withdrawal symptoms after the long-acting benzodiazepine diazepam are not usually apparent until about 5 to 10 days after discontinuation. It is much shorter in patients discontinuing the shorter-acting benzodiazepines (2–4 days). The mildest symptoms and signs are anxiety, tension, apprehension, dizziness, tremulousness, insomnia, and

anorexia. More severe physical dependence is shown by the withdrawal symptoms of nausea and vomiting, severe tremor, muscle weakness, postural hypotension, and tachycardia. Occasionally, hyperthermia, muscle twitches, convulsions, and confusional psychoses may develop.

After normal dose usage, perceptual changes can be particularly troublesome.[13] The proportion of patients taking benzodiazepines chronically who experience withdrawal symptoms on discontinuing medication ranges between 27 and 45 per cent, depending on the criteria used. Sometimes the withdrawal reactions seem very prolonged[14] or depression may supervene.

Management of withdrawal

It is widely accepted that the most appropriate way to manage patients withdrawing from benzodiazepines is to taper the dose gradually, because the severe symptoms of withdrawal, such as epileptic fits and confusional episodes, are more likely to follow abrupt than gradual withdrawal. Views differ as to the rate of withdrawal. Detailed guidelines,[15,16] based on a consensus view in the United Kingdom, recommend minimal intervention first, usually by a general practitioner (Fig. 6.2.2.1). This may comprise a letter to the long-term user, or an interview on a routine visit, with advice to taper the medication. More active intervention involves careful assessment, education, and then the adoption, with the patient's agreement, of a timetable of about 6 to 8 weeks for withdrawal. Some agencies suggest a month of tapering for every year of benzodiazepine use, but this may result in patients becoming preoccupied with their symptoms. One strategy is to try a fairly brisk withdrawal, say over 6 to 8 weeks, and only resort to more gradual tapering if the symptoms become intolerable. Another ploy is first to substitute a long-acting for a short-acting benzodiazepine, say 10 mg of diazepam for 1 mg of lorazepam, and then to taper off the diazepam later.

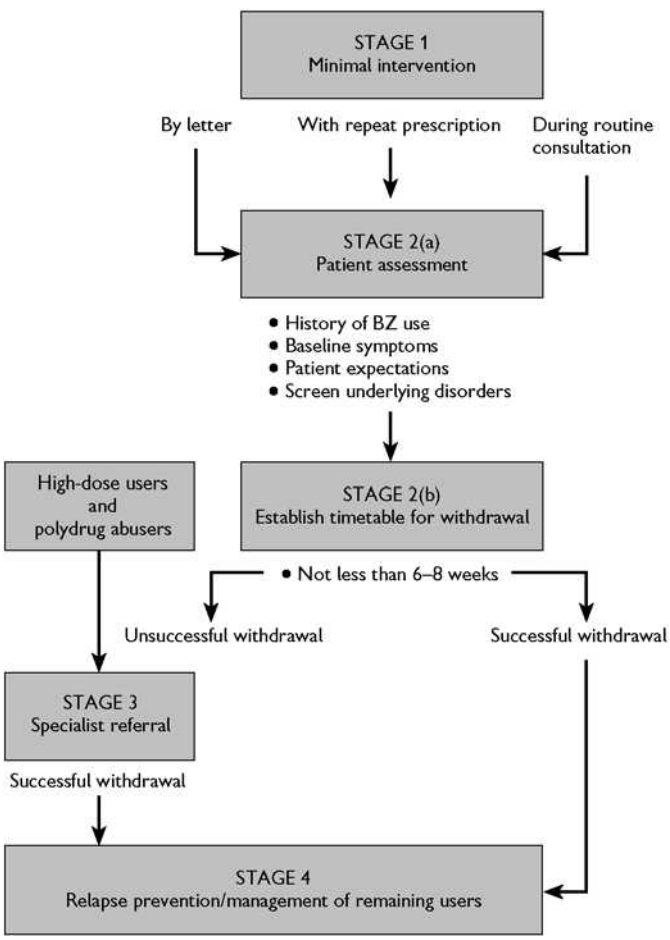

Fig. 6.2.2.1 Guidelines for withdrawal from benzodiazepines (BZ). (Reproduced with permission from J. Russell and M. Lader (eds.), *Guidelines for the prevention and treatment of benzodiazepine dependence*, Mental Health Foundation, London. Copyright 1993, Mental Health Foundation, London.)

Patients must be carefully followed up as a depressive illness is not uncommon and may need vigorous treatment. Such an illness may be reactive to the stress of withdrawal or be a recurrence of an earlier affective episode.

Other drugs have been advocated, but most patients are loath to substitute yet another medication. Depressed patients should have the depression treated before attempting withdrawal. Based on evidence from animal studies, fairly large single doses of flumazenil have been tried with some success.

Psychological support is essential, with the doctor or a practice nurse maintaining close contact with the patient during withdrawal. The physician should show clearly that he understands the problems of withdrawal in order to capture the confidence of the patient. He or she must recognize that patients frequently incubate numerous misconceptions and negative expectations about tranquillizers and withdrawal. These must be elicited, identified, discussed, and corrected.

Cognitive behavioural treatment is currently favoured and is often effective if administered by an experienced professional. Relaxation treatment and training in anxiety management skills in the framework of group therapy can boast of only moderate effectiveness.

Other anxiolytics

Benzodiazepine-receptor partial agonists

The disadvantages of the benzodiazepines include sedation, psychomotor and cognitive impairment, and withdrawal symptoms after long-term use. Increased understanding of benzodiazepine-receptor mechanisms suggested that compounds might be developed which are partial agonists and/or selective to some subtypes of receptor.[17] Such compounds would be less efficacious than full agonists but might have better adverse-effect profiles and less dependence potential, that is superior risk–benefit ratios. Their promise has not been fulfilled, as the risk–benefit ratios of these compounds do not seem superior to those of the full agonists.

5-HT_{1A} partial agonists

These drugs have a complex pharmacology. The first, buspirone, was licensed in many countries some years ago. These drugs suppress activity in presynaptic serotonergic neurones, diminishing serotonin activity, and leading on to down-regulation of 5-HT_2 and perhaps other 5-HT receptors. Buspirone is much less sedative than the benzodiazepines and causes little or no psychomotor or cognitive impairment, nor does it potentiate the effects of alcohol. In formal clinical trials, buspirone was equi-effective and

equipotent to diazepam, but patients taking buspirone improve more slowly.[18] The side effects of buspirone include headache, dizziness, and nausea. Discontinuation is not accompanied by either rebound or withdrawal.

Other 5-HT_{1A} partial agonists have been developed mainly as potential antidepressants and antianxiety agents, but few have been marketed, mainly because of disappointing efficacy.

Pregabalin

This compound is a structural analogue of GABA although it is not active at GABA receptors.[19] It binds with high affinity to an auxiliary α_2-δ subunit protein of voltage-gated calcium channels in the CNS: it acts as a presynaptic modulator of the excessive release of neurotransmitters in hyperexcited neurones. It is predominantly excreted unchanged in the urine. It was initially developed for use as an adjunctive treatment in epilepsy and neuropathic pain. Several clinical trials in GAD have shown it to have efficacy akin to those for benzodiazepines and venlafaxine.[20] It has a rapid onset of action and was effective in preventing relapse over 34 weeks. Tolerance was good during dosage escalation to the usual dose of 150–600 mg/day, mild dizziness and somnolence being the usual adverse effects. No clinically significant withdrawal was seen after tapering. It is approved for the treatment of GAD in Europe, and is a significant introduction.

Antiepileptic drugs

There is a long history of the use of many of these compounds in anxiety disorders,[21] but they are not routine choices.

Antipsychotic drugs

Phenothiazines, such as chlorpromazine and trifluoperazine, and a range of other antipsychotic drugs have been advocated for treating anxiety. The dosage recommended is quite low, typically less than half the initial antipsychotic dose used in psychotic patients. Sometimes, even at this dosage, the antipsychotic drug is not well tolerated by the anxious patient because unwanted autonomic effects, such as dry mouth and dizziness, too closely resemble the symptoms of anxiety. Even more unwelcome are extrapyramidal symptoms such as restlessness (mild akathisia) and parkinsonism, although at the low doses advocated such unwanted effects are uncommon. There may even be a risk of tardive dyskinesia. The chief advantage of this medication is that dependence is virtually unknown, so the main indication for their use is in patients with histories of dependence on other central nervous system depressant drugs such as alcohol or barbiturates.

Antidepressants

Several of these drugs, such as amitriptyline, doxepin, and trazodone, have useful secondary sedative properties. They are widely prescribed for depressed patients with anxiety or agitation. More recently, several SSRI antidepressants such as paroxetine and escitalopram have been evaluated in the treatment of various anxiety disorders. SSRIs are now the treatment of choice in chronic anxiety disorders.[22,23]

MAOIs have been used for many years to treat phobic states, but the well-known range of unwanted effects, including hypotension, limb oedema, and dietary and drug interactions, preclude their routine use.

β-adrenoceptor antagonists

Beta-adrenoceptor antagonists may help patients with anxiety, but usually only those complaining of somatic symptoms. They are still favoured by some primary care doctors.

Antihistamines

The older compounds penetrate the brain readily and are quite sedative. Hydroxyzine has been evaluated in at least two placebo-controlled trials in doses of 50 mg/day: it proved to be significantly better than placebo. The advantages are that paradoxical reactions are rare, cognitive function including memory is largely unaffected, and rebound and withdrawal seem rare.

Clinical effects of hypnotics

Insomnia is a common symptom,[24] especially in the elderly.[25] Nonetheless, many complaints of insomnia are unfounded as the patient has unreal expectations concerning sleep. Elderly people fail to appreciate that it is normal to sleep less and less deeply as they age. Napping during the day also decreases the need for sleep at night. Some people can manage on 5 to 6 h a night indefinitely, and yet worry that this is insufficient. Explanation and reassurance relieve their worries.

In many patients complaining of more severe insomnia, the cause is a physical complaint such as pain, breathlessness, or pruritus. The treatment is for that of the primary complaint. In many other cases, the insomnia is either a symptom of psychiatric distress, anxiety, or depression, or it is iatrogenic, caused by the very drugs prescribed to relieve the insomnia. In the first instance, treatment is directed towards the primary condition; in the second, a careful regimen of drug withdrawal, or substitution and subsequent withdrawal, should be instigated, as discussed earlier for anxiolytic medication. Some drugs, of which caffeine is the most common, induce insomnia. Alcohol may also disrupt sleep, particularly during the latter half of the night.

Despite this, a substantial number of patients cannot be placed into these categories and yet they persistently complain of insomnia (primary insomnia). Careful evaluation of the issues may yet reveal some relationship to stresses, both transient and persistent. It can be established that these patients are responding to unusual or protracted pressures of life: a man worries over possible redundancy, his wife is concerned about their delinquent son, their daughter is lovelorn, and grandmother is anxious over her increasing frailness. Giving drugs may set in train a long-term process culminating in drug-related insomnia without solving the basic problems.

Short-term symptomatic relief is acceptable when the stress is undoubtedly severe but transient. Even so, the hypnotic agent must be chosen carefully. The elimination half-life is the most important consideration. Those with half-lives over 12 h, such as nitrazepam, are only appropriate where an anxiolytic effect is required during the day as well as sleep induction at night. Even here, diazepam 5 to 15 mg, one dose at night, may be preferred. Temazepam with its shorter half-life will encourage sleep onset without leaving the patient with too many residual sedative effects the next day. Unfortunately, it has been extensively abused.

The management of chronic insomnia is much more problematic.[26] The newer compounds zopiclone and zolpidem are also short-acting agents and can help assure a good night's

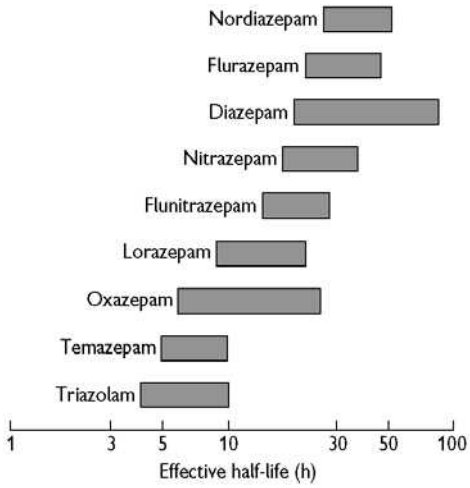

Fig. 6.2.2.2 Table of half-lives.

sleep without much risk of residual sedative effects the next day.[27] This is dependent on the dosage being kept modest, especially in the elderly. Eszopiclone is licensed in the United States for long-term use in chronic insomnia and is already used extensively there.

Zolpidem and zaleplon can be used in a different strategic ways from other longer-acting drugs. Hypnotics are traditionally taken every night before going to bed to induce or maintain sleep. However, the severity of insomnia usually varies from night to night. Consequently, regular usage may be partly, or even largely, unnecessary, and increases the risk of habituation and dependence. Very-short-acting compounds are unlikely to leave residual effects the next day, even taken up to 5 h or so before the expected time of wakening. Consequently, the insomniac can refrain from regular hypnotic usage but, instead, wait up to an hour or so after going to bed to see if natural sleep supervenes before resorting to medication. This changes the regular prophylactic use of hypnotics to 'as needed', and lessens the risk of habituation and dependence. Furthermore, the patient is gratified to feel that he or she has control of the medication instead of vice versa.

Residual effects

Residual effects can be a problem especially when long-acting drugs are used repeatedly. Dosage is important here, since residual effects increase in both magnitude and duration as the dose is increased. It should be remembered that hypnotics are the only class of drugs in which the main therapeutic effect (drowsiness) is identical with the main unwanted effect; the two are merely separated by 8 h in time. A short-acting hypnotic compound will be devoid of residual effects the next day, but the patient may wake early. After taking a longer-acting compound, sleep may be prolonged but hangover effects pronounced.

Idiosyncratic effects

Adverse effects with triazolam alerted prescribers and regulators to possible major adverse effects of short-acting benzodiazepines. The adverse reactions in question include daytime anxiety, amnesic effects, and episodes, and morbid affects such as depression and hostility. In summary, the evidence suggests that these are class effects common to the benzodiazepines, although more likely to occur the shorter the duration of action of the drug and the higher the dose. Alcohol is also capable of producing these effects.

Rebound

Discontinuation of many hypnotics is often followed by worsening of sleep compared with pretreatment levels. In practical terms, insomniac patients find that their sleep is disturbed for a night or two after abrupt discontinuation of what appeared to be effective medication. Some of this rebound is subjective as patients taking sleeping pills tend to overestimate their sleeping time (compared with sleep laboratory recordings); on withdrawal, they underestimate their sleep. The intensity of rebound insomnia is strongly related to dose but less clearly to the duration of use, and marked individual differences exist. The risk of rebound is greater with short-half-life compared with the long-half-life compounds. Tapering off medication lessens the likelihood of rebound. However, despite clinical impressions that rebound insomnia might lead to the resumption of medication, there is little evidence for this.[28]

Dependence

Dependence may supervene on the longer-term use of hypnotics; giving a long-acting benzodiazepine drug only once in 24 h does not protect against such an eventuality. The management of the withdrawal syndrome that may occur is largely the same as with the anxiolytic benzodiazepines.

Abuse

A growing problem with these drugs is abuse—non-medical use, on a regular or sporadic basis, often in a polydrug context. Worldwide, flunitrazepam is the main problem and can be taken orally, by injection, or by sniffing. In the United Kingdom, temazepam is widely abused by injection. The injected drug has a marked sedative and/or disinhibiting effect, resulting in chaotic behaviour, carelessness, and an enhanced risk of the transmission of communicable diseases such as HIV infection and hepatitis.

Other hypnotics

Gaboxadol is a GABA agonist. Preliminary data suggest useful hypnotic properties.

Melatonin preparations

A series of compounds are being developed based on melatonin. This hormone is important in the regulation of sleep and is secreted at night. Some elderly insomniacs seem to be deficient in melatonin. Preparations include Circadin®, licensed in the UK for short-term use in insomnia in over 55s. Ramelteon is a melatonin$_1$ and melatonin$_2$ agonist. It is licensed in the United States for insomnia, and is effective in inducing sleep: it has a favourable safety profile.[29]

Conclusions

In many countries the drug treatment of both anxiety and insomnia still largely revolves around the use of the benzodiazepines. Nevertheless, controversy and disagreement still rage about the risk–benefit ratio of compounds in this area. Short-term use in both indications is well established, with a favourable database as a

rationale for this approach. However, long-term use is still only researched in a limited way. While both the efficacy and safety of long-term use remain unclear, acceptance of current guidelines limiting the use of benzodiazepines seems wise.

The advent of the SSRIs as anxiolytics has driven a wedge between the treatment methods for anxiety and insomnia. Anxiety can be treated just as effectively with an SSRI (and probably, pregabalin) as with a benzodiazepine, and more safely. The treatment of insomnia still relies on the benzodiazepines until the risk–benefit ratio of newer drugs such as the melatonin-related compounds becomes clear.

Nevertheless, in the author's opinion the most important outstanding issue is the relationship between drug and non-drug treatments.[30] The management of anxiety disorders and of insomnia is complex and is hampered by a dearth of information concerning the relative merits of various treatment modalities. Much research is also needed on the optimum strategies for combining all the therapies available to us, and on identifying predictors of response.

Developments in the neuropharmacology of insomnia hold out the promise of new compounds with novel and perhaps more effective modes of action.[31] With respect to anxiety disorders, a major shift of emphasis has followed the demonstration of the efficacy of the SSRIs.[32]

6.2.3 Antidepressants

Zubin Bhagwagar and George R. Heninger

Introduction

Major depressive disorder is a serious, recurrent illness which levies a crippling toll on individuals, families, and society in general. The importance of depression as a major public health problem is emphasized by findings from the World Health Organization Global Burden of Disease survey in showing that in 1990 it was the fourth largest cause of burden of disease (i.e. years of life lost due either to premature mortality or to years lived with a disability). It has been estimated that by the year 2020 it is expected to be the second largest cause of burden of disease.[1] Depression is underdiagnosed and frequently under-treated, and depressed individuals have a much higher risk for suicide. The primary treatment for depression involves the use of antidepressant drugs, and it is therefore important that clinicians become familiar with and adept in utilizing this important group of compounds. Although primarily used for the treatment of depression, drugs within this category also have a number of other important uses. A thorough understanding of the pharmacology of antidepressants will aid the clinician in the selective use of these drugs for patients with depression as well as patients with a number of other disorders.

A brief history of antidepressant discovery and theories of action

Table 6.2.3.1 gives a brief chronology of antidepressant drug discoveries and theories of drug action. It is a comment on our understanding of the illness that some of the major advances in the pharmacotherapy of depression have been serendipitous. Prior to 1954, except for the use of electroconvulsive therapy, there were few effective drug treatments for depression. In 1954, the antidepressant era was initiated with the observation that some patients with tuberculosis displayed mood elevations following treatment with the antituberculosis agent iproniazid.(2) Following this initial serendipitous observation, the antidepressant effect of iproniazid was confirmed(3) and its action of inhibiting monoamine oxidase was reported. Iproniazid had significant toxicity and other monoamine oxidase inhibitors (MAOIs) were subsequently introduced. Independent from the work on MAOIs, imipramine, which has a chemical structure similar to the phenothiazines, was assessed as an agent to treat agitation in psychotic patients where it was found to be ineffective. However, it was noticed (again serendipitously) that imipramine produced an improvement of mood in the subset of patients who had symptoms of depression. Kuhn then reported in 1958 that imipramine was an effective antidepressant.(4)

One of the earliest theories of antidepressant drug action was that the antidepressant effect was produced by an increase of serotonin (5-hydroxytryptamine (**5-HT**)) in brain. This was supported by an initial study showing that an MAOI plus tryptophan, the precursor of 5-HT, was a more effective antidepressant treatment than an MAOI alone.[5] Subsequently, the discovery that imipramine and desipramine had effects in inhibiting the reuptake of noradrenaline (norepinephrine) and adrenaline (epinephrine) into the synapse led to the catecholamine theory of depression, which proposed that antidepressant treatments act by increasing the level of catecholamines at brain synapses.[6,7] Ten years later, it was reported that in laboratory animals most antidepressant treatments lead to downregulation of β-adrenergic receptors. This supported the proposal that antidepressants act by reducing β-adrenergic receptor sensitivity.[8] However, the reduction in β-adrenergic receptor sensitivity occurred within hours and antidepressant effect requires 1 to 3 weeks and futher not all effective antidepressant treatments produce reductions in β-adrenergic receptor sensitivity.

In the 1970s and 1980s, a large number of studies on antidepressants were conducted in laboratory animals which demonstrated that they produced a number of changes in monoamine receptor sensitivity.[9] In the late 1980s, a number of neurophysiological

Table 6.2.3.1 History of discovery of antidepressants and pharmacological theories of antidepressant drug action

Year	Discovery or theory	Reference
1954	Discovery that MAOIs have antidepressant effects	2, 3
1958	Discovery that the tricyclic drug imipramine is an effective antidepressant	4
1963	*Serotonin theory of depression:* MAOIs act by increasing serotonin and tryptamine in brain	5
1965	*Catecholamine theory of depression:* ADTs act by increasing cathecolamines in brain	6, 7
1975	β-*Adrenergic receptor theory of depression:* ADTs act by altering the sensitivity of several monoamine receptor subtypes in brain	8
1981	*Monoamine receptor sensitivity theory of depression:* ADTs act by altering the sensitivity of several monoamine receptor subtypes in brain	9
1987	*Serotonergic augmentation theory of depression:* ADTs act by decreasing sensitivity of presynaptic serotonergic autoreceptors and increasing sensitivity of serotonergic postsynaptic receptors to increase overall efficacy in serotonergic transmission	10
1996	*A molecular and cellular theory of depression:* ADTs act by producing a sustained activation of the CAMP system which increases brain levels of neurotrophic factors that reverse the effects of stres in certain brain areas	14

ADT, antidepressant treatment.

studies provided evidence that the delay in onset of antidepressant effects could be accounted for by a slow decrease in sensitivity at presynaptic serotonergic autoreceptors which has the overall result of increasing serotonergic function after days and weeks of treatment.[10] An elaboration on the receptor sensitivity theory was the discovery that most antidepressants produce alterations in the sensitivity of a specific glycine-sensitive site on the *N*-methyl-d-aspartate (NMDA) receptor.[11] A subsequent study showed that an NMDA antagonist may have antidepressant actions[12]and this line of thought has borne fruit recently in a possible novel mechanism of action for antidepressant treatment. An additional receptor sensitivity change thought to be important in the mechanism of action of antidepressants involved changes in the sensitivity of receptors for glucocorticoids. It was found that antidepressants produce an overall improvement of inhibitory feedback on the hypothalamic-pituitary-adrenal axis[13] and that specific corticotrophin releasing hormone (CRH) antagonists have antidepressant properties.[14]

A more recent theory of antidepressant drug action involves findings that antidepressant treatments affect intracellular pathways and neurotrophins. It was found that many antidepressants, in spite of β-adrenergic receptor downregulation, continue to produce sustained activation of the cAMP system and that this is related to increases of neurotrophic factors in brain.[15] Neurotrophins reverse the effects of stress in some brain areas and this raise the possibility that antidepressants act by increasing neurotrophins which reverse the effects of stress in important brain areas of depressed patients.

Throughout the 1980s, and 1990s a number of compounds that do not fit the standard monoamine theories of depression have been found to be effective clinical antidepressants. One of these drugs, tianeptine, actually increases the uptake of 5-HT into nerve endings, an effect that is opposite to the standard selective serotonin reuptake inhibitors (**SSRI**s).[16] Similarly, while there was intense interest in a report of possible antidepressant efficacy of a substance P receptor antagonist,[17] which does not interact with monoamine systems, clinical trials for this specific compound were disappointing.

Although no single mechanism has been discovered that will account for the antidepressant effects of all effective antidepressant treatments, it is clear that initial effects on monoamine metabolism with subsequent effects of intracellular pathways is important. While clinical wisdom and data suggest that there is a lag of 7–21 days to antidepressant action, recent reports question this notion of delayed onset of efficacy.[18] Recently ketamine, an NMDA antagonist has been shown to have an onset of action much faster than that traditionally seen with conventional antidepressants[19,20] suggesting that the pursuit of novel mechanisms may indeed result in advances in the pharmacotherapy of depression. Using preclinical models, it has been suggested that both nonselective NMDA antagonists as well as NR2B selective antagonists exert their antidepressant effects by regulating the functional interplay between AMPA and NMDA throughput.[21]

Pharmacology and types of compounds available

Antidepressant drugs fall into a wide variety of chemical classes and they have a wide range of neuropharmacological effects. They are grouped in Tables 6.2.3.2, 6.2.3.3, and 6.2.3.4 based on the presumed primary action that leads to an antidepressant effect. Table 6.2.3.2 lists the drugs that inhibit the uptake of the monoamines noradrenaline, 5-HT, and dopamine into nerve endings which in turn is thought to increase the function of the respective monoamine systems in brain. Table 6.2.3.3 lists the drugs that inhibit monoamine oxidase and thereby increase the concentration of many amines in brain. Table 6.2.3.4 lists the drugs with other primary actions that do not primarily involve inhibition of monoamine uptake or monoamine oxidase inhibition.

In Table 6.2.3.2, the first 12 compounds are inhibitors of noradrenaline uptake with a variable potency of inhibiting 5-HT uptake. The drugs with secondary amine structures, desipramine, nortriptyline, protriptyline, amoxapine, and maprotiline are predominantly noradrenaline uptake inhibitors with little effect on 5-HT uptake.[22] It can be seen in Table 6.2.3.2 that clomipramine, in addition to inhibiting noradrenaline uptake, is also a strong 5-HT uptake inhibitor. There are currently three selective serotonin and noradrenaline reuptake inhibitor (SNRI) drugs available; milnacipran (not licensed in the US), venlafaxine and duloxetine. Venlafaxine, inhibits both 5-HT and noradrenaline and 5-HT reuptake,[23] as do milnacipran and duloxetine though in varying proportions. While affinities vary depending on the system studied, milnacipran blocks 5-HT and norepinephrine reuptake with relatively equal affinity, while duloxetine has been suggested to have a slightly greater selectivity for 5-HT and venlafaxine a much greater selectivity for 5-HT.[24] Reboxetine (not licensed in the US) is a highly selective and potent inhibitor of noradrenaline reuptake.[25] It has only a weak effect on the 5-HT reuptake and does not affect the uptake of dopamine.

A key issue in the pharmacology of all antidepressant drugs is the relative specificity of their action. Drugs with a tertiary amine structure tend to produce more antagonism of α_1-adrenergic receptors which can produce hypotension, histamine receptors which can produce sedation, and muscarinic cholinergic receptors which can produce blurred vision, dry mouth, and urinary retention. This leads to more side-effects for these compounds than the drugs with a secondary amine structure. Venlafaxine has relatively less effect on these receptors and thus fewer side-effects[23] (see Table 6.2.3.6).

SSRIs are probably the most widely prescribed antidepressants and represent a class of drugs that selectively inhibit 5-HT reuptake from the synapse. Unlike the tricyclics, they each have different chemical structures. The drugs listed in Table 6.2.3.2 have a relatively specific effect in inhibiting 5-HT uptake,[22] and because of their relatively specific effect on this monoamine system and the lack of antagonism of many other receptors, they have been found to have fewer side-effects. Escitalopram was introduced following the discovery that all of the inhibitory activity of citalopram on 5-HT reuptake resides in the *S*-(+)-enantiomer (*S*-citalopram),[26] with *S*-citalopram being 167 times more potent than *R*-citalopram at inhibiting 5-HT reuptake into rat brain synaptosomes.

MAOIs are listed in Table 6.2.3.3. Two isozymes, monoamine oxidases A and B, are present in many discrete cell populations within the central nervous system, and glial cells also express monoamine oxidases A and B. The main substrates for monoamine oxidase A include adrenaline, noradrenaline, and 5-HT. The breakdown of dopamine in striatal regions of the brain is preferentially by monoamine oxidase B, but it can also be broken down by monoamine oxidase A. Since monoamine oxidase is located on the

[a]Secondary amine.

outside of the plasma membrane of the mitochondria in neurones, it is not able to eliminate amines that are stored inside vesicles. MAOI produces an increase in monoamines in the cytoplasm. It is thought that the increase in monoamine content is the primary mechanism of action of MAOIs, and other secondary changes including β-adrenergic receptor downregulation and other receptor changes are secondary to the increased amine levels.[27]

Four of the six drugs listed in Table 6.2.3.3 are irreversible inhibitors. The two reversible inhibitors are essentially inert substrate analogues, and there is usually a correlation between their plasma concentration and the reversible inhibition of monoamine oxidase A. Since isocarboxazid, phenelzine, and tranylcypromine are irreversible inhibitors of monoamine oxidases A and B, there can be serious side-effects when foods that are high in tyramine or other amines are ingested. In addition, these three drugs have strong interactions with other drugs that alter monoamine

Table 6.2.3.3 Pharmacological actions of antidepressants: drugs that inhibit monoamine oxidase

Drug	Chemical class	MAO A	MAO B	Reversible
Isocarboxazid	Hydrazine	Yes	Yes	No
Phenelzine	Hydrazine	Yes	Yes	No
Tranylcypromine	Amphetamine	Yes	Yes	No
Moclobemide	Morpholine	Yes	No	Yes

Selegiline	Phenethylamine	No	Yes[a]	No

MAO, Monoamine oxidase.

[a]Selective at lower doses; becomes non-selective at higher doses.

Table 6.2.3.4 Pharmacological actions of antidepressants: drugs that do not act by strong inhibition of monoamine uptake or inhibition of monoamine oxidase

Drug	Chemical class	Possible pharmacological action
Trazodone	Triazolopyridine	Mixed 5-HT agonist/antagonist
Nefazodone	Phenylpiperazine	Mixed 5-HT agonist/antagonist, weak monoamine uptake inhibitor
Bupropion	Unicyclic amino ketone	Weak noradrenaline and dopamine uptake inhibitor
Mianserin	Tetracyclic	Antagonist α_2-adrenergic auto- and heteroreceptors, increased 5-HT and noradrenaline release
Mirtazapine	Tetracyclic	Antagonist α_2-adrenergic auto and heteroreceptors, increased 5-HT and noradrenaline release

metabolism and therefore their use as antidepressants is much more limited than the tricyclics, SSRIs, or other antidepressant compounds. Tranylcypromine, which has a structure similar to amfetamine in addition to being an MAOI, is also thought to have a stimulant-type action of rapid onset. With the reversible MAOIs moclobemide and brofaromine, the recovery of monoamine oxidase back to normal levels after the drug is stopped is much shorter than with the irreversible MAOIs. These drugs increase concentrations of 5-HT, noradrenaline, and adrenaline that are short and parallel the time course of the monoamine oxidase A inhibition. These two drugs are more easily displaced by the pressor amines such as tyramine, and therefore, are thought to be safer than the irreversible inhibitors.

Selegiline, which has recently become available as a transdermal patch,[28] is selective at lower doses for monoamine oxidase B but at higher doses it becomes non-selective.[29] It has been primarily used for the treatment of Parkinson's disease and the doses for treating depression need to be much higher (note: selegiline is not licensed in the UK for depression). Since monoamine oxidase B is not involved in the intestinal tyramine interaction, selegiline interactions with ingested monoamines have been minimal.

In addition to inhibiting monoamine oxidase, these compounds have other effects on monoamine systems that can produce side-effects. However, the major concerns are the interactions with dietary amines and other drugs that influence amine function. The combination of dietary interactions and slow recovery of monoamine oxidase following with the irreversible inhibitors makes these drugs one of the more difficult treatments to administer. They are generally reserved for patients not otherwise responding to the other less toxic antidepressants.

In Table 6.2.3.4, compounds that are effective antidepressants but do not inhibit monoamine oxidase or have strong monoamine uptake inhibition are listed. Trazodone has shown receptor antagonist activity at several 5-HT receptor subtypes although its active metabolite *m*-chlorophenylpiperazine (mCPP) is a potent direct serotonin agonist. It is a weak but relatively selective inhibitor of 5-HT reuptake, is an antagonist at 5-HT1A and 5-HT2 receptors in addition to its active metabolite mCPP being a potent 5-HT agonist.[30] This leads to trazodone being classified as a mixed 5-HT agonist/antagonist. It also has relatively weak 5-HT uptake inhibiting properties but with no effect on noradrenaline or dopamine uptake. Trazodone is virtually devoid of anticholingeric activity and therefore it has few side-effects in this area. However, it does produce considerable sedation and hypotension secondary to antagonism of α_1-adrenergic receptors and histamine receptors.

Nefazodone is an analogue of trazodone that was developed to overcome the orthostatic hypotension and sedation caused by the latter. Like trazodone it is a 5-HT receptor antagonist with weak monoamine uptake inhibition activity.[31] It has less affinity for the α-adrenergic receptors and is inactive on many other receptors. It too is metabolized to *m*-chlorophenylpiperazine which is an active serotonergic agonist. Although the initial effects of nefazodone involve alterations of 5-HT neurotransmission, these effects are complex and depend on the biological test used.

Bupropion resulted from focussed research to find antidepressant compounds that would have fewer side-effects than traditional tricyclics (note: buproprion is not licensed in the UK for depression). Bupropion is a mild inhibitor of noradrenaline uptake, has some effects on inhibiting dopamine uptake but has no effect on 5-HT uptake.[32] These effects are not associated with β-adrenergic receptor downregulation as is seen with many other antidepressants. One of the active metabolites is hydroxybupropion which also has an antidepressant profile in laboratory animals. It is of interest that bupropion is one of the few drugs that reduce REM latency since most other treatments increase it. Although the specific mechanisms of bupropions antidepressant effects are not known, its unique profile has led to its use in the treatment of bipolar disorder[33] as well as its use in the treatment of smoking cessation.[34]

Mianserin and mirtazapine both have potent effects on antagonizing α_2-adrenergic auto- and heteroreceptors.[35] They also antagonize other 5-HT receptors but have minimal effects on monoamine uptake or monoamine oxidase activity. Since α_2 receptors inhibit noradrenaline release, their antagonism leads to an increase in noradrenaline release in many brain areas. In addition, antagonism of α_2-adrenergic heteroreceptors located on serotonergic neurones results in an enhanced 5-HT release. With mirtazapine, since 5-HT_2 and 5-HT_3 receptors are blocked, this could result in selective enhancement of 5-HT_1-receptor-mediated neurotransmission. These drugs have low affinity for muscarinic, cholinergic, and dopamine receptors and this is related to a reduced side-effect profile. The combination of increased noradrenaline release and increased 5-HT release resulting from the α_2-antagonism on auto- and heteroreceptors is hypothesized to be the central mechanism of action.

Pharmacokinetics

Data on the pharmacokinetics of antidepressants are listed in Table 6.2.3.5. The tricyclic antidepressants are by and large well absorbed although time to peak plasma concentration can vary from 1 to 12 h depending on the drug and the individual. In general, these drugs are metabolized in the liver to a variety of metabolites, some of which are active. For instance, desipramine is a metabolite of imipramine and nortriptyline is a metabolite of amitriptyline. Most of these compounds have a long half-life (close to 24 h) that will allow for once-daily dosing. All the compounds are highly bound to plasma protein except for venlafaxine and milnacipran. Although many of the compounds have active metabolites, the exact percentage of each metabolite in patients and in their clinical effects is still largely unknown.

There is considerable individual variation in the metabolism of tricyclics, and a large component of this may be genetic. Up to 7 to 9 per cent of the Caucasian population have been classified as slow metabolizers (slow hydroxylators) which can be measured by the rate of hydroxylation of debrisoquin. The slow hydoxylation has been determined to be caused by a polymorphism in a cytochrome P-450 macrosomal enzyme (CYP2D6). It is of interest that many SSRIs are inhibitors of P-450 isoenzymes which can considerably influence the metabolism of tricyclic antidepressants.[36] In general, the increased renal clearance in children and a decreased renal clearance with age need to be taken into account with dosing.

The SSRIs are rapidly absorbed, although there is variability within the drug half-lives. The metabolism into active metabolites can vary the pharmacodynamic effects considerably. For example, fluoxetine is metabolized to norfluoxetine which has similar activity on 5-HT reuptake as fluoxetine. The elimination half-life of norfluoxetine is longer (4–16 days) than that of fluoxetine (4–6 days). The desmethyl metabolite of sertraline although not nearly as

potent as the parent compound, also has a much longer half life. The desmethyl metabolite of citalopram or escitalopram, although a potent noradrenaline uptake inhibitor, is much lower in concentration than citalopram and it weakly crosses the blood-brain barrier. Fluvoxamine, paroxetine, duloxetine or milnacipran do not have any active metabolites. The relatively long half-lives of some of the SSRIs, particularly fluoxetine, require longer drug-free periods before switching to other classes of compounds especially before starting an MAOI.

The MAOIs are all rapidly absorbed. For the irreversible MAOIs, the elimination half-life and protein binding patterns are not as relevant because of the irreversible effects on monoamine oxidase. The reversible MAOIs have shorter half-lives and require multiple daily dosing.[29] With the irreversible MAOIs, once the drug is stopped, there needs to be time for new synthesis of monoamine oxidase. This requires a minimum of 5 to 7 days and the safest recommendation is to wait 2 weeks before starting other drugs that may interact with the MAOIs.

The five other antidepressants listed in Table 6.2.3.5 are rapidly absorbed but there is some variation in their elimination half-life. In general, the half-lives are short enough that multiple daily dosing is required. They are generally bound to plasma protein at a high level. The metabolites of trazodone and nefazodone have mixed effects on 5-HT receptors which results in a complex overall effect. Trazodone and nefazodone undergo extensive hepatic metabolism and one major metabolite is *m*-chlorophenylpiperazine which stimulates 5-HT receptors. Many metabolites have biological activity with half-lives different to the parent compounds.

Bupropion is metabolized in the liver and its metabolites can be at higher concentration than the parent compound. The relationship between plasma bupropion and clinical response has been poor.

Table 6.2.3.5 Pharmacokinetics of antidepressants

Drug	Absorption time to peak plasma concentration (h)	Elimination half-life (h)	Percentage plasma protein binding	Important metabolite
Monoamine reuptake inhibitors				
Imipramine	1.5–3	11–25	92	Desipramine

Side-effects

The history of new drugs becoming available for the treatment of depression reflects the efforts by the pharmaceutical industry to find compounds with reduced side-effects. This is in particularly important in the treatment of patients with medical illness because some of the side-effects can have considerable negative medical consequences. In Table 6.2.3.6, the propensity of the different drugs to produce some of the side-effects caused by antidepressants can be compared. The drugs that have high affinity for the α_1-adrenergic receptors can produce hypotension. Antagonism of histamine receptors has been associated with sedation and there is a long list of anticholinergic effects associated with antagonism of muscarinic cholinergic receptors.

For the tricyclics, it can be seen that drugs with a tertiary amine structure produce increased sedation. There is also an increase in the frequency of side-effects associated with antagonism of muscarinic cholinergic receptors such as dry mouth, constipation, blurred vision, urinary retention, dizziness, tachycardia, memory impairment, and at high and toxic doses, delirium. There is also an increased tendency for these same compounds to produce hypotension and to have unwanted cardiac effects that can lead to serious complications. In addition, the tertiary amines have a tendency to produce more weight gain than the secondary amines. The adverse effects have a particular impact on the tolerance of the patients to taking the medication. Most importantly the anticholinergic and cardiac effects can produce difficult complications in the elderly even leading to delirium when too high a dose is given. Amoxapine can cause extrapyramidal symptoms which are thought to be secondary to blocking dopamine receptors.[37] The most common adverse effects in patients taking reboxetine during clinical trials were insomnia, sweating, constipation, dry mouth, and urinary hesitancy compared with placebo, and the rates of nausea, diarrhea, and somnolence were lower compared with fluoxetine.[38] Nausea, dry mouth, dizziness, headache, somnolence, constipation, and fatigue were reported most frequently with duloxetine.[39]

The propensity to produce orthostatic hypotension is also a serious side-effect, particularly in the elderly. With the increased risk of falls and subsequent fractures in the elderly, this can be a serious health risk. A number of methods such as teaching patients to rise slowly from a supine position, tilting the bed upward, and maintenance of fluid uptake could help prevent this. However, other equally effective newer antidepressants produce much less of many of these side-effects, and they can be more safely used in the elderly.

Many of the drugs that are monoamine uptake inhibitors can cause cardiac conduction delays which may even lead to heart block in patients with pre-existing conditions. Severe overdose of these compounds can produce major and life-threatening cardiac arrhythmias. The secondary amines are generally thought to produce less cardiac effects than the tertiary amines. One of the characteristics of the SSRIs which has led to their widespread use is their low rate of side-effects. The pharmacological specificity of these compounds which bind to the 5-HT transporter, while not binding to the other neurotransmitter receptor types, results in their producing a therapeutic effect without many of the unwanted side-effects. In placebo-controlled trials the incidence of early discontinuation of SSRIs because of adverse events is intermediate between patients treated with placebo and patients treated with tricyclic antidepressants. Some of the symptoms reported with these compounds include agitation, anxiety, headache, sleep disturbance, and tremor. One of the more troublesome side-effects is sexual dysfunction especially anorgasmia. Less frequently, there are changes in appetite with nausea, dry mouth, sweating, and weight change. In general, these effects are less than those observed with the non-SSRI monoamine uptake inhibitors. The interaction of SSRIs with MAOIs to produce the serotonin syndrome is discussed under toxic effects below. Fluoxetine and sertraline induced higher rates of sedation as dosages are increased but in contrast, paroxetine produces a dose-dependent increase in arousal.

In contrast with the fewer side-effects produced by SSRIs and the other antidepressants that are not monoamine inhibitors, the MAOIs tend to produce frequent and often much more serious side-effects. Frequent side-effects include dizziness, headache, insomnia, dry mouth, blurred vision, nausea, constipation, forgetfulness, difficulty with urination, and weakness. There is also sexual dysfunction, including anorgasmia, impotence, delayed ejaculation, and decreased desire. Insomnia has also been reported. The original MAOIs iproniazid and isocarboxazid had a higher frequency of impairing liver function, but this is less with the other drugs. Pyridoxine deficiency has been reported and should be considered in evaluating side-effects. The largest problem with the MAOIs is the interactions with foods and with other drugs. Food interaction is much less of a problem with the reversible MAOIs moclobemide and brofaromine.[37–39]

Trazodone and nefazodone lack the anticholeringic side-effects of many of the tricyclic drugs. This makes them useful compounds in many medical conditions where this effect would be problematic. Trazodone has an acute sedative effect which is useful in the treatment of agitation, anxiety, and insomnia. However, this can be a troublesome side-effect when the patient performs tasks that require full alertness. Trazodone appears to have more propensity to produce orthostatic hypotension than nefazodone, possibility related to the degree of α_1-adrenergic receptor antagonism. Both trazodone and nefazodone, because of their lack of anticholinergic effects, have a low probability of producing difficulties in patients with cardiac illness. There is a slight tendency for weight gain but not nearly as strong as for some of the other antidepressants.[40] A relatively rare but important side-effect with trazodone is priapism. The risk for this side-effect is greatest during the early phase of treatment and the reporting of abnormal erectile function, including inappropriate or prolonged erections, should prompt quick discontinuation of trazodone treatment. Sexual side-effects have also been reported in women.

Bupropion has a very different side-effect profile than the conventional tricyclic antidepressants. It has no anticholinergic effects, is not sedating, and instead of weight gain, it suppresses appetite in some patients. In comparison to the SSRIs and trazodone and nefazodone, it also does not cause sexual dysfunction. There is no orthostatic hypotension, and bupropion does not produce cardiac side-effects. The possible stimulation of dopaminergic systems by bupropion can be related to its activating effects. This may be useful in patients with retardation but may exacerbate patients with agitation and insomnia. Bupropion can make tics in attention-deficit hyperactivity disorder and Tourette's disorder worse.[41] Patients have been described with bupropion-related

psychosis which includes hallucinations and delusions. Psychotropic drugs also modulate seizure threshold and this needs to be carefully evaluated.[42] For example, a serious side-effect of bupropion that is rare but clinically important is the propensity to induce seizures in doses over 450 mg/day. Thus, bupropion should not be used at a dose higher than this and careful evaluation of history of seizures and other medical conditions or treatments that might lower seizure threshold should be evaluated in each patient.

Mianserin often produces drowsiness during the first weeks of treatment but has much less anticholinergic side-effects than other tricyclic antidepressants. It has less effects on producing hypotension and cardiac effects and there is only a low propensity for weight gain. Mirtazapine also has an increased amount of drowsiness and sedation. These side-effects are usually mild and transient. Mirtazapine has a low propensity to produce orthostatic hypotension or cardiac effects. There is a tendency for increased appetite and weight gain, however, which does not appear to be as severe as with tricyclics such as amitriptyline. Mianserin and mirtazapine have not been shown to produce high rates of sexual dysfunction as has been seen with trazodone and there is little evidence of lowering of the seizure threshold.

The side-effect profiles of the antidepressants are thought to relate to their respective effects on a variety of neurotransmitter systems. Clinicians should be aware of the profile of side-effects for each of the antidepressants they prescribe. The dose and duration of treatment interact with the intensity and type of side-effect and should be considered relative to antidepressant effects when evaluating, switching or stopping treatment. Although all antidepressant treatments can provoke switches into mania in vulnerable patients with bipolar disorder, it would appear that the MAOIs have a somewhat higher propensity to do this than the other compounds.

It is important that the nature of somatic and behavioural symptoms be carefully recorded before the onset of treatment so that the emergence of side-effects can be documented for the individual patient.

Toxic effects

There is ongoing concern recently regarding the issue of antidepressant use and suicide. The field has been grapplling with two inter-related issues: the possible risk of suicidal behaviour attributable to antidepressant treatment versus the potential decrease in suicidal behaviour afforded by antidepressant therapy. In 2004, there was an 18 per cent increase in adolescent suicides over the previous year.[43] This coincided with increased publicity about the relationship between antidepressant treatment and suicide risk in children and adolescents and a subsequent decline in antidepressant prescriptions. The Food and Drug Administration (FDA) has issued a black box warning to warn the public about the increased risk of suicidal thoughts and behaviour ('suicidality') in children and adolescents being treated with antidepressant medications.[44]

Often the most serious toxic effects are the result of overdose. Since depressed patients are at increased risk of suicide there is always the possibility that suicidally depressed patients will overdose on their antidepressants. This is a very serious consideration and should be carefully evaluated when prescribing antidepressants. The symptoms and course of events following acute antidepressant overdose are complex and can be confusing unless a clear history of overdose is obtained. With tricyclic antidepressants, restlessness and excitement are initially seen with possible myoclonus, and dystonia and seizures leading to the development of coma. Seriously compromized patients can have depressed respiration with hypoxia, depressed reflexes, hypertension, and hypothermia. With the antidepressants that have antimuscarinic activity, there can be strong anticholinergic effects with mydriasis, flushed skin, dry membranes, and tachycardia.

