Gastrointestinal stromal tumors (GISTs) are tumors of the GI tract characterized by a mutation in the KIT protooncogene. These tumors are often hemorrhagic and involving the antimesenteric portion of the small bowel (Fig. 48.16). Because of the small-bowel mobility, they often drape down into the pelvis and present as pelvic masses easily confused with adnexal tumors on exam and imaging. At laparoscopic assessment, this mobility can allow the tumor and small bowel to retract into the upper abdomen in association with steep Trendelenburg position. The surgeon should be aware of this possibility if no pelvic tumor is found. Absence of a pelvic mass previously demonstrated on exam or imaging should prompt a thorough evaluation of the remainder of the abdomen. Segmental bowel resection is the preferred surgical approach. The mesenteric dissection is minimized as LN metastasis is rare. Tyrosine kinase inhibitors are given in selected patients (unresectable disease, primary tumor >3 cm, high mitotic rate) in the adjuvant setting with improvement in recurrence rate. They have also been used in the neoadjuvant setting with success.

FIGURE 48.14 Meckel diverticulum with recent diverticulitis.

FIGURE 48.15 Large ileal lymphoma (*arrow*).

Epithelial Tumors of Appendiceal Origin

This includes a spectrum of lesions from mucocoeles ([Fig. 48.17](#)) to pseudomyxoma peritonei (PMP). It is not possible to differentiate a benign mucocoele from a cystadenocarcinoma by imaging, so we recommend performing an appendectomy if a cystic lesion is identified in the appendix. If a malignancy is identified, a right hemicolectomy should follow. It is critical that the appendix be handled with care; if a mucocoele is ruptured (either spontaneously or iatrogenically), neoplastic cells can be spread to the peritoneum. This could result in PMP. Treatment of PMP is surgical debulking with or without adjuvant therapy. Five-year survival is up to 75%, but recurrence is expected. PMP patients do benefit from aggressive surgical debulking and intraperitoneal chemotherapy, and this procedure should be performed only in experienced treatment centers. As an aside, when mucinous ovarian tumors are resected, the appendix should be carefully inspected as synchronous or metastatic lesions from appendix to ovary are common.

FIGURE 48.16 Terminal ileal GIST, axial view (*arrow*).

FIGURE 48.17 Mucocoele of the appendix (*arrow*).

Fistulae

Fistulae from the small bowel to small bowel, small bowel to colon, small bowel to bladder, or small bowel to vagina should raise concern for Crohn disease, malignancy, or complications from prior surgery and/or radiation. Fistulae from the sigmoid colon to the bladder or vagina could be associated with any of the previous diagnoses as well as diverticulitis. The fistula should be treated according to the suspected cause. If malignancy is suspected, an en bloc resection is required. If the fistula is associated with an inflammatory or infectious disease, it is generally safe to finger fracture the organs apart, resect the segment of offending bowel, and repair the recipient side of the fistula.

UROLOGIC DISORDERS

Congenital

Pelvic kidney occurs in approximately 1 in 10,000 live births in the United States and can occur as a result of failure of migration of one kidney during embryogenesis or fusion of one pole of each kidney, which can result in a horseshoe kidney. When the fusion occurs at the lower poles, two ureters will be present. Extra care must be taken to identify and protect the ureters and the vascular supply to the pelvic kidney during any dissection. With current imaging modalities, these anatomic variants of ectopic kidneys should rarely present a diagnostic challenge in a case of a pelvic mass, excepting emergency cases. However, in a benign gynecologic procedure done for anatomic indications such as pelvic organ prolapse, imaging may often be omitted. It is paramount that the surgeon considers the possibility of ectopic kidney should a retroperitoneal mass be noted intraoperatively to avoid catastrophic iatrogenic injury.

Urologic Malignancies

Bladder cancer is the most common malignancy of the urinary tract and is most often urothelial in origin. Surgical treatment varies widely from transurethral resection with intravesical bacillus Calmette-Guerin (BCG) immunotherapy to radical cystectomy. Primary malignancy of the ureter is usually urothelial in origin, and in up to half of the patients, a synchronous bladder cancer will be present. Nephroureterectomy is the gold standard surgical procedure for localized disease. Extensive lymphadenectomy is controversial. Both bladder and ureteral cancers are best managed by an urologist, and incidental findings should prompt immediate referral to a urologic oncologist (**Fig. 48.18**).