Antidepressant overdose can be life-threatening and patients should receive immediate emergency medical evaluation. The local poison control centre should be contacted in any case of suspected antidepressant overdose. Appropriate follow-up can include the use of activated charcoal to absorb the drug as well as other medical supportive measures. Different compounds have different probability of serious complications following an overdose and this is related to the amount ingested. However, drugs are often taken in combination, and it is difficult to know the exact composition and amount of the overdose.

Another serious toxic side-effect is the interaction of MAOIs and foods that are high in tyramine and other monoamines. Tyramine has both direct and indirect sympathomimetic actions, has a pressor action, and is present in a number of foodstuffs. It is normally broken down by the MAO enzymes and in the presence of a MAOI will increase in concentration. Some of the foods that should be restricted in the diet of patients taking MAOIs are listed in Table 6.2.3.7. The reaction usually develops 20 min to 1 h following ingestion of food and is characterized by nausea, apprehension, occasional chills, sweating, restlessness and hypotension with occipital headache, palpitations, and possibly vomiting. Neck stiffness, piloerection, dilated pupils, fever, and motor agitation are seen on examination. In severe forms, the reaction can lead to delirium, hyperpyrexia, cerebral hemorrhage, and death. The interaction of the irreversible MAOIs with certain dietary components leading to the hypertensive reaction is one of the most serious drawbacks to the use of these types of compounds. The reversible MAOIs moclobemide and brofaromine have not been found to interact with tyramine in the same fashion as the irreversible MAOIs. Thus, they have much less liability in terms of producing the hypertensive crisis seen with the irreversible MAOIs.[29] Phentolamine (5 mg) administered intravenously or nifedipine (onset of action 5 minutes), a calcium channel blocker, have been shown to be useful in the treatment of hypertensive reactions.

Serotonin syndrome is most often encountered when a MAOI is combined with an SSRI and there is an excess of 5-HT which overstimulates serotonin receptors.[45] This syndrome can manifest itself with sweating, diarrhoea, abdominal pain, fever, tachycardia, elevated blood pressure, myoclonus, hyper-reflexia, and with irritability and agitation. In its severe form, there can be severe hyperpyrexia, motor irritability, cardiovascular shock, and death. This toxic effect can result from the use of irreversible MAOIs and the addition of high amounts of tryptophan or other drugs that release serotonin in the brain. In addition, a common cause of this syndrome can result from the use of SSRIs and irreversible MAOIs concomitantly. Thus, it is strongly recommended that when MAOIs or SSRIs are utilized in sequence that the switch of treatment from one drug to the other has a minimum of a 14-day washout drug-free period before the second drug is started. In the case of discontinuing drugs with long half-lives such as fluoxetine an even longer period of up to 3 to 5 weeks may be necessary to safely avoid any possibility of producing the serotonin syndrome as a possible reaction to the drug combination.

The use of antidepressants during pregnancy is controversial and as always clinicians need to balance up the risks and benefits of treatments for individuals in this situation. Some recent studies have suggested that the use of SSRI medication in the perinatal period may be associated with adverse events like low birth weight and respiratory distress in the new born.[46, 47] However, this needs to be balanced against the fact that women at risk for depression may be at risk if not treated with antidepressants during pregnancy[48] and both these risks need to be balanced against each other.

Table 6.2.3.7 Dietary restrictions for patients on MAOIs

[a] Not over 50g daily.

The elderly are much more susceptible to toxic effects of antidepressants than younger individuals. In elderly patients, there may be other illnesses and the compensatory biological systems are not as resistant as in younger individuals. Mild toxic effects can be life threatening in the elderly. The newer antidepressants with fewer side-effects are the best drugs to use in the elderly.

There are a number of other toxic events that occur with less regularity. Isocarboxizid and phenelzine, since they are hydrazines, have some propensity to produce liver toxicity. Other much less frequent toxic events have occurred following antidepressants such as idiosyncratic individualized allergic reactions to the drug, suppression of the haematopoietic system, unusual dermatological reactions and hyponatremia.[49] There are reports of death in children receiving desipramine[50] though the cause of these deaths is unknown. Similarly, there is literature documenting increased incidence of gastric bleeding in association with SSRI treatment though there is a confounding effect of concomitant non-steroidal anti-inflammatory medication.[51]

Indications

Table 6.2.3.8 lists conditions where some antidepressant drugs have been found to be effective. Not all drugs are equally effective in each condition and very few clinical trials of the different compounds in each of the conditions have been conducted. Since the efficacy of antidepressant drugs is in part related to the dose administered and/or blood levels, it is difficult to be certain of the relative efficacy of one compound versus another when only single fixed doses are used. The expense and difficulty of multidose designs in comparing two treatments are extremely large and this is the main factor limiting comparisons of different drugs across the conditions listed in Table 6.2.3.8. In addition, the large number of compounds available would make this a very difficult task indeed. Another issue is that many of the drugs are only officially approved by the American Food and Drug Administration for use in depressed patients. Many of the indications listed in Table 6.2.3.8 are 'off-label' use of the medication. Since depression is the most prevalent illness, pharmaceutical companies have developed and brought forward drugs with depression as the primary indication. The expense of clinical trials to gain approval for other indications is high. Thus, for many of the conditions listed in Table 6.2.3.8, there is only fragmentary evidence for efficacy of some antidepressants and almost no data or comparable efficacy across drugs.

There are a number of different diagnostic approaches to depression as listed in Table 6.2.3.8. By and large, all of the drugs listed in Table 6.2.3.5 have been shown to be effective in the treatment of major depression. Most drugs have been studied in outpatient samples of patients with major depression. Their relative efficacy in the treatment of more severe conditions such as melancholia, psychotic depression, or bipolar depression remains limited. In addition, the relative efficacy of the different compounds as treatments for the depressive subtype, such as atypical depression, dysthymia, or secondary depression, has not been fully studied. There have been some reports that the MAOIs may be more effective in atypical depression[52] but not all studies have validated this. When depression in the elderly is under consideration, the side-effect profile for each drug becomes a much more relevant consideration when choosing a specific drug.

Anxiety disorders have considerable comorbidity with depression. Imipramine was initially found to be effective in the treatment of panic disorder and since then SSRIs have also been effective as well as MAOIs.[53] Clomipramine was found to be effective in obsessive-compulsive disorder though more recently SSRIs tend to be favoured as they generally have fewer side-effects. Depending on the studies, both SSRIs and MAOIs have been effective treatments in social phobia as well as some tricyclic drugs. In general anxiety disorder and post-traumatic stress disorder, antidepressants have also shown efficacy but not to the same extent as seen in panic disorder.[54]

It is of interest that some antidepressants have been effective in treating eating disorders. They are effective in bulimia nervosa[55] but not in anorexia nervosa.[56] The dose of fluoxetine to treat

Neurological disorders
Enuresis
Attention-deficit disorder
Premenstrual dysphoric disorder
Peptic ulcer
Urticaria pruritus
Premature ejaculation

bulimia nervosa is higher than the treatment of depression. The increase of weight seen following many antidepressants contrasts with some reports of the usefulness of SSRIs in the treatment of obesity.

In clinical practice, many clinicians have used trazodone as a night-time sedative. In the treatment of depression, sleep is one of the first symptoms to show improvement following initiation of most antidepressant treatments. Various reports of use of antidepressants in the treatment of narcolepsy and sleep apnoea have also been published.

Antidepressants have been effective in various pain syndromes. Since there is a wide range of the medical conditions producing pain, the results have been quite variable. In general the antidepressants have been able to reduce many of the painful symptoms as well as be effective in treating the secondary depression associated with chronic pain. However, they do not demonstrate the clear analgesic effect of drugs such as opioids.

Antidepressants have been reported to be effective in many other disorders including substance abuse, alcoholism, and smoking cessation.[57] In children with enuresis a dose of imipramine as low as 25 mg has been seen to be safe and effective. In both children and adults, imipramine, desipramine, bupropion, and nortriptyline have been effective in the treatment of attention-deficient disorder.[58] Antidepressants have found use in the treatment of premenstrual disorders,[59] and they are also useful in the treatment of several neurological disorders.

In general the indications and uses of a specific antidepressant in part depend on their side-effect profile and on the previously demonstrated efficacy. A major issue in the use of drugs to treat the large number of depressed patients with a comorbid medical condition is the careful choice of drug to minimize possible negative interactions with the medical disease.

Contraindications

The major contraindications in the use of antidepressants arise from the interaction of the pharmacological effects of antidepressant treatment with a comorbid condition of the patient or with diet or drug interactions. As mentioned above, the most serious contraindications arise from the use of irreversible MAOIs in patients taking other drugs or a diet that interacts and potentiates monoamine function resulting in a hypertensive crisis. A major contraindication is the use of MAOI in patients who receive anaesthesia.[59] Patients on MAOIs should carry a card for medical emergencies warning of drug interactions. Drugs that potentiate serotonin can interact with SSRIs to give the serotonin syndrome. The more relative contraindications involve the interaction of the side-effect profile of the antidepressant treatment with either the primary medical disease or with other medications that the patient may be taking. Another relative contraindication is the use of antidepressants during pregnancy and breast feeding though clearly there needs to be a risk benefit analysis of the use of the medication.

Drug interactions

Many patients may be taking other medications and many are prescribed more than one psychotrophic drug at a time. Because of this, it is important that clinicians are aware of drug-drug interactions. Drugs that impair the cytochrome P-450 microsomal enzyme system in the liver can interact with other drugs that are dependent on hepatic metabolism. For example, barbiturates and carbamazepine which induce hepatic enzymes can accelerate tricyclic metabolism and reduce steady state blood levels. Another anticonvulsant increasingly prescribed in the control of affective disorders, valproate, can reduce tricyclic drug clearance. Neuroleptics can elevate tricyclic blood levels which may be related to the impairment of the hydroxylation pathway for tricyclic metabolism. One of the more important drug-drug interactions involves the use of SSRIs and tricyclic drugs. This is related to the competitive inhibition of cytochrome by all of the SSRIs except fluvoxamine. This can result in clear elevations of steady state plasma concentrations. If combinations like this are utilized, the tricyclic doses need to be reduced. The utilization of a drug where plasma concentrations can be monitored (see Table 6.2.3.10) would help in the adjustment of dose if the tricyclic is combined with an SSRI.

One of the more serious drug-drug interactions previously mentioned is the interaction of tricyclic drugs with MAOIs. This can lead to hypertensive reactions and possibly stroke as well as possible induction of the serotonin syndrome.[45] Often antidepressants are combined with phenothiazines. There is some evidence that chlorpromazine can block the metabolism of tricyclics and thus when these two treatments are combined a possible reduction in the tricyclic treatment may be required. Other drugs that have been shown to increase tricyclic levels through blocking their metabolism include cimetidine, methylphenidate, and haloperidol. Tricyclic drugs can reduce the effects of clonidine and guanethidine in reducing blood pressure; an anticonvulsant, phenytoin, may be elevated; and the drug warfarin may be increased following tricyclic drugs. With the SSRIs, since there is a narrow pharmacological effect, interactions with anticholinergic agents or antihistaminics or alcohol are generally less than the tricyclics. The one major interaction is through the cytochrome P-450 family of enzymes which are inhibited by most SSRIs and interact with the metabolism of other drugs.

Some of the more serious drug interactions occur with the MAOIs. In addition to the dietary interactions, the MAOIs can interact with many of the 'over-the-counter' medications such as cough syrups and decongestants. Table 6.2.3.9 lists a number of compounds that have adverse drug interactions with MAOIs. Certainly many of the drugs that are direct or indirect adrenergic and dopaminergic agonists can produce overstimulation of the sympathetic nervous system. This can result in increased blood pressure and possibly adverse effects on the central nervous system. These drugs include all of the sympathomimetics, amphetamines, methylphenidate, and other stimulants. This can also occur with drugs such as other MAOIs and tricyclics or SSRIs that increase monoamine levels. MAOIs may worsen hypoglycaemia and require readjustment of the dosage of hypoglycaemic agents. Major concerns arise when patients on MAOIs need surgery because of the interaction with a number of compounds used in anaesthesia. This is more likely to occur with the use of pethidine. Careful consideration should be given to using a minimal 2-week washout for patients on MAOIs under going elective surgery.

The mixed 5-HT agonist drugs also have important drug-drug interactions. Trazodone can potentiate barbiturate and alcohol and it can increase drowsiness and sedation in patients taking these

Table 6.2.3.9 Adverse drug interactions with MAOIs

Other antidepressants	Other MAOIs
Buspirone	Carbamazepine
Stimulants	L-Dopa
Sympathomimetics	Methyldopa
Dopamine	Guanethidine
Amphetamines	Dextromethorphan
Methylphenidate	Pethidine
Adrenaline	Cocaine
Asthma inhalants	Reserpine
Decongestants	Tryptophan
Appetite suppressants	Fenfluramine

agents. It has also been reported to produce the serotonin syndrome at times when combined with an SSRI and possibly buspirone. Trazodone has altered the kinetics of benzodiazepines including alprazolam and triazolam. Trazodone interacts with cytochrome P-450 enzymes and has been shown to increase plasma levels of digoxin. Unlike trazodone, nefazodone does not appear to potentiate the sedative effects of alcohol.

Bupropion undergoes hepatic metabolism and its levels can be altered by other drugs effecting this metabolic route. There is some dopaminergic activation with bupropion and it has had adverse interactions with MAOIs. Because of the dopaminergic activity, there have been interactions with anti-parkinsonian medication. Because bupropion lowers the seizure threshold at higher dosages it can interact and with other medications that would have similar effects to produce seizures. A combination of bupropion and lithium may increase the likelihood of seizures. There are some reports that carbamazepine may decrease bupropion drug levels.

Mirtazapine is metabolized by cytochrome P-450 enzyme systems. There is the potential for interaction with other drugs via this system. The extent of use of mirtazapine is not as great as the older drugs and the drug-drug interactions are not as extensively reported.

In general, a large number of drug-drug interactions have been reported for the antidepressants. The drug-drug interactions can be quite variable depending on the patient and the dosage and duration of treatments. Thus, the adverse drug-drug interactions are one of the main reasons for the recommendations to use monotherapy rather than more than one drug. The use of drug combinations should, on average, be restricted to patients who have a poor response to a single treatment because of the possibility of adverse drug-drug interactions.

Drug withdrawal

Long-term administration of a drug can produce adaptive changes in many aspects of the human biology. When the drug is abruptly discontinued, 'rebound' drug withdrawal symptoms can be observed. This is most clearly seen with longer-term opiate, benzodiazepine, or barbiturate use. Antidepressants are not addictive and dependence does not develop. With the antidepressants some degree of tolerance to the sedative and autonomic effects tends to develop and on abrupt withdrawal patients can have emerging symptoms consisting of malaise, dizziness, nausea, diarrhoea, chills, insomnia, restlessness, and muscle aches. Symptoms emerging during drug withdrawal have been seen following treatment with tricyclics as well as SSRIs.[60] They have been described on occasion for MAOIs and the other non-monoamine uptake antidepressants. One main factor is the drug elimination half-life. Abrupt discontinuation of drugs with a short elimination half-life will produce more emergent side-effects than drugs with a long half-life. Thus, it has been found that patients taking shorter half-life drugs such as paroxetine and sertraline have more of an emergent symptom increase than patients taking the longer elimination half-life drug fluoxetine. Therefore, the dose of drugs with a shorter elimination half-life should generally be tapered over a 2- to 3-week period when being discontinued rather than being stopped abruptly. Drugs with a longer elimination half-life can be stopped abruptly since the parent drug and metabolite may last for many days. Clinicians must be aware that slow elimination means that parent drug and active metabolites remain in the body for up to several weeks.

With the irreversible MAOI inhibitors, since there is a 1- or 2-week period during with monoamine oxidase must recover following discontinuation of the MAOI, emergent side-effects have not been as regularly observed. In general with the other antidepressants the withdrawal syndromes have not been permanent. Clinicians must make special efforts to discriminate between the return of symptoms and the emergence of new symptoms related to drug withdrawal.

Dosages and administration

In Table 6.2.3.10 some of the suggested optimal plasma concentrations for different antidepressant drugs are listed. For nortriptyline, desipramine, imipramine, and amitriptyline there is some evidence for a minimal plasma and concentration necessary for clinical response. An established therapeutic range is available for nortriptyline. Thus, patients with nortriptyline concentrations between 50 and 150 mg/ml seem to do much better. With the other drugs, it is generally thought that the plasma levels reflect a minimal threshold of plasma concentration for clinical response. Below this level patients are less likely to respond and the upper limit indicates that there is increased possibility of the systemic or cardiac toxicity. Bupropion levels between 50 and 100 ng/ml may possibly be the best range. However, it is important that the dose be kept below 450 mg/day because of the possibility of seizures.

Except for nortriptyline and the use of plasma concentrations to obtain a minimal effective level, it is generally the patient's clinical response that dictates dosage adjustments. One difficulty is that some patients with plasma concentrations outside the therapeutic range do respond and many patients with concentrations within the therapeutic range do not. Thus, the dosage needs to be adjusted depending on the individual patient's response. Clearly plasma concentration monitoring can be helpful in many situations such as evaluating plasma levels when higher than standard doses are used, assessing toxicity, use in elderly patients or patients with comorbid conditions to evaluate possible drug interactions, or where compliance is questioned. Blood for drug levels is usually obtained for plasma levels during elimination phase which is usually in the morning 12 h after the last dose.

Table 6.2.3.10 Dosage and administration of antidepressant drugs. Doses in brackets refer to doses recommended for elderly patients

Drug	Initial dose (mg/day)	Theraupeutic dose range (mg/day)	Recommended optimal plasma concentration (ng/ml)
Monoamine reuptake inhibitors			
Imipramine	25–75 (10)	150–300 (30–50)	200–300[d]

6.2.4 Lithium and related mood stabilizers

Robert M. Post

Introduction

Global categorization of the mood stabilizers

Lithium is the paradigmatic mood stabilizer. It is effective in the acute and prophylactic treatment of both mania and, to a lesser magnitude, depression. These characteristics are generally paralleled by the widely accepted anticonvulsant mood stabilizers valproate, carbamazepine (Table 6.2.4.1), and potentially by the less well studied putative mood stabilizers oxcarbazepine, zonisamide, and the dihydropyridine L-type calcium channel blocker nimodipine. In contrast, lamotrigine has a profile of better antidepressant effects acutely and prophylactically than antimanic effects.

Differential responsivity among individual patients

Having grouped lithium, valproate, and carbamazepine together, it is important to note they have subtle differences in their therapeutic profiles and differential clinical predictors of response (Table 6.2.4.1). **Response to one of these agents is not predictive of either a positive or negative response to the others.**[1,2] Thus, clinicians are left with only rough estimates and guesses about which drug may be preferentially effective in which patients. Only sequential clinical trials of agents either alone or in combination can verify responsivity in an individual patient.[3] **Individual response trumps FDA-approval**.

Requirements for method of longitudinal assessment

Given this clinical conundrum, it is advisable that patients, family members, clinicians, or others carefully rate patients on a longitudinal scale in order to most carefully assess responses and side effects. These are available from the Depression Bipolar Support Alliance (DBSA), the STEP-BD NIMH Network, or www.bipolarnetworknews.org and are highly recommended.

Increasing need for complex combination treatment

The importance of careful longitudinal documentation of symptoms and side effects is highlighted by the increasing use of multiple drugs in combination.[2] This is often required because patients may delay treatment-seeking until after many episodes, and very different patterns and frequencies of depressions, manias, mixed states, as well as multiple comorbidities may be present. Treating patients to the new accepted **goal of remission** of their mood and other anxillary symptoms usually requires use of several medications. If each component of the regimen is kept below an individual's side-effects threshold, judicious use of multiple agents can reduce rather than increase the overall side-effect burden.

Patients and family education is a must

There is increasing evidence of reliable abnormalities of biochemistry, function, and anatomy in the brains of patients with bipolar disorder, and some of these are directly related to either duration of illness or number of episodes.[4,5] Therefore, as treatment resistance to most therapeutic agents is related to number of prior episodes, and brain abnormalities may also increase as well, it behooves the patient to begin and sustain acute and **long-term treatment as early as possible**.

Early age of onset and treatment delay are related to an adverse outcome in adulthood

Despite the above academic, personal, and public health recommendations, bipolar disorder often takes ten years or more to diagnose and, hence, treat properly. In fact, a **younger age** of onset is highly related to presence of a **longer delay** from illness onset to **first treatment, and** as well, to **a poorer outcome** assessed both retrospectively and prospectively.[6]

Table 6.2.4.1 Neuroprotective effects of lithium in cultured cells and animal models of diseases

I. Therapeutic Spectrum	Lithium	Carbamazepine	Valproate	Lamotrigine	Nimodipine

C. Neuroprotective	Yes	Yes	Yes	Yes	(Yes)

Legend: ++++ = very marked; +++ = marked; ++ = moderate; + = mild or some effect; +/– = equivocal; () = ambiguous data; 0 = no effect; – = worse.

BDNF: A role in vulnerability, onset, progression, and treatment

New data indicate that the brain growth factor BDNF (brain-derived neurotrophic factor) which is initially important to synaptogenesis and neural development, and later neuroplasticity and long-term memory in the adult is involved in all phases of bipolar disorder and its treatment.[7]

It appears to be: 1) both a genetic (the val-66-val allele of BDNF) and environmental (low BDNF from childhood adversity) *risk factor*; 2) *episode-related* (serum BDNF decreasing with each episode of depression or mania in proportion to symptom severity; 3) related to some *substance abuse* comorbidity (BDNF increases in the VTA with defeat stress and cocaine self-administration); and 4) related to *treatment*. **Lithium, valproate, and carbamazepine increase BDNF and quetiapine and ziprasidone block the decreases in hippocampal BDNF that occur with stress (as do antidepressants).**

More episodes convey more problems

A greater number of prior episodes is related to increased likelihood of: 1) a rapid cycling course; 2) more severe depressive symptoms; 3) more disability; 4) more cognitive dysfunction; and 5) even the incidence of late life dementia.[4,8,9,10]

Early effective treatment may protect the brain

Taken together, the new data suggest a new view not only of bipolar disorder, but its treatment. Adequate effective **treatment may** not only (a) prevent affective episodes (with their accompanying risk of morbidity, dysfunction, and even death by suicide or the increased medical mortality associated with depression), but may also (b) **reverse or prevent some of the biological abnormalities associated with the illness from progressing.**

Thus, patients should be given timely information pertinent to their stage of illness and recovery that emphasizes not only the risk of treatments, but also their potential, figuratively and literally, life-saving benefits. Long-term treatment and education and targeted psychotherapies are critical to a good outcome.

Therapeutic strategy

We next highlight several attributes of each mood stabilizer, but recognize that the choice of each agent itself is based on inadequate information from the literature, and sequencing of treatments and their combinations is currently more an art than an evidence-based science. We look forward to these informational and clinical trial deficits being reduced in the near future and the development of single nucleotide polymorphism (SNP) and other neurobiological predictors of individual clinical response to individual drugs.

In the meantime, patients and clinicians must struggle with treatment choice based on: 1) the most appropriate targetting of the predominant symptom picture with the most likely effective agent (Table 6.2.4.1 and 6.2.4.2) the best side-effects profile for that patient (Table 6.2.4.2 and 6.2.4.3) using combinations of drugs with different therapeutic targets and mechanisms of action

Table 6.2.4.2 Global putative mechanisms of action

(Table 6.2.4.3 and 6.2.4.4) careful consideration of potential advantageous pharmacodynamic interactions and disadvantageous pharmacokinetic drug-drug interactions that need to be avoided or anticipated.

Mood stabilizers

Lithium

In the late 1960s and early 1970s, open and double-blind randomized treatment and discontinuation studies revealed **highly significant effects of lithium in long-term prophylaxis**. These studies followed shortly after a series of studies demonstrating lithium's acute antimanic effects in comparison with both placebo and the existing neuroleptic treatments. High rates of response were touted and lithium clinics were established with the hope that the 60 to 80 per cent response rates revealed in the controlled clinical trials would be mirrored by clinical practice.[11]

However, over the past two decades there has been increasing recognition of the inadequacy of lithium both in acute treatment and long-term prophylaxis, even when used with adjunctive treatments such as antipsychotics, benzodiazepines, and antidepressants.[12,13,14] Given this increasing cognizance of lithium's less than dramatic efficacy in many patients with bipolar illness, alternative and adjunctive treatments were sought.

The anticonvulsants carbamazepine, valproate, and lamotrigine

Carbamazepine and valproate are now well recognized as potential mood-stabilizing anticonvulsants, and initial promising data are emerging for lamotrigine as well. The data are more equivocal for oxcarbazepine and minimal for zonisamide. Importantly, **the GABA-active anticonvulsants gabapentin, tiagabine, and topiramate** are **not effective in acute mania** and thus cannot be considered mood stabilizers. Nonetheless, topiramate may be useful in some common comorbidities of bipolar illness including alcohol and cocaine abuse, bulimia, overweight, migraine, and PTSD. Similarly, gabapentin (which increases brain GABA and acts at the alpha$_2$ delta subunit of the L-type calcium channel) and its close relative pregabalin may have secondary utility in comorbid panic anxiety and social phobia, sleep disorder, alcohol withdrawal, and chronic pain syndromes.

L-type calcium-channel blockers

The dihydropyridine L-type calcium channel blockers became a focus of possible interest for lithium-intolerant and lithium-unresponsive patients based on a variety of clinical and theoretical rationales. Dubovsky *et al.*[15] found increased intracellular calcium in blood elements of patients with bipolar illness, a finding that has been replicated more than a dozen times. Dubovsky *et al.*[16] proceeded to demonstrate the potential antimanic efficacy of the L-type calcium channel blocker verapamil. Many other small

controlled studies were also positive, although less than dramatic results have recently been reported by two groups.[17,18] In addition, one controlled study found that verapamil was not an effective acute antidepressant, even though it appeared to have good antimanic properties.[19] Verapamil was never widely used in clinical practice.

Given these ambiguities with verapamil, Pazzaglia *et al.*[20] and Post *et al.*[21] at the NIMH in the U.S. chose to explore the potential antimanic and antidepressant effects of the dihydropyridine L-type calcium channel blocker nimodipine which has a very different biophysical and pharmacological profile from verapamil.[22] In contrast to the phenylalkylamine verapamil, the dihydropyridine nimodipine is a more potent anticonvulsant that blocks cocaine-induced hyperactivity, sensitization, and dopamine overflow; is positive in animal models of depression; and it improves rather than impairs cognition.

Pharmacology

Lithium

A series of sequential decade-related candidate mechanisms for lithium's psychotropic (mood-stabilizing) actions have been suggested over the last 50 years. These included:

- Effects on enzymes and biosynthetic aminergic neurotransmitter pathways (1950s)
- Effects on presynaptic adrenergic release and reuptake mechanisms (1960s)
- Effects on postsynaptic receptor modulation and impact on receptor supersensitivity (1970s)
- Effects on second messenger systems, adenylate cyclase and G-proteins (1980s)[23]
- Effects on phosphoinositol turnover, protein kinases (PKC and GSK-36), and other signal transduction pathways (1990s)[24,25]
- Most recently, effects on the nuclear level of DNA binding and gene transcription have been found that increase neurotrophic and other factors regulating neuroprotection versus apoptosis and cell death (2000s)[26,27]

Several of these candidate mechanisms are summarized in Figs 6.2.4.1 and 6.2.4.2, and are compared with the mechanisms of some of the other mood-stabilizing anticonvulsants such as carbamazepine and valproate. Lithium's effects on G proteins[20] are conceptually intriguing in relation to lithium's ability to modulate overactive systems, and preliminary support for its adenylate cyclase effects being important for acute mania are based on the finding that novel adenylate cyclase inhibitors are also effective in acute mania.[21] Similarly, recent studies implicating the ability of lithium and valproate to inhibit protein kinase C has been preliminarily validated with the demonstration of antimanic effects of the protein kinase C inhibitor tamoxifen in two double-blind studies.[28,29]

Most recently, lithium has emerged as a possible **neurotrophic and neuroprotective drug** via multiple potential pathways. It inhibits calcium influx through the N-methyl-$_D$-aspartate glutamate receptor;[23] it inhibits GSK-3B; and it increases the ratio of neurotrophic to cell death factors. For example, it increases Bcl-2 and brain-derived neuotrophic factor (BDNF) while decreasing the apoptotic factor BAX and P-53.[25,26] Much work remains to be done to implicate or rule out these changes in the wide array of psychotrophic actions of lithium. Lithium also increases white blood cell count and platelets by increasing granulocyte-macrophage colony-stimulating factor.[30] This effect is sufficient to overcome the benign white count suppression of carbamazepine.[31,32]

The potential clinical relevance of this finding is also evidenced by the data that pretreatment with lithium can decrease the size of a cerebral infarct following middle cerebral artery ligation and decrease the amount of neurological deficit.[33] Given the new findings of altered size of crucial structures involved in emotion regulation in the affective disorders, including amygdale,[34,35] hippocampus,[36] and prefrontal cortex,[4] one can only wonder whether lithium's neuroprotective effects could alter some of these putative neuronal- or glial-based deficits in central nervous system structure and function. The preliminary evidence supports this proposition because lithium increases patients' NAA, a marker of neuronal integrity and, grey matter volume as well.[37,38]

Carbamazepine, valproate, and lamotrigine

As seen in Table 6.2.4.2, since lithium, carbamazepine, and valproate share a group of effects in common, one wonders if they are related to their global antimanic/antidepressant effects. Notable differences among these agents are also present, perhaps also related to some of the differences in therapeutic targets and comorbidities seen in Table 6.2.4.1.

Given the shared effects of carbamazepine and lamotrigine in potent sodium channel blockade and subsequent decreased release of glutamate, one wonders about mechanisms that account for their difference in the epilepsies (carbamazepine exacerbates while lamotrigine improves absence seizures) and bipolar disorder (lamotrigine is a better antidepressant than antimanic). Potential candidates are the effects on different calcium channel subtypes (N,P) and ability to inhibit GABA release, but factors critical to lamotrigine's antidepressant effects remain to be elucidated.[39]

L-type calcium channel blockers

There are several subtypes of voltage-dependent blockers of calcium influx which modulate the L-type channel, i.e. one with relatively long (L) opening times. These subtypes include the widely recognized phenylalkylamines typified by verapamil, the benzodiazepines typified by diltiazem, the diphenylpiperazines typified by flunarizine, and the 1,4-dihydropyridines typified by nifedipine, nimodipine, isradipine, amlodipine, nicardipine, and nitrendipine. Remarkably, even though these agents all potently bind to this voltage-dependent calcium channel and act to inhibit calcium influx, their biochemical and physiological effects are very different, as noted above.

Verapamil and the phenylalkylamines are charged and bind at the outer portion of the calcium channel, while the dihydropyridines, which are uncharged (except amlodipine), bind deeper inside the calcium channel. These different membrane properties and binding characteristics result in a different profile of effects for the dihydropyridines compared with the phenylalkylamines, including increased lipid solubility. It is possible that these differences relate to the increased effectiveness of the dihydropyridines on depression[40] and ultra rapid cycling seen in a small subgroup of lithium-refractory bipolar patients.

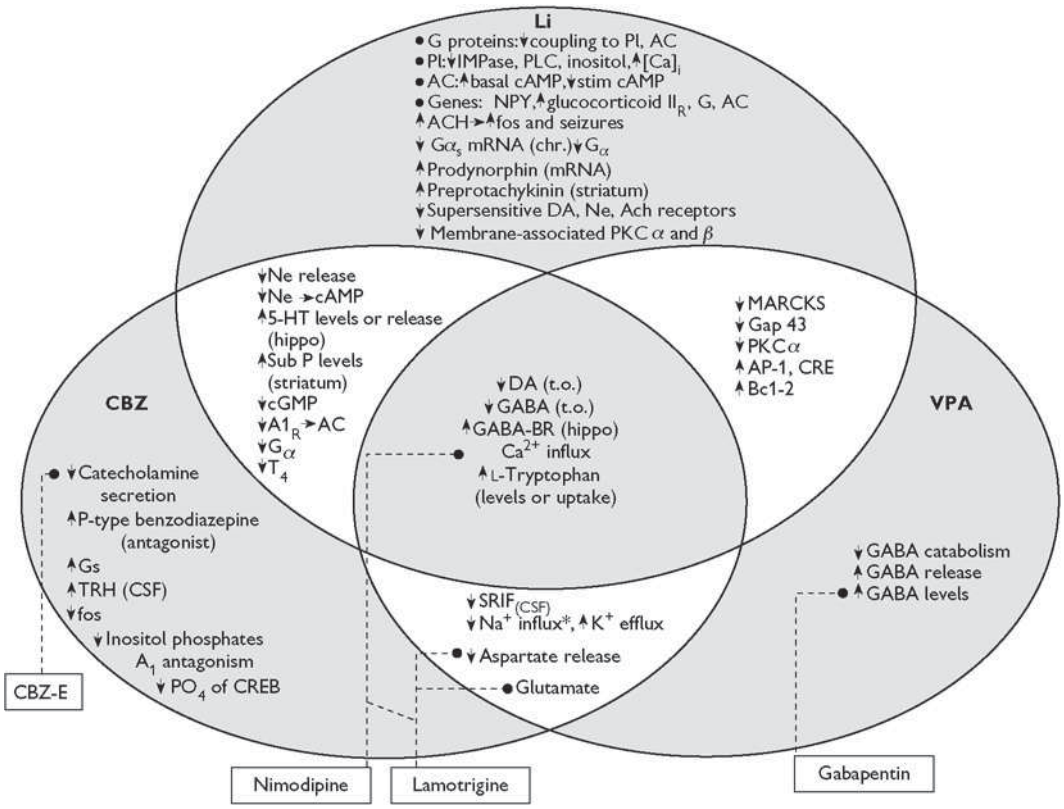

Fig. 6.2.4.1 Common and differential mechanism of mood stabilizers: PI, phosphoinositol; AC, adenylate cyclase; IMPase, inosital monophosphatase; PLC, phospholipase C; cAMP, cyclic adenosine monophosphate; NPY, neuropeptide Y; ACH, acetylcholine; $G\alpha_s$, G protein alpha (s) subunit; DA, dopaminergic; Ne, noradrenergic; PKC, protein kinase C; $A1_R$, adenosine A1 receptors; T_4, thyroxine; Gap 43, growth-associated protein 43; CRE, cyclic response element; CBZ, carbamazepine; TRH, throtrophin-releasing hormone; CREB, cyclic response element binding protein; VPA, valproate; SRIF, somatosatin; t.o., turnover.

Pharmacokinetics, dosage, and administration

Lithium

Lithium blood levels are conventionally described as being therapeutic from 0.5 to 1.2 mmol/l. Within this range, there is a wide agreement that higher doses are associated with increasing numbers of side-effects, but there is disagreement as to whether this is uniformly accompanied by a better therapeutic effect. Gelenberg *et al.*[12] reported that higher doses of lithium in the 0.8 to 1.0 mmol/l range averaging 0.83 mmol/l were 2.6 times as effective as doses achieving blood levels in the lower therapeutic range of 0.4 to 0.6, averaging 0.54 mmol/l. **This increased efficacy** (i.e. lower risk of relapse) **was achieved at the cost of a greater frequency of side effects**. Three times as many patients given doses in the high range withdrew from the study due to side effects. A series of other studies suggest that low to moderate doses of lithium may be just as effective as those in the higher range.[13]

Data of Kleindeinst *et al.*[41] further suggest a differential dose/effect relationship for lithium in mania versus depression prophylaxis. They found higher doses/blood levels more effective in preventing manic episodes while, **paradoxically, lower doses/levels were more effective in preventing depressions**. There is a considerable time lag before lithium reaches steady-state levels and some attempts at lithium loading with large doses from the outset have not been successful. A certain amount of time is needed for lithium to gain access into the central nervous system compartment and steady-state levels are not typically achieved until five half-lives or approximately six days. With the advent of magnetic resonance spectroscopy it has been found that lithium levels in the brain are half those in serum and, based on one small study, may be better correlated with the degree of clinical response than serum levels. **Older individuals have higher intracellular lithium levels**, which may account for the observations of **toxicity at apparently therapeutic blood levels**.

While lithium has traditionally been administered in two, three, or four times daily dosing regimens in attempts to achieve the most consistent and stable blood levels possible, several findings have led to changes in this pattern of dosing. Extended-release preparations are now available and suitable for twice-daily dosing. Even with the original preparations of lithium carbonate many clinicians and investigators have administered lithium in single nighttime doses in order to achieve the highest blood levels (and the potential for side effects) during sleep, and utilize the much lower trough levels at a time when the kidney, for example, can be relatively spared from continuously high lithium levels. Some investigators feel that this might be associated with lower long-term renal side effects, and preliminary data suggest that this paradigm may not be associated with any loss of clinical efficacy. Given lithium's unique anti-suicide

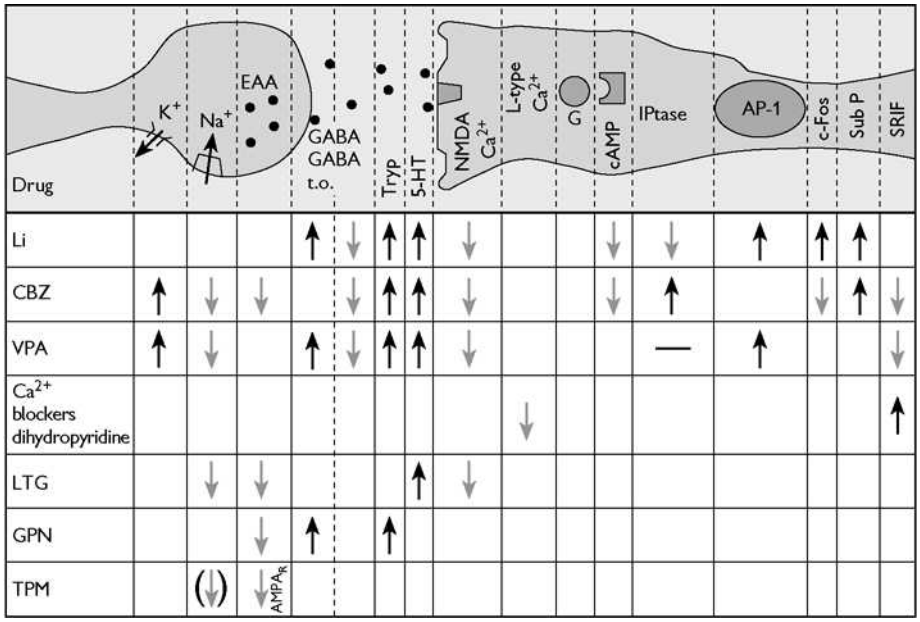

Fig. 6.2.4.2 Mechanisms of mood Stabilization. Depicted schematically at the top of the figure is a synapse with various types of channels, neurotransmitters, and proteins associated with the mechanisms of action of the mood stabilizers listed in the table below. **Row headings**: Li, lithium; CBZ, carbamazepine; VPA, valproate; LTG, lamotrigine; GPN, gabapentin; TPM, topiramate. **Column headings**; K^+ efflux; Na^+ influx; EAA, excitatory amino acids; GABA, γ-aminobutyric acid; GABA t.o., GABA turnover; Tryp, tryptophan; 5-HT, serotonin; NMDA Ca^{2+}; L-type Ca^{2+}; G, G protein; cAMP, cyclic adenosine monophosphate; IPtase, inositol phosphatase; AP-1, activator protein 1; Sub P, substance P; SRIF, somatostatin. Arrows indicate increases or decesases in substance/activity.

effects and strong evidence of neurotrophic and neuroprotective effects in animals at clinically relevant blood levels of 0.5 mmol/l, *administering lithium at whatever doses/blood levels are not associated with side effects would appear to have considerable merit*.

Carbamazepine, valproate, lamotrigine

Carbamazepine, in contrast to oxcarbazepine, is a **potent inducer of CYP 3A4** hepatic enzymes, accounting for **auto-induction after one to three weeks of treatment.**[8] With immediate release preparations, B.I.D or T.I.D. dosing is required, but with long-acting preparations such as Equetro®(Tegretol Retard®), all H.S. dosing should be considered. The dose and blood level to side-effects relationships are highly variable and individual. In non-emergency situations, 200 mg H.S. may be considered as a starting dose with slow upward titration to avoid or accommodate to side effects. In manic inpatients initial dosing of 600 mg to 800 mg on day one may be tolerated.

While blood levels of 4–12 μg/ml are touted as therapeutic in epilepsy, there is no relation of blood level to degree of clinical response across either seizure disorder or affectively ill patients. Therefore, **individualized titration to good clinical effect and minimal side-effects** burden is more appropriate than compulsive blood level monitoring.

Valproate may be given in loading doses of 10 to 15 mg/kg. Efficacy is usually observed between 50–120 mg/ml with a target of 80 mg/ml or more in mania. *Single nighttime doses can be employed* with both immediate release and extended release preparations, which may be better tolerated.

Lamotrigine must be dosed and titrated very slowly in an attempt to avoid the occurrence of a **serious rash**. A typical procedure is to start with 25 mg/day for two weeks and then 50 mg/day for two weeks, and then increase by 25 mg (preferably) to 50 mg/week thereafter. A target dose is about 200 mg/day, but increases to 400 mg/day in those showing partial responses is often tolerated. The rate of titration and target dose of lamotrigine should be halved on **valproate** (which **doubles lamotrigine levels**) and can be doubled on carbamazepine and related potent enzyme inducers.

L-type calcium channel blockers

The pharmacokinetics of the dihydropyridine L-type calcium channel blockers differ markedly. Nimodipine has a T½ of 1–2 h requiring T.I.D. dosing to peak total doses of 240 to 480 mg/day. Isradipine's T½ is 8 h, allowing B.I.D. dosing to a peak dose of 15 mg/day. Notably, amlodipine has a longer half-life and is suitable for single nighttime or twice-daily dosing in comparison with the better psychiatrically studied drugs nimodipine and isradipine. However, as long-acting preparations of these compounds become available, the importance of this half-life dissociation among the different compounds may dissipate. In our patient cohort at the NIMH, the pharmacokinetics of nimodipine (Bay e 9736) and its several metabolites (Bay o 1762, Bay m 5397, and Bay m 8922) were characterized by a rapid peaking (in 30–45 min) and decline in the second hour in response to a 60 mg challenge dose at steady-state blood levels after an overnight fast. Additional small secondary peaks occurred when usual dosing of four-times-a-day was resumed. There were no notable differences between capsule and tablet preparations. The phenylalkylamine verapamil has a 5–8 h half-life, also requiring T.I.D. dosing to a target peak daily dose of 480 mg/day.

Side effects

Lithium

Since lithium has been in use for much of the latter half of the twentieth century, its side-effects profile has been well described. Tremor and gastrointestinal distress, particularly diarrhoea, are generally dose-related, but some patients can have idiosyncratic sensitivity to these side effects, even at relatively low doses. Lithium-induced tremor can be countered with the beta-blocker propranolol in doses of 10 mg four times/day.

Side effects most likely to be associated with non-compliance or discontinuation of the drug include a sense of psychomotor slowing, cognitive dulling, acne or psoriasis, and weight gain. There is preliminary evidence that the anticonvulsants topiramate or zonisamide may help to reverse or stabilize lithium-related weight gain. Cognitive dulling could be treated with dose lowering, assessment of thyroid function, and T_3 (25–50 μg) augmentation even with normal thyroid indices, folate augmentation, and, potentially, an acetylcholinesterase inhibitor such as donepezil (Aricept®).

Lithium interferes with the actions of ADH (i.e. vasopressin) because of its ability to block vasopressin-induced adenylate cyclase. A syndrome of **reversible diabetes insipidus** is thus induced which, in most patients, is not problematic, although in a small percentage of patients, excretion of large volumes of urine can be extreme, inconvenient, and disruptive of normal social routines and sleep. This can be countered with amiloride or the thiazide diuretics (however, the latter also increase lithium levels).

Lithium is clearly able to induce thyroid dysfunction with increases in thyroid-stimulating hormone, sometimes proceeding to more full-blown evidence of chemical hypothyroidism. The threshold for treating lithium-related increases in thyroid-stimulating hormone has not been definitively identified, but with some evidence of lower levels of free thyroxine being associated with increased levels of depression and other low thyroid indices being associated with increased cognitive dysfunction, **replacement of thyroid hormones would appear indicated as thyroid-stimulating hormone begins to exceed normal levels**. Whether thyroid supplementation can reverse or prevent these lithium-related abnormalities remains to be directly assessed in prospective studies.

Some investigators suggest that long-term lithium may be associated with **slowly increasing creatinine levels** and a decrease in creatinine clearance.[40] The incidence of these glomerular filtration abnormalities in lithium-treated patients compared with age- and gender-matched controls remains controversial, as does the mode of treatment in the face of progressive changes in these indices. Given the availability of other potential mood-stabilizing agents, a reduction in lithium levels and supplementation or switching to other agents would be a conservative measure, if tolerated. However, others recommend careful monitoring of continued lithium therapy because the effects of lithium discontinuation on creatinine levels are highly inconsistent.

Severe episodes of lithium intoxication are to be avoided since they can be associated with a syndrome of irreversible cerebellar dysfunction.[42] The use of lithium with very high dose neuroleptic treatment is also to be avoided since occasional idiosyncratic and irreversible organic brain syndromes have resulted on rare occasions. Marked EEG changes and tonic-clonic seizures were also observed with the combination of lithium and clozapine. Lithium can be associated with alterations in calcium homeostasis and frant hyperparathyroidism. As mentioned above, lithium can increase white cells and platelets via its action on granulocyte-macrophage colony stimulating factor.

Valproate has many lithium-like side effects which may also be additive in combination treatment. **Valproate has a black box warning for rare hepatitis/pancreatitis and should not be given to children below two years of age**. It can also cause low platelets, and signs of bleeding tendency should be attended to. Because **valproate increases homocysteine, routine supplementation with folate (and possibly also B6 and B12 in women of child bearing age) would appear prudent**. Valproate can cause asymptomatic to symptomatic hyperammoniumemis; treatment with l-carnitine may be helpful. Zinc and selenium are anecdotally touted as preventing alopecia, but systematic evidence is lacking. Data are mixed as to whether valproate increases testosterone and causes the polycystic ovary syndrome (PCOS). Hirsutism is rarely seen in affectively ill patients and birth control pills will prevent PCOS. Valproate does increase the already high rates of menstrual irregularities seen in women with bipolar disorder.

Carbamazepine has less weight-gain liability than lithium or valproate, but has greater potential for rash and rare but serious hematological problems. **Carbamazepine** routinely causes a benign **drop in white blood cells via its effects on colony stimulating factor; this can be countered by lithium**. More problematic are agranulocytosis and aplastic anemia, estimated to occur in 1 in 20 000 to 50 000 patients. **Patients should be warned to consult their physician** if they develop a fever, sore throat, or other infection that could emanate from a low white blood count, or bleeding gums or petechiae that could reflect low platelets. **Hyponatremia is more common with oxcarbazepine** than carbamazepine, but the hyponatremia of carbamazepine can be treated or prevented with lithium or demeclocycline. Low T_4 on carbamazepine is usually not reflective of hypothyroidism because TSH is not increased, BMR is not decreased, and the degree of drop in T_4 and free T_4 may even be correlated with degree of antidepressive effect.

The **major side-effects concern of lamotrigine is that of a severe rash**, estimated to occur in 1 of 5 000 adults and 1 of 2 500 children. Even a benign rash should lead to drug discontinuation because there is no way to predict when a rash may progress to a Stevens-Johnson syndrome or Toxic Epidermal Necrolysis. Otherwise, the side-effects profile of lamotrigine fits well with bipolar depression treatment because the drug is weight-neutral, non-sedating, and without sexual dysfunction or endocrine dysregulation.

L-type calcium channel blockers

The side-effects profile of nimodipine and related dihydropyridine L-type calcium channel blockers differs considerably from that of lithium. These drugs are primarily used in cardiology for their anti-hypertensive and anti-arrhythmogenic effects. As such, they may cause **side effects related to hypotension including dizziness and tightness in the chest**. Unlike lithium, they are not typically associated with gastrointestinal distress and tend to be slightly constipating rather than associated with diarrhea. Therefore, they might be able to replace some component of lithium's therapeutic action, as noted below, potentially without exacerbating some of lithium's related side effects. Although these agents are often used in migraine prophylaxis, they can also be associated with headache on rare occasions. Redness and erythema with excessive warmth in

the pretibial areas is also an occasional side effect of these agents, as is, more rarely, edema itself.

Nimodipine and related dihydropyridine L-type calcium channel blockers do not appear to share lithium's ability to induce cognitive slowing and, in fact, these agents have been reported to improve performance in some preclinical models of learning and memory deficits as well as in some clinical studies of patients with Alzheimer's disease. This might be related to nimodipine's ability to increase somatostatin upon chronic administration,[43] although other mechanisms remain to be explored.

Also, in contrast to lithium, which is associated with a small incidence of Epstein's anomaly, verapamil is not teratogenic. While systematic data are not available for the other dihydropyridine L-type calcium channel blockers, it is hoped that they will prove to be as safe as verapamil appears to be.

Indications and contraindications

Lithium

The double-blind controlled studies of lithium in acute mania were positive several decades ago, and in the largest randomized study comparing lithium with placebo in a study primarily designed to evaluate the acute antimanic efficacy of valproate, lithium and valproate appeared to show approximately equal efficacy and both were superior to placebo.[44] However, there appear to be a number of subtypes of illness with consistently higher or lower rates of response. As summarized in Table 6.2.4.1, a useful rule of thumb is that lithium is relatively less effective, with a low effectiveness rate of around 30 per cent in acute manic syndrome characterized by anxiety and dysphoria, comorbid substance abuse, comorbid medical conditions, the pattern of illness of depression-mania-well intervals as opposed to mania-depression-well intervals, in those with a negative family history of bipolar illness in first-degree relatives, in those with evidence of **EEG and neurological dysfunction, and in those with a pattern of rapid cycling or multiple prior episodes.**[2]

Lithium used to be considered contraindicated in pregnancy, but with the recognition that major cardiac malformations such as Epstein's anomaly are rare (1 in 1 200 births), many clinicians and patients are deciding to continue lithium when it appears important to continued mood stability.

L-type calcium channel blockers

As discussed earlier, the evidence of verapamil's acute antimanic efficacy is derived from a considerable series of small double-blind studies. While the initial studies were unequivocally positive, more recent studies have not been as positive comparing either verapamil with placebo or verapamil with lithium. Only very preliminary evidence is available for the acute antimanic efficacy of nimodipine, with the open study of Brunet *et al.*[45] being positive in six of six individuals.[18,63] In placebo-controlled studies using an off-on-off-on design, 10 of 30 patients with refractory recurrent affective disorder responded and, in may instances, the antimanic efficacy was demonstrated both in the on-phase and with symptom exacerbation in the off-phase.[46] However, many of these individuals had ultra-rapid or ultra-ultra-rapid (ultradian) cycling patterns and most of the efficacy data reflected effective pharmacoprophylaxis of mania rather than acute antimanic efficacy *per se*.

Dubovsky[47] observed that a prior history of lithium response appears to be associated with a good response to verapamil. However, with the dihydropyridines we have observed some instances of response in those who were previously non-responders to lithium.[46] Among those responsive to the drug were patients with ultra-rapid and ultradian cycling and those with a pattern of recurrent brief depression. As indicated above, a number of these individuals were rechallenged and **responsiveness was confirmed in an off-on-off-on design**. Whether those bipolar patients with increased intracellular calcium would be among those responsive to the L-type calcium channel blockers also awaits completion of such a study, which is now under way.

A promising area of investigation is work using brain imaging, which has found that depressed patients with the classical pattern of relative frontal hypometabolism, and especially in the left insula, were among those who responded best to nimodipine, while equally depressed patients with left insula hypermetabolism responded to carbamazepine.[48] These data raise the possibility that regional topographies of blood flow or metabolism might ultimately help identify a subgroup of patients more responsive to the calcium-channel blocking agents. Also potentially helpful are data showing that nimodipine increases somatostatin in the CSF, and in one small study, that those with lower baseline CSF somatostatin were better responders to the drug.[49]

Interactions

Lithium

Owing to its renal excretion, lithium has renally-mediated rather than hepatically-mediated drug-drug interactions. Lithium excretion is decreased by medications such as thiazides, non-steroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, and, to a lesser extent, furosemide, and by physiological states such as dehydration, advanced age, and renal disease.[50] Owing to lithium's poor therapeutic index, these interactions can result in clinical lithium toxicity unless appropriate dosage adjustment is made. In contrast, lithium clearance is less consistently affected by amiloride, aspirin, and sulindac, and increased with other medications with diuretic effects such as acetazolamide, mannitol, aminophylline, caffeine, and theophylline, as well as during pregnancy.

Valproate, carbamazepine, lamotrigine

Valproate is FDA-approved for migraine prevention and treatment of acute mania. However, it is **widely considered a mood stabilizer and used in long-term prophylaxis of both mood phases**. A modicum of data support acute and prophylactic efficacy in depression. **Valproate decreases alcohol intake** in bipolar patients[51] with this comorbidity and is useful in a wide range of anxiety syndromes.

Valproate is contraindicated in pregnancy because of a several percentage risk of neural tube defects (spina bifida) and, more recently noted, a substantial (20 per cent) incidence of other adverse events,[52] as well as moderate to severe developmental delay in a sizeable number of children.

Carbamazepine is approved for trigeminal neuralgia and the long-acting preparation of carbamazepine (Equetro®/Tegretol Retard®) is approved only in acute mania, but can be considered in long-term prophylaxis for those not responsive to lithium or valproate.

Its profile of effectiveness is almost the converse of that of lithium, with better effects in those with bipolar II illness, anxiety, and substance abuse comorbidity, mood incongruent delusions,[53] and a negative family history of bipolar disorder in first-degree relatives. Carbamazepine should not be used in pregnancy because it carries about a 0.5 per cent risk of neural tube defects.

Lamotrigine is unique because it is approved for only **prevention of depressed episodes** and to a lesser extent, manic and mixed episodes. Robust efficacy in acute depression has been seen in three studies, but not in four others, although the meta analysis remains significantly positive. A small series of patients studied in Canada identified correlates of positive response, including continuous cycling pattern and a **personal and positive family history of anxiety disorders**.[54,55] Only one of five pregnancy case registries showed a significance for the increased occurrence of cleft lip and palate, and this agent clearly appears safer than valproate or carbamazepine. Its overall serious adverse event percentage of 1 per cent does not appear to be different from that of the general population.

L-type calcium channel blockers

Different calcium-channel blockers differentially affect carbamazepine levels. While verapamil and diltiazem increase carbamazepine levels substantially, potentially causing toxicity, this is not the case with nimodipine, isradipine, or amlodipine. Preliminary data from our group and others suggest that carbamazepine decreases nimodipine levels after a 60 mg challenge dose. In our study, group mean peak nimodipine levels during treatment with carbamazepine were about one-half those observed during treatment with nimodipine alone, although this finding showed only a trend level of significance, probably due to small sample size.

When calcium channel blockers are added to ß-adrenergic blocking agents, depression of ventricular function, cardiac slowing, and atrioventricular block can result. Combining calcium channel blockers with ß-adrenergic blocking agents may produce hypotension. Verapamil and nitrendipine increase plasma concentrations of digoxin and produce bradycardia, hypotension, or atrioventricular block.

Effects of withdrawal

Lithium

In addition to the variety of predictors of relative lithium nonresponsiveness from the outset, two relatively new and different mechanisms for the development of treatment resistance or loss of efficacy have been uncovered during long-term follow up in patients who are initially responsive. The first of these is the apparent development of tolerance characterized by an increasing frequency and/or severity of breakthrough episodes despite good compliance and consistent maintenance of lithium blood levels. In a group of 66 patients referred to the NIMH because of lithium nonresponsiveness, 23 patients **(34.8 per cent) displayed this apparent tolerance pattern**.[55] Although it has not been systematically studied, the initial therapeutic manoeuvres in the face of such loss of efficacy at maximum tolerated doses would appear to be augmenting lithium's effects with other putative mood-stabilizing agents with different mechanisms of action, and if lithium should be discontinued, a consideration of its reinstitution with a hope for renewal of responsivity.

In contrast with this tolerance pattern in which patients suffer breakthrough episodes despite remaining under treatment, the phenomenon of lithium-discontinuation-related refractoriness refers to a small group of patients who have done extremely well on their long-term lithium, discontinue the drug, suffer additional relapses, and then fail to re-respond once lithium is reinstituted. This phenomenon accounted for nine of the 66 patients (13.6 per cent) who presented to us as lithium-refractory.[56] The average time well on lithium was 6.6 years, substantially greater than the average well interval of 1.5 years prior to instituting lithium therapy, strongly suggesting that lithium had been effective in these individuals, and if they had remained on the drug, they might have remained well. Sadly, for each of these individuals, this did not prove to be the case.

One patient had been well on lithium for more than 16 years and tapered lithium slowly, suggesting that neither the duration of time well nor the use of a slow taper would necessarily prevent the development of discontinuation-induced refractoriness. A number of other investigative groups have observed such a phenomenon.[57] In these studies, discontinuation-induced refractoriness occurred in anywhere from 3.6 per cent to 18.6 per cent of patients, with a total of 39 of 321 (12.1 per cent), and 12 of 92 (13 per cent) in studies that tracked responders only. Even if it only occurs in about 10 per cent of patients who discontinue their lithium, it would nevertheless appear to be of considerable clinical import and should be included in the informed consent process so that the patient has all of the available data when making decisions of whether or not to continue treatment. That is, in considering the risk-benefit of stopping lithium, **a patient should not only know the very high risk of relapse** (50 per cent in the first five months after discontinuing lithium, 80–90 per cent after 1.5 years,[58] but also that there is **no guarantee that responsivity would be as rapid, robust, or complete** as previously experienced, and that a small subgroup of individuals, perhaps as many as 10 per cent, will not achieve the same good response that they had previously.

Valproate, carbamazepine, lamotrigine

Valproate will displace carbamazepine from its protein binding and inhibit the epoxide hydrolase from converting the active epoxide to the inactive diole. Thus, **carbamazepine dose will need to be decreased when used in combination with valproate**. **Valproate will double lamotrigine levels** such that dosing should be one-half that of normal.

Carbamazepine as a potent 3A4 inducer has many drug-drug interactions. It will decrease levels of oestrogen such that **high dosage forms need to be used with birth control pills**. It will lower levels of lamotrigine, haloperidol, aripiprazole, and many other compounds.

Inhibition of 3A4 will notably increase carbamazepine levels and potentially cause toxicity if a patient is at or near their side-effects threshold. **Erythromycin** and its analogues, **verapamil, and diltiazem** are such examples, and patients should be warned to check with their pharmacists about its many other interactions. Side effects can be avoided with lower carbamazepine doses in advance of such drugs being administered.

Each of these drugs can be discontinued rapidly without a major withdrawal syndrome. Tolerance to the efficacy of each of these

agents has been observed in isolated cases or small series. Increasing doses and/or switching to or adding other agents without cross-tolerance (mechanistically different) are typically used clinically [8] In instances of tolerance development a period of time off the new ineffective drug may be associated with transient renewal of efficacy. Theoretical, but unproven ways of slowing or minimizing tolerance development include: using more maximally tolerated doses, rather than minimally effective ones; holding doses stable and not decreasing them unnecessarily; using combination of drugs; and treating earlier as opposed to later in the course of illness.

L-type calcium channel blockers

Because so few patients have been studied with the L-type calcium channel blockers in long-term prophylaxis, it is uncertain to what extent patients may become tolerant to these agents. However, since tolerance has been observed to virtually every other putative mood-stabilizing agent, it is likely that this will also occur with nimodipine and related agents. Similarly, it is uncertain whether the phenomenon of discontinuation-related refractoriness observed with lithium would extend to the class of L-type calcium channel blockers; while we have not observed this phenomenon in our cohort of nimodipine responders (63), only a small group of patients has been studied to date.

6.2.5 Antipsychotic and anticholinergic drugs

Herbert Y. Meltzer and William V. Bobo

Introduction

The discovery by Delay and Denicker in 1953 that chlorpromazine was highly effective in alleviating delusions, hallucinations, and disorganized thinking, was the seminal breakthrough in the treatment of schizophrenia, the first agent to produce sufficient relief of core psychotic symptoms to permit life outside of institutions for many patients with schizophrenia, and even a return to a semblance of function within normal limits. Chlorpromazine and the other related typical antipsychotic drugs which were introduced over the next 30 years have proven to be of immense benefit to vast numbers of people who experience psychotic symptoms as a

component of a diverse group of neuropsychiatric and medical disorders, as well as drug-induced psychoses. These drugs have been invaluable in providing clues to the aetiology of schizophrenia and other forms of mental illness with psychotic features and as tools in understanding fundamental neural processes, especially those involving dopamine, a key neurotransmitter involved in psychosis. This class of drugs has now been supplanted by the so-called atypical antipsychotic drugs, of which clozapine is the prototype. This chapter will describe the various classes of antipsychotic agents, with emphasis on the atypical antipsychotic drugs, their benefits and adverse effects, recommendations for use in clinical practice, and mechanism of action. The drugs used to treat the extrapyramidal side-effects (EPS) produced mainly by the typical antipsychotic drugs are also considered.

The classes of antipsychotic drugs

Antipsychotic drugs have been classified into two broad categories: typical and atypical.[1] Typical antipsychotic drugs are those which (typically) produce EPS at clinically effective doses, including parkinsonism (muscle rigidity, tremor, bradykinesia), acute dystonic reactions, dyskinesias, akathisia (restlessness), and tardive dyskinesia. They are also called neuroleptics because of their inhibitory effect upon locomotion activity. They are sometimes referred to as first generation antipsychotic drugs, but this has multiple problems as a class designation. The prototype of the atyipcal class of agents is clozapine which was first discovered during the early stages of the development of the drugs called first generation agents. The major mode of action of typical neuroleptics is to block dopamine D_2 receptors in the limbic system, which includes the nucleus accumbens, stria terminalis, and amygdala.

The typical antipsychotic drugs are members of a variety of chemical families (Table 6.2.5.1). They vary in affinity for the D_2 receptor, with low affinity drugs such as chlorpromazine, which require high doses for clinical efficacy, to high affinity drugs such as haloperidol, which are effective at lower doses (Table 6.2.5.1). Kapur and Seeman[3] have proposed that the rate of dissociation of all antipsychotic drugs from the D_2 receptor provides the basis for the distinction between typical and atypical antipsychotic drugs, with atypical antipsychotic drugs dissociating more rapidly. While this is true for clozapine and quetiapine, the atypical drugs risperidone, sertindole, olanzapine and asenapine dissociate no more rapidly or even slower than haloperidol. As such, 'fast dissociation' cannot provide the pharmacological basis for atypicality for most of the drugs that are considered atypical.

Low-potency typical neuroleptic agents are those in which the usual dose range in schizophrenia is equal to or greater than 200 mg/day, while mid- to high-potency agents are those in which the dose range is between 2 and 175 mg/day. In general, the low-potency drugs are more sedative and more hypotensive than the high-potency agents but also have less of a tendency to produce extrapyramidal side-effects. The typical antipsychotic drugs differ from one another with regard to potential for other side-effects, e.g. weight gain and hypotension, but have comparable efficacy as antipsychotic agents.[4]

Atypical antipsychotic drugs are those antipsychotic agents with a significantly lower propensity to produce EPS at clinically effective doses.[1] They are also characterized by a more diverse and complex pattern of pharmacological activity, including serotonin $(5\text{-hydroxytryptamine})_{2A}$ and dopamine D_2 antagonism as well as a variety of activities at other receptors whose contribution to their mode of action is still being elucidated.[2] Substituted benzamides, e.g. amisulpride, also have low EPS at clinically effective doses and may constitute another class of atypical agents. New classes of atypical antipsychotic drugs are emerging from research with considerable frequency at the current time.

The prototypical atypical antipsychotic drug is clozapine, a dibenzodiazepine (Table 6.2.5.1).[5] Others include aripiprazole,[6] olanzapine, quetiapine, paliperidone, risperidone, sertindole, ziprasidone and zotepine, while iloperidone,[7] asenapine,[8] and lurasidone[9] are in development and have a similar pharmacology to that of risperidone. These drugs are all more potent 5-HT_{2A} than D_2 receptor antagonists as well as multireceptor antagonists[9,10] except for aripiprazole, which is a dopamine D_2 receptor partial agonist. Bifeprunox is also a partial D_2 agonist. It lacks 5-HT_{2A} receptor blocking properties, relying instead on 5-HT_{1A} partial agonism to reduce serotonergic tone. Amisulpride and remoxipride are substituted benzamides. Both are selective D_2/D_3 antagonists.[2]

Table 6.2.5.1 Selected antipsychotic drugs and classification schemes

Drug name	Trade name	Chemical class	General class	D2 potency*
Aripiprazole	Abilify	Dihydrocarbostyril	Atypical	
Chlorpromazine	Thorazine	Phenothiazine	Typical	Low
Clozapine	Clozaril	Dibenzazepine	Atypical	
Droperidol	Inapsine	Butyrophenone	Typical	Mid
Fluphenazine	Prolixin	Phenothiazine	Typical	High
Haloperidol	Haldol	Butyrophenone	Typical	High
Loxapine	Loxitane	Dibenzazepine	Typical	Mid
Mesoridazine	Serentil	Phenothiazine	Typical	Low
Molindone	Moban	Dihydroindolone	Typical	Mid
Olanzapine	Zyprexa	Thiobenzodiazepine	Atypical	
Paliperidone	Invega	9-hydroxy metabolite of risperidone	Atypical	
Perphenazine	Trilafon	Phenothiazine	Typical	Mid
Pimozide	Orap	Butyrophenone	Typical	Mid
Promazine		Phenothiazine	Typical	Mid
Quetiapine	Seroquel	Dibenzothiazepine	Atypical	
Risperidone	Risperdal, Risperdal CONSTA	Benzisoxazole	Atypical	
Thioridazine	Mellaril	Phenothiazine	Typical	Low
Tiotixene	Navane	Thioxanthene	Typical	High
Trifluoperazine	Stelazine	Phenothiazine	Typical	Mid
Ziprasidone	Geodon	Benzisothiazole	Atypical	

* Classification on the basis of potency of D2 receptor binding for typical antipsychotic drugs only

Remoxipride was withdrawn shortly after its introduction because of a high rate of aplastic anaemia.

As will be discussed, the atypical antipsychotic drugs differ not only with regard to side-effects but also with regard to efficacy.[11,12] Atypical antipsychotic agents have been shown to have advantages, albeit modest, in treating negative mood symptoms[13–15] and to improve cognitive dysfunction in schizophrenia and perhaps other psychiatric disorders.[16–18]

Pharmacology

There is abundant evidence that dopamine plays a key role in the aetiology of psychosis and the action of antipsychotic drugs.[19] The antipsychotic action of the typical antipsychotic drugs is highly correlated with their affinities for D_2 receptors. Amphetamine and methamphetamine, which increase synaptic concentrations of dopamine, have been found to exacerbate delusions and hallucinations in some patients with schizophrenia This effect is believed to be due to stimulation of a subgroup of D_2 receptors in mesolimbic nuclei.[19,20] The cell bodies of mesolimbic dopamine neurones reside in the ventral tegmentum, the so-called A10 area, and have terminals in the nucleus accumbens, stria terminalis, and olfactory tubercle. The outflow of these regions to the thalamus and the cortex is believed to mediate psychotic symptoms. The firing rate of the mesolimbic dopaminergic neurones is subject to multiple influences, including stimulatory serotonergic input from the median raphe.[21] The origin of the dopamine neurones that terminate on cholinergic neurones in the basal ganglia is the substantia nigra, the so-called A9 region.[20] Blockade of striatal D_2 receptors in this pathway leads to the extrapyramidal side-effects produced by antipsychotic agents. A group of ventral tegmental dopamine neurones project to various regions of the cortex and comprise the mesocortical dopamine system. There is extensive evidence that these neurones are important for cognition, especially working memory,[22] as well as negative symptoms.[23] Neuroleptic drugs occupy 80 to 95 per cent of striatal D_2 receptors in patients with schizophrenia at clinically effective doses, though a lower blockade threshold of 60 per cent for improving positive symptoms has been identified.[24] Extrapyramidal side-effects occur above 80 per cent occupancy of these receptors. Blockade of D_2 receptors in the anterior pituitary gland is the basis for their ability to stimulate prolactin secretion.[25]

The prefrontal cortex has relatively low concentrations of D_2 receptors and has a higher density of D_1, D_3 and D_4 dopamine receptors.[20] The activation of D_1 receptors in prefrontal cortex may be especially critical for normal working memory and other executive type functions subserved by this brain region. However, no D1 agonists are available for treatment at the current time, although several are in development. Drugs which selectively block D_4 receptors have not been found to have an antipsychotic effect.[26] There are only limited data regarding the aetiologic or pharmacological significance of D_3 receptors in schizophrenia.

The typical antipsychotic drugs vary in their *in vitro* and *in vivo* affinities for receptors such as the dopamine D_1, histamine H_1, muscarinic, α-1 and α-2 adrenergic, and serotonergic receptors (Table 6.2.5.2), which mediate effects on arousal, extrapyramidal, cognitive, cardiovascular, gastrointestinal, and genitourinary function (Table 6.2.5.3).[27]

Thioridazine is a relatively potent antimuscarinic agent. Most of the low-potency antipsychotic agents are potent α_1 and H_1 antagonists. These affinities contribute to hypotension and weight gain, respectively. While some typical antipsychotic drugs have a high affinity for 5-HT_{2A} receptors, their affinities for D_2 receptors are even higher, which diminishes the beneficial effects of the 5-HT_{2A} receptor blockade. The specific receptor profile of each atypical antipsychotic is of special interest because it may account for critical differences among these compounds, especially in terms of side effect burden (Table 6.2.5.4).

The affinities of the atypical antipsychotic drug have been related to their efficacy and side effect profiles. As noted above, the most important determinant of atypicality for most of the currently available agents of this type is that they are more potent 5-HT_{2A} than D_2 receptor antagonists. An exception is aripiprazole, which combines potent 5-HT_{2A} antagonism and 5-HT_{1A} agonism, with partial D_2 receptor agonism. Another exception is amisulpiride, which is a selective $D_{2/3}$ antagonist with little pharmacological activity at 5-HT_{2A} receptors. Combined 5-HT_{2A} with less potent D2 antagnoism is the most consistent principle yet discovered to produce a separation between antipsychotic action and interference with motor function. This hypothesis arose from showing that it could distinguish clozapine, the prototypical atypical antipsychotic drug, and a series of other atypical antipsychotic compounds from those which have typical properties.[28] These studies suggested that the low potential for extrapyramidal side-effects of clozapine, and subsequently, olanzapine, quetiapine, risperidone, iloperidone, ziprasidone, paliperidone and asenapine are due, in part, to their relatively stronger 5-HT_2 antagonist and weak D_2 antagonist properties. The serotonin-dopamine interaction in the nigrostriatal and mesolimbico-cortical pathways appears to be mediated by stimulation of 5-HT_{2A} receptors, which are located on dopaminergic cell bodies, whereas antagonism of these receptors may release these neurones from tonic inhibition.

The atypical antipsychotic agents have the ability to increase prefrontal cortical dopaminergic activity compared with subcortical dopaminergic activity.[29] The ability to increase the release of dopamine in the prefrontal cortex may be important for atypical antipsychotic agents to improve cognition and negative symptoms. It may also contribute to decreasing the release of dopamine in the mesolimbic region, because prefrontal dopamine neurones modulate the activity of corticolimbic glutamatergic neurones that influence the release of dopamine from nerve terminals in the limbic region.[22] Typical neuroleptic drugs do not share this ability to increase dopamine efflux in prefrontal cortex. Clozapine and some of the other atypical antipsychotic drugs that are also potent 5-HT_{2A} antagonists, but not typical neuroleptics, also produce marked increases in prefrontal cortical and hippocampal acetylcholine efflux.[30] These atypical agents also produce marked increases in noradrenaline efflux in the prefrontal cortex which is correlated in time and magnitude with the increase in extracellular dopamine.[31] It is of interest that in rodents, combining ritanserin (a mixed 5-HT2a/2B/2C antagonist) or M-100907 (a selective 5-HT_{2A} antagonist) with a selective $D_{2/3}$ antagonist resulted in increased prefrontal dopamine release.[32,33] The combination of haloperidol and M-100907 also increased prefrontal dopamine release, with the greatest effects observed when lower doses of haloperidol were used.[34] Because reduced noradrenergic and dopaminergic function in prefrontal cortex and hippocampus has been

Table 6.2.5.2 Affinities of selected antipsychotic drugs at various neuroreceptors

associated with negative symptoms and cognitive impairment in schizophrenia,[22,35] the cortical release of these two neurotransmitters, and possibly also acetylcholine, may provide a pharmacological basis for the advantages of atypical antipsychotics over typical neuroleptic drugs in the treatment of these critical symptom domains. In patients with schizophrenia who were stabilized on typical neuroleptics, the addition of mianserin, a 5-$HT_{2A/C}$ and adrenergic α-2 antagonist, was associated with improved neurocognitive performance,[36] adding further support to a role of 5-HT_{2A} receptors in the treatment of cognitive dysfunction in schizophrenia.

The importance of serotonin receptors other than 5-HT_{2A} for the action of antipsychotic drugs has received considerable attention. Activation of 5-HT_{1A} receptors are believed to have a dopamine modulating effect similar to that of 5-HT_{2A} antagonism.[37] Under experimental conditions, 5-HT_{1A} agonists have been shown to stimulate cortical dopamine release[38,39] and, in schizophrenic patients who were stabilized on haloperidol, the addition of tandospirone, a 5-HT_{1A} partial agonist, resulted in improved neurocognitive performance.[40] This effect has also been demonstrated more recently for buspirone, another 5-HT_{1A} partial agonist.[41] Serotonin-1A receptors may be important for cognitive effects of at least some of the atypical antipsychotic drugs that are active at this receptor site. Activity at 5-HT_{1A} receptors is not shared by all antipsychotic drugs (Table 6.2.5.2), however. Antagonism of 5-HT_{2C} receptors also appears to result in cortical dopamine and norepinephrine release, as well as in the nucleus accumbens.[42] The cognitive effects of selective 5-HT_{2C} antagonists added to typical neuroleptic drugs in patients with schizophrenia have not been examined. As is the case with 5-HT_{1A} activity, not all atypical antipsychotic drugs are active at 5-HT_{2C} receptors (Table 6.2.5.2). Like antagonism at histamine H_1 receptors,[43] 5-HT_{2C} antagonist activity may be related to antipsychotic induced weight gain.[44]

Atypical antipsychotics may display regional selectivity in terms of their dopaminergic activity, relative to typical neuroleptics. For instance, atypical antipsychotic drugs appear to preferentially block cortical D_2 receptors, relative to those located in the striatum.[45,46] Haloperidol results in proportionally equivalent D_2 blockade in both brain regions.[47] The atypical antipsychotics also increase the expression of the early intermediate gene c-*fos*, in the prefrontal cortex and the shell of the nucleus accumbens, while sparing the core of the latter region and the striatum. Typical neuroleptic drugs have the opposite effect on c-*fos* expression. Sparing the dorsal

striatum is believed to be related to the low potential for extrapyramidal side-effects of these agents.[2,21]

Clozapine, olanzapine, risperidone, and quetiapine are able to block the interference in prepulse inhibition produced by d-amphetamine, apomorphine, or phencyclidine at doses that do not interfere with locomotor function. Clozapine and M100907 are able to block the effects of phencyclidine, an *N*-methyl-D-aspartate receptor antagonist, on locomotor activity in rodents. This suggests the ability of rat 5-HT_{2A}-receptor blockade to block some of the effects of phencyclidine which is one of the more important models for schizophrenia.[2,21] In a recent single photon emission tomography (SPECT) study, patients with schizophrenia who received treatment with clozapine evidenced reduced NMDA-active radiotracer binding compared with healthy controls, drug free patients with schizophrenia, and patients with schizophrenia who were treated with typical neuroleptics.[48] The extent of involvement of other atypical antipsychotic drugs relative to typical antipsychotics at NMDA receptors and other glutamatergic targets is an area of active interest. Other receptor targets that are of special interest in terms of improving cognitive functioning and selected psychotic symptoms include M1 muscarinic, α-7 nicotinic, and α-1 and α-2 adrenergic receptors.

Administration, pharmacokinetics, and dosage

Administration

(a) Typical antipsychotic drugs

The major uses of the antipsychotic drugs are for the treatment of schizophrenia, mood disorders typically with psychotic features, and senile psychoses.[4,49] Other indications are discussed elsewhere in this book in the consideration of the management of specific disorders, such as Tourette's syndrome, and aggression. The major advantage of the typical neuroleptic drugs is their ability to improve positive symptoms, i.e. delusions and hallucinations. Administration of typical neuroleptic drugs leads to the complete or nearly complete elimination of positive symptoms and disorganization of thought and affect in about 60 to 70 per cent of patients with schizophrenia and an even higher proportion of those with psychotic mania and psychotic depression.[49] The antipsychotic response in schizophrenia and mania is sometimes apparent within a few days in many patients but usually takes up to several weeks or months. A reasonable duration for a therapeutic trial with one of these agents is 4 to 6 weeks. It is not appropriate to switch medications after 1 or 2 weeks, even if a response is not apparent, unless side-effects pose a serious problem. Positive symptoms (delusions and hallucinations) do not respond to typical neuroleptic drugs in about 10 per cent of schizophrenic patients even during the first episode.[50] Another 20 per cent of patients with schizophrenia develop resistance to these agents during the subsequent course of their illnesses.[51] Development of resistance to typical neuroleptic drugs may occur at any time during the course of treatment, even after many years of control of positive symptoms. Such patients are more likely to respond to clozapine[51] or one of the other atypical antipsychotics.[50,51]

The average doses of the typical neuroleptic drugs are given in Table 6.2.5.5. The best results with these drugs in terms of efficacy and side-effects may be expected with the lowest dose needed to produce control of positive symptoms with the fewest extrapyramidal side-effects.[4,49]

There are some patients for whom higher doses are indicated, but most controlled studies have failed to find benefits from high-dose strategies of combining two or more of these agents. Increasing the dose of these agents when patients fail to respond rapidly, for example within days, is not recommended. Augmentation with a benzodiazepine may be useful to decrease anxiety until the lower doses of neuroleptic drugs produce adequate control of positive symptoms.[4,49] Patients who may require higher doses of neuroleptic drugs to respond adequately are at greater risk of hyperprolactinaemic effects, EPS, and tardive dyskinesia and are generally better treated with an atypical antipsychotic drug.

However, the improvement in positive symptoms which is often achievable with the typical antipsychotic drug is only one element in the treatment of schizophrenia and is not sufficient grounds for judging response to be adequate. Additional efficacy factors of major importance are summarized in Table 6.2.5.6.

Tolerability and safety factors, such as compliance, tardive dyskinesia, weight gain, and medical morbidity are also major elements in outcome and are influenced by the choice of a typical or atypical antipsychotic drug. Typical neuroleptic drugs are not as effective for improving primary negative symptoms of schizophrenia in the majority of patients.[52,53] There is a consensus that typical neuroleptic drugs can improve negative symptoms that are secondary to positive symptoms and depression while at the same time possibly causing secondary negative symptoms due to their ability to produce extrapyramidal side-effects.[52] Abnormalities in specific domains of cognition (Table 6.2.5.6) are present in first-episode schizophrenic patients at a moderate to severe level and show slight to moderate, rarely severe, deterioration during the course of illness.[54,55] Approximately 85 per cent of patients with schizophrenia are clinically impaired in one or more domains of cognition.[55,56] Cognition has been shown to be perhaps the most critical determinant of functional capacity among patients with schizophrenia, even more so than positive symptoms.[57] Typical neuroleptic drugs usually do not improve cognitive function.[58] Those typical neuroleptic drugs such as thioridazine and mesoridazine, which have strong antimuscarinic properties, may produce further impairment in some memory functions.[58]

All of the typical neuroleptic drugs are likely to be equally effective in treating either the initial presentation or recurrent psychosis due to breakthrough of symptoms, despite compliance, or because of having stopped medication[4,49,51] First-episode patients with schizophrenia usually require much lower doses than patients with two or more episodes, suggesting some progression of the disease process or development of tolerance to the mechanism of action of these drugs.[59] Doses for more chronic patients should be in the range of 5 to 10 mg haloperidol equivalents per day (Table 6.2.5.5) for up to 4 to 6 weeks unless there is a major need for chemical means to prevent harm to self or others, to decrease excitement, or induce sleep.[60] Auxiliary medications for anxiety and sleeplessness, for example benzodiazepines, may supplement these low doses of antipsychotics.[61]

Parenteral injections of haloperidol, chlorpromazine, or other neuroleptics may be needed for patients who refuse oral medication or where very rapid onset of action is needed to control acutely dangerous behaviours if less restrictive means either fail or cannot be utilized safely. Commonly, haloperidol (2–10 mg) with or without lorazepam (2–4 mg) is delivered intramuscularly every 30

Table 6.2.5.5 Oral dosing of antipsychotic drugs

Typical antipsychotic drugs				
	Equivalent doses (mg/day)	**Starting dose**	**Titration schedule**	**Dose range (mg/day)**
Chlorpromazine[a]	100	15–50 mg BID-QID	As clinically indicated	300–1000 (divided QD-QID)
Fluphenazine[b]	2	0.5–10 mg/day (divided Q6–8 hours)	As clinically indicated	5–20
Haloperidol[c]	2	0.5–5 mg BID	As clinically indicated	5–20
Loxapine	10	10 mg BID	As clinically indicated	30–100
Mesoridazine	50			150–400
Molindone	10	50–75 mg/day divided TID-QID	As clinically indicated	30–100
Perphenazine[d]	10	4–8 mg TID (8–16 mg BID-QID if hospitalized)	As clinically indicated	16–64
Thioridazine	100	50–100 mg TID	As clinically indicated	300–800
Tiotixene	5	2 mg TID	As clinically indicated	15–50
Trifluoperazine	5	2–5 mg BID	As clinically indicated	15–50

For elderly patients, or those with renal or hepatic problems, doses of drug may need to be reduced by one-half or more

[a] Short-acting IM formulation may be given 25–50 mg (may repeat after 1–4 hrs as required); may gradually increase dose up to 400 mg IM Q 4-6 hrs (maximum of 2000 mg/day) may be needed for severe cases

[b] Short-acting IM formulation may be given 2.5–10 mg/day in Q6–8 hr intervals; Depot IM formulation may be given 12.5–25 mg Q 3 weeks

[c] Short-acting IM formulation may be given 2–5 mg Q 1–4 hrs; Depot IM formulation may be given at approximately 10–20 times the stable oral dose Q 4 weeks

[d] Short-acting IM formulation may be given 5–10 mg Q 6 hrs (maximum of 30 mg/day)

Atypical antipsychotic drugs			
	Starting dose	**Titration schedule**	**Dose range (mg/day)**
Aripiprazole[a]	10–15 mg daily	As clinically indicated, every 2 weeks	10–30
Clozapine	12.5 mg QD-BID	Increase by 25–50 mg/day until usual effective dose of 300–450 mg/day after 2–4 weeks	150–600
Olanzapine[b]	5–10 mg daily	As clinically indicated, by 5 mg/day every 7 days	10–30
Paliperidone	6 mg/day	As clinically indicated, by 3 mg/day Q 2–4 week increments, up to 12 mg daily	6–12
Quetiapine	25 mg BID	Increase by 25–50 mg BID-TID on days 2 and 3, to target dose of 300–400 mg daily (QD – TID) by day 4. Further increases as clinically indicated by 25–50 mg BID every 2 days.	300– 800
Risperidone[c]	0.5–1 mg BID	Increase by 0.5–1 mg BID on days 2 and 3, with further dose increases thereafter by 0.5–1 mg increments Q 7 days as required	2–8
Ziprasidone[d]	20 mg BID with food	Increase by 20–40 mg BID every 2 days to target dose of 80 mg (all doses with food)	120–200

For elderly patients, or those with renal or hepatic problems, doses of drug may need to be reduced by one-half or more, and titration may be slower

[a] Short-acting IM formulation may be given at 9.75 mg, though the lower 5.25 mg dose may be indicated in some situations.

[b] Short-acting IM formulation may be given 10 mg as required (may be repeated after 2 hrs, up to 30 mg/day).

[c] Long-acting IM formulation may be initiated at 25 mg Q 2 weeks (continue oral risperidone dose for 3 weeks), with increases as clinically indicated every 4 weeks up to a dose of 50 mg Q 2 weeks

[d] Short-acting IM formulation may be given 10–20 mg as required (may be repeated Q 2–4 hrs as needed, up to 40 mg/day)

to 60 minutes as required, up to three doses. Doses of haloperidol given intramuscularly in such situations generally should not exceed 18 mg per day. Oral medication should be substituted as soon as feasible. If positive symptoms fail to respond to a single trial of a typical neuroleptic drug at adequate doses in patients with schizophrenia, there is evidence that switching to another typical antipsychotic, even of a different chemical class, is unlikely to produce greater control.[4,49,51] This is likely to be true for other indications for the use of antipsychotic agents as well.

In cases of repeated illness relapse due to poor compliance or when patients prefer it, the use of long acting (e.g. depot) injectable antipsychotic medications, typically administered once every 2–4 weeks, may be used. The use of injectable antipsychotic medication has been associated with lower rates of relapse and rehospitalization and greater global improvement compared with oral typical neuroleptics,[62] possibly as a result of ensured drug delivery. Long acting injectable drugs should not be given to ameliorate acute behavioural disturbances.

(b) Atypical antipsychotic drugs

As implied above, there are major advantages for many patients to be treated with the atypical antipsychotic drugs and it is generally

Table 6.2.5.6 Target signs and symptoms for the pharmacological management of schizophrenia

Target	Description	
Positive syndrome	Hallucinations Delusions	◆ Typically the most amenable to treatment with all antipsychotic drugs
Negative syndrome	Avolition Apathy Anhedonia Lack of responsiveness Poor rapport with others Passive social withdrawal Poverty of speech Affective flattening	◆ Robustly correlated with functional impairment in schizohprenia ◆ More difficult to treat pharmacologically, and may required longer to respond than positive signs and symptoms ◆ Pharmacological adjuncts may be needed, though under-studied ◆ Atypical antipsychotic drugs are believed to be more efficacious than typical neuroleptics
Hostility/excitement	Verbal or physical aggression	◆ Typically amenable to treatment with all antipsychotic drugs ◆ Use of parenteral formulation may be required
Mood and anxiety symptoms	Depressed mood Anxious mood Nervousness Panic symptoms Suicidal ideation	◆ Believed to be more responsive to treatment with atypical antipsychotic drugs ◆ Clozapine has demonstrated superiority for treating chronic suicidality in schizophrenia
Cognitive impairment (psychopathological definition)	Disorientation Problems with abstraction Attentional problems Preoccupations Disorganized thought processes	◆ Some domains respond favourably to antipsychotic drug treatment, though response is often incomplete
Cognitive impairment (neuropsychological testing definition)	Working memory Attention/vigilance Verbal learning/memory Visual learning/memory Problem solving Processing speed	◆ Neuropsychological deficits, like negative signs and symptoms, are robustly correlated with functional outcome in schizophrenia ◆ Very difficult to treat with medication alone ◆ Atypical antipsychotic drugs are believed to be superior to typical neuroleptics, though effect sizes are only mild to moderate for the former

recommended that, where possible, these agents be considered as the first-line treatment.[63,64] The atypical antipsychotic drugs are the dominant antipsychotic treatment for schizophrenia, mania, and psychotic depression in clinical practice in many parts of the world. However, there is considerable international variation in their usage. Cost factors may explain part of the variance in the use of these agents within and between countries. The typical neuroleptic drugs are no longer covered by patent protection and are available in inexpensive generic forms. There are a number of patients whose psychosis is adequately controlled by these agents and they (and their families and prescribers) are content to continue them even when informed of the potential advantages of the newer antipsychotic agents. When only the cost of medication is considered, it may seem that fiscal reasons argue for continuation of typical neuroleptic drug treatment since the atypical agents can cost up to 100 times more. In addition, the widely accepted notion of greater overall benefit from treatment with atypical antipsychotic drugs, as opposed to typical neuroleptics, was recently challenged by results from two effectiveness studies. The first of these demonstrated no significant difference in all-cause discontinuation from the study as the primary endpoint, as well as discontinuation for lack of efficacy, between atypical drugs, with the exception of olanzapine, and the typical neuroleptic perphenazine.[65] The latter study reported a lack of significant differences in quality of life between patients who received naturalistic treatment with typical or atypical antipsychotic drugs.[66] Methodological limitations, detailed discussion of which is beyond the scope of this chapter, limit the conclusions that can be drawn from these reports about the relative merits of one class of antipsychotics versus another, both of which are in disagreement with the majority of the clinical literature that documents differences between these broad classes of antipsychotic drugs across a wide range of outcomes. Because medication costs account for, at most, 5 per cent of the total costs of schizophrenia, with the major costs being hospitalization and indirect costs such as lost income and disability income to support patients in the community, more effective and tolerable medications may offset their greater cost.[67,68] As such, atypical antipsychotic drugs are recommended as first line treatments of schizophrenia and related psychotic disorders. Each will be discussed separately.

(i) Clozapine

Clozapine was synthesized in 1959 as part of a project to discover antipsychotic drugs with low potential for extrapyramidal side-effects. It proved to be one of the most interesting and clinically important compounds ever discovered. It was labelled as atypical because of its ability to block amphetamine-induced locomotor activity, one of the most widely accepted models for antipsychotic activity, without producing catalepsy in rodents, the leading model for causation of extrapyramidal side-effects in humans. Subsequent clinical studies showed it to have the lowest extrapyramidal side-effects of any antipsychotic drug known.[5,69] Clinical trials in the 1960s and 1970s suggested it was also superior in

efficacy with regard to control of positive symptoms, but given the standards of clinical trials of that era, these conclusions could not be relied upon.[70] In 1975, 6 years after its introduction in Europe, clozapine's ability to cause granulocytopenia or agranulocytosis was first reported. Six deaths occurred in clozapine-treated patients in a geographically restricted area of Finland over a short period of time. The role of clozapine in these deaths is still uncertain because no other such clustering has ever occurred in Finland, or elsewhere. Nevertheless, clozapine was withdrawn from general use, although it remained available for humanitarian use in patients who had previously received it, for individual cases where it seemed indicated because of its low potential for extrapyramidal side-effects, and for research purposes.[69]

Clozapine was reintroduced in 1989 after it was demonstrated to be superior to chlorpromazine to improve positive and negative symptoms in 300 patients who were resistant to the action of at least three typical neuroleptics.[71] Thirty per cent of the patients treated with clozapine responded after 6 weeks of treatment compared to 4 per cent of the chlorpromazine-treated patients. Subsequent studies have shown that up to 60 to 70 per cent of patients will respond within 6 months of treatment. Patients with shorter duration of illness tend to respond better. Some predictors of response include weight gain and absence of atrophy in the prefrontal cortex.[52] Clozapine has been reported in several studies to reduce the risk of suicide.[52,72] It has been shown in a large number of studies to improve some aspects of cognitive function, especially verbal fluency, immediate and delayed verbal learning and memory, and attention.[16–18]

Because of the side-effect profile of clozapine, it is not generally used as a first-line drug. On the other hand, monitoring the white blood count for the development of agranulocytosis or granulocytopenia, as well as improved methods of treating agranulocytosis, have made it much safer to use. Clozapine is still probably underutilized in many parts of the world. Any patient with an unsatisfactory response to the typical neuroleptics and at least one atypical antipsychotic should be considered for clozapine treatment. This amounts to at least 20 per cent of schizophrenics. Clozapine use may also be considered for patients with schizophrenia who are at high risk for suicide, even if the aforementioned threshold of inadequate response to other drugs has not yet been met.

Clozapine is usually given twice daily, but sometimes more than half of the dose or the entire dose is given at sleep time to minimize daytime sedation. The daily dosage is gradually titrated to the target range described in Table 6.2.5.5. Patients who are treatment resistant may require higher doses. Typical or non-clozapine atypical antipsychotic drugs should be discontinued either before beginning clozapine or by eliminating them over a 1- to 2-week period as the dose of clozapine is increased. Because clozapine produces only about 40 to 50 per cent occupancy of striatal D_2-receptors,[73] and some of its key advantages are believed to be related to its low D_2-receptor blockade, concomitant administration of typical neuroleptic drugs would be predicted to interfere with some of the benefits of clozapine and, thus, should not ordinarily be prescribed with clozapine. However, some patients with persistent positive symptoms despite an adequate trial of clozapine monotherapy might be expected to benefit from the addition of low-dose haloperidol, or its equivalent, to provide additional low level D_2-receptor blockade.