Nephrolithiasis

Small stones (<4 mm) will usually pass spontaneously and stones greater than 10 mm in diameter are unlikely to pass. Stones that lead to urinary sepsis are treated with antibiotics and appropriate drainage (stenting or percutaneous nephrostomy). Most of these stones will then require lithotripsy or endoscopic removal after clearance of any associated infection. An urologist should be consulted for any obstructing stones found incidentally in the operating room.

P.1136

FIGURE 48.18 Urothelial cancer presenting as a pelvic mass (*arrow*).

VASCULAR NEOPLASMS

Angiomyxoma

Aggressive angiomyxoma is an uncommon hypervascular soft tissue tumor that is usually seen in the pelvis and perineum (**Fig. 48.19**). They often present as a perineal bulge or mass palpated on pelvic exam that is in the ischiorectal fossa. It is classified as a benign lesion as they rarely metastasize, but they are usually large and

locally aggressive. Surgical resection is the treatment of choice, but local recurrence is very common (70% at 2 years). Complete resection is critical to minimize risk of recurrence and often requires a combined abdominal and perineal approach.

Hemangiopericytoma

Malignant hemangiopericytoma is a rare vascular tumor that may arise from small venules or capillaries of any structure. They are often found in the abdomen and/or pelvis and may be misdiagnosed preoperatively as an ovarian neoplasm. Surgery is first-line therapy, and use of adjuvant chemotherapy and radiation is described. Because of the vascularity, preoperative embolization of feeding vessels is often recommended to decrease the risk of catastrophic blood loss ([Fig. 48.20](#)).

FIGURE 48.19 Angiomyxoma (*arrow*).

FIGURE 48.20 Hemangiopericytoma, vascularity appreciated on angiography.

P.1137

PRESACRAL TUMORS

Many congenital, benign, and malignant lesions can originate in the retrorectal or presacral space, and they are often asymptomatic. As these masses enlarge, they may cause nonspecific symptoms from displacing or invading other structures ([Figs. 48.21](#) and [48.22](#)). Many of these lesions will be appreciated during the digital rectal examination and close inspection of the perineum, including the paracoccygeal region, during the preoperative physical examination. Careful inspection on exam and imaging will reveal a location that is atypical for most gynecologic processes as it will be far posterior in the pelvis, often retrorectal as opposed to disease in the cul-de-sac originating from the adnexa or+ uterus. There is typically limited mobility and fixation to the posterior pelvis. Congenital cystic lesions include developmental cysts, epidermoid and dermoid cysts, duplication cysts, and tailgut cysts. Tailgut cysts can harbor malignancy in up to 25% of cases. Meningoceles and meningocele are caused by herniation of the dural sac through a defect in the anterior sacrum. The sacrum of patients with meningoceles is abnormal with a “scimitar sign,” which can be seen on a preoperative plain x-ray. Biopsy of a meningocele could result in fatal meningitis.

FIGURE 48.21 Large tailgut cyst displacing the rectum laterally (*arrow*).

FIGURE 48.22 Pelvic schwannoma.

Solid lesions in the presacral space include teratomas and chordomas. Teratomas can be solid, cystic, or heterogeneous. They are usually benign, but malignant degeneration is common in adults. Chordomas are the most common malignancy of this region and are locally invasive with high recurrence rates despite radical resection.

As a general rule, if any of these lesions associated with the spine or fixed posteriorly are found incidentally, they should not be resected. Biopsies also should not be performed without consulting first with an expert in the field. Biopsies, if necessary, can usually be obtained percutaneously. These lesions all require specific preoperative workups and multidisciplinary approaches to their surgical management.

SUMMARY

With the availability of modern imaging, it is rare to proceed to the operating room without a narrow differential diagnosis. Gynecologic surgeons should be aware of the most common nongynecologic findings in the pelvis and lower abdomen and should prepare the patient and obtain an operative consent prior to the planned surgery which includes potential bowel resections and stomas.

BEST SURGICAL PRACTICES

- Consider broad differential preoperatively, and try to anticipate nongynecologic causes for a pelvic mass. Preoperative imaging and appropriate workup are essential.
- Establish functional close working relationships with nongynecologic surgical disciplines in your institution.

This facilitates communication and availability for pre- and intraoperative consultations in emergent situations.

- If the diagnosis is uncertain, consider preoperative preparation with stents, bowel enemas, stoma markings, and appropriate consent.
- Assess the entire abdomen and pelvis, running the intestine from the ligament of Treitz to the rectosigmoid junction. This affects the choice of incision.
- Consult the expert when in doubt.
- Do not biopsy or attempt resection of any retroperitoneal mass.