Determination of clozapine plasma levels is useful whenever patients are not responding adequately. If response is inadequate, various approaches to augment response have also been utilized. In addition to adding a low dose of a typical neuroleptic, as mentioned above, it may be useful to augment clozapine treatment with valproic acid or other mood stabilizer (such as lithium, carbamazepine, lamotrigine or topiramate), anxiolytic drugs, or an antidepressant.[52] The choice of augmenting agent is largely driven by symptomatic considerations, or pharmacokinetic interactions in the case of fluvoxamine. However, none of these strategies have strong empiric support. One exception may be the addition of sulpiride, which may result in a significant reduction in symptom burden when added to clozapine.[74] Electroconvulsive therapy (ECT) also resulted in a modest further reduction in symptoms when used in conjunction with clozapine, and appears to be well tolerated.[75] It is difficult to postulate a rationale for adding another atypical antipsychotic, with the exception of amisulpride, because of their similarity in pharmacology to clozapine. It should be discontinued if side-effects are intolerable, or if there is no apparent response after a 6-month trial of clozapine alone and subsequent trials with augmentation therapy. Clearly, further studies involving clozapine partial- or non-responders are urgently needed. It should be noted that discontinuation of clozapine can precipitate a severe relapse even when clozapine is slowly tapered.[76]

(ii) Risperidone

Risperidone is useful as a first-line drug for the treatment of all forms of schizophrenia, including residual schizophrenia.[77–79] Definitive data are lacking for its efficacy in patients who are neuroleptic resistant or who have failed to respond to other atypical antipsychotics, including clozapine.[80] Clinical experience is not supportive of widespread efficacy in these groups but there may be some responders. However, risperidone may be useful in patients who fail to tolerate other antipsychotic agents because of side-effects not shared by risperidone, such as anticholinergic effects. Risperidone is well-tolerated in low doses by the elderly and has been widely used in the United States for the treatment of a variety of senile psychoses.[81,82] Its efficacy against haloperidol was established in a series of multicentre trials which demonstrated advantages for risperidone in overall psychopathology in mainly chronic schizophrenic patients in an acute exacerbation at doses in the 6 to 8 mg/day range.[11,77] However, these doses have proven to be higher than is needed for most patients in clinical practice, possibly reflecting some of the problems in generalizing from controlled clinical trials. The doses for schizophrenia most often used in non-elderly adults are now 4 to 6 mg/day. First-episode patients may not tolerate higher doses (e.g. above 5 mg per day), and some may respond to as little as 1 to 2 mg/day. Some treatment-resistant patients may need doses higher than 6 mg/day; however, the results of clinical studies in this population have been mixed. Whether prolonged trials, i.e. up to 6 months, are useful in such patients, as they are in clozapine patients, is not yet known.

Beyond treatment of acute symptoms, the position occupied by risperidone as a first line treatment option is also supported by long term maintenance phase and relapse prevention studies. For instance, relative to haloperidol, risperidone has also been associated with a lower risk of relapse (34 vs. 60 per cent) over a

minimum of 12 months of treatment.[83] In another study that |retrospectively compared rates of rehospitalization for patients who received treatment with risperidone, olanzapine, or typical neuroleptics, rehosptialization rates for risperidone and olanzapine were similar, and both were significantly less than those of patients treated with typical neuroleptics.[84]

Risperidone is usually initiated at low doses (e.g. 1–2 mg daily) and is titrated into the dosage range provided in Table 6.2.5.5. The medication is often initiated in twice daily dosing; however, because its primary active metabolite, 9-OH risperidone, is pharmacologically equivalent to its parent drug and because it has a longer elimination half-life, once daily dosing is also possible. Risperidone is available in soluble wafer and liquid forms, which may be advantageous for patients who have swallowing difficulties or require taking their medication in a non-pill form for other reasons, including their own preference.

For patients who have a history of poor compliance leading to frequently relapsing illness, or for those who prefer it, a long acting injectable form of risperidone is available (Table 6.2.5.1) for administration typically every two weeks. For treatment responsive patients, response may be expected to occur in the 25–50 mg (per every two week dose) range,[85] however, oral risperidone must be continued through at least the first 3 weeks of treatment with the long acting injectable form before being slowly tapered. Supplementation with oral medication may be required when the dose of the long-acting drug is upwardly adjusted due to breakthrough psychotic symptoms. As is the case with long-acting injectable typical antipsychotics, long-acting injectable risperidone should not be used acutely to control dangerous behaviours.

Risperidone has more of a tendency to produce extrapyramidal side-effects than any of the other atypical antipsychotics but this can be minimized by using the lowest dose which controls positive symptoms and adding an anticholinergic drug, if necessary.[82] Addition of a typical neuroleptic to risperidone will increase the risk of extrapyramidal side-effects. Risperidone is not well tolerated by patients with Parkinson's disease because of extrapyramidal side-effects. There are some data suggesting the risk of tardive dyskinesia in patients with schizophrenia, and especially the elderly, with risperidone is less than that of the typical neuroleptic drugs.[86]

Among atypical antipsychotic drugs, risperidone and paliperidone appear to be the most liable in terms of increasing prolactin release. As is the case with EPS, the effect of risperidone on prolactin concentration appears to positively correlate with dose.[25] The changes may occur in both men and women; however, the greatest elevations appear to occur among women. Elevations in prolactin levels as a result of treatment with risperidone do not always translate into clinical symptoms such as sexual dysfunction or gynaecomastia in men and menstrual changes and breast discharge in women; however, patients should be monitored clinically for these effects, and prolactin concentrations measured if these symptoms occur.

The issue of whether the improvement in negative symptoms by risperidone and other atypical antipsychotic drugs is due to an effect on so-called primary negative symptoms versus secondary negative symptoms has been much debated. Data from large multicentre trials of risperidone versus clozapine show an effect on primary negative symptoms as residual change left after adjusting for improvement due to decreases in positive or depressive symptoms and extrapyramidal side-effects.[87] In addition, results from a meta-analysis of 6 studies comparing risperidone to typical neuroleptic treatment indicated greater response rate for negative symptoms (defined as achieving >20 per cent reduction in negative symptom burden) as well as greater reduction in anxious/depressive symptoms among risperidone treated patients.[88] Risperidone has a greater ability to improve cognition in schizophrenia than the typical neuroleptic drugs.[17] Improvement in working memory has been the strongest finding, while improvements in attention, executive function, and verbal learning and memory have also been reported. Risperidone has been shown to be a cost-effective treatment for schizophrenia,[89] especially in its long-acting injectable form,[90] and to improve quality of life,[91] firm conclusions about relative cost-effectiveness between atypical antipsychotic drugs for non-treatment-resistant schizophrenia are difficult to draw at this time. Further research in this important area is needed.

In summary, risperidone is a first line pharmacological treatment of schizophrenia and other forms of psychosis. It may produce significant advantages over typical neuroleptic drugs with regard to negative symptoms, cognition, and extrapyramidal side-effects, but it does produce dose dependent increases in EPS risk, and increases in serum prolactin levels resembling those of typical antipsychotic drugs. It should be used at the lower doses where possible. A long-acting injectable form of this medication should be considered a first line treatment option in cases of frequent relapse due to poor medication compliance.

(iii) Olanzapine

Olanzapine is indicated as a first-line treatment for all forms of schizophrenia[63,92] with the caveat that it has not been shown to be as effective as clozapine in neuroleptic-resistant patients at conventional doses.[8,60] However, some patients of this type do respond to olanzapine,[93] perhaps at high doses.[94,95] There are no means yet to determine which of this group of patients will respond to olanzapine (or risperidone) so some clinicians may elect a trial with either of these agents before considering clozapine.

The efficacy of olanzapine in treating psychosis and negative symptoms in patients with an acute exacerbation of schizophrenia has been firmly established in a variety of large-scale, multicentre trials.[92] In these trials, olanzapine at doses of 10 to 20 mg/day has been superior to placebo and equivalent or superior to haloperidol in some measures of total psychopathology, positive, or negative symptoms. For example, in the North American multicentre trial, high-dose olanzapine (15 ± 5 mg/day) was superior to haloperidol (15 ± 5 mg/day) in the treatment of negative symptoms.[96] The effect of olanzapine to improve negative symptoms was found to be on primary rather than secondary negative symptoms.[97]

Olanzapine has also been found to be effective as a maintenance treatment of schizophrenia.[98] The estimated relapse rates, defined as the need for hospitalization, during a 1-year period in three studies of patients receiving olanzapine for maintenance treatment were 19.6 to 28.6 per cent. These rates were significantly lower than those in patients receiving placebo, ineffective doses of olanzapine, or haloperidol.[98] Olanzapine has some efficacy in treating anxious and depressive symptoms,[99] as well as cognitive dysfunction,[17,18] associated with schizophrenia or schizoaffective disorder. Pharmacoeconomic studies and investigations of medication effects on quality of life measures indicate that olanzapine has

a beneficial cost-outcome profile. For instance, in one investigation, the higher cost of olanzapine relative to haloperidol was offset by olanzapine-treatment associated reductions in rehospitalization and overall treatment costs.[100] Olanzapine treatment has also been associated with better outcomes as assessed by overall and health-related quality of life relative to haloperidol.[101] As mentioned above, olanzapine was found to be the most effective antipsychotic drug in the recent Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) phase I study.[65]

The average clinical dose of olanzapine is 12.5 to 20 mg/day but many patients may be expected to respond to lower doses (e.g. 10 mg daily).[102] A principle advantage of olanzapine is its once daily dosing and the feasibility of starting the medication at a dose that is clinically effective for most patients. Doses higher than 20 mg/day are rarely more effective than lower doses, especially for non-refractory cases. Augmentation of olanzapine with typical neuroleptic drugs or risperidone should be done sparingly to avoid extrapyramidal side-effects and possibly compromising efficacy. Olanzapine is also available in a soluble wafer form that may be preferred to the pill form by some patients, especially those with swallowing difficulties and related problems.

For acute situations where rapid control of agitation, hostility or other dangerous behaviours is required, olanzapine is available as a short-acting injectable medication (Table 6.2.5.1).[103] Similar to short-acting typical neuroleptic drugs, the medication is delivered intramuscularly. Doses of 5 to 10 mg per injection may be given, depending on the severity of the target behaviours. A long-acting formulation is in clinical testing.

In summary, olanzapine has found wide acceptance as an atypical antipsychotic drug because of its once-a-day administration, efficacy for negative symptoms, improvement in cognitive function, and low extrapyramidal side-effect profile. Significant weight gain and other metabolic effects may be a problem for some patients, as will be discussed below.

(iv) Quetiapine

Quetiapine has been shown to be as effective as typical antipsychotics, with fewer extrapyramidal side-effects and no effect on serum prolactin levels.[104,105] Part of the reason for this may be that quetiapine and clozapine both appear to bind more loosely to striatal D2 receptors than other antipsychotic drugs, and that both drugs show antipsychotic activity at D2 receptor occupancies that are well below the 60 per cent threshold identified for most other antipsychotic drugs.[106] In spite of this similarity with clozapine, quetiapine does not appear to have efficacy comparable to clozapine for treatment-resistant patients.

The efficacy of quetiapine for acute phase schizophrenia is supported by results from several randomized, controlled trials that documented superiority of quetiapine relative to placebo across several doses, with some patients with some patients responding to 150 mg/day and others requiring 750 mg/day.[104] For instance, in one high- (750 mg/day) versus low-dosage (250 mg/day) study, both dosage groups evidenced greater reduction in positive symptoms relative to placebo; however, the differences were significant only for the high-dose group.[105] In another study that assessed multiple fixed doses of quetiapine (75 to 750 mg/day) compared with haloperidol and placebo, significant differences in improvement over placebo for quetiapine were observed in the dosage range of 150 to 750 mg/day.[104]

Quetiapine's effect on negative symptoms continue to be investigated. One placebo controlled comparison documented improvements in negative symptoms with quetiapine treatment across a wide range of doses, with the greatest improvement reported at 300 mg daily.[104] In the high- vs. low- dose study reviewed above, the high-dose group also experienced greater improvement in negative symptoms relative to placebo.[105] Like risperidone and olanzapine, quetiapine appears to improve depressive symptoms[107] and certain cognitive deficits[17,18] associated with schizophrenia or schizoaffective disorder. The improvements in cognition with quetiapine appear to be superior to those of haloperidol.[108]

These results suggest that, overall, the greatest improvement in positive and negative symptoms may occur when quetiapine is used at the higher end of its dosage range. The average clinical dose appears to be between 300 and 500 mg/day, usually given twice daily though some benefit from the medication when given only once daily. The effects of using higher doses for patients who do not respond adequately to these doses are uncertain. A titration of the dosage is required after initiating the medication. From the viewpoint of EPS and hyperprolactinaemic effects, quetiapine appears to confer only low risk. As such, it, like clozapine, appears to be well tolerated even among patients with idiopathic Parkinson's disease.[109] Sedation may be a limiting side effect for some, especially during dosage titration. Weight related, metabolic, and other adverse effects will be discussed in greater detail below.

In summary, quetiapine also appears to be effective for a wide range of schizophrenia-associated symptoms and confers a lower level of risk in terms of antidopaminergic adverse effects. The dosage range of this medication may be quite wide, though patients may have a greater chance of benefiting from the medication at the higher end of this range.

(v) Ziprasidone

Ziprasidone has a varied receptor occupancy profile. Like most atypical antipsychotic drugs, it displays high affinity 5-HT2A binding coupled with relatively lower affinity D2 receptor binding. Ziprasidone is also a 5-HT1A agonist, as well as both a serotonin and norepinephrine reuptake pump inhibitor.[110] This profile predicts a wide range of pharmacological activity against core psychotic symptoms, negative and affective symptoms, as well as neurocognition.

Ziprasidone, like quetiapine, has been shown to be superior to placebo for the reduction of total psychopathology and positive and negative symptoms.[111,112] There is limited evidence to suggest superiority over typical neuroleptics with regard to improvement in positive and negative symptoms.[111,113] Studies of multiple fixed doses of ziprasidone vs. haloperidol at conventional doses indicate that ziprasidone yields similar efficacy to haloperidol for reducing positive symptoms and global psychopathology at a dose of 160 mg/day.[113] Doses greater than 160 mg/day have not been systematically investigated.

Ziprasidone significantly improved negative symptoms and reduced the risk of relapse compared to placebo in a 1-year maintenance study in stable hospitalized chronic schizophrenic patients.[114] These maintenance phase effects were not dependent on the daily dose of ziprasidone. In a 28-week comparison with haloperidol, the two groups evidenced similar overall effects for positive symptoms; however, between groups differences were

documented favouring ziprasidone for negative symptoms and EPS.[115] Ziprasidone was effective against depressive symptoms associated with schizophrenia in one study at a dose of 160 mg/day.[116] Significant improvements in multiple cognitive domains have been reported among ziprasidone treated patients in a variety of treatment contexts.[117] Such changes appear to be unrelated to improvements in other symptoms of schizophrenia. Ziprasidone treatment has been associated with significant improvement in quality of life measures in one post hoc data analysis.[118] Further investigation of the effect of ziprasidone on health related quality of life and similar outcomes are warranted. Ziprasidone treatment of schizophrenia appears to be cost-effective relative to no treatment.[119] Further cost-benefit studies are needed.

The dose range of ziprasidone for acute treatment appears to be between 80 and 160 mg/day, higher doses within this range may be more effective (Table 6.2.5.5). Doses greater than 120 mg/day appear to be required to achieve >60 per cent dopamine D2 receptor blockade,[120] the D2 receptor occupancy threshold that appears to coincide with efficacy against positive symptoms, as presented earlier. The medication is usually given twice daily, although some may take the medication once daily at night time. A titration of the total daily dose into the recommended range is required after initiating the medication. One critical aspect of medication administration for ziprasidone is the requirement that the medication be taken with food. There appear to be profound differences in bioavailability at equivalent doses between the fed and unfed state.[121] A full meal, as opposed to a light snack, appears to be required. Therefore, patients are encouraged to take their medication with meals.

A short-acting intramuscular formulation of ziprasidone has been developed which should be useful in situations where more rapid action is needed. This formulation is available in two doses (10 and 20 mg), the preferred dosage being 20 mg due to significantly greater reduction in agitation relative to lower dose.[122] The use of the short-acting injectable form can facilitate a transition to oral medication, and may reduce that time required to titrate the daily dose of ziprasidone to one that is likely to be effective.

Ziprasidone appears to be well tolerated. Treatment-emergent EPS burden is low.[112,113] Initial problems with somnolence or behavioural activation are usually self limited, although temporary use of clonazepam or other benzodiazepine at low doses may improve tolerability, especially during the titration phase, should the latter occur. Importantly, data from both short- and long-term studies indicated that ziprasidone is not associated with clinically significant changes in weight, glycaemic measures, or markers of lipid homeostasis.[123]

Ziprasidone can result in partial blockade of the slow potassium rectifier current in the cardiac conduction system, which may result in prolongation of the QTc interval (discussed in greater detail below).[124] On the other hand, there is only one case report of ziprasidone induced *torsades de pointes*, the risk of which is believed to be increased if the QTc interval is >500 msec.[125] There have also been no reported deaths in the context of overdose with the medication. Under routine circumstances, screening electrocardiograms are not required. Nevertheless, caution may be warranted for individuals who are at risk for significant prolongation of the QTc, including patients who take medications other than ziprasidone that prolong the QTc. Concomitant use of CYP-450 3A4 inhibitors does not appear to pose a significant risk.[126]

In summary, ziprasidone appears to be a useful additional atypical antipsychotic agent because of its favourable side-effect profile, including no weight gain—a major problem with olanzapine and clozapine-and no prolactin elevation, which is a less serious side-effect of risperidone. Patients should be instructed to take the medication with food. Ziprasidone treatment may result in an increase in the QTc interval; however, in a great majority of cases, this is not clinically significant.

(vi) Aripiprazole

Among the atypical antipsychotics, aripiprazole is pharmacologically unique in that it combines partial D2 receptor agonism with high potency 5-HT2A antagonism. Because it is a partial D2 receptor agonist, it binds to the receptor with full affinity, but exerts only a fraction of the intrinsic activity at that site that would be expected of endogenous dopamine. As such, in states of relative dopamine excess, as is believed to be the case in the ventral striatum among schizophrenic patients who experience positive symptoms, aripiprazole is believed to exert relative antagonist activity at D2 receptors.[127] Conversely, it is believed to act primarily as an agonist in cases of relative hypo-dopaminergia, as may be the case in the prefrontal cortex in patients with schizophrenia.[22] For this reason, aripiprazole and other D2 partial agonists in development are sometimes referred to as 'dopamine stabilizers.' Aripiprazole also functions as a potent 5-HT1A partial agonist.[128]

The efficacy of aripiprazole in the treatment of acute schizophrenia at doses ranging between 10 and 30 mg (taken once daily) was established on the basis of four short-term randomized controlled studies.[129] Relative to placebo, efficacy against negative symptoms was also demonstrated.[130] Long term superiority of aripiprazole (vs. placebo) for relapse over 26 weeks[131] and medication compliance and symptom response (vs. haloperidol) for up to 52 weeks has also been established.[133] One study reported on the effectiveness of flexibly dosed aripiprazole (15–30 mg daily) among patients with schizophrenia with a history of resistance to treatment with olanzapine or risperidone.[133] The utility of aripiprazole in the setting of well defined treatment refractory schizophrenia requires further systematic investigation.

The overall effectivenss of aripiprazole has been evaluated in two recent studies. One study reported the effectivenss of flexibly dosed aripiprazole over 8 weeks of treatment (53 per cent response rate at mean endpoint dose = 19.9 mg/day) among a cohort of patients with chronic schizophrenia and schizoaffective disorder under routine treatment conditions in a community healthcare setting.[134] The second study documented comparable effectiveness with olanzapine over 52 weeks of treatment, with more favourable effects for aripiprazole for several metabolic adverse effects.[135] As is the case with other atypical antipsychotic drugs, early evidence indicates that aripiprazole may also have beneficial effects on neurocognitive performance in patients with schizophrenia at recommended doses.[136] Further study of the effects of this medication on cognition is indicated. Clinically relevant improvement in quality of life has been documented in one study.[137] More cost-outcome studies of aripiprazole are needed.

Treatment with aripiprazole is usually initiated with 10 to 15 mg daily, although some patients may not be able to tolerate these doses due to agitation, nausea or vomiting. The dose can be increased up to 30 mg if needed, and tolerated. An oral solution form is also available. Aripiprazole is also available in a soluble

wafer as well as an acute intramuscular form. The acute injectable form appears to be effective in the dosage range of 5.25 to 15 mg.[138] The recommended dose is 9.75 mg.

Aripiprazole is generally well tolerated, with an adverse effect profile similar to placebo in short-term studies involving patients with acute schizophrenia and in longer-term studies of chronic, stable patients.[129] As is the case with all atypical antipsychotic drugs, the EPS burden is lower than that of typical neuroleptics. Some patients, however, may encounter this effect if the dose is started too high or if the titration is too aggressive. Aripiprazole treatment does not appear to significantly increase, and may cause a slight decrease, in prolactin levels.[25] Importantly, short- and longer-term studies indicated that, similar to ziprasidone, aripiprazole is not associated with a high risk of significant changes in weight, glycaemic measures, or markers of lipid metabolism.[123]

In summary, aripiprazole appears to be effective as an acute and long-term maintenance treatment for schizophrenia and related psychotic disorders at recommended doses, though some patients may require higher doses. Aripiprazole was initiated in most studies at doses of 10 to 15 mg once daily; however, some patients may require a slower titration following a lower starting dose. This medication is available in many dosing forms, all of which appear to be very well tolerated. Important benefits from a tolerability viewpoint include very low rates of prolactin elevation, and low risk of weight gain and metabolic adverse effects.

(vii) Paliperidone

Paliperidone is the most recent antipsychotic drug to gain approval for use in the US. It is the 9-OH metabolite of risperidone, which has a longer elimination half-life than the parent compound, as reviewed above. Additionally, paliperidone, which is pharmacologically similar with regard to receptor occupancy profile to risperidone, is available commercially in an extended release form.

The short-term efficacy of paliperidone has been established on the basis of three randomized, placebo controlled studies, two of which have been published,[139,140] that investigated the clinical efficacy of 5 fixed doses (3, 6, 9, 12, and 15 mg) given once daily relative to placebo. In each of these studies, all doses of paliperidone were superior to placebo for reducing global psychopathology and positive symptoms, as well as negative symptoms, anxious/depressive symptoms associated with schizophrenia, and hostility/excitement. In addition, all doses of paliperidone were superior to placebo for improving measures of functional capacity. Paliperidone has not been investigated in the context of treatment refractory schizophrenia. Paliperidone appears to be effective for the prevention of relapse on the basis of one published study.[141]

The recommended starting dose of paliperidone in its extended release form is 6 mg, given once daily. Even though there is a suggestion of greater improvement in terms of symptom reduction from the paliperidone registration studies at higher doses, the adverse effect burden may also be greater (discussed below). Doses may be upwardly adjusted at 3 mg/day increments, up to 12 mg daily. Investigatons of doses greater than 6 mg daily for patients who do not respond adequately have not been performed. A long acting injectable form of paliperidone is currently in development.

Pooled analysis of data from the three short-term, acute phase studies indicate that paliperidone appears to be well tolerated, and that the recommended starting dose (6 mg once daily) was associated with a placebo-like overall adverse effect profile.[142] At doses higher than 6 mg, there appeared to be an increase in the reported incidence of EPS, though not to the degree at any of the doses tested that would be expected with typical neuroleptic treatment. Elevations in prolactin levels appear to be consistent with those observed with risperidone treatment, and appear to be greater in magnitude at higher doses. This effect appears to be especially pronounced among female patients. There were no significant changes from baseline in weight or measures of lipid or glucose handling. Data from long term investigations will provide a more comprehensive picture of paliperidone's tolerability profile.

In summary, paliperidone, the newest atypical antipsychotic drug, appears to be safe and effective for both short- and long-term treatment of schizophrenia. The EPS and prolactinemic adverse effect burden may resemble that of risperidone, but this notion requires prospective investigation. Paliperidone in its extended release form can be started at a clinically effective dose. A long-acting injectable form is currently in development.

(viii) Amisulpride

The efficacy of amisulpride for the treatment of positive symptoms has been established over a wide dosage range (200 to 1200 mg daily) in treatment studies of up to 12 months duration.[143] In general, it appears that higher doses (above 400 mg/day) are effective for treating patients with predominately positive symptoms, although efficacy against negative symptoms has also been demonstrated in this dosing range.[144,145] Low-dose amisulpride (≤ 300 mg/day) has been shown to be effective in treating negative symptoms in schizophrenics with predominantly negative symptoms.[146–148] Evaluation of the effect of amisulpride in patients with minimal extrapyramidal side-effects and positive symptoms suggests amisulpride is able to improve primary negative symptoms, even in patients with deficit syndrome schizophrenia.[146–148] At both dose ranges, amisulpride produces minimal extrapyramidal side-effects, but may result in increased prolactin levels. Amisulpride has been directly compared with haloperidol, and with both risperidone and olanzapine. In general, amisulpride appears to be as clinically effective as all three drugs for treating positive symptoms. Improvement in negative symptoms is superior to haloperidol and appear equivalent to olanzapine and risperidone. Improvement in depressive symptoms related to schizophrenia were also equivalent between amisulpride and olanzapine; however, in a meta-analysis of three studies, amisulpride was shown to be superior to high dose risperidone (8 mg daily) and haloperidol.[149] It is unknown if it is effective in neuroleptic-resistant patients. Because its pharmacology is quite distinct from that of the 5-HT_{2A}-based receptor antagonists previously discussed, amisulpride may be useful in patients who fail to tolerate that class of drugs. Amisulpride has also been demonstrated as being superior to haloperidol on quality of life measures and global functioning.[150] Pharmacoeconomic analyses indicate that amisulpride has a beneficial cost-outcome profile.[151]

(c) Iloperidone and asenapine

Clinical trials are currently taking place with both of these atypical agent to determine its efficacy and side-effect profile compared with typical and other atypical antipsychotic drugs. Like most other atypical antipsychotic drugs, both asenapine and iloperidone combine potent 5-HT2A antagonism with less potent D2 receptor antagonism. Asenapine is currently undergoing investigation in phase 3

clinical trials. Short-term, acute phase efficacy of iloperidone for symptom reduction relative to placebo has been demonstrated at daily doses of 20 to 24 mg daily, with less certain effects at lower doses.[152] Long-term investigations thus far indicate a low incidence of EPS, lack of effect on prolactin release, and minimal effect on body weight.[152] It has the potential to be made into a long-acting form, which would be of great value.

Pharmacokinetics, metabolism, and drug interactions

(a) Typical neuroleptics

The typical neuroleptics are well absorbed when administered orally or parenterally. Intramuscular injection leads to more rapid and higher plasma levels. Peak plasma levels are reached in 30 min after intramuscular injection and 1 to 4 h after oral injection. Steady state is achieved in 3 to 5 days. The half-life for elimination is in the range of 10 to 30 h. Substantial amounts of the antipsychotics are stored in lipids, including in the brain. There is controversy about how long these drugs persist in the system after discontinuation. By the criterion of elevations of plasma prolactin levels, the concentrations are too low to be biologically active within 48 h after discontinuing oral medication. On the other hand, some rodent and human positron emission tomography studies suggest that long-acting forms of haloperidol or fluphenazaine may persist for 1 to 3 months. Metabolism of the typical and atypical antipsychotic drugs occurs in the liver for the most part, via conjugation with glucuronic acid, hydroxylation, oxidation, demethylation and sulphoxide formation. Much of this metabolism occurs via the hepatic cytochrome (CYP)-450 enzymes, particularly the 2D6 and 3A4 sub-families for most drugs. Some metabolites have significant biological activity, for example mesoridazine, and 7-hydroxyloxapine. Dosing of typical neuroleptic medications are determined by clinical effects, less by pharmacokinetic factors.

Pharmacokinetic drug-drug interactions at the level of protein binding are expected to be minimal, even though most typical neuroleptics are tightly bound to plasma proteins. Even so, appropriate therapeutic monitoring of drugs that are also tightly bound to plasma proteins but have a narrow therapeutic index (e.g. warfarin, digoxin, phenytoin) when used in conjunction with typical neuroleptics is warranted. Interactions at the level of the CYP-450 system are also thought to be minimal for most agents. Because smoking is so common among patients with schizophrenia and because smoking can be associated with potent induction of CYP-450 1A2 isoenzymatic activity, dosage adjustments may be needed for selected antipsychotic drugs during any changes in smoking status. Other combinations with typical neuroleptics may be worth avoiding for other reasons, such as increased central nervous system affects (e.g. anxiolytics, other central nervous system depressants, anticholinergics, certain antihypertensive drugs), increased EPS (e.g. metoclopramide, D2 blocking anti-nausea drugs, caffeine), impaired cardiac conduction (certain drugs combined with typical neuroleptics known to prolong the QTc interval), and neurotoxicity (lithium), especially among individuals who are more advanced in age.

(b) Atypical antipsychotic drugs

(i) Clozapine

There are wide variations in the pharmacokinetics of clozapine in patients. The average half-life is 6 to 12 h. Plasma concentrations are higher in Chinese patients than in Caucasian patients, in non-smokers than smokers, and in females than males. The bioavailability is not affected by food intake, metabolism occurs mainly in the liver. The chief metabolite is *N*-desmethylclozapine, which has some biological activity. Clozapine is metabolized by CYP1A2, and several potential drug-drug interactions are thus possible. When agents that induce CYP-1A2 are prescribed or ingested, close monitoring of patients for a worsening of symptoms is warranted. Plasma levels of clozapine of approximately 350 ng/ml are more often associated with good response than lower levels,[153] and should be checked in such cases. Upward adjustment of the clozapine daily dosage will typically correct the problem. On the other hand, if a CYP1A2 inducer is discontinued or a potent inhibitor is added, this may result in a rise in clozapine concentration, and an increase in adverse effect risk.[154] Caution may also be warranted for drugs that are potent inhibitors of CYP 2C19 and CYP3A4.[155] In addition, caution is warranted when considering concomitant use of drugs which can also cause bone marrow suppression (e.g. carbamazepine) or precipitously drop seizure threshold.

(ii) Risperidone

Risperidone is well absorbed from the gut and is extensively metabolized in the liver by CYP2D6 to 9-hydroxyrisperidone in approximately 92 to 94 per cent of Caucasians.[156] Thus, 9-0H risperidone is an active species in the majority of patients. About 6 to 8 per cent of Caucasians and a small proportion of Asians have a polymorphism of the CYP2D6 gene, which leads to poor metabolism of risperidone. For poor metabolizers of risperidone, the active moiety is mainly the parent compound. The half-life of the 9-hydroxy metabolite is about 21 h whereas the half-life of risperidone is about 3 h. Thus, risperidone can be used on a once-a-day schedule for normal metabolizers whereas multiple doses are needed for those who are poor metabolizers. Risperidone should be titrated from 2 to 5 mg/day over at least a 3-day period to minimize hypotensive and neuro muscular side-effects. Drugs known to induce or inhibit CYP2D6 and 3A4 may alter plasma levels of risperidone; thus, close monitoring is advised when such agents are added to ongoing risperidone treatment.

(iii) Olanzapine

Olanzapine has a half-life of 24 to 30 h, which indicates that single daily administration is adequate.[92] The metabolic pathways of olanzapine involves CYP2D6, CYP1A2 and flavin-containing mono-oxygenases, as well as *N*-glucuronidation. It has a low potential for drug-drug interactions and requires extremely high concentrations not likely to be achieved under clinical conditions to inhibit cytochrome P-450 systems. Plasma levels of approximately 9.3 mg/ml have been reported to predict better clinical response to olanzapine in inpatients with an acute exacerbation.[157] Drugs that are known inducers or inhibitors of CYP1A2 may significantly affect plasma levels of olanzapine and alter its clinical effects at a given dosage; thus, active monitoring of symptoms and adverse effects is indicated if such agents are added. As is the case with clozapine, gender and smoking status may influence olanzapine levels leading to adjustment in dosage.[153]

(iv) Quetiapine

Quetiapine is well absorbed and is approximately 83 per cent protein bound.[158] Quetiapine is absorbed better after eating.[158] It has a half-life of 6 h. It is metabolized in the liver by CYP3A4 to inactive metabolites. Quetiapine has significant interactions with several inducers and inhibitors of CYP3A4. Co-administration with

these agents may require dosage adjustment. Thioridazine may also significantly increase the clearance of quetiapine,[159] thus necessitating dosage adjustment. Despite the short half-life, a clinical trial compared three dosing regimens (450 mg/day given in two or three divided doses, and 50 mg/day given twice daily). Both of the higher-dose groups were superior to the low-dose group and there were no differences between the two high-dose schedules. Once daily dosing, which is also a common dosing strategy for quetiapine, is also supported in the literature.[160] The feasibility of such a dosing schedule, which does not seem to be predicted by peripheral pharmacokinetic parameters, is possible because quetiapine appears to interact centrally with both D2 and 5-HT2A receptors much longer than its 6 h elimination half-life.[161]

(v) Ziprasidone

Ziprasidone has a half-life of 4 to 10 h. Twice-daily administration is possible despite this relatively short half-life. Clinically, many patients are prescribed this medication only once daily. Regardless, ziprasidone should always be taken after eating in order to facilitate absorption. About two-thirds of ziprasidone is metabolized by aldehyde oxidase into inactive metabolites. The remainder is metabolized by CYP3A4 and CYP1A2 into inactive metabolites. At the current time, there are no known drug interactions with ziprasidone at the level of aldehyde oxidase, since enzymatic activity does not appear to be altered by coadministered drugs. Although CYP3A4 appears to play only a minor role in the metabolism of ziprasidone, potent inhibitors or inducers of CYP3A4 may significantly alter plasma concentrations of ziprasidone,[162] and may thus necessitate an adjustment in dosage. The use of concomitant medications that may prolong the QTc interval should be avoided. Ziprasidone is contraindicated for patients with a history of known QT prolongation, recent acute myocardial infarction, or uncompromised heart failure.

(vi) Aripiprazole

Aripiprazole is well absorbed from the gut, and has an elimination half-life of 75 hours. It is metabolized primarily by CYP3A4 and 2D6 isoenzymes into an active metabolite, dehydro-aripiprazole, which has a half-life of 94 hours. This pharmacokinetic pattern supports once daily dosing. Because aripiprazole is metabolized by CYP3A4 and 2D6, known inhibitors or inducers of these isoenzymes may result in increased or decreased clearance of aripiprazole and dehydro-aripiprazole.[163]

(vi) Paliperidone, Iloperidone, and Amisulpride

Paliperidone is currently marketed in the US and abroad only in an osmotically controlled extended release formulation, which results in steady release of active drug over a 24 hr period. Hepatic metabolism is not considered a major route of clearance. Paliperidone is converted into metabolites that are not believed to contribute significantly to its overall pharmacological activity. Few significant drug-drug interactions at the level of the CYP450 system are therefore anticipated. Even so, the plasma concentration of paliperidone may be altered by drug interactions at CYP3A4.[164]

Iloperidone has a half-life of 12 to 15 h. Its absorption is not affected by food. It should be titrated slowly because of orthostatic hypotension, and close monitoring is warranted when it is combined with antihypertensive drugs or drugs that are associated with orthostatic effects. The optimal dose has not yet been established but is likely to be in the 5 to 10 mg/day range. Amisulpride has a half-life of 10 to 15 h. It is well tolerated. As yet, there are no known drug interactions. More information regarding the metabolic handling and potential for drug-drug interactions for both of these medications is anticipated as they continue to be further developed.

Side-effects

Typical neuroleptics

The adverse effects that are most routinely concerning for antipsychotic drug treatment are extrapyramidal adverse effects (EPS), especially for typical neuroleptic mediations. For typical neuroleptics, high-potency drugs such as haloperidol and fluphenazine are more likely to produce EPS than low-potency agents such as chlorpromazine and thioridazine. The latter may have lower potential for extrapyramidal side-effects than other typical neuroleptics because of its relatively higher affinity for muscarinic receptors. Atypical antipsychotic drugs are less likely to cause EPS during acute and long term tretment. There are a wide range of extrapyramidal side-effects produced by the typical neuroleptics, including dystonic reactions when first administered, akathisia during the first 2–3 weeks, parkinsonism during the first several weeks with variable persistence, neuroleptic malignant syndrome at any time point but usually in the initial weeks, and tardive dyskinesia.

Dystonic reactions due to neuroleptic drugs can be treated with parenteral anticholinergic agents or diphenhydramine, an antihistamine with some anticholinergic properties. The use of anticholinergic and other agents to manage parkinsonism due to typical neuroleptic drugs will be discussed subsequently.

Akathisia may be the most common of the EPS effects, occurring in up to 70 per cent of patients treated long term with haloperidol.[165] The term refers to a subjective uncomfortable experience of motor restlessness which is relieved by movement. As such, patients will complain of discomfort, and manifest increases in psychomotor behaviour. These symptoms can be so distressing as to increase the risk of agitation or even suicidal behaviours.[166] Although patient age does not seem to influence risk of developing akathisia, women are believed to be at higher risk. Accurate diagnosis of this condition is necessary in order to prevent inadvertent increases in neuroleptic dose from a belief that the patient's discomfort from akathisia is due instead to worsening psychosis. This effect may be managed by reduction in dosage or switching medications to an atypical antipsychotic drug or a drug that is less likely to cause akathisia. When these strategies are not feasible, the symptoms may respond to anticholinergic medications, usually within 3–7 days. Other options include low doses of benzodiazepines or beta-adrenergic blockers, assuming no contraindications to either.

Parkinsonism caused by antipsychotic drugs resembles idiopathic parkinsonism. Diagnostically, severe neuroleptic induced parkinsonism may resemble depression or negative symptoms of schizophrenia; however, the associated motor signs and time course of symptoms in relation to starting antipsychotic treatment distinguish the former. Like akathisia, the onset and severity of antipsychotic induced parkinsonism is related to medication

dosage; thus, a lowering of the dose or switching to a medication that is less likely to cause this effect may provide significant relief, or ameliorate the parkinsonian signs and symptoms altogether. When this is not feasible, anticholinergic medications may provide relief, typically within 3–7 days. The response to anticholinergic medication is quite variable, however.

Tardive dyskinesia emerges at various rates depending upon age, sex, and diagnosis.[167,168] The rate in younger patients is between 3 and 5 per cent per year. It is higher in bipolar than schizophrenic patients and much higher in people above the age of 60. It is related to dose and will be less likely with lower doses of typical neuroleptics. Tardive dyskinesia is ordinarily reversible, although irreversible and/or extremely severe and rarely life-threatening forms can occur. The best way to minimize its occurrence is to use an atypical antipsychotic drug in lieu of a typical agent, since these drugs as a class are associated with a much lower risk of tardive dyskinesia.[167] Patients with mood disorders should generally not receive maintenance treatment with typical antipsychotic drugs unless mood stabilizers alone prove insufficient because they are at greater risk for tardive dyskinesia. There are no definitive treatments for tardive dyskinesia. Generally, the best strategy is prevention through the use of atypical antipsychotic drugs, and periodic screening with a structured assessment tool such as the Abnormal Involuntary Movement Scale (AIMS). There is some suggestion in the literature that continuation of antipsychotic treatment does not worsen tardive dyskinesia, and may eventually result in a stabilization and improvement of tardive symptoms. Switching to clozapine appears to be helpful, although such an effect is not invariable.

Neuroleptic malignant syndrome is a rare life-threatening side-effect related to an apparent compromise of the neuromuscular and sympathetic nervous systems.[169] It usually occurs at the initiation of treatment with a high-potency agent but may occur with any of the typical (or atypical agents) at any point. Immediate discontinuation of the medication is essential. The condition is characterized by muscle rigidity, breakdown of muscle fibres leading to large increases in plasma creatine kinase activity, fever, autonomic instability, changing levels of consciousness, and sometimes death. It may be treated by discontinuing all antipsychotic drug treatment, applying external hypothermia, supporting blood pressure, and administering a direct-acting dopamine agonist such as bromocriptine or pergolide, and dantrolene sodium, which blocks the release of intracellular stored calcium ions. After its successful treatment, an atypical antipsychotic should be used even though these agents, including clozapine, may also induce neuroleptic malignant syndrome.

The typical neuroleptic drugs produce a wide variety of **other side-effects**, including weight gain, seizures (especially pimozide), sedation, hypotension, elevated liver enzymes, retinitis pigmentosa (thioridazine), orthostatic hypotension, prolongation of the QTc interval (low potency phenothiazines, pimozide) and anticholinergic effects (mesoridazine, chlorpromazine, thioridazine). All the typical neuroleptic drugs produce marked increases in serum prolactin levels, with the increases being greater in females than males.[25] Prolactin elevations may affect sexual function in both males and females, with difficulty achieving erection or orgasm among the most common side-effects.[25]

Atypical antipsychotic drugs

(a) Clozapine

(i) Agranulocytosis

It has now been reliably established that clozapine produces agranulocytosis in slightly less than 1 per 100 patients.[170, 171] This is 15 to 30 times the rate associated with the phenothiazines and possibly higher than that for the butyrophenones. The peak of agranulocytosis with clozapine occurs between 4 and 18 weeks, and then falls off sharply. Weekly monitoring of the white cell or absolute neutrophil count is required for 26 weeks in most countries, with the frequency decreasing to biweekly or monthly thereafter, sometimes on a voluntary basis. In the US, monthly monitoring is required assuming no hematological abnormalities after one year of treatment. The cost-effectiveness of monitoring after a year has not been studied but it is probably in the range that would lead to its abandonment by current standards. With monitoring, agranulocytosis can usually be detected before infection sets in or becomes overwhelming. Discontinuation of clozapine, beginning treatment with colony cell stimulating factors, and the usual procedures for treating an infection are usually effective in restoring the white cell line.

(ii) Other side-effects

Clozapine produces a wide range of side-effects.[171] These can generally be managed by dose adjustment and concomitant medications. Clozapine produces hypotension because of its potent α_1-adrenoceptor antagonism and must be slowly titrated in most patients. Low-dose glucocorticoid treatment may be helpful in some patients with severe hypotension. Clozapine rarely if ever produces significant extrapyramidal side-effects, although some cases of akathisia and neuroleptic malignant syndrome have been reported.

Major motor seizures are another important side-effect of clozapine. They are dose related, with the incidence being about 2 per cent in patients at low doses and 6 per cent at doses greater than 600 mg/day. They are sometimes preceded by myoclonic jerks. Valproic acid and dose reductions are usually effective in preventing the progression of myoclonic jerks or treating major motor seizures. Other anticonvulsants can be combined with clozapine if needed, though caution would be clearly warranted with the use of carbamazepine due to its potential for bone marrow suppression.

Hypersalivation is another side-effect. It usually responds to anticholinergic therapy or to clonidine. Exacerbation of obsessive-compulsive symptoms has been reported with clozapine. Augmentation with an SSRI or lithium carbonate is usually effective.

Weight gain is a frequent side-effect of clozapine, with about 30 per cent of patients gaining more than 7 per cent of body weight.[171] Diet and exercise are useful in minimizing this effect. A related problem is the emergence of insulin resistance or type II diabetes, or exacerbation of existing diabetes, with or without atherogenic changes in serum lipid profile. There have also been reports of diabetic ketoacidosis that emerged in the context of clozapine treatment. Of the atypical antipsychotic drugs, clozapine and olanzapine are associated with the highest risk for clinically significant weight gain, as well as abnormalities in glycaemic control and lipid homeostasis.[123]

Somnolence, tachycardia, hypertension, constipation and stuttering are also produced by clozapine. Tachycardia is treated only when the pulse is greater than 100 beats/minute. β-Blockers are effective to reduce the heart rate, but may also result in synergism of hypotensive effects.[171]

There have been reports of clozapine-associated myocarditis and cardiomyopathy.[172] The presence of eosinophilia accompanied by cardiotoxic signs such as tachycardia, fatigue, orthostasis, or respiratory problems (many of which are adverse effects of clozapine) should alert the clinician to the possibility of myocarditis and the need for medical evaluation.

Finally, treatment with clozapine may not uncommonly result in an asymptomatic mild elevation in hepatic transaminase levels; however, there have also been reports of hepatotoxicity in the setting of clozapine treatment. Polypharmacy appears to be a risk factor. Cases of fulminant hepatotoxicity leading to liver failure are rare.

(iii) Risperidone

Risperidone is associated with moderate weight gain, comparable to that of typical neuroleptic drugs in most cases, and less than that of clozapine and olanzapine.[123,173] Risperidone also produces some postural hypotension because of its α_1-adrenoceptor blocking properties. Risperidone produces greater increases in serum prolactin secretion than any of the other atypical antipsychotic drugs.[25] The increases appear to be at least comparable to those of typical neuroleptics.[173] At higher doses, particularly above 6 mg daily in most adults, the incidence of EPS also increases,[77] though typically not to the degree observed when using typical neuroleptic drugs in clinical practice. Risperidone, like clozapine and other agents of this type, can sometimes exacerbate or induce symptoms of obsessive-compulsive disorder and tics, probably due to its antiserotonergic properties. This can be counteracted in some patients by the addition of an SSRI. Risperidone is not associated with agranulocytosis or increased risk of seizures. Because of its low affinity for muscarinic receptors, risperidone treatment is not associated with significant anticholinergic effects.

(iv) Olanzapine

Olanzapine also produces dose-dependent extrapyramidal side-effects, including some dystonic reactions in patients with schizophrenia, but these are less frequent and severe than those produced by typical neuroleptic drugs or risperidone.[173] Olanzapine is less well tolerated than clozapine in patients with Parkinson's disease. Olanzapine, like other atypical antipsychotic drugs, is associated with a lower risk of tardive dyskinesia than typical neuroleptics.

The major side-effect of olanzapine is weight gain.[173] Large weight gains due to increased appetite occur in 10 to 15 per cent of olanzapine-treated patients during the first 6 months of treatment. Another 20 to 35 per cent gain between 7 and 10 per cent of body weight. These gains tend to become permanent for as long as patients continue the medication. Like clozapine, olanzapine is also associated with higher risk of insulin resistance, glycaemic changes, and development of atherogenic changes in lipid profile.[123] Cases of diabetic ketoacidosis associated with olanzapine treatment have been reported.

Olanzapine is also associated with some increase in liver enzymes, orthostatic hypotension, anticholinergic side-effects, and sedation. Many of these adverse effects are time limited and reduce in intensity or resolve over the first few weeks of treatment with continuous use. Olanzapine produces transient increases in serum prolactin levels, which are smaller in magnitude than those produced by typical neuroleptic drugs or risperidone.[25, 173]

Olanzapine, like other agents of this type, can occasionally exacerbate or induce symptoms of obsessive-compulsive disorder and tics, probably due to its antiserotonergic properties. This can be counteracted in some patients by the addition of an SSRI. Olanzapine is not associated with agranulocytosis or increased risk of seizures.

(v) Quetiapine

Quetiapine appears to have fewer extrapyramidal side-effects than either risperidone or olanzapine.[158,173] Quetiapine is tolerated in patients with Parkinson's disease to a much greater extent than risperidone or olanzapine. The incidence of extrapyramidal side-effects with quetiapine in schizophrenic patients appears to be comparable to placebo. The major side-effects with quetiapine are headache, agitation, dry mouth, dizziness, weight gain, and postural hypotension.[173]

With regard to weight gain and other metabolic effects, quetiapine treatment appears to confer moderate risk—similar to that of risperidone, but less than that associated with clozapine or olanzapine treatment.[123] Far less is known about the long term effects of quetiapine on markers of glycaemic and lipid homeostasis. Nevertheless, clinically significant changes in serum lipids have been reported.

Decreased serum thyroid hormone levels, increased hepatic transaminases and elevated serum lipids have been reported. Decreases in total and free thyroxine, when they occur, are mild, non-progressive, and are not believed to be clinically signficiant. The effect may be dose dependent. Similar to clozapine, asymptomatic elevations in hepatic transaminases may be encountered early in the course of treatment, followed by a return to baseline values. Animal studies suggest an increased risk of cataracts.[173] Periodic ophthalmological screening for lenticular opacities is recommended by the manufacturer, though no causal relationship between the use of quetiapine and the development of cataracts has been demonstrated to date.

(vi) Ziprasidone

Ziprasidone does not increase serum prolactin levels and is virtually devoid of extrapyramidal side-effects, weight gain, and changes in markers of glucose handling and lipid metabolism. Its major side-effects are nasal congestion and somnolence,[173] the latter of which is usually transient. There has been some concern of cardiovascular side-effects, for example increased QTc interval; however, perusal of the available data does not reveal a significant problem in this regard. However, caution is warranted when considering the coadministration of ziprasidone with other drugs that are known to prolong the QTc interval, since ziprasidone has been associated with a significant increase in the QTc interval of 16.6 msec, which was greater than that of other atypical antipsychotics and haloperidol, but less than thioridazine.[174] Screening for electrolyte abnormalities and cardiac disease (including recent myocardial infarction, congestive heart failure symptoms and arrythmias with or without syncope) may be indicated prior to starting ziprasidone.

(vii) Aripiprazole and paliperidone

Aripiprazole is well tolerated, and does not appear to routinely cause EPS or hyperprolactinaemic changes at recommended dosages. This also appears to be the case for higher than recommended doses. Aripiprazole is also not associated with clinically significant increases in weight, or changes in markers of glucose handling or lipid homeostasis. Both aripiprazole and ziprasidone are therefore believed to be the atypical antipsychotic drugs with the most advantageous metabolic risk profile.

Paliperidone in its extended release form also appears to be well tolerated during short term, acute phase treatment. In these studies, the most common side effect was tachycardia. Rates of discontinuation due to adverse effect burden were also very low. The risk of hyperprolactinaemic changes with paliperidone appears to resemble those of risperidone, although no head-to-head comparisons have been carried out. The changes in prolactin levels may be dose related. The EPS burden associated with paliperidone during the short term studies was low for the 6 mg dose; however, at higher doses, the incidence of EPS appears to be higher. Measures of weight and metabolic effects during 6 week treatment with paliperidone showed no significant changes from baseline. Similar results were found for paliperidone during medium-term treatment.[141] Future long term studies will add greatly to our understanding of paliperidone's adverse effect profile.

Indications and contraindications

The main indication for the antipsychotic drugs is the treatment of all phases of schizophrenia, including acute, florid symptoms of psychosis, prevention of relapse, and deficit symptoms. Important other uses include the psychotic phase and prophylaxis of mania, depression with psychotic features, the psychosis, agitation, and aggression of various dementias, the treatment of psychoses due to l-dopa or other dopamine agonists in Parkinson's disease, Tourette's syndrome, treatment-resistant obsessive-compulsive disorder, self-injurious behaviour, porphyria, antiemesis, intractable hiccoughs, and as antipruritics. Some current research has suggested that the antipsychotic drugs may be of use to prevent the onset of schizophrenia by administering them to individuals who are in the prodromal phase of the illness. The atypical antipsychotics may be effective for augmenting antidepressants in patients with treatment-resistant non-psychotic depression, and are being tried on an experimental basis for various character disorders such as borderline, schizoid, and schizotypal personality disorders. Clozapine, which has the lowest incidence of extrapyramidal side-effects of any of the antipsychotic drugs, has some special applications in neurological conditions such as essential tremor and the treatment of the water intoxication syndrome in schizophrenic patients. The uses of the classical antipsychotics such as chlorpromazine and haloperidol have been limited by their side-effects, especially parkinsonism and tardive dyskinesia, a slowly developing, sometimes irreversible series of abnormal involuntary movements involving facial, limb, and girdle muscles. As has been discussed, the atypical antipsychotic drugs such as clozapine, olanzapine, quetiapine, and risperidone, as well as iloperidone and ziprasidone, which are in development, have significant advantages with regard to parkinsonism. Clozapine definitely has a vastly reduced risk of tardive dyskinesia and the other atypical agents most likely have a risk that is less than that of the typical neuroleptic drugs but more than clozapine. Uses in other psychiatric and neurological conditions may be expected to emerge as the safety profile of these agents is better described.

Antiparkinsonian agents

Anticholinergic drugs

Antiparkinsonian medications, including anticholinergic, antihistaminic, benzodiazepines, dopamine agonists, and β-blockers are of importance in the management of extrapyramidal side-effects. They are usually needed with the typical neuroleptic drugs but some patients will require antiparkinsonian treatment with olanzapine, risperidone, or quetiapine. The anticholinergics and the antihistaminics (e.g. diphenhydramine) are used to treat acute dyskinesias and dystonias, pseduoparkinsonian symptoms (tremor, rigidity, bradykinesia, shuffling gait), and akathisia. These agents act centrally in the basal ganglia to block the effects of increased acetylcholine release due to D_2-receptor blockade. The most widely used anticholinergic drugs are benztropine, biperiden, procyclidine, and trihexyphenidyl. Benztropine is given in doses of 1 to 6mg/day usually in divided doses. Biperiden is given in doses of 2 to 16 mg/day in two or three doses. Procyclidine is given in divided doses of 5 to 30 mg/day. Trihexylphenidyl is given in doses of 1 to 15 mg/day, in a single or divided dose.

These agents are competitive antagonists of the five subtypes of muscarinic receptors that have been identified and which are labelled M_1 to M_5. They have minimal antagonist effect at nicotinic cholinergic receptors. Blockade of cholinergic receptors on intrastriatal neurones by these agents restores the cholinergic balance, which is disrupted by blockade of D_2 dopamine receptors by some antipsychotic agents. Other central effects include impairment of various forms of memory. Elderly patients in particular may develop anticholinergic-induced agitation, irritability, disorientation, hallucinations and delirium because of the natural loss of cholinergic neurones with aging.

Side-effects

These agents have some preference for the central nervous system but some peripheral anticholinergic effects are to be expected. Blockade of vagal tone in the heart produces tachycardia. Other adverse effects include decreased bladder function and urinary retention and decreased bowel motility leading to constipation and impaction. Decreased saliva and bronchial secretion contribute to dry mouth and increased dental caries while decreased sweating increases the risk of heat stroke. Blockade of muscarinic receptors in the eye cause pupillary dilation and inhibition of accommodation, leading to photophobia and blurred vision. Rarely, narrow-angle glaucoma may ensue. The muscarinic receptors in the basal ganglia are predominantly M_2 whereas those in the periphery are M_1. The rank order of the anticholinergic drugs for relative selectivity for the M_2 receptor is biperiden, procyclidine, trihexylphenidyl, and benztropine. All these agents can cause dry mouth, blurred vision, urinary retention, constipation, and increased intraocular pressure. They may cause anticholinergic delirium in elderly patients or after taking high doses. Biperiden is less likely to cause peripheral anticholinergic effects. Benztropine, biperiden, and trihexyphenidyl may cause euphoria because of their ability to inhibit dopamine reuptake and may be subject to abuse.

Indications

The anticholinergic drugs or the antihistamine diphenhydramine are given intramuscularly for the treatment of acute dystonic reactions. They are usually effective within minutes and may have to be repeated. It is usually not necessary to prescibe an oral anticholinergic following a dystonic reaction, though some may require their brief use depending on which anipsychotic is prescribed. These agenst should not be given prophylactically unless the patient is at established risk for EPS at the dose of antipsychotic which is being started. If akathisia or parkinsonism develops following treatment with a typical neuroleptic drug, the first consideration should be whether to continue to use the offending agent and drop the dosage or to substitute an atypical antipsychotic drug. If decreasing the dose of antipsychotic drugs does not suffice or is not clinically feasible, substituting an atypical agent is the clearly the recommended choice since it avoids all the unpleasant side-effects of the anticholinergic agents.

Other drugs

Amantadine, which also has antiviral actions, is able to increase the release of dopamine in the basal ganglia, which diminishes the release of acetylcholine. It may improve acute dystonias, akathisia, akinesia, parkinsonism, and tardive dyskinesia. It has also been reported to improve sexual function and decrease weight gain due to neuroleptic drugs. It may cause increased arousal, agitation, and indigestion, however. The usual oral dose is 100 to 400 mg/day.

β-Blockers such as propranolol, atenolol, and pindolol are useful for treating akathisia and tremor. They may cause bradycardia, and particularly immediate-release forms should not be stopped abruptly due to rebound tachycardia.

Benzodiazepines, such as clonazepam, lorazepam, and diazepam, are useful for treating akathisia, acute dystonias, and acute dyskinesias. They can cause drowsiness and lethargy, and have abuse potential.

Conclusions

Antipsychotic drugs are invaluable tools in treating a large variety of patients with schizophrenia and other conditions. Their main benefits are, in fact, to treat psychotic symptoms, but the newer agents in particular may improve negative symptoms, cognition, mood, anxiety, and aggression as well. The evidence for atypical antipsychotic drugs to improve cognition is steadily increasing and this should be one of the driving forces behind the substitution of these agents for the typical antipsychotic drugs. Recent evidence of volumetric increases in cerebral cortical gray matter associated with atypical, but not typical, antipsychotic drugs may be related to improvement in such symptoms.[175] As such, atypical antipsychotic drugs may produce 'disease modifying' rather than just 'symptomatic' effects, a matter that is of considerable current interest.

Antipsychotic drugs are useful as both acute and maintenance treatments to prevent the recurrence of psychotic symptoms. The extrapyramidal side-effects and greater tardive dyskinesia risk of the typical antipsychotics, coupled with their lesser efficacy to improve negative symptoms and cognition suggest that newer agents are preferred. Clozapine, despite its risk of agranulocytosis, is the treatment of choice for patients who fail to respond to other typical or atypical antipsychotic agents. Risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole and paliperidone have somewhat different pharmacologic profiles. It is not clear which of these agents should be tried in a given patient but on going research may clarify that. These agents, and clozapine, appear to differ significantly in their propensity for causing clinically significant changes in weight and markers of metabolic status. Amisulpride has a mechanism of action different from that of the other atypical agents, with some preference for treating negative symptoms. These compounds, as well as others expected to be approved for use in the near future, for example iloperidone and asenapine, will need to be compared with each other to determine if differential indications exist. Side-effect differences among these drugs as well as the availability of long-acting preparations may help clinicians choose among them. Cost-effective analyses currently favour use of the atypical antipsychotic drugs because of better compliance leading to less frequent relapses and shorter hospital stays. They also facilitate retention of work skills and return to work which decreases the indirect costs of illness in patients still young enough to be able to work. As long as the typical antipsychotics remain in use, and for some patients who receive atypical agents, anticholinergic and other antiparkinsonian drugs will continue to be necessary to treat extrapyramidal side-effects.

Because of the compliance problem, which is less with the atypical than the typical antipsychotics, it is important to develop more long acting atypical drugs. Risperidone is currently available in such a form, and paliperidone and olanzapine will also be in the near future. While the current group of atypical antipsychotic drugs is predominantly characterized by relatively more potent 5-HT_{2A} than D_2 receptor antagonism, it is likely that a number of different strategies will emerge for compounds which produce fewer extrapyramidal side-effects than the typical neuroleptics. Because these compounds are so effective in that regard, the real challenge is to develop agents which address other key features of schizophrenia, especially cognitive impairment and negative symptoms, without the side-effect burden of this group of compounds.

6.2.6 Antiepileptic drugs

Brian P. Brennan and Harrison G. Pope Jr.

Introduction

Several drugs originally developed to treat epilepsy have been found effective in certain psychiatric disorders. This chapter reviews the antiepileptic drugs most extensively studied in psychiatric disorders: valproate, carbamazepine, lamotrigine, and topiramate. We then briefly mention six other antiepileptics currently under investigation in various psychiatric disorders, but not yet extensively studied: gabapentin, oxcarbazepine, levetiracetam, tiagabine, zonisamide, and pregabalin. The antiepileptic drug phenytoin is rarely used in psychiatric disorders, and is therefore not included in this chapter. The benzodiazepines, which have antiepileptic properties, are also omitted here, as they are discussed in Chapter 6.2.2. We briefly list studies documenting the efficacy of these various agents in psychiatric disorders, but the reader is referred to the individual chapters on specific disorders for a more detailed discussion of treatment strategies.

Valproate[1]

Introduction

Valproate (valproic acid) is a simple branched-chain carboxylic acid, first used as an organic solvent in the late 1800s (see Fig. 6.2.6.1). Its antiepileptic properties were discovered serendipitously in 1963, and its clinical use as an antiepileptic drug began in 1964. As early as 1966, valpromide (the amide precursor of valproate) was reported to be effective in the treatment of bipolar disorder.(1) Since then, valproate has been used effectively in the treatment of numerous psychiatric and neurologic conditions, and is now widely used as a mood stabilizer in the treatment of bipolar disorder.

Valproate is currently available as five different preparations: valproate (Depakene), sodium valproate (Depakene syrup), divalproex sodium (Depakote) (which is an equal proportion of sodium valproate and valproic acid), divalproex sodium sprinkle capsules (Depakote sprinkle capsules), and valpromide (the amide precursor of valproate, which is available in Europe, but not in the United States).

Pharmacology

The mechanism of action of valproate in the treatment of epilepsy is unclear, but appears to be related to increased levels of gamma-aminobutyric acid (GABA) in the brain. It inhibits the breakdown and turnover of GABA, increases its release, and increases the density of the GABA-ββ receptor subtype.(2) Its mechanism of action in treating psychiatric disorders is unknown.

[1] Valproate is marketed in the British Commonwealth as 'valproic acid' and as 'sodium valproate' in the US, but these are effectively interchangeable as they both yield valproate in the bloodstream.

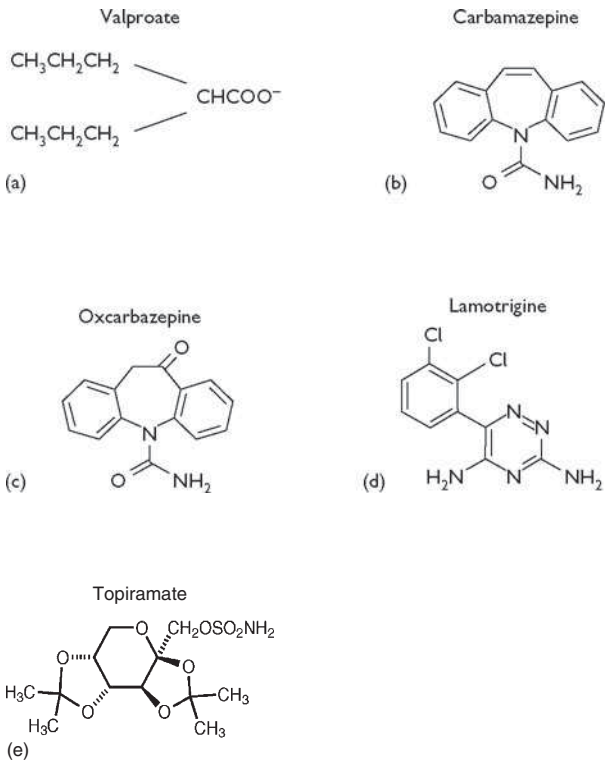

Fig. 6.2.6.1 Molecular structures of selected antiepileptic drugs. (a) Valproate, (b) Carbamazepine, (c) Oxcarbazepine, (d) Lamotrigine, and (e) Topiramate.

Pharmacokinetics

All preparations of valproate are completely absorbed after oral administration. The rate of absorption varies slightly with the different preparations, but these differences are probably not clinically significant. Co-administration with food can delay absorption. Valproate is approximately 90 per cent protein-bound. Only the unbound drug crosses the blood brain barrier and is pharmacologically active in the CNS. As total serum valproate concentration increases, the unbound portion of valproate is disproportionately increased, presumably due to saturation of the protein-binding sites. Therefore, at higher serum concentrations, small increases in dose may result in significant changes in efficacy and side effects. Valproate is metabolized by the liver to a glucuronide conjugate or one of several metabolites, some having antiepileptic activity. The half-life of valproate ranges from 6 to 17 h. Enzyme-inducing antiepileptic drugs, such as carbamazepine and phenytoin, shorten the half-life of valproate (see Interactions).[3]

Side effects

Valproate is often associated with minor side effects, but can rarely cause life-threatening, idiosyncratic reactions. Common side effects include gastrointestinal symptoms, such as nausea, vomiting, abdominal pain, and diarrhoea; and neurological symptoms, such as tremor, somnolence, and dizziness. Weight gain is also common. Hair loss occurs in some patients, but is often transient and reversible upon discontinuation of the drug. Rare, but potentially fatal, idiosyncratic reactions include hepatic failure, acute haemorrhagic pancreatitis, and agranulocytosis.[2,4] Known risk factors for irreversible hepatic failure include young age (especially less than 2 years old), developmental delay, a metabolic disorder, or concomitant administration of other antiepileptic drugs.[5] Because of this risk, liver function tests are recommended prior to initiation of therapy and periodically thereafter (see Dosage and Administration).

Toxic effects

(a) Overdose

Overdose with valproate can result in heart block, coma, and death. Haemodialysis may be useful in clearing the drug rapidly, and naloxone may reverse the CNS depressant effects.[3]

(b) Pregnancy

Valproate increases the risk of neural tube defects (such as spina bifida) to approximately 1–2 per cent of pregnancies when administered in the first trimester. Other reported congenital anomalies include craniofacial defects and cardiovascular malformations. Valproate is found in human breast milk, at approximately 1–10 per cent of serum concentrations, but its effects on the nursing child are unknown.[6]

Indications and contraindications

Controlled trials confirm that valproate is effective in the treatment of multiple seizure types, including complex partial, simple and complex absence, generalized tonic–clonic, and myoclonic seizures.[3] Several controlled studies indicate efficacy in the treatment of acute mania,[7–13] mixed episodes,[12,14] and in the prophylaxis of recurrent mood episodes.[13,15,16] One small controlled study has offered limited evidence for the efficacy of valproate in the treatment of bipolar depression.[17] There is growing support from controlled studies for the efficacy of valproate, combined with both typical and atypical antipsychotics, in the treatment of acute exacerbations of schizophrenia[18,19]; particularly when the presentation includes agitation and hostility.[20] There are also several small controlled studies demonstrating the benefit of valproate in the treatment of mood instability and impulsivity associated with borderline personality disorder.[21–23] Other conditions for which valproate may sometimes be useful include pain syndromes, anxiety disorders, alcohol and sedative withdrawal syndrome, impulse control disorders, and behavioural and affective disturbances associated with intellectual disability and dementia.[2]

Valproate is contraindicated in patients with known hypersensitivity to the drug. It should be used cautiously in patients with significant hepatic disease.

Interactions

In general, valproate can be combined safely with other psychotropic medications and antiepileptic drugs. However, given that valproate is highly protein-bound and can inhibit hepatic enzymes, some drug–drug interactions have been identified.[3] **Aspirin**, which is highly protein-bound, elevates the free fraction of valproate, resulting in increased effects of valproate on the CNS. Valproate can displace **diazepam**, **phenytoin**, **carbamazepine**, and **warfarin** from protein-binding sites, resulting in increased activity of these drugs. Co-administration of valproate with **lamotrigine** significantly increases the half-life of the latter and can increase the risk of lamotrigine-induced rashes. When administered with **carbamazepine**, three potential interactions may occur: (1) valproate can increase the concentration of carbamazepine's metabolite, carbamazepine-10,11-epoxide, by inhibiting its further metabolism; (2) carbamazepine may lower the valproate level; and (3) valproate may increase the carbamazepine level.[24] Therefore, close monitoring of serum

concentrations of both drugs is important when they are combined. **Amitriptyline** and **fluoxetine** may increase serum valproate concentrations, possibly by inhibition of valproate metabolism.

Effects of withdrawal

As with other antiepileptic drugs, valproate should be tapered gradually over several weeks to minimize the risk of rebound seizures.

Dosage and administration

Before initiating treatment with valproate, it is advisable to obtain a baseline complete blood count (CBC), liver function tests (LFTs), and if appropriate, a pregnancy test. CBC and liver function tests should be performed monthly for the first 3 months, and, if no abnormalities are found, every 6 to 12 months thereafter. If hepatic transaminase levels increase to more than three times normal, valproate should be discontinued. If the transaminase levels eventually return to baseline and the patient responded to valproate previously, re-challenge can be considered. If hepatic transaminase levels increase, but are less than three times normal, monitoring should be increased to once every 1–2 weeks until transaminase levels stabilize, and then monthly thereafter.[2]

The initial starting dose of valproate in adults is 250 to 1000 mg per day, given in two or three divided doses (see Table 6.2.6.1 for dosage forms). The dose may be increased every 1–3 days depending on the patient's response and tolerance. The usual therapeutic concentration is between 50–100 μg/ml (drawn 12 h after the last dose) for both psychiatric and neurological disorders. Some clinicians give the entire daily dose of valproate at bedtime. In patients with seizure disorders or acute mania, an oral loading strategy can be used.[25] In this situation, the patient receives 20 mg/kg as a bolus on the first day, resulting in rapid achievement of therapeutic levels. However, psychiatric patients who are not acutely manic usually have difficulty tolerating the oral loading strategy.

Table 6.2.6.1 Available dosage forms of antiepileptic drugs

Drug (proprietary name)	Preparation
Valproate	
Valproate (Depakene)	250 mg capsule
Valproate syrup (Depakene syrup)	250 mg/5 ml
Divalproex sodium (Depakote)	125, 250, and 500 mg tablets
Divalproex sodium extended release (Depakote ER)	250, 500 mg tablets
Divlaproex sodium sprinkle capsules	125 mg capsule
Carbamazepine	
Carbamazepine (Tegretol®)	100, 200 mg tablets; 100 mg chewable tablets; suspension of 100 mg/5 ml
Carbamazepine extended-release tablets	
(Tegretol XR®)	100, 200, and 400 mg tablets
(Carbatrol®)	100, 200, and 300 mg capsules
(Equetro®)	100, 200, and 300 mg capsules
Oxcarbazepine (Trileptal®)	150, 300 and 600 mg tablets; suspension of 300 mg/5 ml
Lamotrigine (Lamictal®)	25, 100, 150, and 200 mg tablets; 2, 5, and 25 mg chewable tablets

Carbamazepine

Introduction

Carbamazepine (Tegretol®) is an iminostilbene derivative with a structure similar to the tricyclic antidepressant imipramine (see Fig. 6.2.6.1). It was initially developed as a potential antidepressant in the 1950s, but was found to have antiepileptic and analgesic properties, and has been marketed for the treatment of seizures and pain syndromes since 1963. For many clinicians, it has been the preferred treatment for partial and generalized tonic–clonic seizures, as well as neuropathic pain. Its clinical use in affective disorders began in the early 1970s; since then, it has become widely used in psychiatry.

Pharmacology

Carbamazepine's mechanism of action in the treatment of seizures and pain syndromes is controversial, but probably results from blockade of voltage-sensitive sodium channels or enhancement of gamma-aminobutyric acid (GABA) activity. Its mechanism of action in psychiatric disorders is unknown, and may be different, given that it affects numerous neurotransmitter systems.[26,27]

Pharmacokinetics

Carbamazepine is absorbed slowly, with peak plasma levels occurring 4–5 h after administration of the tablets. Absorption is faster for the carbamazepine liquid, and slower for carbamazepine extended-release tablets. Oral bioavailability is about 80 per cent; plasma protein binding is approximately 75 per cent. The half-life of carbamazepine is variable, as it induces its own metabolism with chronic administration (autoinduction). Initially, the half-life ranges from 18–65 h, but after autoinduction is complete (usually 3–5 weeks), it is decreased to 5–25 h. Children metabolize carbamazepine more rapidly than adults, and therefore require higher doses to achieve similar levels. Carbamazepine is metabolized in the liver by the cytochrome P_{450} system to a wide variety of metabolites, some with antiepileptic activity. The predominant metabolite, carbamazepine-10, 11-epoxide (CBZ-E), is further metabolized by epoxide hydrolase to an inactive form. Most of carbamazepine's metabolites are excreted as glucuronide conjugates in the urine.[28,29]

Side effects

Carbamazepine is generally well tolerated, with less than 5 per cent of patients discontinuing the medication because of adverse effects. Common side effects seen during initiation of treatment include dizziness, ataxia, sedation, nausea, and diplopia. These are often mild in severity, and frequently resolve with continued treatment.

(a) Haematological side effects

Carbamazepine commonly causes a benign suppression of white blood cell count, but in rare cases may cause severe and potentially fatal blood dyscrasias, including agranulocytosis, pancytopenia, and aplastic anaemia. The incidence of these non-dose-related, idiosyncratic reactions has been estimated to range between 1 in 10 000 to 1 in 300 000.[4]

(b) Hepatic toxicity

Carbamazepine is frequently associated with benign transaminase elevations. Very rarely, a non-dose-related, idiosyncratic reaction causes hepatic failure, which can be fatal.

(c) Cardiovascular effects

Carbamazepine slows intracardiac conduction, and is relatively contraindicated in patients with heart block.

(d) Dermatologic effects

Rashes occur in 5–15 per cent of patients. These are usually benign, but rarely lead to exfoliative dermatitis, Stevens–Johnson syndrome, or toxic epidermal necrolysis. Therefore, it is usually recommended that the drug be discontinued if any rash develops.

(e) Endocrine effects

Carbamazepine can exert antidiuretic effects, which result in hyponatremia in 5–40 per cent of patients.[30] Usually, this effect is clinically insignificant.

Carbamazepine can result in decrease in free T_3 and T_4, but clinical hypothyroidism is extremely rare.

Toxic effects

(a) Overdose

Carbamazepine overdose can be fatal. Common symptoms include nystagmus, tremor, ophthalmoplegia, and myoclonus. Life-threatening effects include atrioventricular block, coma, seizures, and respiratory depression.[31]

(b) Pregnancy

Carbamazepine exposure in the first trimester results in neural tube defects in approximately 1 per cent of infants. Craniofacial abnormalities and developmental delay have been reported as well. Carbamazepine is found in breast milk, but its effects on the nursing infant are unknown.[6,32]

Indications and contraindications

Carbamazepine is indicated for the treatment of simple partial, complex partial, and generalized tonic–clonic seizures. It is ineffective against absence seizures, and may even exacerbate them. Carbamazepine is also indicated in the treatment of trigeminal neuralgia and other neuropathic pain syndromes. Several double-blind, placebo-controlled trials confirm carbamazepine's efficacy in treating both the manic and mixed phase of bipolar disorder.[33,34] There is limited evidence demonstrating efficacy in the treatment of either bipolar or unipolar depression. Uncontrolled reports also suggest that carbamazepine may be useful in the treatment of personality disorders, impulse control disorders, and alcohol/sedative withdrawal syndrome.

Carbamazepine is contraindicated in patients with a history of previous bone marrow depression, hypersensitivity to the drug, or hypersensitivity to any of the tricyclic antidepressants (given its structural similarity to imipramine). Its use with monoamine oxidase inhibitors is not recommended, and carbamazepine should be used with caution in patients with cardiac disease.

Interactions

Given that carbamazepine is extensively metabolized by the liver and induces hepatic enzymes, it produces many significant drug–drug interactions (Table 6.2.6.2).[35–37] Many drug levels are reduced by carbamazepine and can become subtherapeutic. Therefore, it is important to monitor concomitantly administered medications, as dosage adjustments may be necessary.

Table 6.2.6.2 Carbamazepine (CBZ)-drug interactions

CBZ decreases drug levels	Drugs that increase CBZ levels
Alprazolam	Acetazolamide
Clobazam	Cimetidine
Clonazepam	Clarithromycin
Clozapine	Danazol
Dicoumarol	Dextropropoxyphene
Doxycycline	Diltiazem
Ethosuximide	Fluoxetine
Fentanyl	Gemfibrozil
Haloperidol	Isoniazid
Imipramine	Itraconazole
Lamotrigine	Ketaconazole
Mesuximide	Loratadine
Methadone	Macrolide antibiotics
Methylprednisolone	Metronidazole
Oral contraceptives (can result in contraceptive failure)	Nicotinamide
Pancuronium	Nicotinic acid
Paracetamol	Propoxyphene
Phensuximide	Remacemide
Phenytoin (can either increase or decrease)	Rifampicin
Prednisolone	Stiripentol
Primidone	Terfenadine
Remacemide	Valproate
Theophylline	Verapamil
Tiagabine	Viloxazine
Topiramate	
Valproate	
Vecuronium	
Warfarin	
CBZ increases drug levels	**Drugs that decrease CBZ levels**
Clomipramine (possibly)	Cisplatin
Phenytoin (can either increase or decrease)	Doxorubicin
Primidone	Felbamate
	Rifampicin
	Phenobarbital
	Phenytoin
	Primidone
	Theophylline

Effects of withdrawal

As with other antiepileptic drugs, carbamazepine should be gradually tapered over several weeks in order to avoid rebound seizures.

Dosage and administration

Carbamazepine is generally initiated at a starting dose of 100–400 mg, taken either as a single dose or two divided doses (see Table 6.2.6.1 for dosage forms). The dose is gradually increased by 100 or 200 mg every 2 weeks as the patient tolerates. The usual therapeutic serum concentration is 4–12 mg/l (20–50 µmol/l), which is measured before the first morning dose. The half-life of

carbamazepine will decrease with chronic administration due to autoinduction, necessitating frequent monitoring of the serum carbamazepine concentrations and continued dosage adjustment in the first 2 months of therapy.

Laboratory screening

Given the risk of severe blood dyscrasias and hepatic failure, some authorities recommend obtaining a CBC and LFTs at the initiation of treatment. These tests are often repeated every 2 weeks for the first few months of treatment, and then every 3 to 6 months thereafter. However, some authorities argue that testing is unnecessary, since idiosyncratic reactions are rare and may occur too rapidly to be detected by routine laboratory monitoring.

Lamotrigine

Introduction

Lamotrigine (Lamictal®) is a phenyltriazine compound, structurally unrelated to other antiepileptic drugs (see Fig. 6.2.6.1). It was introduced in Ireland in 1993 and in the United Kingdom and the United States in 1994.

Pharmacology

Lamotrigine is thought to act by blocking voltage-sensitive sodium channels, and by inhibiting the release of glutamate. In experimental animal seizure models, it has an antiepileptic profile similar to that of phenytoin and carbamazepine.[38]

Pharmacokinetics

The oral bioavailability of lamotrigine approaches 100 per cent, and absorption is unaffected by food. Peak plasma concentrations are reached 2–3 h after an oral dose. The half-life of lamotrigine is approximately 30 h, but is altered by the presence of other antiepileptic drugs (see Interactions). Plasma protein binding is approximately 55 per cent. Lamotrigine is metabolized by the liver to an inactive glucuronide conjugate, and then excreted in the urine. The clearance of lamotrigine may be reduced in patients with renal impairment and Gilbert's syndrome, and these individuals may benefit from dosage reduction.[39]

Side effects

In general, lamotrigine has few side effects and is better tolerated than other antiepileptic drugs. The most common side effects include dizziness, headache, diplopia, ataxia, blurred vision, nausea, somnolence, and rash. The most concerning side effect is skin rash, which can be life-threatening. Approximately 10 per cent of adults develop a rash while taking lamotrigine, but the majority of these are benign. However, about 1 in 1000 will develop a life-threatening rash, such as Stevens–Johnson syndrome or toxic epidermal necrolysis. The incidence of rash is much higher in paediatric patients, occurring in 1 in 50 to 1 in 100 patients; therefore, lamotrigine should be used with caution in patients less than 16 years of age. Starting at a low dose and slowly increasing it can minimize the risk of rash. Co-administration of valproate can increase the risk of rash. Given the difficulty in predicting who will develop a life-threatening rash, lamotrigine is usually discontinued at the first sign of any rash.

There are a few reports of possible idiosyncratic reactions in patients taking lamotrigine. These include disseminated intravascular coagulation, multiorgan failure, and acute hepatic necrosis.[40] It is unclear, however, if these conditions were actually caused by the drug itself.

Toxic effects

(a) Overdose

The few reported cases of overdose on lamotrigine (at doses up to 4000 mg) were not fatal, but resulted in symptoms such as excessive sedation, dizziness, and headache.

(b) Pregnancy

The effects of lamotrigine on human pregnancy and breast-fed infants are unknown.

Indications and contraindications

Several double-blind, placebo-controlled, add-on trials confirm lamotrigine's efficacy in treating some patients with partial or generalized tonic–clonic seizures.[39] Clinical trials also suggest efficacy against absence, atypical absence, and myoclonic seizures, as well as seizures associated with the Lennox–Gastaut syndrome.[41] Lamotrigine demonstrated efficacy in the treatment of bipolar depression in a large placebo-controlled trial.[42] However, it does not appear to be beneficial in the treatment of acute mania, largely due to the drug's long titration schedule. Several controlled studies have also demonstrated efficacy in the maintenance treatment of bipolar disorder.[39,43–45] and in the rapid-cycling subtype of bipolar disorder.[46] In addition to bipolar depression, lamotrigine has shown some benefit in two small placebo-controlled studies when added to selective serotonin reuptake inhibitors (SSRIs) as an augmentation strategy in the treatment of unipolar depression.[47,48] Preliminary evidence from two small placebo-controlled studies also indicates that lamotrigine may have benefit as an augmentation therapy with conventional and atypical antipsychotics in treatment-resistant schizophrenia.[49,50]

Interactions

Lamotrigine does not appear to affect the kinetics of other antiepileptic drugs or oral contraceptives, but its own kinetics are markedly affected by the concomitant administration of other antiepileptic drugs. Valproate inhibits the metabolism of lamotrigine, resulting in a doubling of the half-life to almost 60 h. The enzyme-inducing antiepileptic drugs, such as carbamazepine and phenytoin, decrease the half-life to approximately 15 h. These interactions necessitate dosage adjustments when starting lamotrigine (see Dosage and Administration).[38]

Effects of withdrawal

As with other antiepileptic drugs, lamotrigine should be tapered gradually over several weeks in order to avoid rebound seizures.

Dosage and administration

Lamotrigine must be started at a low dose and increased with caution to a therapeutic dosage in order to minimize the risk of rash. The patient should be informed of the risk of developing a rash, and instructed to contact the physician immediately if one appears. The starting dose depends upon the concomitant administration of other antiepileptic drugs. See Tables 6.2.6.3–6.2.6.5 for the appropriate lamotrigine titration schedules. Table 6.2.6.1 shows dosage forms.

Table 6.2.6.3 Suggested lamotrigine titration schedule for patients taking carbamazepine, phenytoin, phenobarbital, primidone, or rifampicin and not taking valproate

Week 1	25 mg daily
Week 2	50 mg daily
Week 3	100 mg daily, in divided doses
Week 4	100 mg daily, in divided doses
Week 5	200 mg daily, in divided doses
Week 6	300 mg daily, in divided doses
Week 7	Up to 400 mg daily, in divided doses

Table 6.2.6.4 Suggested lamotrigine monotherapy for patients not taking carbamazepine, phenytoin, phenobarbital, primidone, or rifampicin and not taking valproate

Week 1	12.5 mg daily
Week 2	25 mg daily
Week 3	50 mg daily
Week 4	50 mg daily
Week 5	100 mg daily
Week 6	150 mg daily

Week 6	75 mg daily
Week 7	100 mg daily

Topiramate

Introduction

Topiramate (Topamax®) is a sulfamate-substituted monosaccharide originally developed as an oral hypoglycemic agent. It was subsequently found to have antiepileptic effects. It is currently approved for epilepsy in over 60 countries and for migraine prophylaxis in more than 20 countries.

Pharmacology

Topiramate is believed to act through several different mechanisms including: (1) inhibition of sodium channel conductance; (2) inhibition of L-type calcium channels; (3) increase in GABA release through an unknown mechanism; (4) decrease in glutamate-mediated excitation through blockade of kainate receptors; and (5) inhibition of carbonic anhydrase.[51]

Pharmacokinetics

There is almost complete, linear, and rapid absorption of topiramate across dose ranges.[52] The absorption of topiramate is not affected by food. It is not significantly protein-bound. Hepatic metabolism (~20 per cent) is less important than renal clearance (~80 per cent) and inactive metabolites comprise less than 5 per cent the administered dose.[52] The normal half-life of topiramate is 19–23 h; this is not influenced by the administration of hepatic enzyme-inducing medications such as carbamazepine or phenytoin.[52]

Side effects

The most common side effects of topiramate are memory and concentration difficulties, paresthesias, somnolence, dizziness, anorexia, and weight loss. In clinical trials with topiramate, kidney stones are reported 2–4 times more frequently than in the general population, probably as a result of the drug's inhibition of carbonic anhydrase. Patients predisposed to developing kidney stones should maintain good hydration during topiramate therapy to minimize the risk of renal stone formation. Rarely, topiramate has been associated with acute myopia precipitating secondary angle closure glaucoma and with oligohidrosis leading to hyperthermia.

Toxic effects

(a) Overdose

Several cases of topiramate overdose have been recorded, with signs and symptoms including severe metabolic acidosis, convulsions, drowsiness, speech disturbance, blurred vision, diplopia, lethargy, tupor, hypotension, abdominal pain, agitation, and dizziness. The clinical consequences in most cases were not severe. However, deaths have occurred after poly-drug overdoses involving topiramate.

(b) Pregnancy

The effects of topiramate on human pregnancy and breast-fed infants are unknown.

Indications and contraindications

Topiramate has confirmed efficacy as monotherapy for partial-onset seizures or primary generalized tonic–clonic seizures for patients 10 years and older and as adjunctive therapy for the same seizure types, including seizures associated with Lennox–Gastault syndrome, in patients of age 2 and older.[52] In addition, several large controlled studies have demonstrated benefit in the prophylaxis of migraines.[53–55] It may also be helpful in the treatment of essential tremor and chronic pain syndromes. There are no large placebo-controlled studies investigating the use of topiramate as monotherapy for bipolar disorder. However, there is limited evidence from several small open-label studies for topiramate as an adjunctive treatment for both the depressive[56] and manic[57,58] phases of bipolar disorder. Controlled studies have demonstrated efficacy in eating disorders including binge eating disorder[52] and bulimia nervosa.[59] Given its ability to reduce weight, the utility of topiramate may be greatest as an adjunctive treatment in bipolar disorder with comorbid obesity. Several small placebo-controlled studies have also suggested that topiramate may have benefit in the treatment of alcohol dependence,[60] impulse control disorders such as pathological gambling,[61] and borderline personality disorder.[62]

Interactions

Topiramate does not typically alter the metabolism of any other drugs. One important exception to this is that the effectiveness of

the ethinylestradiol component of oral contraceptives is reduced when more than 200 mg of topiramate is prescribed daily.[52] Topiramate occasionally leads to a modest increase in phenytoin concentrations (0–25 per cent) and to modest increases in the clearance of risperidone, pioglitazone, and lithium.[52] Hydrochlorothiazide can lead to modest increases in serum concentration of topiramate.[52] Concomitant administration of topiramate and valproate has been associated with hyperammonemia with or without encephalopathy in patients who have previously tolerated either drug alone.

Effects of withdrawal

As with other antiepileptic drugs, topiramate should be tapered gradually over several weeks in order to avoid rebound seizures.

Dosage and administration

The recommended dose for monotherapy treatment of epilepsy in adults and children 10 years of age or older is 400 mg/day in two divided doses. It is recommended that therapy be initiated at 25–50 mg/day followed by titration to an effective dose in increments of 25–50 mg/week. The recommended total daily dose for migraine prophylaxis is 100 mg/day administered in two divided doses. In patients with renal impairment one-half of the usual adult dose is recommended.

Other antiepileptics

Several other drugs with antiepileptic activity are currently under investigation in various psychiatric disorders, but have not as yet shown well-documented efficacy. Gabapentin (Neurontin®), a structural analog of gamma-aminobutyric acid (GABA), has been marketed for use as adjunctive therapy in the treatment of epilepsy since 1993 and also carries a clinical indication for postherpetic neuralgia. It displays a pharmacological profile similar to phenytoin and carbamazepine in animal seizure models.[63]

Several placebo-controlled trials confirm gabapentin's efficacy as adjunctive therapy in some patients with partial seizures, especially complex partial seizures and partial seizures with secondary generalization.[42] Additionally, several controlled studies have demonstrated benefit in the treatment of various pain syndromes, particularly neuropathic pain.[64,65] In a large, multicentre, controlled study gabapentin failed as an adjunctive treatment with lithium and/or valproate in the treatment of acute manic or mixed episodes, and actually performed significantly more poorly than placebo.[66] Since that time, however, a small controlled study has suggested that gabapentin may have efficacy as an adjunctive maintenance treatment for bipolar disorder.[67] Two small controlled studies have also demonstrated efficacy for gabapentin in the treatment of panic disorder[68] and social anxiety[69] respectively.

Oxcarbazepine (Trileptal®), the 10-keto analog of carbamazepine, has an antiepileptic effect similar to carbamazepine, but has fewer side effects, and has not been associated with severe blood dyscrasias. The drug also has fewer effects on hepatic enzyme activity, and hence causes fewer drug interactions. Given its similarity to carbamazepine, oxcarbazepine might be expected to be effective for the manic phase of bipolar disorder. However, despite some promising uncontrolled observations, there are as yet no large controlled trials of oxcarbazepine as monotherapy in adult bipolar disorder. A large double-blind study of oxcarbazepine in children with manic or mixed episodes did not demonstrate efficacy.[70] Preliminary evidence from one small open-label study suggests that oxcarbazepine may also reduce the risk of relapse prevention in alcohol abuse.[71]

Zonisamide (Zonegran®) is an antiepileptic that causes carbonic anhydrase inhibition; it is somewhat similar in its pharmacologic profile to topiramate. Like topiramate, it frequently causes weight loss, and has been shown effective for weight loss in a controlled study of obese individuals with binge eating disorder.[72] It also increases the risk of kidney stones to at least the same degree as topiramate. Small open-label studies have suggested that zonisamide may be effective in the treatment of both the manic and depressed phases of bipolar disorder.[73,74]

Tiagabine (Gabitril®) is believed to exert its anticonvulsant effects by enhancing the effects of GABA. This is thought to occur through blockade of reuptake of GABA into presynaptic neurones. Tiagabine showed efficacy in the treatment of generalized anxiety disorder in a large double-blind study.[75] In addition, several small open-label studies have demonstrated preliminary evidence benefit in the treatment of posttraumatic stress disorder,[76] major depressive disorder with comorbid anxiety,[77] and as an augmentation therapy for generalized anxiety disorder.[78] Tiagabine demonstrated limited efficacy as an add-on treatment for treatment-refractory bipolar disorder in one small clinical case series.[79]

Levetiracetam (Keppra®) is a novel anticonvulsant with an unclear mechanism of action. It has demonstrated benefit in the treatment of social anxiety disorder in one small controlled study, warranting further investigation into this potential use.[80]

Pregabalin (Lyrica®) is a structural derivative of GABA. However, it does not act by altering GABA levels or by binding to the GABA receptor. The exact mechanism of action of pregabalin is unknown, although it is most likely related to its high affinity for the alpha$_2$-delta site on voltage-gated calcium channels. Pregabalin has shown promise as an anxiolytic. Three separate large placebo-controlled studies have demonstrated benefit with pregabalin in the treatment of generalized anxiety disorder.[81–83] Pregabalin also demonstrated efficacy in the treatment of social anxiety disorder in one large controlled study.[84]

It is important to note that soon after the completion of this text, the United States Food and Drug Administration released an alert recommending that patients taking antiepileptic drugs be closely monitored for changes in behavior that could indicate worsening of depression or the emergence of suicidal thoughts or behavior. This warning was based on a meta-analysis of placebo-controlled trials involving eleven antiepileptic medications, including both trials in epilepsy and trials in psychiatric disorders. This meta-analysis revealed that patients receiving antiepileptic drugs had approximately twice the risk of suicidal behavior or ideation (0.43%) compared to patients receiving placebo (0.22%).[85] Further investigation and analyses of this possible association are ongoing.

6.2.7 Drugs for cognitive disorders

Leslie Iversen

Introduction

Cognitive disorders are among the most difficult of all nervous system illnesses to treat as they affect the most complex and least clearly understood aspects of brain function. Animal studies cannot accurately mirror the complexities of human cognition, and there are few, if any, animal models of human cognitive illnesses. As so few drugs have been found to exert clinically significant effects, animal models for testing novel cognition-enhancing agents have unknown predictive value. However, progress has been made in recent years with improved international agreement on the criteria used to approve new cognition-enhancing drugs, and the introduction of new drugs for the treatment of dementia.

Alzheimer's disease

It is important to define the objective of drug treatment in this, the most common of all forms of senile dementia. Alzheimer's disease (**AD**) is a progressive illness; drug treatment could treat the symptoms without influencing the course of the disease, or it might seek to delay or arrest the progressive cognitive deterioration which such patients suffer. Although the latter aim is the subject of intensive research in academic and industrial laboratories,[1] there are no drugs that target the underlying pathology, and only palliative treatments are, as yet, available.