Chapter 49

Malignancies of the Vulva

Mitchel S. Hoffman

Xiaomang B. Stickles

DEFINITIONS

Lymphoscintigraphy—A nuclear medicine study examining the distribution of uptake of radiocolloid (injected peritumorally) into the lymphatic system.

Modified radical vulvectomy—Radical removal of the portion of the vulva containing the tumor with approximately a 2-cm margin.

Neoadjuvant therapy—Therapy given prior to definitive surgical treatment, usually with the intention to decrease the required radicality of surgical resection.

Radical vulvectomy—Removal of the vulvar soft tissue. The lateral borders are the labiocrural folds. The anterior border is located in the mons pubis. The posterior border is across the perineal body. The medial borders are within the vestibule.

Sentinel lymph node—The concept of a sentinel lymph node in the context of malignancy relies on the presumption that this lymph node(s) is the initial site of metastatic disease and that the histology of the sentinel lymph node reflects the histology of the rest of the lymph nodes in the basin.

Superficial inguinal lymphadenectomy—Removal of the inguinal lymph nodes superficial to the cribriform fascia, mainly associated with the great saphenous and superficial epigastric veins.

INTRODUCTION

Carcinoma of the vulva is an uncommon malignancy accounting for only 2% of all female genital malignancies. It is predominantly a disease of older women. In this country as a whole, the steady increase in life expectancy has brought carcinoma of the vulva into a place of more importance among gynecologic malignancies. The predominant histologic type is squamous cell carcinoma, which accounts for about 90% of the tumors in most series. This malignancy metastasizes primarily through the lymphatic system in an orderly manner through the superficial inguinal, deep inguinal, and pelvic lymph nodes.

During the first half of the 20th century, the absolute 5-year survival rate for carcinoma of the vulva was 15%. During the late 19th and early 20th centuries, principles of surgical oncology were developed and put into clinical practice. The application of these surgical principles to the treatment of vulvar cancer resulted in a significant improvement in survival. The survival of patients with invasive squamous cell carcinoma of the vulva is dependent on a number of histopathologic factors, but it most closely relates to the pathologic status of the inguinal lymph nodes. Until the early 1980s, patients with invasive carcinoma of the vulva were routinely treated with radical vulvectomy and bilateral inguinofemoral and pelvic lymphadenectomy. Accumulation of data on vulvar cancer during the mid- to late 20th century led to earlier diagnosis and a better understanding of the nature and modes of spread of this disease. Especially over the past several decades, treatment of this malignancy has undergone a number of significant modifications resulting in less radical surgery with good survival rates and significantly better quality of life for women with this malignancy.

This chapter first reviews the epidemiology, clinical characteristics, staging, and prognostic factors for invasive carcinoma of the vulva. The broad spectrum of treatment of this disease is then reviewed with an emphasis on the surgical treatment. Finally, histologic variants of vulvar malignancy and their treatment are discussed individually.

EPIDEMIOLOGY

Invasive squamous cell carcinoma of the vulva is typically a disease of postmenopausal women, with a median age at diagnosis of about 65 years (Fig. 49.1). However, the age range is wide, and there appears to be an increasing incidence in younger women. This has been mainly attributed to infection with the human papillomavirus (HPV), which accounts for approximately 60% of vulvar squamous cell carcinoma. HPV subtypes 18 and 33 account for about half of HPV-associated vulvar cancers. HPV does not appear to play as significant of a role in the pathogenesis of invasive squamous cell carcinoma of the vulva in older women, who frequently have coexisting lichen sclerosis. In the older population, vulvar carcinoma commonly arises from a background of chronic inflammation without evidence of HPV involvement. Other sexually transmitted factors that have been epidemiologically associated with vulvar cancer are the granulomatous venereal diseases, especially in countries where these are prevalent.

It is to yet to be determined what effect the implementation of HPV vaccination will have on the incidence of vulvar squamous cell carcinoma. The full impact will likely not be known for many decades as vulvar carcinoma is most common in older women.

Vulvar carcinoma in situ (Fig. 49.2), like cervical carcinoma in situ, is considered a precursor to invasive disease, although the risk of progression appears to be lower. Although Jones and Rowan found in 7 of 8 women with untreated vulvar intraepithelial neoplasia (VIN) that invasive cancer developed within 8 years, three other studies found progression rates of 5% to 16%. In a recent systematic review of 3,322 published patients, 8 of 88 untreated women with VIN 3 progressed to invasive cancer in 12 to 96 months. In a large review, 3.2% of women treated with partial or total vulvectomy for VIN were found to have occult invasive cancer. However, several selected series showed higher rates of 16% to 22%. The risk

for invasive cancer may be greater with perianal location, increased age, immunosuppression, and previous radiotherapy.