The approval of new medicines for the symptomatic treatment of AD in recent years has led regulatory agencies to define more clearly what criteria should be used in assessing the clinical benefits derived from drug treatment. AD is a disease characterized by disturbances in higher cortical function, including disorders of recent memory, language function, praxis, visual perception, abstract thinking, and decision making. A variety of composite dementia assessments designed to provide an overall summary of cognitive status, for example the Mini Mental State Examination (**MMSE**), Alzheimer's Disease Assessment Scale-Cognition (**ADAS-Cog**), and the Brief Cognitive Rating Scale are used.[2] Most studies with cholinesterase inhibitors in AD have used ADAS-Cog (a 70-point scale), and a two to three-point improvement for the drug-treated group versus placebo at 6 months has generally been accepted. However, statistically significant, but small, drug-induced improvements in cognitive assessment scores do not necessarily represent a clinically significant improvement to the patient or to their doctor; they must be supplemented by evidence of clinical improvement, using some form of Clinical Global Impression of Change as an outcome measure, usually rated by a clinician on a seven-point scale.

The development of agreed scientific and clinical standards for the approval of new drugs has largely eclipsed most of the older drugs that had been used in the treatment of AD and other dementias, since none of them can meet these standards. The older drugs include a range of cerebral vasodilators (e.g. dihydroergotoxin, papaverine, isoxsuprine, cinnarizine) and the so-called 'nootropics' (e.g. piracetam, oxiracetam, aniracetam), which were widely used in some European countries, as well as the so-called 'metabolic enhancers' (e.g. idebenone and indeloxazine) which were popular for a while in Japan.

Cholinergic agents

Attention has focused instead on the cholinergic agents. The 'cholinergic hypothesis' of dementia. was boosted by the discovery in the 1970s that cholinergic neurones are particularly damaged or absent from the brains of patients dying with AD, and that the extent of damage to the cholinergic system correlates with the severity of dementia in life.[3] In AD the damage appears to be particularly severe in the system of cholinergic neurones located deep in the forebrain in the nucleus basalis of Meynert, whose fibres branch extensively and innervate most areas of the cerebral cortex. This neuronal system forms part of the ascending reticular activating system, which plays a key role in the process of selective attention—essential for the laying down of new memories. Consequently, there has been considerable interest in the possibility that 'cholinergic replacement therapy' might relieve the symptoms of AD, in the same way that dopamine replacement therapy has successfully been employed in the treatment of Parkinson's disease. The most successful approach so far has been the use of inhibitors of the enzyme acetylcholinesterase.

Inhibitors of acetylcholinesterase have been known since the nineteenth century with the discovery of physostigmine, a plant

product used as an arrow-tip poison. Irreversible organophosphate inhibitors of acetylcholinesterase were later developed as chemical warfare agents ('nerve gases'), and for more peaceful uses as insecticides. Despite their colourful past, low doses of this class of compounds have proved effective as cognitive enhancers in a wide range of animal tests, including those in which cholinergic function is deliberately impaired.[4] The first clinical trials in patients with AD were performed with physostigmine, and confirmed that the drug had significant beneficial effects on cognitive performance in AD patients.[5] However, it has limited usefulness because, although it is absorbed rapidly, it has only a very short half-life in plasma. This means that to obtain any sustained cognitive benefit it has to be given in doses that are sufficiently high to elicit a number of adverse side-effects; thus, the therapeutic window was very narrow.

Subsequently four other cholinesterase inhibitors with improved profiles have gained approval for use in AD: **tacrine**, **donepezil, rivastigmine, and galantamine**, but tacrine is no longer actively marketed owing to liver toxicity. Clinical data from several thousand patients with AD involved in trials with these cholinesterase inhibitors are now available.[6–8] The first of these to gain approval in 1997 was donepezil. Results of large-scale clinical trials with donezepil and the other cholinesterase inhibitors over periods of 15 and 24 weeks have yielded similar results for the three compounds in patients with mild to moderately severe AD. The drugs caused small but significant improvements in the ADAS-Cog, CIBIC, and MMSE scores. The most common side-effects were transient mild nausea, insomnia, and diarrhoea. Not all patients with AD will benefit from treatment with cholinesterase inhibitors; the proportion ranges from 30 to 50 per cent; although the clinical benefits of drug treatment in patients showing a response can persist for up to 24 months.

The approval of cholinesterase inhibitors for the treatment of Alzheimer's disease was an important landmark. They are reasonably well tolerated and produce significant, if modest, beneficial effects in patients with mild to moderately severe AD. However, they have not gained immediate and universal acceptance. In some countries (e.g. the United Kingdom) it has been argued that the drugs are too costly and provide at best only a modest improvement.

Some studies have also found the cholinesterase inhibitors to be effective in treating the cognitive deficits in vascular dementias, but the effects are small and less consistent. Rivastigmine has also been shown to have beneficial effects in treating the cognitive deficits in Parkinson's disease with dementia.[9] The cholinesterase inhibitors may thus find other applications as cognitive enhancers in conditions other than AD.

An alternative approach to cholinergic replacement therapy has been to develop **drugs that mimic acetylcholine** and act as agonists at the muscarinic cholinergic receptors in brain, but which, unlike acetylcholine itself, are bioavailable and brain-penetrant. Attention has focused on the discovery and development of muscarinic agonists that show selectivity for the m_1-receptor subtype, which is the predominant form present in the cerebral cortex. The most thoroughly studied cholinomimetic to date is xanomeline, a compound that acts as a highly potent and selective m_1-receptor agonist. Clinical effects were assessed in a multicentre study of 343 patients with AD.[10] Patients on the highest dose showed significant improvement when assessed using the ADAS-Cog scale and also showed a significant overall global improvement using CIBIC. In addition to cognitive improvements, patients receiving xanomeline also exhibited significant behavioural improvement, with dose-dependent reductions in vocal outbursts, suspiciousness, delusions, agitation, and hallucinations. Xanomeline is unlikely to be used in the treatment of AD because of its relatively short duration of action, but these results suggest that further research on cholinomimetics may still be justified.

An entirely different pharmacological approach is exemplified by the drug **memantine**, the first to be approved for the treatment of moderate to severe AD. Memantine is thought to act by virtue of its ability to block the NMDA sub-type of glutamate receptors in the brain. Clinical trials in AD showed small but significant beneficial effects on cognitive tests and in global clinical outcome, but curiously the effects were most notable in patients with advanced stage disease and less in patients with mild to moderate AD.[11] Although the effects of memantine are small, it remains the only effective treatment for advanced stage AD.

Attention-deficit hyperactivity disorder

Attention-deficit hyperactivity disorder (**ADHD**) is one of the most thoroughly studied disorders in child psychiatry, and the increasingly common use of stimulant drugs to treat this disorder has become the focus of much public attention and debate in recent years.[12] ADHD is defined in terms of three key features: lack of sustained attention, impulsivity, and hyperactivity. According to the DSM-IV definition the diagnosis of ADHD now includes more than 10 per cent of children.[13]

Because of the interest in the drug treatment of ADHD, a number of assessment tools have been developed. These include the widely used Conners' Teacher Rating Scale, the Conners' Parent Rating Scale, and a variety of tests designed to measure hyperactivity, problem behaviour, attention, and other aspects of cognition, as well as academic performance.[14]

The most commonly used drugs are the psychostimulants **amfetamine** and **methylphenidate**. Methylphenidate (Ritalin®) is by far the most widely prescribed. In more than 100 published trials these drugs have been found to have significant beneficial effects on all three key symptoms of ADHD in approximately 70 per cent of the treated children, and also in an adult form of ADHD.[15] Amfetamine (Adderall®) is approved for treatment of adult ADHD (not licensed in UK).

The mechanism of action of all three agents is similar; they act principally as inhibitors of the dopamine-uptake mechanism in the brain and promote the release of this neurotransmitter, thus stimulating dopaminergic mechanisms. The drugs also act to an important extent on noradrenaline-containing neurones to promote an increased release of this monoamine.[16] This may be relevant;a selective inhibitor of the noradrenaline transporter in brain, **atomoxetine**, has been approved as the first non-scheduled stimulant for the treatment of ADHD in both children and adults.[17]

Another non-amfetamine **modafinil** is also non-scheduled and is widely used in the United States for the treatment of ADHD,[18] although the drug has not yet gained regulatory approval from FDA because of possible serious adverse skin reactions. The mode of action of modafinil is unknown but it is used for the treatment of narcolepsy.

It is paradoxical that stimulant drugs, whose actions include an ability to promote hyperactivity, should have a calming effect

on hyperactive children. One explanation is that actions of these amfetamine derivatives show the 'rate dependency' typical of other central nervous system agents, i.e. they tend to stimulate low rates of behaviour and to suppress high rates.[19] An alternative view is that the relatively low doses of amphetamines used in the treatment of ADHD would not have stimulant effects even in normal healthy adults. There are few animal models that can be used in the study of psychostimulant use or ADHD. Mice that are genetically engineered to delete the genes for the dopamine and other monoamine transporters have proved valuable.[20] Animals which lack the dopamine transporter have elevated levels of dopamine in their brains and are behaviourally hyperactive. Paradoxically, d-amfetamine decreases activity in these animals, in keeping with the 'rate-dependency' hypothesis.[20]

The use of amfetamines, particularly methylphenidate, has increased rapidly during the past 30 years, particularly in the United States where in some states more than 10 per cent of school-age boys receive the drug.[12] The use of amfetamines in Europe has been at a much lower level so far, although their use in ADHD has also been increasingly rapidly.[12] In turn, such widespread use of psychostimulants creates problems about diversion and abuse.[12]

6.2.8 Drugs used in the treatment of the addictions

Fergus D. Law and David J. Nutt

Medical treatment of the addictions remains controversial, with addiction itself viewed as a lifestyle problem, a hijacking of brain systems by drugs, or as a medical illness. Many of these controversies may be avoided by taking a goal-oriented approach to treatment, in which clinical objectives are defined, and both medications and psychological interventions are used to facilitate progress towards these. The effectiveness of medications is maximized when they are used as one component of a comprehensive treatment plan.

There are no 'magic bullets' in addiction treatment—the same pharmacological principles apply to these drug treatments as to any other. Drugs need to be given in effective doses, at appropriate intervals, allowed time to reach steady state, and also to dissipate when terminated on the basis of their half-life. Some drugs also have an abuse potential of their own (e.g. opiates, sedative-hypnotics) especially those with a rapid onset of action, and such

drugs need to be particularly closely monitored and controlled, to minimize their diversion and misuse.

Medications in perspective

The clinical goal-oriented approach requires clarity about the clinical objectives at each phase of the treatment process. A typical treatment plan involves three primary clinical objectives:

- drug and psychosocial stabilization
- detoxification when appropriate
- prevention of relapse or recurrence.

Stabilization with a substitution treatment (e.g. methadone or buprenorphine in opiate addiction) involves prescribing a pharmacological equivalent to the abused drug to stop illicit use, crime, etc. It allows time for stabilization to occur and to consider later objectives. Stabilization itself may be either short-term with the primary goal of terminating illicit drug use 'on top' of the prescription, or longer-term where it is commonly known as maintenance. The goals of maintenance are either psychosocial stabilization in preparation for detoxification, or harm reduction in patients where abstinence is not practicable or safe. Unless a sufficient degree of stabilization has been achieved prior to detoxification, the chances of success are strictly limited. The harm-reduction goal has generated much controversy, but one of its major benefits is the reduction in the spread of HIV among injecting drug users. In this group stable long-term maintenance treatment is preferable to repeated cycles of premature discontinuation followed by relapse to uncontrolled drug use with its attendant elevated risk of death from overdose as tolerance wanes. Monitoring by using drug screens and clinical assessments is required to ensure that patients do not use 'on top' of their prescription.

Specific drugs used in addiction treatment

This chapter deals with methadone, levacetylmethadol (LAAM), codeine and dihydrocodeine tartrate, buprenorphine, clonidine, lofexidine, naltrexone, naloxone, acamprosate, disulfiram, and clomethiazole (chlormethiazole), and covers addiction indications only. Many of these drugs are not licensed for use in addiction treatment (e.g. methadone tablets and injection), or are currently licensed in only one or a few countries (e.g. clonidine in Germany, lofexidine in the United Kingdom).

Methadone[1,2] (Methadose®, Physeptone®, Synastone®)

This is a long-acting opioid analgesic which has been the mainstay of opioid substitution treatment, but is often difficult to stop due to its prolonged withdrawal syndrome.

Pharmacology: it is a strong full μ-opioid agonist.

Types of compounds available: it is available in liquid, injectable, and tablet formulations.

Pharmacokinetics: t_{max} 2 to 4 h after oral dosing; 1 h after intramuscular injection; its half-life is 25 h.

Side-effects: as with other μ-opioids, its side-effects include mental blunting, sweating, constipation, nausea, and analgesia.

Toxic effects: acute overdose leads to respiratory depression and pulmonary oedema.

Indications: opiate maintenance, stabilization, and detoxification; it is also indicated for use during pregnancy.

Contraindications: respiratory or severe liver disease, monoamine oxidase inhibitors; caution should be exercised in elderly people.

Interactions: respiratory depression especially in combination with other sedative drugs; metabolism affected by hepatic enzyme induction and inhibition; plasma levels are affected by HAART drugs.

Effects of withdrawal: these include moderate but prolonged abstinence syndrome, especially poor sleep.

Dosage and administration: single daily dose, occasionally twice daily; dose depends on the level of dependence—if unknown, initially 10 to 20 mg daily. The minimum dose that covers withdrawal symptoms for 24 h should be given, and increased by 5 to 10 mg as necessary. Close monitoring is necessary by clinical assessment and drug screen. Some centres use intravenous preparations in those who don't respond to oral preparations.

LAAM[3] (ORLAAM®)

LAAM is a methadone variant with a much longer half-life, requiring only three visits a week for full supervision of medication. However, take-home medication is not allowed and its use is restricted to specialist clinics and is reserved for patients who have failed other treatments. Its licence in Europe has been withdrawn due to QTc prolongation.

Pharmacology: it is a synthetic μ-opioid agonist with active metabolites which are more potent than the parent drug.

Types of compounds available: aqueous solution.

Pharmacokinetics: t_{max} 2 to 4 h; duration of action is 48 to 72 h; half-lives for LAAM and its metabolites are 2 to 4 days; it takes 2 weeks to reach steady state.

Side-effects: too rapid escalation of the dose may result in sedation, orthostatic hypotension, poor concentration, and overdose.

Toxic effects: as for methadone; QTc prolongation; overdose occurs with too frequent (daily) dosing, use of multiple drugs, or 'on-top' use due to impatience with its slow onset of action.

Indications: opiate maintenance, stabilization, and detoxification.

Contraindications: pregnancy (transfer to methadone); QTc prolongation prior to induction of treatment; dose should be reduced in elderly people, and in renal and hepatic impairment.

Interactions: as for methadone; other drugs prolonging QTc interval.

Effects of withdrawal: as for methadone, but with a milder withdrawal syndrome due to longer $t_{1/2}$.

Dosage and administration: pre-treatment ECG to identify prolonged QTc intervals, repeated 12–14 days after initiating treatment and periodically thereafter to rule out alterations to the QTc; give three times a week or on alternate days; increase dose by 20 to 40 per cent when transferring form 48 h to 72 h dosing interval. Transfer methadone to LAAM by giving 1.2 to 1.3 times the daily methadone dose; and LAAM to methadone by waiting at least 48 h and then giving 0.8 times the LAAM dose. If low or unknown tolerance, the initial dose is 20 to 40 mg three times weekly. Adjust dose in 5- to 10-mg steps, but no more frequently than

weekly at the most. Strongly warn patients of the risk of supplementation with street drugs especially prior to steady state. LAAM is detected by urine screens for methadone.

Buprenorphine[4,5] (Subutex®, Suboxone®, Temgesic®, Buprenex®)

Advantages over methadone and other full μ-agonists are its safety in overdose, the attenuation of the drug 'high' during on-top use, and its low levels of psychological reinforcement and withdrawal symptomatology during detoxification.

Pharmacology: a partial μ-opioid agonist, which explains the ceiling on respiratory depression; slow onset of action; dissociates slowly from the μ-receptor.

Types of compounds available: 0.2-, 0.4-, 2- or 8-mg sublingual tablets, or 0.3-mg ampoules for injection; it is also available in combination with naloxone in a 1:4 ratio (Suboxone®) to reduce misuse if diverted.

Pharmacokinetics: sublingual tablets absorbed rapidly into the buccal mucosa and released slowly into the blood stream; t_{max} 2 to 6 h.

Side-effects: withdrawal symptoms if either too little or too much is given; nausea and vomiting are rare in addicts.

Toxic effects: as for methadone, but less constipation and respiratory depression.

Indications: opiate maintenance, stabilization, and detoxification, including in pregnancy; may be especially suitable for opioid antagonist-assisted withdrawal; no dosage adjustment needed in renal failure or elderly people.

Contraindications: severe respiratory disease; use with care in severe liver disease.

Interactions: rare; sedation with benzodiazepines.

Effects of withdrawal: there is a mild but delayed withdrawal syndrome.

Dosage and administration: initial dose is 0.8–4 mg increasing by 4 to 8 mg daily until the required dose level is reached; usual daily dose 8 to 32 mg; doses above 12 mg may be given on alternate days; minimize withdrawal symptoms after long-term use by reducing by 1 mg every 3 to 4 days or less often; buprenorphine-assisted heroin detoxification by rapid reduction over 5 to 10 days; the injectable form is not recommended for use in addiction treatment. Monitor clinical state and perform drug screens for compliance and on-top use.

Codeine phosphate and dihydrocodeine tartrate[6,7] (DF118 Forte®, DHC Continus®)

Advantages over methadone occur in situations where long-acting opioids may be inappropriate. These are often preferred by patients, and by doctors treating the young, low-dose users, and in acute situations (e.g. in police custody). Disadvantages are its ease of misuse, high levels of psychological reinforcement due to its rapid onset of action, and its unfavourable side-effect profile.

Pharmacology: it is a weak short-acting μ-opioid agonist.

Types of compounds available: Codeine: 15-, 30- and 60-mg oral tablets, linctus, syrup and injection; dihydrocodeine tartrate: 30- or 40-mg oral tablets for use three to six times a day, and a 60-, 90-, or 120-mg slow-release preparation (DHC Continus) for use every 12 h; also parenteral preparation and elixir.

Pharmacokinetics: peak plasma levels at 1 to 2 h; half-life 3.5 to 4.5 h.

Side-effects: it is more likely to cause sedation, dizziness, stimulation, euphoria, constipation, histamine release, psychomimetic effects, and disturbing dreams than other opioids.

Toxic effects: precipitation of life-threatening exacerbations of asthma; in overdose, coma with myotonic twitching, grand mal convulsions, and rarely rhabdomyolysis may occur.

Indications: opiate maintenance, stabilization, and detoxification

Contraindications: acute exacerbations of asthma, lower respiratory tract infection, respiratory depression, and hepatic failure, increased intracranial pressure; caution should be exercised in renal impairment and elderly people.

Interactions: as for methadone; it may enhance the effects of warfarin.

Effects of withdrawal: mild withdrawal syndrome.

Dosage and administration: dose depends on level of dependence; monitor clinical state and urine screen to confirm compliance and termination of on-top use.

Naltrexone[8–11] (Nalorex®, Opizone®)

Naltrexone is used to maintain abstinence in detoxified opiate addicts during the period of highest vulnerability to relapse following detoxification. It blocks the 'high' produced by opiates and promotes the extinction of conditioned responses. It also has a role in alcohol misuse and ultra-rapid opioid detoxification. Nalmefene is a related long-acting μ receptor antagonist that has a licence for alcoholism in some countries.

Pharmacology: it is a long-acting non-selective opioid antagonist.

Type of compound available: 50-mg oral tablet.

Pharmacokinetics: t_{max} 1 h; duration of action is dose related, and a single dose can be effective for up to 48 h.

Side-effects: opiate withdrawal syndrome may occur on induction; occasionally, gastrointestinal irritation, headaches, arthralgia, flattening of mood, and rash occur.

Toxic effects: severe opioid withdrawal in dependent addicts lasting 2 days; reversible liver toxicity at high dose in obese and elderly people; liver function tests should be monitored especially if baseline tests are impaired.

Indications: prevention of impulsive relapse following detoxification in opioid users; opioid antagonist-assisted withdrawal; it reduces the reinforcing effects of alcohol.

Contraindications: acute hepatitis or liver failure, and active peptic ulcer; caution should be exercised in hepatic or renal impairment.

Interactions: competitive opioid blockade, so potentially can be overcome using very high opiate doses.

Effects of withdrawal: none, but risk of opioid overdoes following withdrawal (loss of toerance).

Dosage and administration: treatment initiated following LFTs and opioid-negative urine screen (or a negative naloxone challenge). Twenty-five mg is given on the first day, and then 50 mg daily for 3 to 6 months. Thrice weekly dosing (100/100/150 mg) may occasionally improve compliance. Supervision of consumption by a supportive person, urine tests to monitor compliance, and regular reviews are very important in maximizing effectiveness.

Naloxone[12] (Narcan®)

Naloxone is a short-acting antagonist used in the treatment of opioid overdose, during detoxification, and naltrexone induction. Take home naloxone may be used to treat opiate overdoses in the community by patients trained in its use.

Pharmacology: it is a short-acting competitive opioid antagonist.

Types of compounds available: it is available in injectable form for intramuscular, intravenous, or subcutaneous use.

Pharmacokinetics: half-life 1 to 2 h.

Side-effects: withdrawal in opiate-dependent subjects; nausea and vomiting; rarely, high blood pressure and pulmonary oedema can occur.

Toxic effects: very occasional deaths due to acute pulmonary oedema, extreme hypertension, and ventricular arrhythmias have occurred in those with known myocardial disease.

Indications: naloxone reverses the effects of opioid overdose, and in high doses may help in overdose due to alcohol and benzodiazepines. Naloxone is also occasionally used as the diagnostic test of opioid dependence, and as a challenge test prior to naltrexone initiation. It is also used for opioid antagonist-assisted withdrawal, and in combination with oral opiate agonists to reduce misuse by the injectable route (e.g. Suboxone®). In neonates it is used for the reversal of the effects of opioids given to mothers during labour.

Contraindications: none if not opioid dependent (safe in neonates, children, pregnancy, elderly people); caution is advisable in opioid dependence, painful conditions, and cardiovascular disease.

Interactions: severe hypertension following reversal of coma due to clonidine overdose.

Effects of withdrawal: none.

Dosage and administration: in opioid overdose, give 0.4 to 2 mg intravenously (5 to 10 μg/kg in neonates and children) and repeat at 2- to 3-min intervals until desired response; may also be given intramuscularly in overdose; lower doses are used in adults (0.1–0.2 mg) to reverse opioid-induced respiratory depression, but higher doses are needed with buprenorphine and σ-receptor agonists. Continue naloxone by infusion or repeated injection if necessary to maintain recovery. During naltrexone induction, give 0.2 mg parenterally followed by 0.8 mg 30 min later (or 0.6 mg 30 s later if given intravenously). In equivocal cases give 1.6 mg.

Clonidine hydrochloride[13, 14] (Catapres®, Dixarit®)

Clonidine is an α_2-adrenoceptor agonist used to suppress some symptoms of opioid withdrawal, especially methadone-assisted withdrawal. It is ineffective for subjective symptoms, muscle/bone aches, stomach cramps, and insomnia.

Pharmacology: clonidine is an antihypertensive agent that decreases central and peripheral (sympathetic) noradrenergic activity by stimulating presynaptic receptors in the locus coeruleus.

Types of compounds available: it is available as tablet, liquid, sustained release capsule, and transdermal preparation; the tablet is licensed in Germany.

Pharmacokinetics: t_{max} 90 min; half-life of 20 to 25 h

Side-effects: it causes hypotension, sedation, dry mucous membranes, bradycardia, depression, impotence, constipation and diarrhoea, sleep disturbance, fluid retention, headache, euphoria, and Raynaud's phenomenon.

Toxic effects: a clonidine withdrawal syndrome may occur on abrupt withdrawal or non-compliance; paralytic ileus, psychotic features, or depression can also occur; coma or severe sedation can occur on acute overdose.

Indications: rapid opiate withdrawal and opiate antagonist-assisted withdrawal; it is also used as adjunct for alcohol, benzodiazepine, and nicotine withdrawal.

Contraindications: low baseline blood pressure, disorders of cardiac pacemaker activity and conduction, cardiovascular and cerebrovascular disease, and porphyria; caution is necessary in renal and hepatic impairment, peripheral vascular disease, and where there is a history of depression or psychosis.

Interactions: combinations with sedative drugs; phenothiazines may increase hypotension. Tricyclic antidepressants may block its effects.

Effects of withdrawal: an increase in sympathetic activity with symptoms mimicking the opiate withdrawal syndrome may occur 18 to 72 h after the last dose on abrupt termination. Blood pressure rebound is rare when used for less than 1 month. The effects are minimized by gradual withdrawal.

Dosage and administration: expertise is needed to monitor cardiovascular signs and adjust dose during a clonidine detoxification over 1 to 3 weeks. Start clonidine after discontinuation of the opioid. Following a test dose, 0.1 mg tablets are given four to six times daily building up to 2 mg daily over a few days in inpatients but half this dose in outpatients. Patches applied once weekly and supplemented by tablets if withdrawal symptoms occur. Frequent monitoring for hypotension and bradycardia is needed.

Lofexidine[13–15] (BritLofex®)

Lofexidine is an analogue of clonidine, but easier to use because there is less hypotension and sedation.

Pharmacology: as for clonidine; differences occur possibly because it is more potent at the A subtype of α_2-adrenoceptors.

Types of compounds available: 0.2-mg oral tablets; these are licensed in the United Kingdom only.

Pharmacokinetics: t_{max} 3 h; half-life of 15 h.

Side-effects: these are the same as for clonidine, but with markedly less hypotension and other side-effects.

Toxic effects: as for clonidine; it has little rebound effect on blood pressure, and no psychiatric complications or misuse has been reported.

Indications and contraindications: as for clonidine.

Interactions: as for clonidine.

Effects of withdrawal: as for clonidine, but less rebound.

Dosage and administration: treat for 1 to 3 weeks; dose may be started before opiate is stopped; on day 1, give 0.8 mg in divided doses, and build up by 0.4 to 0.8 mg daily. Aim for a minimum of 1.6 mg daily in four divided doses, increasing to a maximum daily dose of 2.4 mg. Plan for a peak in the dose when the peak of withdrawal symptoms are expected. Blood pressure should be monitored 2 h after the initial dose, and daily as the dose is increasing. After peak opiate withdrawal lofexidine should be withdrawn gradually over at least 2–4 days. The dose should be reduced by 0.2–0.4 mg daily.

Acamprosate (calcium acetylhomotaurinate)[16,17] (Campral EC®)

Acamprosate is a non-aversive agent used to maintain abstinence in alcohol-dependent patients during the most vulnerable period following detoxification, which may work as an anticraving agent.

Pharmacology: this is not fully understood. It affects the brain's γ-aminobutyric acid (inhibitory) and glutamate (excitatory) systems.

Types of compounds available: oral enteric-coated tablets containing 333 mg acamprosate.

Pharmacokinetics: t_{max} 5 h; half-life 21 h; steady state after 7 days.

Side-effects: there are a range of dose-related side-effects which are mainly mild and transient, including diarrhoea and other gastrointestinal effects, pins and needles in the limbs, skin pruritus, confusion, and sexual effects. Transient reductions in blood pressure occur in those with alcohol-induced hepatic cirrhosis.

Toxic effects: hypercalcaemia is a theoretical possibility following overdose.

Indications: maintenance of abstinence following alcohol detoxification; it is suitable for use in those with liver dysfunction.

Contraindications: renal impairment and severe hepatic failure.

Interactions: concomitant food decreases bioavailability.

Effects of withdrawal: none.

Dosage and administration: begin treatment as soon as possible after detoxification, and continue for 1 year. Four tablets a day (2–1–1) with meals if body weight is less than 60 kg, but six tablets a day (2–2–2) if over 60 kg. The drug should be continued during alcohol relapses.

Disulfiram[18–20] (Antabuse®)

An unpleasant disulfiram-ethanol reaction occurs when alcohol is consumed, acting as a deterrent or punishment if drinking occurs. Disulfiram is used under specialist supervision during periods of vulnerability to relapse.

Pharmacology: disulfiram is an aldehyde dehydrogenase inhibitor leading to the accumulation of acetaldehyde after ethanol consumption.

Types of compounds available: 200-mg oral tablets.

Pharmacokinetics: inhibition of alcohol dehydrogenase develops slowly over 12 to 24 h and peaks at 48 h.

Side-effects: relatively non-toxic on its own, but may cause drowsiness, fatigue, halitosis, nausea, vomiting, and a decrease in libido. With alcohol, disulfiram causes nausea, vertigo, anxiety, blurred vision, hypotension, chest pain, palpitations, tachycardia, facial flushing, and throbbing headache. Symptoms can last 3 to 4 days, but may persist for 1 week. Symptoms may occur even with small amounts of alcohol, but 25 to 50 per cent of patients experience little or no reaction at standard doses.

Toxic effects: the disulfiram-ethanol reaction may be very severe with respiratory depression, cardiovascular collapse, cardiac arrhythmias, coma, cerebral oedema, hemiplegia, convulsions, and death. Chronic treatment and overdose may cause high blood pressure, hepatotoxicity, and neuropsychiatric complications.

Indications: it is used as a deterrent to the use of alcohol and maintenance of abstinence, especially if there is high motivation and good compliance in the patient.

Contraindications: cardiac failure, cardiovascular or cerebrovascular disease, hypertension, peripheral neuropathy, psychosis, severe personality disorder, suicide risk, pregnancy, and breast feeding. It should be used with caution in hypertension, diabetes mellitus, epilepsy, impaired hepatic or renal function, respiratory disorders, cerebral damage, and hypothyroidism, as it may exacerbate these conditions. Caution should be exercised in the elderly.

Interactions: caution with phenytoin, diazepam, chlordiazepoxide, theophylline, warfarin, and caffeine metabolism; acute psychosis or confusional state may occur with metronidazole. Concurrent tricyclic antidepressants may exacerbate the disulfiram-ethanol reaction and cause a toxic confusional state.

Effects of withdrawal: none but restoration of alcohol dehydrogenase depends on *de novo* enzyme synthesis which occurs over 6 or more days.

Dosage and administration: after 24 h without alcohol, give 800 mg as a single dose on day 1, then reduce dose over 5 days from 100 to 200 mg daily. Effectiveness is dose related. Blood pressure should be monitored regularly if the patient is taking over 500 mg/day. Compliance is improved with monitoring (carbon disulphide breath test) and supervision. Patients should be warned not to ingest any alcohol, including alcohol in food, liquid medicines, and even toiletries. An alcohol challenge test may be done in specialist centres. The patient should be reviewed every 6 months at a minimum. Alcohol should be avoided for at least 1 week on terminating disulfiram.

Clomethiazole (edisylate)[21] (Heminevrin®)

Clomethiazole (previously known as chlormethiazole) is a sedative-hypnotic-anxiolytic which also inhibits the metabolism of alcohol resulting in a more gradual elimination of alcohol from the body.

Pharmacology: it is an agonist at the picrotoxin/barbiturate site of the GABA-A receptor, a glutamate antagonist, and an inhibitor of alcohol dehydrogenase.

Types of compounds available: oral and parenteral forms.

Pharmacokinetics: t_{max} 1 h (oral dosing); plasma half-life is 4 h but is double this in elderly people.

Side-effects: conjunctival irritation, nasal congestion, tingling in the nose, headaches, and reversible elevation of liver function tests.

Toxic effects: respiratory depression, sudden fall in blood pressure, anaphylactic reactions, and death (often due to combination with alcohol).

Indications: acute alcohol withdrawal and delirium tremens in inpatients.

Contraindications: alcohol addicts who continue to drink, pulmonary insufficiency, pregnancy, and lactation; caution is advised in renal impairment, severe liver damage, and cardiac and respiratory disease.

Interactions: alcohol and diazoxide may cause severe respiratory depression. Plasma levels are increased by cimetidine. It causes severe bradycardia with propranolol.

Effects of withdrawal: rebound insomnia and anxiety (as with other sedative drugs).

Dosage and administration: titrate using three or four daily doses according to patient response. Initially give 2 to 4 capsules, then 9 to 12 in divided doses over the next 24 h, 6 to 8 capsules on

day 2, 4 to 6 on day 3, reducing it to 0 by day 6 to 9 in order to avoid dependency. Only use it by infusion where resuscitation facilities are available; initially give 3 to 7.5 ml/min, then reduce dosage to 0.5 to 1 ml/min (infusion no longer available in UK).

6.2.9 Complementary medicines

Ursula Werneke

Complementary medicines pose a particular challenge to medical practitioners who may feel that their patients need conventional treatment but often find themselves out of their depth when patients ask about complementary therapies. Pharmacological options include herbal medicines, certain foods, and nutritional supplements such as vitamins and minerals. Physical treatments include acupuncture, massage, and osteopathy to name a few. Treatments, which purport to achieve their effects through changes in internal 'energy flow' include reiki, reflexology, healing, and therapeutic touch, and also homeopathy and traditional Chinese acupuncture. All these treatments are either used alternatively, i.e. instead of, or complementary, i.e. in addition to, conventional medicine. In patients with mental health problems, depending on the definition and inclusion criteria, estimates of the prevalence of complementary medicine use range from 8 per cent to 57 per cent. Depression and anxiety seem to be the most common indications.[1]

Herbal remedies and supplements

Principles of treatment

Herbal remedies and supplements may come in many different forms and formulations. Since they are currently not subject to the same regulatory requirements as conventional medicines they can vary substantially in contents and dose even if they purport to contain the same ingredients. The pharmacological properties of an extract or a supplement may depend on many different factors (Table 6.2.9.1).

Condition-specific remedies

Cognitive enhancers

Cognitive enhancers are either used in the treatment of dementia to enhance mental performance or prevent cognitive decline in healthy people. One strategy aims at increasing choline availability, e.g. by inhibiting acetylcholine esterase. Alternative non-cholinergic neuroprotective strategies have been postulated. These rely on antioxidants scavenging free radicals thereby reducing neurotoxicity or anti-coagulants and increasing cerebral blood flow.[4] Suggested herbal cognitive enhancers for which some positive trial evidence has been collated include ginkgo (*Ginkgo biloba*), panax

Table 6.2.9.1 Determinants of pharmacological properties of complementary medicines

Factor	Problem	Example
Material production	Quality may depend on plant material used, time of harvesting, geographical location, or other environmental factors	St John's wort extracts prepared from the flowers are more potent than extracts prepared from the leaves
Extraction method	Determines remedy composition	Alcoholic valerian extracts may be safer than aqueous extracts such as teas because harmful volatile substances (valepotriates) are eliminated more easily. The resulting extracts may be less potent though, since valepotriates have GABAergic properties.[2] Conversely, aqueous kava extracts may be safer than alcoholic extracts because liver protective substances such as glutathione are retained
Standardization	Difficult to achieve if active ingredient is unknown	St John's wort is based on the extract traditionally standardized on hypericin, a photosensitive red pigment. However, current evidence suggests that standardization should be based on hyperforin, which inhibits the reuptake of monoamines[1]
Dosing	Depends on standardization	300 mg of St John's wort extract standardized on 0.5% or 5% hyperforin most likely have different pharmacodynamic effects
Contamination	Increased and sometimes unexpected toxicity	Contamination with e.g. fertilizer residuals or heavy metals. Association of eosinophilicmyalgic syndrome and some 5-hydroxy-tryptophan products may be at least in part due to contamination of some batches
Adulteration	May lead to serious side effects and drug interactions falsely ascribed to the remedy *per se*	Adulterants include steroids, NSAIDs, anticonvulsants, benzodiazepines, hypoglycemic agents, erectogenic agents, and warfarin[3]

ginseng (*Panax ginseng*), hydergine (*Claviceps purpurea*), sage (*Salvia officinalis*), and vitamin E. The potential side effects can be derived from the purported mechanisms of action. For example, remedies increasing the cerebral blood flow such as ginkgo may increase the risk of cerebral haemorrhage. *Panax ginseng* has been associated with manic episodes and hydergine can lead to ergot poisoning unless dosed carefully. Some sage species can lower the seizure threshold. Others contain camphor, which can be toxic in high doses.[2] Also, evidence is emerging that taking vitamin E above the recommended level may increase all-cause mortality.[5]

Anxiolytics and sedatives

Drugs considered to be either anxiolytics or sedatives essentially have the same underlying mechanisms of action. The stronger an agent the more sedating it will be, leading to coma in extreme cases. Four mechanisms of action have been implicated; binding to γ-aminobutyric acid (GABA) receptors leading to hyperpolarization of the cell membrane through increased influx of chlorine anions; inhibition of excitatory amino acids (EAA) thereby also impairing the ability to form new memories; sodium channel blockade, reducing depolarization of the cell membrane; and calcium channel blockade, reducing the release of neurotransmitters into the synaptic cleft.[4] The most commonly used CAMs for anxiolysis and sedation, such as valerian (*Valeriana officinalis*), passion flower (*Passiflora incarnata*), kava (*Piper methysticum*), and German chamomile (*Matricaria recutita*) are GABAergic. Lemon balm (*Melissa officinalis*) has cholinergic and GABAergic properties. For other plant remedies, including hops (*Humulus lupulus*), oats (*Avena sativa*), lavender (*Lavendula angustifolia*), and starflower also known as borage (*Borago officinalis*), the actual mechanism of action remains unknown. Melatonin regulates the circadian rhythm and also has some GABAergic properties although trial evidence remains inconclusive. Some of these remedies can potentially have serious side effects. For instance, kava extracts have been associated with significant and potentially fatal hepatotoxicity. Starflower contains γ-linolenic acid that may lower the seizure threshold. Some passion flower extracts may contain cyanide components. As expected, all remedies in this class can lead to drowsiness when taken in high doses and can potentiate the effect of synthetic sedatives.

Antidepressants and mood stabilizers

Most complementary antidepressants are thought to work through serotonergic and noradrenergic pathways. The most robust clinical data are available for St John's wort (*Hypericum perforatum*), having been extensively reviewed in meta-analyses.[1] Hyperforin, inhibiting the reuptake of monoamines, is thought to be the most likely active component. Supplements, such as *S*-adenosylmethionine (SAMe), folic acid, L-tryptophan, and 5-hydroxytryptophan are components or co-factors in the serotonin synthesis. For SAMe, equivalence to tricyclic antidepressants has been demonstrated. However, SAMe is very expensive and a suitable oral formulation may be difficult to obtain. Selenium has also been suggested but the mechanism of action, albeit still unclear, seems to be different. Its antioxidant properties may reduce nerve cell damage. Selenium also facilitates conversion from thyroxin (T4) to thyronine (T3), and T3 substitution is one possible augmentation strategy for antidepressants. As for lithium, the therapeutic index is narrow. Omega-3 fatty acids are known to stabilize membranes and to facilitate monoaminergic, serotonergic, and cholinergic neurotransmission. The currently available evidence supports the use of eicosapentaeonic acid on its own or in combination with docosahexaonic acid as adjunctive treatment.[6] Serotonergic remedies should not be combined with each other or with conventional antidepressants because of the increased risk of serotonin syndrome. Equally, herbal antidepressants may induce mania in vulnerable patients although current evidence relies on case reports only. Finally L-tryptophan and 5-hydroxytryptophan should be avoided until the associated risk of eosinophilic myalgic syndrome is fully explained.

Remedies for psychosis

Rauwolfia (*Rauvolfia serpentina*) extracts were traditionally used before synthetic antipsychotics became widely available. Several alkaloid derivatives including reserpine were introduced in the 1950s. They block vesicular storage of monoamines so that the presence of monoamines in the cytoplasm is prolonged, enabling them to be more easily degraded by monoamine oxidases. In consequence, the amount of neurotransmitter available on depolarization of the cell membrane is reduced.[4] On the one hand, this may lead to a reduction of dopamine and the resolution of psychotic symptoms. On the other hand, less serotonin and noradrenaline will be available, which explains why drugs such as reserpine may precipitate depression. An alternative strategy is the augmentation of antipsychotic treatment with omega-3-fatty acids, but the results of clinical trials remain inconclusive and larger trials will be needed to clarify effectiveness.[6,7]

Remedies for movement disorders

Attempts have been made to treat tardive dyskinesia with antioxidants. This approach relies on the assumption that tardive dyskinesia is not only due to dopamine receptor super-sensitivity but is also related to oxidative tissue damage induced by antipsychotics. Clinical trials suggest that vitamin E may prevent the progression of tardive dyskinesia. One trial found actual improvement. However, the benefits have to be offset against taking vitamin E long-term, particularly when higher than recommended daily doses are used.[5] A far more powerful antioxidant than vitamin E is melatonin attenuating dopaminergic activity in the striatum as well as hypothalamic dopamine release.[8]

Remedies for the treatment of addiction

Only few plants have been identified as having the potential to counter addiction. Such may be ibogaine, derived from the West African shrub *Tabernanthe iboga*. It has hallucinogenic properties, and has been used to counter nicotine, cocaine, and opiate addiction. It causes dose-dependent CNS stimulation ranging from mild excitation and euphoria to visual and auditory hallucinations. The therapeutic value of ibogaine is limited since it is highly neurotoxic and can cause irreversible cerebellar damage. A synthetic derivative with similar reported effects, but without cerebellar toxicity is 18-methoxycoronaridine (18-MC).[4] Between 1990 and 2006, twelve deaths after ibogaine use were reported. More deaths may have occurred but may not have been reported due to the 'underground nature of ibogaine treatment'. Passion flower and valerian, by virtue of their GABAergic properties, may ameliorate withdrawal symptoms. Kudzu, Japanese arrowroot (*Pueraria lobata*), has traditionally been used for the treatment of alcohol hangover. The active ingredient, puerarin, counteracts the anxiogenic effects associated with alcohol withdrawal.[9]

Examples of remedies commonly used for chronic somatic conditions

Many different remedies are available for somatic conditions. Their use may be problematic in chronic conditions such as cancer or HIV where the therapeutic margin of conventional medicines is narrow.[10] For example, echinacea (*Echinacea purpurea*) is used to boost immune system. This may be detrimental where immunosuppression is desired since echinacea may potentially stimulate the growth of malignant or infectious cell lines. Patients with breast cancer may often resort to phytoestrogens such as soy (*Glycine max*), wild yam (*Dioscorea alata*), or liquorice (*Glyccyrhiza glabra*) to reverse the effects of antiestrogenic therapies such as tamoxifen. Phytoestrogens, however, can theoretically stimulate breast cancer cells and thus should be advised against in this patient group. Liquorice is a popular ingredient of many traditional Chinese medicines and may cause hypokalemia if used excessively. Evening primrose (*Oenothera biennis*) oil is a popular remedy for premenstrual syndrome and mastalgia. Like starflower it contains γ-linolenic acid and may lower the seizure threshold or reduce the efficacy of antiepileptic drugs.

Drug interactions

Determining interactions between complementary and conventional medicines can be extremely difficult. In the first instance, the clinician must be prepared to consider such a possibility and take a corresponding history. As often, association does not prove causality. Drug interactions can be distinguished into pharmacodynamic and pharmacokinetic interactions. Pharmacodynamic interactions occur when remedies act as agonists, antagonists or inverse agonists to conventional medicines. Additive toxicity, e.g. hepatotoxicity due to pyrrolizidine alkaloids, or increase of coagulability due to coumarinic constituents may also be of concern. Pharmacokinetic interactions include interactions with the cytochrome microsomal enzyme system (CYP) or membrane transporter proteins expressed through the ABC cassette genes (Table 6.2.9.2).[1,2,11,12]

The CYP system

The pharmacokinetics of most anticancer drugs is highly variable and may be genetically determined. For instance, the oxidative metabolism depends on the CYP system. The effects of CYP inducers and inhibitors are essentially differential depending on whether metabolites are more or less active (Table 6.2.9.2). If metabolites are less active than the original agent, CYP inhibitors increase whereas inducers reduce therapeutic effectiveness. Conversely, if metabolites are more active than the original agent, CYP inhibitors reduce whereas as inducers increase therapeutic effectiveness. Often such interactions have only been studied *in vitro* and it remains unclear whether they translate into tangible clinical effects.[11,12] In clinical practice, it is often possible to monitor combination of medicines more closely or to adjust the doses of conventional drugs in the required direction rather than to advise discontinuation of complementary remedies. Interactions with CYP 3A4 are of particular concern, since this enzyme metabolizes up to 60% of all clinically used drugs including HIV protease inhibitors, HIV non-nucleoside reverse transcriptase inhibitors, warfarin, ciclosporin, oral contraceptives, digoxin, theophylline, anticonvulsants, and various psychoactive drugs.[13]

ABC transporters

The ABC cassette genes represent proteins binding to ATP and use this energy to drive various molecules through cell membranes. The transport is mostly unidirectional. The ABC genes have been mainly explored for their capacity to cause multi-drug resistance in cancer chemotherapy.[12] Thus remedies exerting such effects may be of particular interests to the liaison psychiatrist. The most commonly known transporter is p-glycoprotein involved in the

Table 6.2.9.2 Examples of potential drug interactions of commonly used psychotropic remedies

Remedy	Pharmacodynamic	Pharmacokinetic
Ginkgo	Antithrombolytic agents	1A1, 1A2, 2B1/2, 2C9, **2C19***, 3A1, **3A4** inhibition
Panax ginseng	Insulin and oral hypoglycaemics, antithrombolytic agents, MAOIs (phenelzine), loop diuretics	1A1, 1A2, 1B1, 2C9, 2C19, **2D6**, 2E1 inhibition3A4 inconclusive; p-glycoprotein inhibition
Hydergine	Serotonergic antidepressants, choline-esterase inhibitors	
Vitamin E	Anticoagulants and antiplatelet drugs; prevention of nitrate tolerance possible; ↑ effect of sildenafil and related phophodiesterase-5 inhibitors possible; ↓ effect of chemotherapies relying on oxidative stress	CYP 3A11 induction
Valerian	↑ Effect of sedatives	**CYP 3A4** and p-glycoprotein inhibition
Passion flower	Anticoagulants, ↑ effect of sedatives	CYP 3A4 inhibition
Kava	↓ Effect of levodopa	Potentiation of liver toxicity of other drugs CYP 1A2, 2C9, 2C19, 2D6, 3A4 and 4A9/11 inhibition
Melatonin	Anticoagulants, ↑ effect of sedatives; ↓ effect of chemotherapies relying on oxidative stress	
St John's wort	Serotonergic antidepressants	CYP 3A4, 1A2, 2C9, **3A4**and **2E1** induction:, p-glycoprotein induction
Omega 3 fatty acids	↑ Effect of warfarin, aspirin and non- steroidal anti- inflammatory drugs	CYP 3A4 and p-glycoprotein inhibition
Rauwolfia	↑ Effect of anti- psychotics and barbiturates; ↓ effect of levodopa; severe bradycardia with digitalis glycosides; hypertension in combination with sympathomimetics	
Iboga	Cholinergic and anticholinergic drugs	
Echinacea	↓ Effect of immunosuppressants	CYP **2A1**, 2C9, and **3A4** inhibition, CYP 3A4 induction also possible depending on extract
Evening primrose oil	Other drugs reducing seizure threshold, anticoagulants	1A2, 2C9, 2C19, 2D6, 3A4 inhibition

*Bold font: *In vivo* evidence available.

transport of many psychotropic drugs through the blood brain barrier. St John's wort, valerian, and panax ginseng are remedies shown to change p-glycoprotein activity (Table 6.2.9.2).[11,12] However, whether such effects are sufficiently powerful to affect conventional treatments remains unclear.[14]

Conclusions

At present, the evidence base for the use of psychotropic complementary medicines is extremely limited. Due to the large variability of formulations it can be extremely difficult to conduct clinical trials with replicable results even if a candidate plant has been identified. Pooling results of existing trials in meta-analyses may be unhelpful if the trials are too small or heterogenous or if the analysis is not adjusted for the extract types used. Equally, systematic pharmacovigilance is difficult to implement in the absence of a regulatory framework.