FIGURE 49.1 Invasive squamous cell carcinoma of the vulva. This is a 1.8-cm ulcerative lesion on the right anterior vulva.

Vulvar carcinoma in situ tends to be multifocal with a lower risk of invasive cancer in younger women, but it tends to be unifocal with a higher risk of invasive disease in older women. Most patients with VIN 3 should be treated, and long-term follow-up is mandatory. Although progression of VIN from grade 1 to grades 2 and 3 has been demonstrated, in the absence of atypical changes, other vulvar epithelial abnormalities do not appear to have significant precancerous potential. Patients who have cervical neoplasia are at increased risk for developing vulvar neoplasia and vice versa. This so-called field phenomenon should heighten the physician's surveillance for the development of other lesions once a lower genital tract neoplasm occurs.

FIGURE 49.2 Carcinoma in situ of the vulva. Vulvar intraepithelial lesions can be white, brown, or red.

Hypertension and diabetes mellitus are common in patients with invasive vulvar cancer, but this may simply be related to the elderly population affected. The association of vulvar cancer with obesity is unclear. There does not appear to be any significant association with parity or race. Smoking is associated with an increased risk of vulvar cancer. One group that does appear to be at particular increased risk for the development of invasive vulvar cancer is chronically immunosuppressed women.

CLINICAL PRESENTATION

The most common initial symptom of vulvar cancer is pruritus, which may be of long duration. Vulvar pain, discharge, and bleeding are less commonly reported. The patient often becomes aware of a lesion on her vulva; but because of the superficial nature of the lesion, delay in seeking medical help is common. Physician delay has also been commonly reported, often related to prolonged empiric medical treatment before a biopsy is done. Invasive squamous cell carcinoma of the vulva may present as an exophytic, cauliflower-like lesion or it may have an ulcerative appearance ([Fig. 49.3](#)). It involves the labia majora in about two thirds of patients. The remaining tumors involve the clitoris, labia minora, posterior fourchette, and perineum. These cancers can be exophytic, ulcerating, or flat. Rarely, a patient may present with erosive tumor growth from the groin nodes if symptoms have been ignored for long

periods of time.

FIGURE 49.3 Invasive carcinoma of the left vulva with extensive associated carcinoma in situ involving both labia.

P.1143

HISTOLOGY

Squamous cell carcinoma accounts for about 90% of the invasive vulvar malignancies. Melanoma is the second most common histologic type, accounting for 5% to 10% of vulvar cancers. Some of the less common vulvar malignancies include Bartholin gland carcinoma (either adenocarcinoma or squamous carcinoma), basal cell carcinoma, verrucous carcinoma, invasive Paget disease, and sarcomas.

PRETREATMENT INVESTIGATION

Biopsy

The relative rarity of vulvar cancer and the general lack of awareness of typical signs and symptoms, even by medical professionals, frequently lead to a delay in diagnosis. These observations underscore the need for patient and physician education with regard to the early diagnosis of carcinoma of the vulva. Therefore, biopsy of any questionable vulvar lesion prior to empiric treatment is warranted. Vulvar biopsy is a simple procedure that can be done in the office under local anesthesia. Biopsy technique is demonstrated in [Chapter 23 \(Fig. 23.1\)](#).

Preoperative Clinical Evaluation

Patients with carcinoma of the vulva are generally elderly and often have coexisting medical problems. A thorough preoperative evaluation by internal medicine and anesthesiology consultants should be requested when appropriate. As previously discussed, these women have an increased incidence of cervical and vaginal neoplasia, indicating the importance of a careful pelvic examination and Pap test screening.

Imaging Studies

Beyond physical examination and a chest radiograph, routine studies to rule out metastases are generally not indicated except in the presence of locally advanced disease. Cystoscopy, intravenous pyelography, or proctoscopy (or all three) is indicated if it appears that locally advanced cancer may involve the bladder, urethra, or rectum. Magnetic resonance imaging (MRI) or computed tomography (CT) may help to determine resectability and treatment planning. When a locally advanced tumor or inguinal lymph node enlargement is noted, CT scan of the groins, pelvis, and abdomen is suggested. This aids in determining the resectability of the tumor and metastases, extension to the pelvic lymph nodes, and distant metastases ([Fig. 49.4](#)). Increasingly, positron emission tomography (PET) has been utilized to evaluate the presence or absence of metastatic disease, though scant data exist to support its use in vulvar cancer ([Fig. 49.5](#)). In a small series of 15 patients reported by Cohn and colleagues, the sensitivity of PET in detection of pathologically confirmed groin metastasis was 67% and specificity was 95%. Another recent analysis by Kamran et al. showed a sensitivity of only 50% and specificity and positive predictive value of 100%. Larger studies validating its utility are lacking. Due to limited sensitivity, omission of lymphadenectomy should not be based on PET results alone.