Clinicians need to be aware that patients may use complementary therapies regardless of the evidence available and should inquire about such forms of self-medication. Pattern of use may vary with cultural background and health beliefs. Given the complex pattern of potential interactions, conventional health care professionals should not be afraid to discuss complementary use with their patients. For instance, complementary medicines should be considered a potential cause when the clinical presentation, the treatment result, adverse effects, or even diagnostic investigations are unusual or unexpected. Equally, patients should be encouraged to disclose information about complementary medicines to health care professionals. On the one hand, discussions need to be conducted sensitively in order to avoid alienating patients who may feel that they have not been taken seriously or have been criticized for using complementary medicines. On the other hand, uncritical encouragement of potentially harmful or inappropriate use of complementary medicines may possibly lead to litigation.(15) In most cases, remedies may not have to be discontinued if conventional treatments are closely monitored and adjusted. A constructive discussion about complementary medicines may potentially be a gateway towards enhancing compliance with conventional treatments.

6.2.10 Non-pharmacological somatic treatments

Contents

6.2.10.1 Electroconvulsive therapy

Max Fink

Introduction

Convulsive therapy (ECT or electroshock) is an effective treatment for those with severe and persistent emotional disorders. It is safe for patients of all ages, for those with debilitating systemic illnesses and during pregnancy. It relieves symptoms in a briefer time than do psychotropic drugs. To achieve remission, treatments are usually given three times a week for two to seven weeks. To sustain recovery, treatments are continued either weekly or biweekly for several months. The overall duration of the treatment course is similar to that of the psychotropic medications frequently used for the same conditions.

The treatment is severely stigmatized and its use is discouraged, even interdicted, in the belief that the electricity or the seizures irreversibly damage the brain.[1–5] Few physicians are tutored in its use and facilities are limited making ECT unavailable to many who would benefit. The ease in the use of psychotropic medications, and neither greater efficacy nor greater safety, encourages their preferential use as ECT is relegated to the 'last resort.' In countries where psychotropic medications are expensive, ECT is prescribed, but the expense for anesthetics limits its use to its unmodified form.

Despite these hurdles of stigma, expense and lack of training, its use has persisted for more than 70 years. Indeed, its use is increasing. Whole societies where it was interdicted at the end of the 20th century, as in the Netherlands, Germany, Austria, Italy, and Japan, interest and usage has increased, texts have been written or translated, and local psychiatric societies formed to encourage its use.[4–6]

Origins

At the turn of the century when malarial fevers were used to treat patients with neurosyphilis, it was deemed possible to treat one illness by developing another. Reports that patients with dementia praecox were relieved of their psychosis after suffering convulsions supported a concept of an antagonism between epilepsy and psychosis. An explanation was seen in the reports that the concentrations of brain glial cells in patients with dementia praecox were low and in those with epilepsy were high.[7] Was it possible that the root of schizophrenia lay in the paucity of glia and would their increase relieve the illness?

After testing ways to induce a grand mal seizure in animals, Ladislas Meduna, a Hungarian neuropathologist and psychiatrist, on January 24, 1934, injected camphor-in-oil into a man with the catatonic form of schizophrenia. The patient seized and recovered without incident. Following the model of malarial fever therapy, Meduna repeated the injections every three days, and after the fifth seizure, the patient, for the first time in four years, talked spontaneously and fed and cared for himself. After three additional treatments he was discharged home, returned to work, and was well when Meduna left Hungary in 1939.[7]

Chemically induced seizures, either with camphor or pentylenetetrazol (Metrazol), were rapidly adopted worldwide as the treatment for dementia praecox, but the treatments were painful and

frightening, so alternative means were sought. In 1938, the Roman psychiatrists Ugo Cerletti and Luigi Bini demonstrated the ease of administration and the efficiency of electrically induced seizures. Quickly, 'electroconvulsive therapy' (ECT, electroshock) became the commonest method of inducing seizures and is the standard induction today.[4–5,8]

For whom is ECT effective?

Established DSM diagnoses are usually cited as the indications for ECT. The diagnoses are imprecise, however, offering heterogeneous population samples. A syndromic view offers more homogeneous populations for treatment.[9–11]

Defined by DSM Classification. The DSM defined conditions for which ECT is prescribed are cited in established texts[12–15] (Table 6.2.10.1.1). The breadth of its clinical efficacy across major DSM diagnostic classes is striking, reflecting commonalities in the pathophysiology of different disorders. This experience challenges the concept that DSM classified disorders are distinct biological abnormalities, and supports the 19th century concept of a unitary psychosis.[16]

ECT is ***not*** useful for a patient with neurosis, situational maladjustment, personality disorder (character pathology), or drug dependence. It is of limited benefit for anyone with a lifelong history of mental and emotional dysfunction, unless the onset of the present illness is acute and well defined, or affective, psychotic, or catatonic features dominate the presentation[12–15] (Table 6.2.10.1.2).

Defined by syndrome. DSM-III and DSM-IV classify illnesses based on the check-off of symptoms modified by duration criteria. The DSM criteria identify heterogeneous populations that do not support useful treatment algorithms or the search for biological roots of the illnesses. Clinical syndromes describe more homogeneous populations, often substantiated by biological tests and/or a high specificity of interventions. Melancholia, psychotic depression, catatonia, delirious mania, and acute schizophrenia are syndromes that are particularly responsive to ECT (Table 6.2.10.1.3). These syndromes are not readily identified in the established classification systems. Summary descriptions are offered here; the interested reader will find more extensive descriptions in the cited literature.

(a) Depressive mood disorders

Convulsive therapy is most effective against mood disorders, depression and mania. Depressive mood disorders are dominated by sadness, hopelessness, fears, and thoughts that life is no longer worth-living. Variants are recognized, dominated by vegetative and motor abnormality (melancholia), by delusions (psychotic depression), by severe cognitive deficit (pseudodementia), or by catatonia.[14]

While all variants respond to induced seizures, some also respond to other specific treatments. Melancholic and pseudodementia patients respond to tricyclic antidepressants. Psychotic depressed patients require high doses of both antidepressant and antipsychotic medications.[11] Anticonvulsant sedative drugs, the barbiturates and the benzodiazepines, are useful in catatonic patients.[9]

(i) Melancholia

Motor signs (retardation or agitation) and vegetative symptoms of inability to sleep, feeding, and weight loss are its features. Work, sex, and family are disregarded. Thoughts of suicide are prominent.[10–11]

** specifier for psychosis

Hypercortisolemia is characteristic of the syndrome.[17] Cortisol metabolism is influenced by hypothalamic, pituitary, and adrenal interactions. Melancholic patients exhibit elevated serum levels of cortisol, obtunded diurnal rhythmicity, and serum levels remain elevated despite an administered dose of dexamethasone. The abnormality is measurable by the dexamethasone suppression test (DST) or its variant, the dexamethasone/corticotrophin releasing factor test (Dex/CRH). Elevated cortisol levels normalize with treatment and become abnormal again with relapse. In the 1980s, the specificity of the DST was considered poor for the major depressions defined by DSM-III and the test was discarded. But the re-assessment of the literature and recent reports find the test as

both sensitive and specific for melancholic depression, where it has a positive predictive value.[11,18]

After an extensive review of the literature, Taylor and Fink (2006) concluded that classifying mood disorder patients as either melancholic or non-melancholic offered more homogeneous populations with better outcomes with TCAs and ECT than did the DSM classification of major depression and bipolar disorder.[11] In their formulation, melancholia is a syndrome of depressive mood, with motor and vegetative abnormalities and with evidence of cortisol abnormality.

(ii) Delusional (psychotic) depression

Overwhelmed by feelings of helplessness, hopelessness, and worthlessness, the patient believes others are watching or talking about him, reporting voices when no one is present. He imagines that events depicted on a television or movie screen apply directly to him. This form is labelled psychotic depression and is remarkably responsive to ECT.

In 1975, Glassman and his associates at Columbia University reported that only three of 13 delusional depressed patients (23 per cent) improved when they were treated with high doses of imipramine, while 14 of 21 non-delusional patients (66 per cent) improved under the same treatment.[18] Nine of the 10 unimproved delusional patients responded well to ECT. These findings have been repeatedly verified.[11,12]

In a study of 437 depressed hospitalized patients treated with imipramine in doses of 200 to 350 mg/day for 25 days or longer, 247 (57 per cent) were evaluated as recovered and were discharged.[19] When the 190 unimproved patients were treated with bilateral ECT, 156 (72 per cent) were recovered. Most of the depressed patients who had not improved with imipramine were delusional as well as depressed.

Only a third of delusional depressed patients recover when treated with antidepressant drugs alone and half recover with antipsychotic drugs alone.[11, 19–20] Two-thirds of those treated with ECT or with high doses of both antidepressant and antipsychotic drugs regain their health.

In a two-year study of late-life depression, 47 per cent of the delusional depressed patients treated with medication relapsed earlier and more often than the nondelusional depressed (15 per cent), indicating that delusional depression is particularly resistant to medication.[21] It is, however, so amenable to ECT that it is considered a primary indication for its use.[11–14] But the condition is difficult to diagnose making inadequate treatment common. In a three-hospital research study of ECT and continuation medications, only 2 of 52 delusional depressed patients had adequate courses of medication treatment before they were referred for ECT.[22] The same failure was found in another multi-center study with only 5 of 106 patients failing adequate courses of treatment before referral to ECT.[23]

Many reviews find psychotic depression to have a more severe pathophysiology and just using the same treatments as for non-psychotic depression, even at much higher doses is not adequate.[11,12] Yet, bilateral ECT is remarkably effective. In a multi-site collaborative ECT study, of 253 patients with unipolar major depression, 77 were psychotic depressed. Their remission rate was 95 per cent compared to 83 per cent for the non-psychotic depressed, with the speed of response faster for the psychotic depressed patients.[24, 25]

(iii) Pseudodementia (reversible dementia)

Because the depressed patient ignores daily events, little of what happens to him is registered and memory is compromised. The condition is hardly distinguishable from Alzheimer's dementia. The onset is usually more rapid and severe compared to the onset of a structural dementia, and patients often report a history of prior depressive episodes.[11,14]

Because the syndrome is not well known, patients are often sent to nursing home care. An example of a 58-year old woman who developed a reversible dementia and was not adequately treated for eight years is reported. Once the diagnosis was considered, antidepressant treatment relieved the syndrome and returned the patient to a more normal family life.[14]

(iv) Catatonia

When the patient is mute, sitting rigidly in a chair or lying motionless on his bed, and unresponsive to questions and commands, he appears as in a stupor. The state is called *catatonia* or *depressive stupor*. Catatonia is seen among patients with many DSM diagnoses.[9] It is discussed in detail below.

(b) Manic mood disorders

A mood disorder dominated by grandiosity, expansiveness, feelings of increased power and energy, and excitement, can last for hours, days, weeks, or months. Even after it is relieved, it may recur or alternate or combine with episodes of depression. When the switches occur within one or a few days, the experience is labelled *rapid cycling*, a malignant form of the illness. *Bipolar disorder* is the label applied to both mania and mixed forms of the illness.[11,26]

Disturbances in eating and sleeping, thinking, memory, and movement are features of mania. The patient does not sleep, eats poorly, loses weight, and concentrates thoughts poorly. Memory is impaired, often severely; he may be so disorganized as to appear demented and delirious. Melancholia, psychosis, pseudodementia, and catatonia variations are commonly seen.

Delirious mania is a striking form of mania. A normal person suddenly becomes excited, restless, and sleeps poorly, fears that neighbors are watching him, and is easily frightened. He may hide in the house or leave it abruptly, dressed inappropriately, sometimes naked, and wander about the streets. His hallucinations are vivid, his thoughts disorganized. Confusion alternates with mutism, posturing, rigidity, and stereotyped repetitive movements. Physical exhaustion even to the point of death occurs.[11,27]

Before ECT, patients were sedated with opiates, bromides, or chloral and many died of poor care, inanition, and pneumonia. A 1994 summary of the reports of manic patients treated with ECT finds 371/562 (66 per cent) remitted or showed marked clinical improvement.[28] The introduction of chlorpromazine and other sedative drugs quickly replaced ECT for efficacy and ease of use. But when chlorpromazine and other antipsychotic drugs were used in place of ECT, the doses often carried the risks of sudden death and neuroleptic malignant syndrome, as well as tardive dyskinesia and tardive dystonia.[9]

Anticonvulsant drugs are now preferentially recommended, even though the evidence for their efficacy is poor. Many authors encourage the use of lithium for immediate relief and for prophylaxis. In 438 manic patients treated with ECT or lithium, 78 per cent of the ECT treated group showed marked improvement compared to 62 per cent of those treated with adequate doses of lithium and 56 per cent of those treated with inadequate doses.[29] The group receiving neither ECT nor lithium fared least favourably with only 37 per cent improved.

No matter the array of medications and polypharmacy for mania, ECT is an effective alternative.

(c) Catatonia

Muscular rigidity, posturing, negativism, mutism, echolalia, echopraxia, and stereotyped mannerisms, the signs of catatonia, appear suddenly and immobilize patients.[9] When the disorder is transient, it may be disregarded, but when it persists, it threatens life. Patients undergo forced feeding and develop bedsores, muscular atrophy and pulmonary embolization. Repeated bladder catheterizations induce infections.

Catatonia is recognized in patients with affective illnesses, both depression and mania, in patients with systemic disorders, and in those with toxic brain states caused by hallucinogenic drugs. For decades, the prevailing belief was that each instance of catatonia represented schizophrenia. The major classification systems in psychiatry — DSM-III and IIIR of the American Psychiatric Association and the International Classification of Diseases (ICD-IX, ICD-X) — assigned patients with catatonia to the diagnosis of schizophrenia, catatonic type. Few patients were treated with anticonvulsant sedatives or ECT, despite their known efficacy, because neither was recommended for schizophrenia. This short-sighted view was somewhat corrected in the 1994 classification system of the American Psychiatric Association (DSM-IV), which recognized catatonia as secondary to systemic illness in the class of "*Catatonic disorder due to . . . . (Indicate the General Medical Condition)* [293.89]".[30] The experience that catatonia is not limited to patients with "schizophrenia" has led to the call for a separate category in DSM-V.[9,31]

Catatonia is defined by the persistence of two or more characteristic motor signs for more than 24 h in a patient with a mental disorder.[9,31] Posturing and staring can be observed, but most signs require elicitation in the examination. The accepted motor signs and a formal examination are cited in catatonia rating scales.[9] An intravenous challenge of lorazepam or amobarbital verifies the diagnosis in more than 2/3 patients with catatonia, and a positive test response augurs well for high dose benzodiazepine therapy. When this treatment fails, ECT is effective, although the treatment schedule may require daily treatments.

Catatonia may be transitory or may persist for months or years. It appears in many guises.[9,32] Prominent examples are *malignant (pernicious) catatonia* (MC) with a high risk of death and the *neuroleptic malignant syndrome* (NMS) that follows on the administration of neuroleptic drugs.

(i) Malignant catatonia

Descriptions of patients who develop an acute febrile delirium with excitement or stupor dot the literature. They often exhibit signs of catatonia. Vegetative dysregulation is often severe and death was a frequent feature before the introduction of ECT. Descriptions by Bell (1849), Stauder (1934), and Bond (1950) highlight the lethal nature of the syndrome. In 1952, Arnold and Stepan described patients in whom ECT rapidly relieved malignant catatonia, but to avoid mortality it had to be used within the first five days.[9]

(ii) Neuroleptic malignant syndrome (NMS)

A toxic response to neuroleptic drugs evinced by fever, motor rigidity, negativism, mutism, and cardiovascular and respiratory instability is a toxic response to neuroleptic drugs. It is indistinguishable from malignant catatonia.[9,32] It is an MC variant as the diagnostic criteria and effective treatments are the same as for MC. MC occurs with almost all neuroleptics, most commonly with the high-potency agents like haloperidol, fluphenazine, and thiothixene, but also with atypical neuroleptics.

One hypothesis explains the syndrome as a consequence of an excessive reduction in the amount of brain dopamine. Those who believe this association prescribe the dopamine agonists bromocriptine or levodopa and relieve muscular rigidity by prescribing the muscle relaxant dantrolene. Neither of these treatments has proved effective and dantrolene use is associated with considerable toxicity.[33] These are best not used and patients are best treated with sedative anticonvulsants and ECT.

(iii) Toxic serotonin syndrome (TSS)

A toxic syndrome is occasionally described in association with the SSRI antidepressant drugs. TSS is similar to MC with prominent gastrointestinal symptoms. The diagnosis and treatment follows the protocol for MC.[9]

(d) Psychosis

A severe impairment of thought characterized by delusions is a feature of many psychiatric conditions, notably manic delirium, psychotic depression, post partum depression, and toxic psychosis. It is broadly defined as a psychosis and diagnosed within the major class of psychoses as schizophrenia. In this class ECT is hardly considered. But when we consider the efficacy of ECT in the psychotic variants of the mood disorders, we appreciate that ECT is an effective treatment of psychosis.[34]

Convulsive therapy was introduced for the treatment of dementia praecox and was widely and quickly adopted. Comparisons with chlorpromazine found both treatments effective in acute and severe short-term illnesses, but neither was useful in chronic states. Chlorpromazine was favoured since its cost is considerably less and

its image better. As more patients failed to respond to medications, however, a cadre of 'medication resistant' psychotic patients developed. Families asked whether anything else could be done to better the patients' lives. Friedel (1986) augmented a failed course of thiothixene therapy with ECT, returning each of nine patients to community life. The finding was replicated in the successful augmentation in 8/9 psychotic patients.[34]

Clozapine was described as a treatment for psychotic patients who had failed to respond to two different antipsychotics. As the experience with this treatment grew, clinicians were again faced with treatment failures and ECT augmentation was tried. A synergy for ECT and clozapine was described and offers an effective treatment for patients who have failed conventional antipsychotics and clozapine.[34]

It is reasonable to consider ECT in the treatment of psychosis, whether in an affective illness or in schizophrenia. For the affective illnesses, ECT is used alone. In schizophrenia, ECT is effective alone or in augmenting neuroleptics.[34]

(e) Delirium

Acutely ill psychotic patients often exhibit disturbances in consciousness and are confused. Delirium is common in toxic states, either drug induced (alcohol being the most common), or secondary to drug withdrawal, or associated with systemic illnesses. Delirium is a feature of acute manic states (e.g. delirious mania) and the confusional state described as oneirophrenia. With few resources to treat acute psychoses, ECT was applied with favourable results.[14,35] The relief of delirium by ECT is an unrecognized effect that warrants consideration as an alternative to the risks of high potency neuroleptic drugs inducing NMS (MC).

(f) Neurological syndromes

ECT is well appreciated in catatonia, but it is also useful in status epilepticus (SE), non-convulsive status epilepticus (NCSE), and Parkinsonism.

(i) Status epilepticus

SE and NCSE are emergency conditions with high mortality rates. The pathophysiology is the persistence of seizures as biochemical inhibitory mechanisms fail to terminate a seizure.[36] Despite ever larger doses of anticonvulsant medications, proceeding from lorazepam to phenytoin, phenobarbital, and general anesthesia with midazolam, propofol, or barbiturates, patients persist in SE and NCSE.

ECT is another effective intervention. During the course of electroconvulsive therapy, the seizure threshold rises, encouraging seizure termination. The first report of the relief of intractable epilepsy by ECT in 1943 has been sporadically verified.[37]

An explanation for this application is physiologically interesting. The strength of a seizure can be judged by the immediate rise in serum prolactin after a sustained epileptic seizure. Within the hour after a seizure, the level of serum prolactin indicates whether the seizure is a cerebral grand mal event or a pseudoseizure. Serum prolactin levels do not rise in SE but remain normal. This suggests that the SE seizures are partial or incomplete and that they fail to stimulate an inhibitory termination process. But even in patients in SE, ECT elicits maximal seizures, making it a reasonable alternative to general anesthesia as a treatment for intractable seizures.

(ii) Parkinsonism

In treating older depressed patients with concurrent Parkinsonism with ECT, motor and facial rigidity were also relieved. In Parkinsonism, brain dopamine levels are reduced, making dopamine agonists effective treatments. In ECT, brain and CSF levels of dopamine increase. Experiments in Parkinsonian patients without mood disorder found motor rigidity to be relieved.[38] For those patients who are not relieved by conventional treatments, periodic ECT has been helpful. Continuation treatments, like continuation pharmacotherapy, are necessary to sustain the benefit.

(g) Suicide

All psychiatric disorders carry the risk of suicide. ECT reduces this drive. The impact of medications on suicide risk is not well defined but compared to ECT, the efficacy is less favourable.[6,11] Comparisons of ECT and TCAs across different treatment eras find the frequency of suicides decreased in the ECT era. A study of the psychiatric status of 519 patients six months after discharge from hospital treatment for depression found 0.8 per cent of the ECT treated patients had made a subsequent suicide attempt compared to 4.2 per cent for those rated as receiving adequate and 7 per cent of those receiving inadequate courses of antidepressant drugs. At the 6-month follow-up no suicides were reported in 34 women treated with ECT, but two suicides occurred in the 84 patients treated with antidepressants (2.4 per cent).[39]

In a study of the expressed suicide intent (changes in Item 3 of the HAMD rating scale) in 148 patients treated with ECT, the baseline average score was 1.8. It reduced to 0.1 in 72 responders and to 0.9 in 76 non-responders. For the total sample, there was a greater decrease in the suicide item scores than in the overall HAMD scores.[40]

In another study of 444 patients referred for ECT, 131 had high expressed suicide intent scores.[6] The scores dropped to zero in 106 (80.9 per cent) with treatment, occurring in 38.2 per cent (50/131) after 3 ECT (one week), in 61.1 per cent (80/131) after 6 ECT (two weeks); and in 76.3 per cent (100/131) after nine ECT (three weeks).

ECT's effect on the death rate in the mentally ill, particularly those with mood disorders, must be a major consideration in treatment recommendations.

Principles of treatment

When to consider ECT? Psychotropic drugs and psychotherapy are the first treatments of the psychiatrically ill, with referral to ECT when these treatments fail. Since ECT is effective in medication treatment failures, would it not be wise to spare patients a prolonged illness and risks of suicide by offering ECT as the initial treatment? ECT is indeed considered the first treatment when there is a need for a rapid, definitive response, as in suicidal patients who require constant observation and restraint, in hyperactive patients who may be at risk of harm to themselves or others, in those with malignant disorders as malignant catatonia, neuroleptic malignant syndrome, or delirious mania, or in those whose lives are in jeopardy from systemic illness. It is also preferred in those patients who have had a prior illness that responded well to ECT or who have had a poor experience with medications.[11–15]

How many failed trials of medications are reasonable before ECT is considered? For some patients, especially those whose practitioners are not knowledgeable about ECT, medication trials

become interminable and ECT is considered only when the patient seeks care elsewhere. A reasonable guideline is derived from the experimental trials with clozapine, an agent with life-threatening risks.[41] To put patients at risk and yet obtain the possible benefits of clozapine, the researchers decided that patients should not be offered clozapine unless they had experienced two unsuccessful courses of neuroleptic treatment. A similar standard seems reasonable for recommending ECT. After patients have failed two different courses of medications at adequate doses and for adequate periods, ECT is to be considered.

Financial considerations affect the decision. If the patient is severely ill and has only a limited ability to pay for extended care, repeated unsuccessful medication trials are unwarranted. All practitioners should balance the cost of medication trials and the effective use of ECT.

Consideration of age. ECT is an accepted treatment for adults. For decades, the attitudes of child and adolescent psychiatrists precluded consideration of ECT for their patients except the most devastatingly ill. The acknowledged safety of ECT in adults relaxed prejudices against its use and led to more treatment trials. Once it became clear that the response of adolescents was similar to that of adults, the attitude changed and ECT is now an accepted treatment for adolescents with the same illnesses that are successfully treated in adults.[42]

ECT is probably effective in similar conditions in children, but their expression of mood and psychotic disorders is different than in adults and difficult to interpret. The published experience in the few children treated with ECT finds that conditions that respond in adults and adolescents also respond in children.

ECT is widely used in geriatric patients. Indeed, it is increasingly called on when the side effects of medications become intolerable and when medication trials fail. The safety of modern ECT is such that even the frailest and systemically ill elderly can be safely treated with ECT. We acknowledge no absolute contraindication to ECT other than the lack of skill of the clinicians.[11–15]

The treatment process

Consent. The referral of a patient to an ECT service starts the treatment process. As in surgical treatment, the patient and family members are educated as to the risks and processes of the treatment course, and a signed voluntary consent, witnessed by a family member if possible, is obtained. In response to the turmoil of the 1970s when a draft for an unwelcome war led to widespread questioning of authority, attacks on ECT as a forced involuntary treatment led the profession to suggest procedures for informed voluntary consent. These procedures are well established.[1,2,4,12]

An explanation of why the treatment is recommended, specific anticipated benefits and risks, the names of the responsible physicians, and a statement that the patient may, at any time, discontinue the treatment are elements of a valid consent.[4,13,14] Although voluntary consent is the basis for ECT in almost all Western countries, provisions for involuntary treatment for patients who may not be able to understand the severity of their illness nor the need for treatment is provided in state laws with courts authorizing treatment. In a few venues, surrogate consent by family members is accepted. Educational videotapes and books for laymen support the consent process.[4,12,43]

Procedures. Treatments are usually given in an equipped room with access to the in-patient wards. Increasingly, as more than half the treatments are given to out-patients, units are established with ready access to the community.[12,13]

Prior to treatment, systemic medical examinations usually advised for general anaesthesia are completed. These include complete blood count, electrocardiogram, and urinalysis. If systemic illness is present, the treatment is optimized. Often, an anaesthesiologist will examine the patient and the record before treatment, obtaining a separate anaesthesia consent. Although no medical examinations relative to the ECT process are required, some centers unnecessarily insist on pre-treatment brain scans and EEG for all patients.

Anaesthesia. When curare and succinylcholine were introduced to modify the convulsion, patients thought they were suffocating as respiratory muscles relaxed. Momentary amnesia was provided by a barbiturate and the combination of barbiturate-induced amnesia and succinylcholine muscle relaxation became standard procedure.[8,12] When psychiatric practice changed from an office to a hospital venue, and anaesthesiologists administered medications, misunderstanding of the role of anaesthesia ensued and the benefits of treatments were reduced by high anaesthetic doses that made effective seizures difficult. Present practice is detailed in anaesthesiology texts.[44]

Monitoring and electrode placement. To monitor the physiologic effects of induced seizures, EEG and ECG electrodes are applied. To monitor the motor seizure, a blood pressure cuff is usually applied to the calf of one leg, inflated before the administration of a motor relaxant to observe the motor seizure duration. Two stimulating electrodes are required for ECT. In the early years, the electrodes were applied to both temples, with the maximum energies passing through the intervening brain tissues, especially the centrencephalic structures of the hypothalamus and pituitary. Relocating the electrodes on one side of the head to avoid stimulating the dominant temporal lobe led to seizures with less immediate impact on cognition. 'Right unilateral ECT' (RUL-ECT) became popular until clinicians realized that the efficacy of such treatments was significantly less than through bilateral electrodes (BL-ECT).[8,12]

At one time we believed that any seizure was therapeutic, but we now know that this is not so. A seizure with EEG or motor durations under 20 sec rarely develops a full grand mal convulsion. At first, effective treatments were characterized as those with a motor seizure of at least 25 sec. But not all seizures of such length are effective. Seizures induced through unilateral electrodes at near-threshold energies (experimentally identified as 1.5 and 2.5 times the calibrated seizure threshold) are not as effective as seizures induced through bilateral electrode placements.[45] Energies for seizure inductions in unilateral ECT must be at least 6 to 8 times the calibrated seizure threshold to achieve equal efficacy; at such high energies the advantage in minimizing immediate memory effects is lost.[46] As there is a linear relationship between age and seizure threshold, the energy levels with modern devices that deliver brief pulse electrical currents for BL-ECT is estimated by the half-age formula.[47] In devices that deliver 500 mC of energy at 100 per cent, the energy level for the first induction is set at half the patient's age. The quality and duration of the EEG seizure are a guide to later induction energies. In present clinical practice, electrodes are applied to both temples (BT-ECT) or over the outer canthus of each eye in 'bifrontal' (BF-ECT) placement. While the

advantages of BF-ECT and BT-ECT are being assessed in large studies, their efficacy seems equivalent. There is little justification for the use of RUL-ECT in clinical practice.

We now rely on the ictal EEG to define an effective treatment, and modern ECT devices record either one or two channels of brain electrical activity. The typical ictal EEG presents a build-up of energies, then high-voltage spike activity mixed with high-voltage slow waves (3–6 Hz), followed by trains of lesser voltage slow waves, and an abrupt end to the electrical activity with electrical silence. Such EEG patterns, generally of 35–130 sec in duration, are associated with motor seizures that are 10–20 per cent shorter. If seizures do not show these well-defined phases, we repeat the treatment at different energy settings until a robust EEG sequence is elicited.[11–15]

A rise in the post-ictal serum prolactin is another index of seizure adequacy. Grand mal seizures release brain peptides into the CSF and blood. Serum prolactin, easily measured, rises rapidly reaching a peak at about 25–30 min, and falls to a baseline level within 2 h. The absence of a dramatic rise in serum prolactin is a sign of inadequate treatment.[48]

The ECT course. Occasionally a single treatment relieves a disorder, but such instances are so rare as to be noteworthy. The basic course is more often between 6 and 20 treatments. These are usually given three times a week at the onset and, after the symptoms show some relief, are reduced to twice or once a week. The resolution of catatonia (MC, NMS) is frequently accomplished in three to five treatments but these are best administered daily. Depressive disorders require 6–12 treatments for resolution. Manic and psychotic disorders require 20 or more treatments.

Discontinuing treatment at the point of immediate resolution of symptoms is associated with high relapse rates. Continuation treatment, often continuation ECT, is as essential a part of ECT management as it is for pharmacotherapy.[49,50]

Continuation treatments. High relapse rates are the most common complaint in ECT practice. When patients are given a short course of treatments, early relapse is common. Because ECT is complex, frightening, and expensive, patients seek the shortest course of treatment, and physicians accede by prescribing a limited number of treatments on referral or at the time the patient signs the consent.[4]

Short courses of treatments may relieve symptoms but relapse is quick.[49,50] Continuation treatment is necessary. Two recent studies guide present practice. In a 3-hospital collaborative study of depressed patients referred for ECT, remitted patients were randomly assigned to 6-month courses of medication. Relapse rates were 84 per cent for placebo, 60 per cent for nortriptyline and 39 per cent for the combination of lithium and nortriptyline under serum level control.[50] In the 4-hospital collaborative study, depressed patients treated with bitemporal ECT were randomly assigned to continuation with ECT or the same lithium and nortriptyline combination. The 6-month relapse rates were 32 per cent for continuation medication and 37 per cent for continuation ECT.[49] These rates are statistically indistinguishable in the two studies.

ECT and psychotropic drugs.[12, 51] With the exception of antipsychotics, we lack evidence of synergy between psychotropic drugs and ECT.[11,12,14] TCA, MAOI, and SSRI antidepressants are usually discontinued during an ECT course. Anticonvulsants and sedative drugs affect seizure thresholds and may interfere with efficacy. ECT augmentation of antipsychotics is seen as safe and effective.

When ECT is administered to a patient with clinically effective serum lithium levels, generally seen as 0.8–1.2 mEq/l, there is the risk of a post-seizure delirium. If lithium treatment is sustained during ECT, the dosages are reduced so that the serum lithium levels do not rise above 0.6 mEq/l on treatment days.

Systemic drugs, especially those used to treat cardiovascular disorders, may put the patient at risk for hypotension, ataxia, or exaggerated cognitive deficits, but these effects can be easily managed, so they are usually continued during ECT.

Inducing adequate seizures in patients who have been receiving benzodiazepines may be difficult. Intravenous flumazenil, the benzodiazepine antagonist, effectively minimizes the inhibiting effects of benzodiazepines. Such use is encouraged for patients with catatonia or mania who have been treated with benzodiazepines.[9]

Risks and contraindications

Bone fractures, tardive seizures, and cardiac arrhythmias were common risks of early ECT, but the routine use of muscle relaxation with succinylcholine markedly reduced them.[8,12] Headache, tongue injury, and post-seizure delirium continue to be systemic risks. Headaches respond to analgesics, delirium to benzodiazepines, and tongue injury can be prevented by the proper application of bite-blocs. The principal risks of ECT today are cognitive effects and unacceptable relapse rates.

In a post-seizure delirium, which occurs in about 10 per cent of the treatments, the patient is poorly aware of where he is and may thrash about and be confused. It is more common in the first and second treatments than in later ones. Reassurance, calm talk, and gentle handling of movements that might be harmful can usually allay such states. If the restlessness does pose risks, it can be calmed by intravenous diazepam.

Persistent amnesia is the most dreaded risk of ECT.[12–15] Patients usually forget the personal events that occurred during the illness and treatment. On treatment days, both the anesthesia and the seizure alter cognition, temporarily interfering with the memory of events. In the first decades of ECT use, adequate ventilation was not assured and untoward effects on cognition were profound and frequent. But changes in practice have reduced these effects. Ventilation with pure oxygen, changes in the type of electrical current and the amounts of energy, and selected electrode placement reduced the effects on cognition, so that within a few weeks after the course is over, the patients' performance on memory tests usually surpasses their pre-treatment abilities.

Contraindications. There are no systemic illnesses that preclude the administration of ECT when the treatment is clearly warranted. Some conditions — severe hypertension, uncontrolled cardiac arrhythmia, bleeding tendencies, recent myocardial infarction, increased intracranial pressure, and a brain or cerebrovascular lesion — call for special care. The case literature offers suggestions for the appropriate treatment with ECT of patients with these conditions.[12–15]

Mechanism of action

When convulsive therapy was introduced, its most prominent side effect was amnesia, and much debate centered on whether amnesia

was, in fact, the mechanism for improving thought and mood. Experiments with different electrode placements discouraged this explanation.[4,12]

Others focused on the physiologic effects of seizures, especially the changes in the interseizure EEG. Such changes were found to be necessary, but not sufficient, for recovery.[8,52] Interest in this hypothesis is revived by recent studies.[53]

Explanations based on neurohumours and their receptors are important in our present views of the action of drug therapies. These are also cited to explain the benefits of ECT. The experimental data fail to support these explanations.[8,12,54]

Meduna thought that the concentration of glia was a factor in illness and that seizures elicited increased gliosis and recovery.[6] Recent reports cite increased neurogenesis as an active brain response to induced seizures.[55]

My view is that the neuroendocrine system is the most likely agent for the clinical changes brought about by induced seizures.[8,56] Neuroendocrine dysregulation is prominent in patients with the mental disorders for which ECT is effective. Thyroid, adrenal, sex gland, and hypothalamic dysfunction are common in patients with disorders in mood, thought, motor activity, feeding, sleep, sex, growth, and maturation. Indeed, every aspect of body physiology and mental activity is affected by these glands, as exemplified by the action of the adrenal glands in depressive mood disorders.

In the severely depressed patients, the adrenal glands produce too much cortisol.[17, 18, 56] The high blood levels disrupt the normal diurnal rhythms of other glandular discharges, and the glands do not respond to the usual feedback mechanisms. The most prominent features of depression — failure to eat, loss of weight, inability to sleep, loss of interest in sex, inability to concentrate thoughts, and difficulties in memory — are distortions of the functions regulated by the neuroendocrine glands in a self-adjusting feedback.

Each seizure stimulates the hypothalamus to discharge its hormones, which causes the pituitary gland to discharge its products, which then affects the level of cortisol. The first effects of this cascade are transitory, but repeated seizures restore the normal interactions of the hypothalamic-pituitary-adrenal axis. Feeding and sleep become normal, followed by motor activity, mood, memory, and thought.

How does a seizure elicit such profound changes in physiology? In ECT, the currents from the stimulating electrodes on each temple pass through the central parts of the brain, stimulating both the hypothalamus to discharge its hormones and the centrencephalic structures to produce a bilateral grand mal seizure. (One of the flaws in unilateral electrode placement is that the currents have to take indirect routes to affect the pertinent areas of the brain.) The massive amounts of hypothalamic and pituitary hormones that enter the bloodstream during ECT are measurable within a few minutes. They circulate throughout the body, affecting all the body's cells — a compelling and welcome sign of recovery.

After some courses of ECT, the return to normal endocrine function persists. At other times, the glands revert to their abnormal activities and the mental disorder becomes evident again. In these cases, repeated stimulation of the hypothalamus and the pituitary by continuation ECT restore and sustain normal glandular functions and support a normal mental state.

Suggested replacements for ECT

Although Meduna's experiments and numerous studies of ECT and sham ECT support the seizure as evidence of the brain changes essential to a therapeutic benefit, the introduction of electricity focussed attention away from the seizure and onto electricity as the medium for the treatment's efficacy. This interest is not new. Soon after Galvani and Volta demonstrated that electric currents could stimulate nerves and muscles, medical applications were enthusiastically sought. The first electrical experiments in the mentally ill are ascribed to Gale in New York State in 1802 and Aldini in Italy in 1803.[3,16,54] Electrical experiments were publicly demonstrated by Franklin, Mesmer, and Marat in the first years of the 19th century. Little benefit was recorded and most efforts are best considered quaint explorations.[3] At the time of World War I, faradization was a treatment for hysteria and applied in the military.[57]

During the second half of the 20th century, many techniques have been suggested as replacements for ECT, the latest being transcranial magnetic stimulation (rTMS), vagus nerve stimulation (VNS), and deep brain stimulation (DBS).[58] In rTMS rapidly alternating magnetic fields are delivered to stimulate the brain. At very high intensities, a seizure may be induced and some experiments have been undertaken to compare the seizure induced by magnetic currents with those induced by electric currents. The technique, called magnetic seizure therapy (MST), is reported to have a mild antidepressant effect.[58]

In VNS an electrical stimulator is implanted in the chest wall and electrodes are threaded through the neck to the left vagus nerve. The stimulator is similar to that used to reduce seizures in patients with severe epilepsy. The side effects of hoarseness, nausea, and vomiting are common. In DBS, the stimulating electrodes are placed in the brain, a technique occasionally used in severe Parkinsonism. We lack sufficient evidence for the efficacy of rTMS, VNS and DBS in psychiatric disorders to warrant their routine clinical use.

Device manufacturers who seek a market for their products encourage the technologies. The bad image and the stigma of ECT make its replacement the basis for exploration. At the time of this writing (Spring, 2007), no evidence has been published that any of these techniques have persistent therapeutic effects, and none are replacements for ECT.

The future in ECT

Induced seizures effectively allay severe psychiatric disorders. The treatment's stigma, however, inhibits its use and research into its mechanism. When neuroscientists recognize the unique nature of the seizure — a phenomenon that is ubiquitous in animal life — and seek to understand its biology, they will then seek ways to replace the gross process of induced seizures by more acceptable interventions. Understanding the mechanism will clarify the aetiology of psychiatric disorders. ECT will be replaced when we understand its mechanism better; for the present, continued usage is assured since no alternative intervention with its efficacy and safety is in our *materia medica*.

6.2.10.2 Phototherapy

Philip J. Cowen

Introduction

Phototherapy or artificial bright-light treatment, has been used in the management of a number of medical disorders including psoriasis and hyperbilirubinaemia of the newborn. From the point of view of psychiatric treatment, the notion that light might help people with certain psychological symptoms has an ancient lineage. For example, Wehr and Rosenthal[1] cite Aretaeus who suggested in the second century AD that 'lethargics are to be laid in the light and exposed to the rays of the sun (for the disease is gloom)'. In 1898, a ship's physician named Frederick Cook recorded that the 'languor' which affected members of an Antarctic expedition during the winter darkness could be relieved with bright artificial light.[1]

The first systematic study of phototherapy as a psychiatric treatment was carried out in 1984 by Rosenthal *et al.*[2] who used bright artificial light to treat patients with the newly identified syndrome of seasonal affective disorder. Seasonal affective disorder is a recurrent mood disorder in which patients experience regular episodes of depression in autumn and winter with remission in spring and summer. Since then phototherapy has become the mainstay of the treatment of seasonal affective disorder, particularly in patients with atypical depressive features such as hyperphagia and hypersomnia. Phototherapy has also been used as an investigational treatment in other psychiatric disorders but the evidence for its efficacy in these conditions less established.

Mechanism of action

Light and seasonal and circadian rhythms

Animals and humans show circadian and seasonal rhythms in aspects of their physiology and behaviour that are influenced by environmental cues or *zeitgebers*. The light–dark cycle is believed to be one of the most important *zeitgebers* regulating circadian and seasonal rhythmicity in mammals. Mammalian circadian rhythms are driven by an 'oscillator' in the suprachiasmatic nucleus of the hypothalamus. Environmental light influences the activity of this nucleus via a neuronal pathway which runs from the retina to the hypothalamus. Thus appropriately timed bright light is able to advance or delay endogenous circadian rhythms.[3]

Lewy *et al.*[4] suggested that in patients with seasonal affective disorder the delayed onset of dawn in the autumn causes endogenous circadian rhythms to become phase-delayed with respect to clock time and the sleep–wake cycle. Bright-light treatment is able to correct this abnormality by phase advancing circadian rhythms, thereby re-synchronizing them with the sleep–wake cycle. This proposal is supported by the fact that controlled trials show that in most patients morning phototherapy is more effective than evening phototherapy.[5] While this hypothesis gives a good account of how bright-light treatment might ameliorate the symptoms of seasonal affective disorder, its possible efficacy in other conditions such as non-seasonal depression is difficult to explain by this mechanism.

Light treatment and monoamines

It is possible that bright-light treatment, through its interaction with the hypothalamus, could alter the circadian activity of the monoamine neurotransmitters involved in mood regulation. For example, some studies have shown that the antidepressant effects of phototherapy can be reversed by treatments that diminish both catecholamine and serotonin neurotransmission.[6] This has been taken as evidence that the antidepressant effects of bright light are mediated via activation of serotonin and catecholamine pathways. An alternative explanation is that in the absence of concomitant drug treatment, recovered depressed patients are vulnerable to depletion of these neurotransmitters in any case. However, effects of bright light on monoamines could account for the therapeutic effects of light in mood disorders other than winter depression.

Forms of phototherapy

The most common form of phototherapy uses a light box, which contains fluorescent tubes mounted behind a translucent plastic-diffusing screen. Depending on the fluorescent tubes employed, the light emitted is either full spectrum, which contains a little ultraviolet light, or cool white light which has no ultraviolet. The light box usually rests on a table or desk at about the eye level of a seated subject. The output of different light boxes varies but is usually between 2500 and 10 000 lux. Light sources producing 10 000 lux are more expensive but allow a reduced duration of exposure (30 min compared with 120 min) to secure a therapeutic effect.[7]

Phototherapy has also been administered using head-mounted units or light visors. These instruments are attached to the head and project light into the eyes allowing subjects to remain mobile while receiving treatment. While light visors are more convenient to use than light boxes, results from placebo-controlled trials have not been encouraging.[7]

Another form of light therapy involves the use of dawn-simulating alarm clocks. These clocks are programmed to simulate the illumination that would be experienced out of doors during sunrise on a spring day.[8] In practice, the clocks begin a gradual illumination of the bedroom about 2 h before normal wake time, increasing to a maximum of about 250 lux at the point of waking. Overall the effects of dawn-simulation in the treatment of winter depression seem equivalent to those of bright-light treatment[9] and patients often find dawn-simulating clocks more convenient (although a partner sleeping in the same room may not).

Adverse effects

Generally phototherapy is well tolerated although mild side effects occur in up to 45 per cent of patients early in treatment. These include headache, eye strain, blurred vision, eye irritation, and increased tension. Insomnia can occur particularly with late-evening treatment. Rare adverse events that have been reported include manic mood swings and suicide attempts, the latter putatively through light-inducing alerting and energizing effects prior to mood improvement. Whether these rare events are actually adverse reactions to the light is uncertain. There is no evidence that phototherapy employed in recommended treatment schedules causes ocular or retinal damage.

Indications and contraindications to light treatment

Seasonal affective disorder

The best established indication for light treatment is seasonal affective disorder where patients experience autumn and winter depressions. Clinical predictors of a response to light treatment include the following:

- Increased sleep
- Increased appetite and winter weight gain
- Carbohydrate craving
- Afternoon slump in energy
- Complete remission of symptoms in the summer

Several controlled trials have assessed the efficacy of bright-light treatment in the treatment of winter depression. In a meta-analysis of nine randomized studies, Golden *et al.*[9] found a significant benefit of bright light over dim light control with an effect size of 0.84 (95 per cent confidence interval, 0.6–1.08). A similar benefit was apparent for six studies of dawn simulation which had a mean effect size of 0.73 (95 per cent confidence interval, 0.37–1.08). While these data are compelling it needs to be remembered that it is often difficult to arrange a placebo treatment that will match the therapeutic expectation of bright light or dawn simulation.

Other mood disorders

Patients with more typical melancholic symptoms (e.g. weight loss and insomnia) do less well with bright-light treatment, even when the disorder is seasonal in nature. However, bright light has also been used in the treatment of non-seasonal depression both as a sole treatment as an adjunct to more conventional therapy. The evidence for the efficacy of bright light for this indication is less established but a Cochrane review[10] suggested that morning light treatment was significantly better than control treatment when applied as an adjunct to drug treatment or sleep deprivation. Most of these studies were of short-term duration and there are suggestions that the added benefit of light therapy does not persist when treatment stops.[11] In these studies, hypomania was more common in light-treated subjects. Phototherapy may also be of benefit in other conditions characterized by depressed mood and overeating (e.g. premenstrual dysphoria and bulimia nervosa). The literature contains reports of a number of controlled trials in such disorders where light treatment has improved depression ratings. However, the difficulty of distinguishing the specific and placebo effects of bright-light treatment relative to dim light control makes the current data difficult to interpret.