FIGURE 49.4 Computerized tomography (CT) image of the inguinal area showing enlarged lymph nodes typical for metastatic cancer (*arrows*).

FIGURE 49.5 Positron emission tomography (PET) of the groin areas showing significantly increased FDG uptake in bilateral nodes very typical of metastatic cancer (same patient as in [Fig. 49.4](#)).

STAGING

Route of Spread

Squamous cell carcinoma of the vulva can spread by local extension to involve the vagina, urethra, anus, or pubic bone. Metastasis is primarily via the lymphatic system, but hematologic spread is also possible. The lymphatics of the labia communicate to the inguinal lymph nodes. The lymphatics of the perianal area drain in a similar manner, but lesions that involve the vagina, anus, or rectovaginal septum can drain directly into the pelvic lymph nodes. Although there are channels that interconnect the clitoris to the deep pelvic nodes, it appears that they are of minimal clinical significance. The lymphatics of the vulva are numerous and tend to cross the midline. The regional lymph nodes include the superficial inguinal nodes, the deep inguinal-femoral nodes, and the pelvic lymph nodes. The superficial inguinal lymph nodes are the primary nodal group of the vulva. Depending on the location of the primary carcinoma, one or two of these superficial inguinal nodes is the first site of metastatic spread. This node is referred to as the *sentinel lymph node*. Because of the predictably orderly progression of lymph node metastases in vulvar cancer, involvement of the deeper femoral lymph nodes or the pelvic nodes is very infrequent if the sentinel node(s) is uninvolved. These superficial inguinal lymph nodes drain through the cribriform fascia to the femoral lymph nodes. Drainage from here is under the inguinal ligament into the pelvic lymph nodes. The pelvic lymph nodes are virtually never positive in the absence of inguinofemoral lymph node metastases. The invasion of lymph node metastases roughly correlates with the size of the primary tumor.

P.1144

TABLE 49.1 2009 FIGO Staging System for Vulvar Cancer

STAGE	EXTENT
IA	Lesion ≤ 2 cm and stromal invasion ≤ 1 mm, confined to vulva or perineum, no nodal metastasis
IB	Lesion > 2 cm or stromal invasion > 1 mm, confined to vulva or perineum, no nodal metastasis
II	Tumor of any size with extension to adjacent perineal structures (one-third lower urethra, vagina, or anus), no nodal metastasis
III	Tumor of any size with or without extension to adjacent perineal structures with positive inguinofemoral lymph nodes
IIIA	(i) With one lymph node metastasis (≥ 5 mm) (ii) One to two lymph node metastasis (< 5 mm)
IIIB	(i) With two or more lymph node metastasis (≥ 5 mm) (ii) With three or more lymph node metastasis (< 5 mm)

IIIC	With positive nodes with extracapsular spread
IVA	(i) Upper urethral and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone (ii) Fixed or ulcerated inguinofemoral lymph nodes
IVB	Distant metastasis, including pelvic lymph nodes

FIGO Staging System

In 1979, the International Federation of Gynecology and Obstetrics (FIGO) approved a clinical classification for invasive squamous cell carcinoma of the vulva. This was based on an analysis of tumor (T) by size and location; node (N) status by palpation; distant metastases (M) as assessed by physical examination; endoscopic evaluation of the bladder or rectum, or both; and radiologic investigation. Most patients with invasive carcinoma of the vulva are treated surgically, and it was recognized that the clinical evaluation of inguinal lymph node metastases was often inaccurate. Therefore, in 1988, FIGO approved a surgical staging system. This staging system has undergone several revisions over the years as new surgical pathologic findings have been correlated with outcome. The most recent FIGO staging classification adopted in 2009 is shown in [Table 49.1](#).

Stage I is divided into stages IA and IB because primary tumors less than 2 cm in diameter with very superficial invasion have a very low incidence of lymph node involvement and these patients have an excellent prognosis. However, a number of patients with small tumors have been reported with metastatic disease, which emphasizes the importance of surgical staging whenever possible ([Table 49.2](#)).