Circadian rhythm disorders

Because bright light is an effective *zeitgeber* for circadian rhythms it may also have a useful place in the treatment of disorders characterized by circadian rhythm disturbances. Such disorders encompass a range of conditions including phase-delayed or phase-advanced sleep disorder, jet lag, and problems related to shift work. In addition, disturbances of the sleep–wake cycle are common in older people with cognitive impairment. There are several reports of the utility of light treatment in these conditions; however, there is a paucity of randomized trial data.[7]

Contraindications

There are no absolute contraindications to phototherapy, except the obvious caveat that since the therapeutic effect depends on retinal activation, subjects must have sufficient visual function to allow this to occur. Otherwise it would seem prudent to avoid phototherapy in patients with pronounced and untreated agitation because this symptomatology could be worsened. In addition, evening phototherapy may worsen insomnia.

A substantial minority of patients with seasonal affective disorder meet criteria for bipolar II disorder, raising the concern that phototherapy may trigger hypomania in such individuals. Particular caution might be needed in patients with a bipolar I syndrome. Some regimes of phototherapy might lead to a degree of sleep deprivation which could also destabilize mood in bipolar patients.

Interactions

One of the advantages of phototherapy in seasonal affective disorders is that the use of antidepressant drugs may be avoided. Despite this, many patients with winter depression use phototherapy concomitantly with antidepressant medication without an obvious potentiation of adverse effects. However, a case report described apparent serotonin toxicity where phototherapy was combined with selective serotonin re-uptake inhibitors.[7]

Like bright light, the pineal hormone, melatonin, also has the ability to shift the timing of circadian rhythms[2] and theoretically melatonin taken at an inappropriate time of day could offset the antidepressant effect of light. It is also possible that bright-light treatment could exacerbate the ability of some drugs (e.g. chlorpromazine, St John's Wort) to cause skin photosensitivity reactions.[7]

Effects of withdrawal of phototherapy

If a patient with seasonal affective disorder responds to light treatment, withdrawal of treatment during the period of seasonal vulnerability leads to a return of symptomatology within a few days. It may be possible, however, to lessen the daily duration of treatment particularly towards the end of winter without inducing relapse. Otherwise cessation of light treatment does not seem to cause a specific withdrawal syndrome.

Administration of phototherapy

Since the best established indication for phototherapy in psychiatry is seasonal affective disorder, the following account will describe the use of bright-light treatment in winter depression. One of the major practical difficulties in phototherapy is the time needed to administer treatment. For this reason a 10 000 lux light box may be preferred because the daily duration of treatment can be reduced to 30 min. It seems likely that cool-white light and full-spectrum light have equivalent clinical efficacy, but because cool-white light is free of ultraviolet light it is theoretically safer and should be preferred.

The balance of evidence suggests that bright-light treatment of winter depression is most effective when administered in the early morning.[4] However, treatment given later in the day may be effective for some patients. In an initial trial, therefore, it is best to recommend early morning treatment but to advise the patient that the timing of therapy can eventually represent a balance of therapeutic efficacy and practical convenience. Treatment in the late evening should be avoided because of the possibility of sleep disruption.

Early-morning phototherapy should start a few minutes after waking. Subjects should allow themselves a 30 min duration of treatment with a 10 000 lux light source. They should seat themselves about 30 to 40 cm away from the light box screen. They should not gaze at the screen directly but face it an angle of 45° and glance across it once or twice each minute.

The antidepressant effect of light treatment usually appears in a few days but in controlled trials up to 3 weeks can be needed before the therapeutic effects of bright light exceed those of placebo treatment. If no benefit is noted after the third week of therapy, light treatment should probably be abandoned. As noted above mild side effects are common in the early stages of treatment but usually settle without specific intervention. If they are persistent and troublesome the patient can sit a little further away from the light source or reduce the duration of exposure. Exposure should also be reduced or stopped if elevated mood occurs.

Once a therapeutic response has occurred it is usually necessary to continue phototherapy up to the usual time of natural remission, otherwise relapse will occur. It may be possible, however, to lower the daily duration of treatment. Phototherapy can also be started in advance of the anticipated episode of depression as this may have a preventative effect; however, the evidence for this is limited and doubts have been expressed.[7,12]

6.2.10.3 Transcranial magnetic stimulation

Declan McLoughlin and Andrew Mogg

Introduction

Transcranial magnetic stimulation (TMS) is a means of non-invasively stimulating the cerebral cortex using a hand-held coil applied to the scalp. In recent years TMS has been increasingly used to target neuronal circuitry implicated in neuropsychiatric disorders.

A key milestone in the development of TMS occurred in 1831 when Michael Faraday discovered the phenomenon of electromagnetic induction whereby a time-varying magnetic field can induce electrical currents through a conductor lying in proximity to the field. The French biophysicist D'Arsonval in 1896 induced phosphenes, vertigo, and syncope in human subjects by placing an induction coil around their heads. In the late 1950s, Kolin stimulated peripheral nerves (the frog sciatic nerve) with a magnetic field and a few years later the same technique was used in human subjects, inducing muscle twitching by applying a pulsed magnetic field over the ulnar, peroneal, and sciatic nerves.

In the mid-1980s, Barker and colleagues in Sheffield developed a magnetic stimulator to directly stimulate the human motor cortex.[1] They applied a circular coil, through which a large (4000 A), brief (110 μs) current was passed to the scalp. The resulting pulsed magnetic field was used to stimulate the motor cortex, evoking movements in the contralateral limbs and is known as transcranial magnetic stimulation. This ability to non-invasively stimulate the motor cortex with a magnetic field soon replaced high-voltage transcutaneous electrical stimulation for assessing central motor conduction times and mapping corticospinal pathways in a variety of neurological conditions. In the late 1980s machines capable of delivering multiple TMS pulses were developed. Repetitive TMS (rTMS), unlike single pulses of TMS can produce effects that last after the period of stimulation. For example, it has been shown that rapid rTMS (at frequencies of 5 Hz and greater) enhances motor excitability whereas slow rTMS (at 1 Hz or less) transiently depresses excitability.[2] The underlying principle of rTMS treatment is that the normal balance of excitatory and inhibitory processes within certain neuronal pathways may be disrupted in psychiatric conditions such as depression. Stimulating the brain using rTMS provides a means of increasing and decreasing excitation and inhibition in these pathways, having a neuromodulatory effect and allowing a focal targeting of specific neuronal circuitry.

Mechanism of action

The underlying mechanisms of the effects of rTMS remain poorly understood. This is in part because, as with attempting to understand the mode of action of psychotropic medication, it is difficult to establish links between cellular and physiological changes and alterations in emotion, thinking, and behaviour. Techniques used to try to better understand the molecular and physiological effects of rTMS have included neuroimaging and animal studies.

Neuroimaging has demonstrated that rTMS may exert effects on the brain at a considerable distance from the site of stimulation. For example, serial positron emission tomography scanning has been used to measure regional cerebral blood flow in medication-free patients with major depression before and after courses of fast and slow rTMS administered over the left prefrontal cortex.[3] It has been demonstrated that fast rTMS causes increases in regional cerebral blood flow in bilateral frontal, limbic, and paralimbic areas whereas slow rTMS caused decreases in blood flow in the right prefrontal cortex, left medial temporal cortex, and left basal ganglia and amygdala.

It has been suggested that rTMS of the left prefrontal cortex may modulate brain function by an effect on dopamine release. Elevated extracellular dopamine concentrations in the dorsal hippocampus have been demonstrated in the brains of rats who received rTMS. However, one of the problems with using animal models of rTMS is that currently small rTMS coils are not available and it is therefore impossible to focally stimulate one particular area of the small rodent brain. In humans it has been shown that rTMS to the dorsolateral prefrontal cortex can induce the release of dopamine in the ipsilateral caudate nucleus.[4]

Side-effects

Being non-invasive and not requiring a general anaesthetic, rTMS is considered to be a relatively safe treatment and few side-effects have been reported. The most significant potential side-effect is the risk of unintended seizure induction. There have been six reports to date of seizure induction in healthy volunteers. In half of these, very high stimulation intensities and frequencies were used. There have only been three reports of seizures in patients receiving rTMS and one of these patients had a pre-existing diagnosis of temporal lobe epilepsy. Researchers generally follow safety guidelines that exclude high-risk patients, (e.g. those with a stroke, brain tumour or pre-existing epilepsy) from receiving rTMS. These guidelines also suggest limits to the intensity, frequency, and stimulus duration of the rTMS used.[5]

The most common side-effect of rTMS is headache or facial discomfort that is the result of direct stimulation of muscle and nerves in proximity to the coil. Approximately 10–30 per cent of subjects experience these symptoms, which are generally short-lived and well-tolerated.

Technique

rTMS equipment comprises a stimulator unit, booster modules, a laptop computer, and a figure-of-eight coil. The stimulator unit contains the charging circuitry, energy storage capacitors, control electronics and discharge, and safety circuitry. It is connected to booster modules, which charge the high-voltage capacitors, enabling trains of high-intensity magnetic stimulation to be produced. The stimulating coil consists of tightly wound copper wire in a figure-of-eight through which a rapidly alternating electric current passes to produce a pulsed magnetic field. Various stimulation parameters including train duration, frequency of stimulation, stimulus intensity, and length of inter-train interval can be altered using computer software.

rTMS treatment is delivered via the figure-of-eight coil applied to the scalp surface. Typically, prior to treatment, TMS will be used

to map the motor area of the right abductor pollicis brevis (APB), and measure its motor threshold. The stimulus intensity delivered during treatment is then calculated in relation to this motor threshold. The main method of localizing the stimulation site has been to use a fixed point in anatomical relation to a specific motor area, for example the dorsolateral prefrontal cortex has generally been defined as the point 5 cm anterior to the APB motor area in the parasaggital plane. More recently some studies have used magnetic resonance imaging to more accurately delineate the area to be stimulated.

rTMS and depression

Transcranial magnetic stimulation was first postulated to have potential applications in psychiatry by Bickford and colleagues who noted transient elevation in mood in several healthy subjects who had received single pulses of TMS to the motor cortex.[6] Several small open studies followed that suggested that low frequency rTMS over the vertex may have antidepressant effects. Since the mid 1990s most interest has focussed on high-frequency rTMS applied to the left dorsolateral prefrontal cortex (LDLPFC), a region reported to be underactive in depression. To date there have been approximately 30 randomized trials of real and placebo rTMS in depression. In addition there have been several published meta-analyses including a Cochrane review.[7] This reviewed 16 trials, 14 of which were suitable for quantitative analysis. They found that high-frequency rTMS to the LDLPFC and low-frequency rTMS to the right dorsolateral prefrontal cortex (RDLPFC) were both superior to sham treatment but only for one measure (the Hamilton Depression Rating Scale) and at one time point (immediately after 2 weeks of treatment). The difference between real and sham was not large, leading to the conclusion that at this stage there was not strong evidence to support the use of rTMS as an antidepressant therapy.

There has been considerable heterogeneity between studies. Nearly all the trials have comprised patients with major depressive disorder defined using DSM-IV criteria. However there has been considerable variability with respect to pharmacotherapy received, with some trials specifying treatment resistance (variously defined) and some specifying medication-free participants. In two of the studies patients were started on antidepressant treatment either shortly before or simultaneously with the rTMS treatment.

The choice of appropriate sham condition is an important methodological consideration. There are two main approaches. Most studies have relied on tilting the active coil (usually through 45° or 90° with one or both wings of the coil touching the scalp). However intracerebral voltage measurements in a rhesus monkey have shown that, depending on how the coil is tilted, sham conditions obtained by coil tilting can induce voltages in the brain to levels only 24 per cent below active rTMS.[8] The fact that some 'sham' coils produce significant cortical stimulation may account for some of the benefit seen in those receiving sham stimulation and may underestimate the difference between real and placebo treatment. The other approach is to use a specially designed placebo coil. This looks identical to the real coil and makes the same noise but does not cause any cortical stimulation. However, neither does it cause sensation to the scalp, meaning that subject blinding may still be less effective. Indeed the problem of maintaining blinding in studies with rTMS continues to be a major methodological issue.

Most studies have given high-frequency rTMS to the LDLPFC, probably as a result of the positive early studies when this area was stimulated. Several investigators have used low-frequency rTMS to the RDLPFC. Low-frequency rTMS is much less likely to induce a seizure and is probably better tolerated by patients. Since slow rTMS has an inhibitory effect in contrast to the excitatory effect of fast rTMS and since there is considerable evidence that the left and right hemispheres have contrasting functions in regulating mood, it could be speculated that slow rTMS to the right cortex may have a similar effect to fast rTMS to the left.

Studies of high-frequency rTMS in depression have generally used stimulation frequencies of 5 to 20 Hz. There is a suggestion from animal studies that higher frequency stimulation may have a greater antidepressant effect but so far the numbers of subjects in human studies have been too low to show if a difference in effect of varying stimulation frequency exists. Likewise, the optimal stimulus intensity, length of treatment course, and total number of stimulations is not yet clear from the published data. However, longer trials with an increase number of stimulations appear to make little difference.[9]

Most of the rTMS studies in depression have been small, the largest until recently having 70 patients. However, recently a much larger industry-sponsored (Neuronetics) trial submitted their findings to the US Food and Drug Administration (FDA), seeking licensing approval for an rTMS device. In this study 301 patients were randomized to real or sham rTMS. Participants received 10 Hz rTMS of the left dorsolateral prefrontal cortex, 3000 pulses per day for 20 days. Although there was a marginal difference between the groups in favour of rTMS at the end of treatment, there was no significant group difference on an intention-to-treat analysis of the primary outcome measure (Montgomery-Åsberg Depression Rating Scale). In January 2007 the FDA Neurological Devices panel considered Neuronetic's application to have its rTMS equipment licensed for therapeutic use. The panel felt that there was insufficient evidence to support its efficacy. The final FDA decision is expected in summer 2007 (website: http://www.fda.gov/cdrh/panel/summary/neuro-012607.html, accessed: 5 June 2007).

In the United Kingdom the National Institute for Clinical Excellence (NICE) has issued recommendations stating 'Current evidence suggests there are no major safety concerns associated with transcranial magnetic stimulation for severe depression but there is no evidence that the procedure has clinically useful efficacy' (website: http://www.nice.org.uk/article.aspx?o=ip346consultation, accessed: 5 June 2007).

Comparisons with ECT

In addition to comparisons with placebo treatment, rTMS has also been directly compared with ECT in several studies. While ECT is the most effective treatment for severe depression in the short-term its use is limited by several issues, including acceptability to patients, the requirement to be anaesthetized, and the occurrence of side-effects, particularly cognitive side-effects. rTMS could be a potential alternative if it proved effective. In total there have been six published randomized controlled trials to date comparing ECT and rTMS. These trials have all had relatively small numbers of

patients, particularly when compared with trials of antidepressant medications. They have either shown rTMS to be less effective or not statistically different from ECT. The most recent and largest trial to date included 46 patients and compared 3 weeks of treatment with rTMS to a course of ECT.[10] The mean reduction in the Hamilton Depression Rating Scale achieved at the end of treatment was 14.1 points in the ECT group, compared with 5.4 points for the rTMS group, translating into a mean percentage reductions from baseline of 58 and 22 per cent, respectively. Overall, ECT was shown to be substantially more effective as a short-term treatment of depression than rTMS.

rTMS and schizophrenia

While most studies of rTMS within psychiatry have focussed on depression, there has been a growing interest in using rTMS as a possible treatment for schizophrenia. It has been used to treat both auditory hallucinations and to alleviate negative symptoms of schizophrenia.

Auditory hallucinations occur in approximately 70 per cent of patients with schizophrenia and in about a quarter of cases respond poorly if at all to antipsychotic medication. Recent advances in neuroimaging have enabled measurement of neural activity while hallucinations are being experienced and it has been demonstrated that auditory hallucinations are associated with activation in a number of brain areas, including the temporal cortex bilaterally. This area has been targeted in several rTMS studies using slow rTMS to reduce excitability.

The first account of using rTMS to treat auditory hallucinations reported improvement in the severity of hallucinations of three patients with schizophrenia who had 40 min/day of 1 Hz rTMS over 4 days.[11] There have now been 15 published treatment studies of rTMS targeting auditory hallucinations in schizophrenia. Ten sham-controlled trials (involving 212 patients) were included in a recent meta-analysis[12] which concluded that overall rTMS was significantly better than sham stimulation in the treatment of auditory hallucinations.

Negative symptoms of schizophrenia include alogia, avolition, anhedonia, and affective flattening and are associated with attentional impairment and executive dysfunction. Negative symptoms are often resistant to neuroleptic medication and are associated with poor clinical outcome. There is increasing evidence that negative symptoms are related to reduced cortical activation, particularly involving the left prefrontal cortex. Therefore one treatment approach has been to attempt to increase activation within this region. There have been four published randomized controlled studies comparing real and sham rTMS of the left dorsolateral prefrontal cortex to target negative symptoms of schizophrenia, of which three found no difference between real and sham treatments and one found 2 weeks of high-frequency rTMS significantly improved negative symptoms. Novak *et al.*[13] additionally performed a battery of neuropsychological tests and follow-up patients for 6 weeks after treatment but found no significant differences between treatment groups at either time point for primary or secondary outcome measures. The most recent study[14] did not provide evidence that rTMS to the DLPFC improved negative symptoms of schizophrenia in patients with prominent negative symptoms but did suggest that rTMS may improve cognitive functioning in this patient group, at least in the short-term. However larger studies with longer periods of follow-up will be required to further examine this preliminary finding.

rTMS and obsessive–compulsive disorder

There have been several studies that have attempted to treat symptoms of obsessive–compulsive disorder (OCD) by modulating activity in prefrontal and motor circuits using rTMS. The earliest blinded trial of rTMS for OCD included 12 patients and found that a single session of right prefrontal high-frequency cortical stimulation significantly decreased compulsive urges for over 8 h.[15] Obsessive thoughts did not change significantly. This study suggested that rTMS may be a useful probe of neuronal circuitry associated with symptoms of OCD. However a number of subsequent studies have failed to replicate these findings. A Cochrane review in 2003 examined three randomized controlled trials and concluded that there were currently insufficient data to draw conclusions about the efficacy of rTMS in the treatment of OCD.[16]

The most recent, and largest trial of TMS in OCD to date randomly allocated 33 patients with OCD to receive 10 sessions of either active or sham low-frequency (1 Hz) rTMS over the LDLPFC.[17] This study did not demonstrate any difference between real and sham treatments.

rTMS and other neuropsychiatric disorders

rTMS has been postulated as a potential treatment in a variety of other neuropsychiatric disorders. There is emerging evidence that it may improve some of the motor symptoms of Parkinson's disease. In a recent study six daily sessions of high-frequency rTMS were given to 55 unmedicated patients with Parkinson's disease.[18] Patients received either 10 Hz or 25 Hz rTMS bilaterally to the motor cortex arm and leg areas or to the occipital cortex (control group). It was found that stimulation to the motor areas improved all measures, e.g. walking time, key-tapping speed, and self-assessment and that 25 Hz stimulation yielded greater improvement than 10 Hz. The effect was sustained for a month after treatment and restored by further booster sessions. The authors concluded that 25 Hz rTMS can lead to cumulative and long-lasting benefits on motor performance in Parkinson's disease.

A recent study explored the effect of low-frequency rTMS to the left temperoparietal region on chronic tinnitus.[19] Patients received 1200 stimuli per day for 5 days of either real or placebo treatment in a randomized controlled crossover trial. Overall active rTMS induced a transient, but significant improvement in the symptoms of tinnitus.

rTMS has also been used in an attempt to provide relief from chronic neuropathic pain.[20] A recent review summarized that high-frequency rTMS to the motor cortex is able to produce pain relief but that the effect is brief and that research in this area is required.

rTMS has also been used as a probe of neuronal circuits in dementia and in attention deficit hyperactivity disorder although any possible therapeutic role for it in these conditions appears some way off.

Summary

rTMS has an increasing role as a useful investigational tool for probing neuronal circuitry in a variety of neuropsychiatric disorders. However its therapeutic value is at present less certain.

The antidepressant efficacy of rTMS has now been investigated for over 15 years and despite initial early enthusiasm there is still not clear evidence for its usefulness as a treatment in depression, reflected in the recent FDA and NICE decisions. Further research is required to identify specific brain regions in specific conditions that may be appropriate targets for treatment with rTMS, allowing tailoring of treatments for individual patients. The recent development of neuronavigational techniques using MRI imaging should aid treatment site localization. Other future research should be directed at establishing optimal rTMS parameters, e.g. the intensity, frequency and number of treatments.

6.2.10.4 Neurosurgery for psychiatric disorders

Keith Matthews and David Christmas

Ablative neurosurgery

Definition

Historical definitions of Neurosurgery for Mental Disorder (NMD), previously known as 'psychosurgery', have either made distinctions between neurosurgery for psychiatric or 'psychological' illness and disorders assumed to have a clearer 'biological' origin (e.g. epilepsy, Parkinsons' disease); or, have emphasized control of behaviour as a therapeutic objective rather than the control of symptoms. A more recent definition, and the one used throughout this chapter is that provided by the UK Royal College of Psychiatrists:[1]

> *A surgical procedure for the destruction of brain tissue for the purposes of alleviating specific mental disorders carried out by a stereotactic or other method capable of making an accurate placement of the lesion.*

Historical overview

The first attempt at treating psychiatric illness by surgical methods is commonly attributed to Gottlieb Burckhardt, a Swiss psychiatrist, who in 1888 performed 'temporal topectomy' on six patients who were most probably suffering from schizophrenia. His intention

was to sever the connections between the frontal lobes and the rest of the brain. Results were mixed: one patient was reported as improved; two were 'quieter'; and two showed no change. However, one patient died; another developed epilepsy; and a further had motor weakness. His results were met with a mixture of ridicule and hostility and he never again wrote on the subject.

In 1935, James Fulton and Carlyle Jacobsen operated on the frontal lobes of two chimpanzees named Becky and Lucy after first studying their responses to frustration in behavioural experiments. They found their behaviour dramatically changed after the surgery. Becky's previous agitated responses to frustration became more passive whilst Lucy was much more agitated. At a London meeting in 1935, they presented their findings to an audience which included Egas Moniz, a Portuguese neurologist.

Moniz teamed up with Almeida Lima, a neurosurgeon, and in a 30-min operation in November 1935, they performed frontal leucotomy on their first patient. The procedure first involved injecting alcohol into the white matter tracts of the frontal lobes, but they later would change to using an instrument of their own design, the leucotome, to extirpate 'cores' of tissue. In 1936, they published their report on the outcomes of 20 patients who were probably suffering from depression, panic disorder, and schizophrenia. One-third were better, one-third were worse, and one-third were unchanged.

Shortly after their paper was published, Walter Freeman, a US neurologist, wrote an enthusiastic review and quickly secured the collaboration of a neurosurgeon, James Watts. They modified the procedure slightly and began practising what Freeman termed bilateral frontal lobotomy. Over the next decade, Freeman became frustrated with the cumbersome requirements of a neurosurgical theatre and team. Adapting a technique first described in the 1930s, Freeman infamously developed the transorbital lobotomy in 1946. Notorious for the initial use of an ice-pick, the procedure involved forcing a tool (an 'orbitoclast') under the upper eyelid and through the base of the skull into the frontal lobes. Also known as the 'ice-pick lobotomy', the relative ease with which the procedure could be performed resulted in the widespread adoption of the technique throughout the United States and Europe. However, it was the indiscriminate overuse of such 'freehand' procedures and the associated adverse effects that occurred in many patients that led to public and professional antipathy towards neurosurgery for psychiatric illness, which peaked in the late 1950s. The introduction of chlorpromazine in 1954 also meant that for the first time there was a non-surgical treatment for schizophrenia.

Despite a reduction in the use of neurosurgery for mental disorder in the late 1950s and early 1960s, the development of stereotactic techniques (which had been demonstrated in 1908 by Horsley and Clarke and adapted for human use in 1947 by Spiegel and Wycis) meant that greater accuracy and greater consistency in neurosurgery could deliver better outcomes in selected patients. Procedures became more selectively and reliably targeted and lesions became more discrete.

Procedures

All NMD procedures have targeted one or more of three main regions: (i) fronto-limbic connections within the orbital or cingulate cortices; (ii) subcortical limbic circuitry; and (iii) limbic cortex, including the amygdala and cingulate cortex.

Four 'modern' stereotactic procedures have been described with only two remaining in regular usage in the Western World. Anterior capsulotomy is still performed in Cardiff (UK), Spain, Belgium, and Scandinavia, whilst anterior cingulotomy is the procedure of choice in Dundee (UK), Poland, South Korea, and North America.

(a) Subcaudate tractotomy (SST)

Developed in the United Kingdom by Geoffrey Knight in 1965, lesions were originally created using radioactive Yttrium^{90} rods. SST targets the white matter tracts of the 'substantia innominata' connecting the orbital cortex to limbic regions, and probably involved lesioning the nucleus accumbens.

(b) Anterior capsulotomy (ACAPS)

Described by Jean Talairach in 1949 and further developed by Lars Leksell for the treatment of chronic pain, ACAPS places lesions in the anterior limb of the internal capsule—a large white matter bundle connecting the frontal cortex with the thalamus and limbic structures. Lesions are generated using focused gamma radiation (gammacapsulotomy) or thermal damage (thermocapsulotomy). (See figure 6.2.10.4.1 for typical ACAPS lesions.)

(c) Anterior cingulotomy (ACING)

The cingulate gyrus was first proposed as a target by John Fulton in the late 1940s. Hugh Cairns, an English neurosurgeon and a friend of Fulton's, performed 'cingulectomy' in 1948. The less destructive 'cingulotomy' was first performed by Eldon Foltz and Lowell White in 1962 for the treatment of pain. (See figure 6.2.10.4.2 for typical ACING lesions.)

(d) Limbic leucotomy

First developed by Desmond Kelly in 1973, it represented a combination of cingulotomy and subcaudate tractotomy lesions.

Indications

During the 1960s and 1970s, a variety of other operations were explored as treatments for hypersexuality, aggression, and criminality. These included hypothalamotomy and amygdalotomy. Reports of outcomes from such interventions were often favourable, but interpretation has been complicated by issues of diagnosis, patient selection, and assessment. Such clinical presentations are not considered appropriate indications for surgery today.

Three main indications exist for modern NMD: obsessive-compulsive disorder (OCD); anxiety disorders; and major depression. Only individuals who have experienced chronic, disabling symptoms that have failed to respond after the diligent pursuit of available treatments (pharmacological and psychological) should be considered for ablative neurosurgery.

There are few absolute contraindications to NMD. There is no evidence to support the use of NMD as a treatment for eating disorders, schizophrenia, or personality disorders. However, where these exist as significant comorbid conditions alongside depression or OCD, these do not represent absolute contraindications and careful consideration is required.

Ethical considerations

One of the most persistent concerns for the public and for health professionals is that NMD is used to treat patients in the absence of informed consent. Although the absence of informed consent was likely to be an issue for early procedures, to the best of our knowledge,

all contemporary centres performing NMD today insist upon the patient's ability to give informed consent. In Scotland, the Mental Welfare Commission must authorize any proposed NMD as being in the patient's best interests and must confirm that the patient is capable of providing informed consent. In England and Wales, the Mental Health Act Commission has a duty to set-up multi-disciplinary panels to authorize NMD for consenting patients under Section 57 of the Mental Health Act, 1983. Similarly, in most other countries where the procedure is available, the procedure can only go ahead with the approval of an independent review board.

Criteria for NMD

General criteria for suitability show little variation between centres. Key inclusion and exclusion criteria for NMD in Dundee are shown below in Table 6.2.10.4.1.

Outcomes from NMD

Whilst placebo-controlled trials are considered the ideal assessment for intervention trials, they have frequently been described as unethical in the case of NMD. Despite this, there have been three isolated double-blind trials, involving a total of 6 patients. Despite suggestions of non-response in all cases, follow-up was brief and there is inadequate detail to make informed judgements of outcome.

(a) Combined outcomes for different procedures

Comparisons across studies are of limited value due to differences in procedure, patient characteristics, and the use of different rating scales. However, Spangler *et al.*[2] reviewed outcomes from different procedures and for different indications, defining a positive outcome as being a score of 1 or 2 on the Clinical Global Impression (Improvement) scale.[(2)] Positive outcome rates were: ACAPS (67 per cent); ACING (61 per cent); SST (37 per cent); and limbic leucotomy (67 per cent). The most effective procedures for affective disorder and OCD (respectively) were limbic leucotomy followed by ACING. The least effective procedure for both disorders (and overall) was SST.

Table 6.2.10.4.1 Inclusion and exclusion criteria for NMD

Inclusion criteria	Exclusion criteria
1. Age ≥20 years	1. Age <20 years
2. *Legal status*: both formal and informal patients can be considered	2. Failure to fulfil ICD-10 criteria for a suitable indication
3. *ICD-10 diagnosis of*: severe depressive episode; recurrent depressive disorder, current episode moderate to severe; bipolar affective disorder, current episode severe depression	3. *Primary diagnosis of*: substance misuse; organic brain syndrome; adult personality disorder; pervasive developmental disorder
4. *Duration of episode of illness*: minimum of 3 years, with at least 2 years of unremitting symptoms despite active treatment. Only in exceptional circumstances would a duration<5 years be considered	4. Absence of evidence of an adequate therapeutic trial of psychological treatment
5. *Consent*: the patient must be capable of providing sustained, informed consent	5. Absence of evidence of extensive trials of adequate pharmacological treatment

(b) Anxiety disorders

The crude rate of improvement following NMD (all procedures) for anxiety disorders ($n = 290$) is 77 per cent.[(1)] More recent reports of ACAPS would support a claim to effectiveness but this may be at the expense of significant adverse effects (apathy and dysexecutive symptoms).

(c) Obsessive-compulsive disorder

The combined rate of 'Completely Improved' or 'Improved' outcomes following SST is 52 per cent. More recent studies involving ACAPS or ACING report improvements on the Yale-Brown Obsessive-Compulsive scale (Y-BOCS) in the region of 30 per cent. Despite this relatively low figure, approximately 85 per cent of patients ($n = 478$) will have a marked or lesser improvement following NMD for OCD.[(1)]

(d) Depression

There is only one report of outcomes from ACAPS for depression. Herner (1961) described outcomes for 19 patients with a 'depressive state'.[(3)] Outcomes included: 'permanent improvement' (74 per cent); unchanged (5 per cent); and worse (5 per cent). In all 75 per cent experienced permanent side effects.

Spangler *et al.* (1996) reported that 53 per cent of those with affective disorder ($n = 10$) responded to ACING, with a 60 per cent response rate in unipolar depression.[(2)] Dougherty *et al.* (2003) reported a mean reduction in Beck Depression Inventory (BDI) score of 33 per cent in 13 patients following ACING.[(4)] With regards to limbic leucotomy, there are few studies looking at outcomes solely in depression but Mitchell-Heggs (1976) reported that 7 of 9 patients with depression improved after surgery.[(5)]

(e) Bipolar disorder

There are only two reports of NMD for bipolar disorder, both following SST.[(6,7)] Each involved small numbers ($n = 9$) but described improvements in cycle frequency with a greater effect on manic episodes than depression. Improved drug responsiveness was also alleged.

Mechanism of action

The mechanism of action of NMD is unknown, but almost all neurosurgical procedures involve lesioning white matter tracts connecting the prefrontal cortex with the thalamus, cingulate gyrus, and areas of the limbic system such as the amygdala and hippocampus. Neuroimaging studies have suggested that this circuitry is dysfunctional in depression and interrupting parts of these circuits may rectify emotional and cognitive processing within these brain areas. In the case of OCD, there is compelling evidence that symptoms arise from functional circuits connecting the frontal cortex, thalamus, and basal ganglia and that lesioning parts of this circuit may serve to eradicate many of the symptoms.

Adverse effects

(a) General adverse effects

Transient adverse effects such as headache are relatively common and tend to resolve in the first week after surgery. Post-operative confusion can occur in 3–10 per cent of patients with higher rates following SST. Incontinence is relatively uncommon with modern procedures, but the reported rates are: 1.1 per cent after SST;

5.5 per cent after ACING; and 9.5 per cent with limbic leucotomy. Apathy has been reported to occur in up to 24 per cent of patients following limbic leucotomy, but not all studies report its occurrence and this is likely to be a relatively high estimate. The incidence of weight gain varies greatly: 6.2 per cent after SST; 65.5 per cent after ACAPS; and 5.5–21.4 per cent after ACING. Similarly, there is wide variation in the reported rates of seizures: 1.6–3.3 per cent after SST; 0–7.7 per cent after ACAPS; 1–9 per cent after ACING; and 14.2 per cent after limbic leucotomy. Finally, suicide rates range from 1 per cent after SST to 12 per cent after ACING but these rates may reflect differing severities of illness.

(b) Effects on personality

It is certainly the case that early procedures such as leucotomy had marked effects on the personality and behaviour of large numbers of patients. However, with the advent of stereotactic procedures and more focused lesions, the effects on personality appear to be mild, sometimes even absent. It is acknowledged, however, that it is difficult to make robust appraisals of personality without assessment tools designed for such a purpose and in the context of symptom reduction in chronic illnesses.

Most published studies have reported normalization of personality traits following modern procedures such as ACING and ACAPS. In addition, there is a trend towards reductions in neuroticism and increases in extraversion. There are some recent reports of adverse effects on executive function following ACAPS for anxiety disorders[8] but many such studies lack preoperative assessments of personality making conclusions difficult to draw.

(c) Effects on neuropsychological function

As with personality changes, the detrimental effects of earlier procedures upon neuropsychological functioning were probably significant. However, the majority of studies reporting neuropsychological outcomes from ACAPS, ACING, and limbic leucotomy from the early 1970s onwards report either no deterioration on general measures (such as IQ, attention, memory) post-operatively or, more frequently, improvement. It is likely that improvements in performance are mediated through symptom reduction.

Vagus nerve stimulation (VNS)

Overview

The vagus nerve is the longest of the 12 cranial nerves and 80 per cent of its fibres are sensory afferents. These fibres terminate in the nucleus tractus solitarius, sending ascending fibres to the forebrain via the locus coeruleus and parabrachial nucleus. The vagus nerve, therefore, provides an access route to modify information which is processed in brain regions involved in mood regulation.

VNS involves the subcutaneous implantation of a programmable pulse generator in a location similar to a cardiac pacemaker. Electrodes connect the generator to the left cervical portion of the vagus nerve. Stimulation is delivered in an intermittent pattern (typically 30 s every 5 min) but parameters are changed using a palmtop computer and a programming wand held over the pulse generator.

VNS was first used to treat epilepsy in 1988 and became available for the treatment of refractory partial seizures in 1994. The first trials in depression began in 1998.

Outcomes in depression

There are a number of short, open trials of VNS which typically report a 3-month response rate (≥50 per cent reduction in the 24-item Hamilton Rating scale for Depression; $HRSD_{24}$) of 30–40 per cent, and a remission rate ($HRSD_{24} \leq 9$) of approximately 15 per cent.

Larger, 12-month trials have demonstrated 12-month response rates of 27.2–46 per cent and remission rates of 15.8–29 per cent.[9,10] In a 12-month controlled comparison of VNS versus Treatment-As-Usual (TAU), George *et al.*[11] reported response rates of 27 per cent for VNS + TAU versus 13 per cent for TAU. Such improvements appear to be maintained at 2 years, with response rates of 42 per cent and remission rates of 22 per cent.[12] In the only randomized, controlled trial of VNS, Rush *et al.*[13] reported 10-week response rates on the $HRSD_{24}$ of 15.2 per cent in the VNS group versus 10.0 per cent in the placebo group, changes which were non-significant.[13] Despite positive results in uncontrolled trials, definitive evidence of efficacy remains elusive.

Adverse effects

Most adverse effects are related to stimulation, and in most people they are fairly mild and improve over time. Many can be managed by altering the stimulation parameters. In the initial stages, common effects are: hoarse voice (53 per cent); headache (23 per cent); neck pain (17 per cent); cough (13 per cent); and dyspnoea (17 per cent). At 12-months, the only adverse effect to persist at rates higher than 10 per cent is hoarse voice (21 per cent).[9]

Deep brain stimulation (DBS)

Overview

As with VNS, DBS has evolved from a treatment for neurological disorders to a putative intervention for psychiatric illness. The most

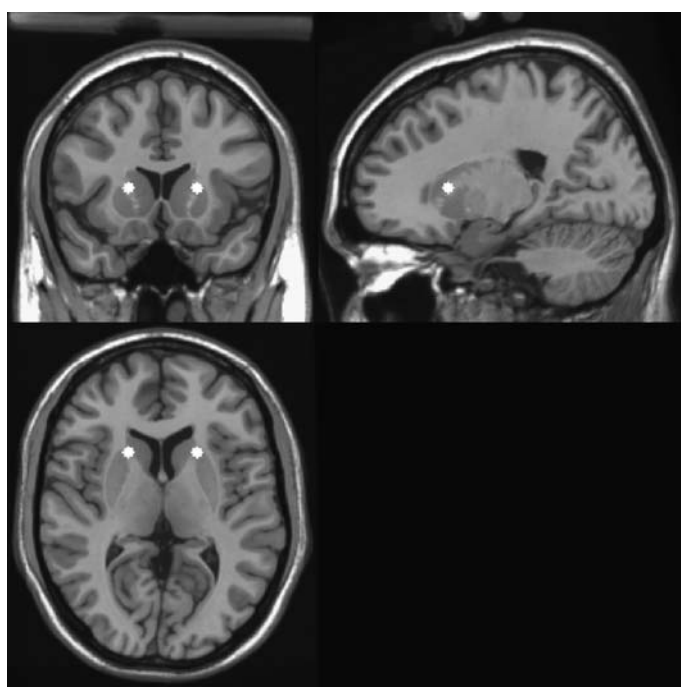

Fig. 6.2.10.4.1 Typical locations of anterior capsulotomy lesions superimposed upon normalized T1 MRI scan.
Lesions not to scale.

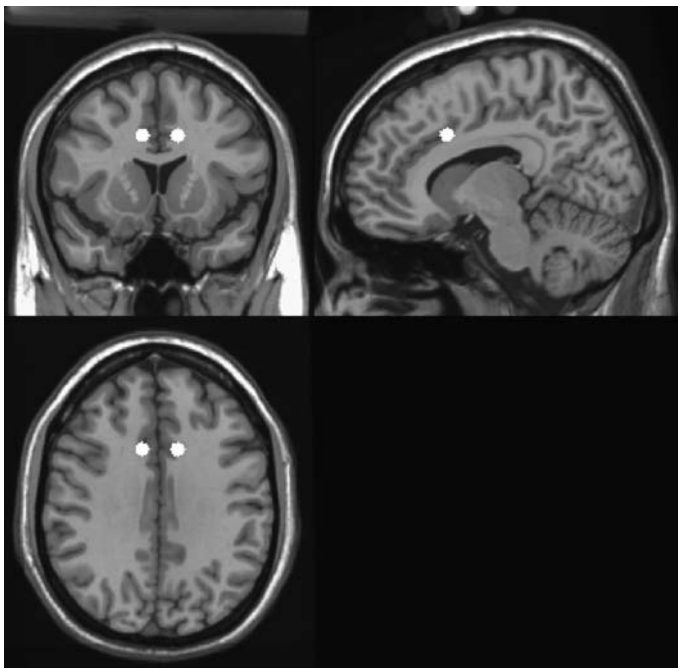

Fig. 6.2.10.4.2 Typical locations of anterior cingulotomy lesions superimposed upon normalized T1 MRI scan. Lesions not to scale.

effective targets for OCD and depression have yet to be determined but a number of possible locations for stimulation exist. However, DBS should be considered as an experimental treatment for both disorders.

The procedure involves the bilateral implantation of electrodes using stereotactic guidance with post-operative confirmation of location using MR scanning. The electrodes are connected to a generator typically implanted in the abdomen. Following surgery, the stimulation settings are programmed using immediate/short-term changes in symptoms as a guide.

DBS for obsessive-compulsive disorder

The most common target for DBS for OCD, thus far, has been ventral portion of the anterior limb of the internal capsule, the same site as ablative anterior capsulotomy. In a double-blind cross-over trial of anterior capsular stimulation in four patients Nuttin *et al*. (2003) reported reductions in symptoms of 36.8 per cent which were maintained after 21 months. In a small case series of four patients Abelson *et al.*[14] described marked improvements in one patient, with a lesser improvement in another. Greenberg *et al*. (2006) reported responses (≥35 per cent reduction in Y-BOCS score) in 4 out of 8 patients with DBS in the internal capsule.

Other proposed targets include the nucleus accumbens and the ventral caudate nucleus, but all targets may involve stimulation of a common anatomical area.

DBS for depression

In the only published report of DBS for depression, Mayberg *et al.*[15] stimulated the white matter tracts of the subgenual cingulate gyrus in six patients. Four patients were responders whilst two showed no change. Randomized on-off-on-off trials confirmed a stimulation-related improvement which was associated with a reduction in local cerebral blood flow in the subgenual cingulate and dorsolateral prefrontal cortex.

Adverse effects

Adverse effects that have been reported include: throbbing or buzzing sensations; nausea; and jaw tingling. A number of reports have described problems with battery life with the stimulators being replaced every 5 to 12 months. Battery failure has often been associated with a recurrence of symptoms over a few days which has been associated with marked depressive symptomatology and suicidal ideation. One study has reported a suicide, but commented that this was unrelated to stimulation. Numbers of reported cases are too small to determine if this is indeed the case.

Conclusions

Despite its chequered past, modern NMD bears little similarity to historical freehand procedures. Advances in neuroimaging mean that anatomical substrates for depression and OCD are being elucidated. Ablative procedures such as ACAPS and ACING are unlikely to undergo randomized controlled trials but prospective clinical audit suggests that such procedures may offer improvement to selected patients with treatment-refractory depression and OCD. Interventions such as VNS and DBS offer the possibility of double-blind testing but as yet there is insufficient evidence to suggest that such procedures offer greater effectiveness.

Psychological treatments

Contents

6.3.1 Counselling

Diana Sanders

Introduction

People seek counselling for many reasons. Sometimes those who have had no previous need for mental health services are literally stopped in their tracks by life events—illness, family breakdown, intolerable stresses. People with long-term difficulties may turn to counselling when they feel the statutory services are not able to meet their needs, or as an adjunct to health care provision. With greater social mobility and the separation of family members, counselling increasingly provides the care and support previously offered within local communities. The provision and acceptability of counselling is on the increase. Counselling is possibly the most commonly delivered form of psychological therapy[1,2] and the British Association for Counsellors and Psychotherapists have over 30 000 members, with equivalent numbers in other countries. Professional training programmes in counselling have mushroomed in response to demand. Counsellors are found in many statutory and voluntary settings—mental health, primary care and medical settings, workplaces, drug and alcohol services, voluntary and charitable organizations, trauma services, and educational settings—as well as in private practice.

But what exactly is counselling? What do counsellors do? Is counselling the same as psychotherapy? And, is it an effective form of treatment? Although counselling is a major growth area within mental health, it can be difficult for consumers and purchasers of counselling services to know what kind of counselling and counsellor to use, with lack of clarity about what works for whom. There are many different models of counselling, types of counsellor and many different training courses. It is difficult to make clear distinctions between counselling and psychotherapy. Much of the work of counsellors has not historically been amenable to standard methods of evaluation, and research is relatively new. Currently there is no statutory regulation for the term 'counsellor', which means that people are able to practise as counsellors without registration or accreditation. By definition, people who seek counselling are likely to be vulnerable, and the issue of public protection is paramount.

The aim of this chapter is to clarify these issues and examine the place of counselling in psychiatry. The chapter begins by looking at the definition of counselling, and how counselling is both similar to, and distinct from, psychotherapy. The chapter goes on to look at the key features of counselling, and different models of counselling. Although counselling can and is used for many psychological difficulties, the chapter selects specific problems where there is evidence that it is an effective intervention: mild to moderate depression, adjustment difficulties, bereavement, trauma, and relationship problems. I then consider counselling in different settings, again selecting a few which illustrate the work of counsellors—primary care, mental health settings, student counselling, and the workplace—looking at the way counselling can be adapted according to the needs of the service. The chapter concludes by looking at issues of training, quality, and standards, commenting on the need for the control of an ever-developing profession without loss of the growing availability of effective counselling services to those in need.

Defining counselling

No single definition of either counselling or psychotherapy exists in spite of many attempts in Britain, North America, and elsewhere to arrive at one.[3] Currently, neither the British Association of Counselling and Psychotherapy (BACP) nor the American Counseling Association has either proprietary rights of the terms or even official definitions, although, as discussed below, the move towards statutory regulation for counselling and psychotherapy may ensure greater clarity for practitioners and consumers.

At its broadest, counselling is conceptualized as a way of helping or assisting others to make their own adjustment and decisions in the face of life problems. Counselling aims to offer a safe relationship within which the individual can explore personal difficulties and, through developing a deeper understanding of themselves, move towards change. The Department of Health defines counselling as . . . a *form of psychological therapy that gives individuals an opportunity to explore, discover, and clarify ways of living more resourcefully, with a greater sense of well being. Counselling may be concerned with addressing and resolving specific problems, making decisions, coping with crises, working through conflict, or improving relationships with others.*[4]

In contrast with other forms of psychological therapy, where the focus may be on treating specific problems, many counselling models give equal if not more weight to the *process* of change. The journey through which a client goes—to greater understanding, awareness, and resolution—is as important as the outcome. Counsellors practise within all therapeutic approaches, strongly influenced by humanistic, experiential, and psychodynamic principles. They tend not to link their work to diagnostic categories, preferring to see each client as an individual, and using an approach matching the client's needs rather than diagnosis. Counsellors may define themselves by the model they practise—for example, humanistic or psychodynamic—and/or by the type of problems they work with, such as bereavement or relationship counsellors.

Counselling may also be defined in terms of *key elements* and *goals*,[5] as shown in Table 6.3.1.1. Again, the key elements and goals illustrate the variation within counselling. For example, what is meant by counselling ranges from providing a safe arena for people to gain understanding and insight, to offering more direction and guidance leading to decision-making and problem-solving.

Table 6.3.1.1 The key elements and goals of counselling (Reproduced from Feltham, C. What are counselling and psychotherapy? In The Sage Handbook of Counselling and Psychotherapy, (eds. C. Feltham and I. Horton), pp. 3–10, copyright 2006, Sage Publications.)