In the FIGO staging revision of 2009, the involvement of lower one third of the urethra, vagina, or anus was downgraded from stage III to stage II. Stage III was subdivided to reflect the prognostic significance of both the number and extent of lymph node involvement.

With increasing use of sentinel lymph node biopsy for staging and improvements in anesthetic techniques and perioperative care, it is rare today that a patient cannot be surgically staged, but the old clinical staging system should be used with appropriate notation in such patients.

TABLE 49.2 Tumors with Invasion of Less Than 1 mm with Nodal Disease, Either at Diagnosis or Recurrence

INVESTIGATOR	PATIENT AGE	TUMOR SIZE (CM)	TUMOR GRADE	TUMOR DEPTH (MM)	CAPILLARY OR LYMPHATIC SPACE INVOLVEMENT	MONTHS TO DIAGNOSIS OF NODAL DISEASE	STATUS

PROGNOSTIC FACTORS

Primary Tumor Characteristics

Primary tumor factors that appear to have prognostic importance include tumor diameter, depth of invasion or tumor thickness, tumor differentiation, lymph-

vascular space involvement, and surgical margin status. Tumor involvement of the distal urethra, vagina, or perineum is also an adverse prognostic factor. Sedlis and colleagues reported on a Gynecologic Oncology Group (GOG) study of 272 patients with early vulvar cancer less than or equal to 5 mm in tumor thickness. They found that histologic grade, capillary-like space involvement, tumor thickness, and clitoral or perineal location were all significant predictors of groin node metastases. A subsequent GOG study reported by Homesley and associates on 588 evaluable patients with invasive carcinoma found lymphovascular space involvement, tumor differentiation, age, and tumor thickness to be significant independent risk factors for groin node metastases. Factors that predicted an increased risk of local recurrence included margin status, large tumor size, and deep invasion. Tumor extending to less than 8 mm from surgical margin was associated with an increased risk of recurrence.

A few histologic variants of squamous cell carcinoma have been associated with a more favorable prognosis, including verrucous carcinoma (discussed later), warty carcinoma, carcinoma in situ with early stromal invasion, and keratoacanthoma.

Stage	Patients (n)	Mean age (yr)	Overall survival (%) at					Hazards ratio ^a (95% CI)
			1 year	2 years	3 years	4 years	5 years

Lymph Node Status

The status of the groin nodes is clearly the most important prognostic factor for patients with invasive squamous cell carcinoma of the vulva. This disease has a relatively low propensity for distant metastases. Recurrences tend to be local or regional, and even unremitting disease tends to remain locoregional for long periods of time.

The overall 5-year survival rate for all treated patients is about 60%, with a corrected 5-year survival rate of about 70%. In the GOG study previously mentioned, 65.5% of the patients had negative groin nodes and 34.5% had positive nodes; this is consistent with other reports in the literature. In this large surgically treated series, the survival rate was 90.9% for patients with negative lymph nodes and 57.7% for patients with lymph node metastasis. When the pelvic lymph nodes are known to be positive, the survival rate decreases to about 20%. **Figure 49.6** shows the survival of patients with squamous cell carcinoma of the vulva staged with the older FIGO staging classification. No large studies have reported long-term results with the 2009 staging.

Metastatic involvement of multiple lymph nodes further decrease the prognosis that was recognized in the 2009 FIGO staging system, which subdivided stage III disease depending on the number of nodes involved and the size of the metastatic deposits. Several studies have shown that when only one lymph node is involved, survival is still quite good. However, survival decreases drastically with metastases to three or more

P.1146

nodes or with bilateral nodal involvement. On the basis of limited data from a few studies, it appears that large nodal diameter, extensive nodal replacement, and especially extracapsular extension of a lymph node metastasis are adverse prognostic factors. In a report by Origoni and colleagues in 1992 that was based on 53 vulvar cancer patients with groin node metastases, the survival rate varied from 90.9% when the diameter of the metastasis was less than 5 mm to 20% when it was larger than 15 mm, and from 85.7% to 25% when the metastases were intracapsular and extracapsular, respectively. Especially important are the data from the 19 patients in that study with a single positive node. For these patients, the 5-year cancer-related survival rate was 90% when the metastasis diameter was less than 5 mm versus 37.5% when it was 15 mm, and 85.7% when the metastasis was intracapsular versus 20% when it was extracapsular. Results from a study by Paladini and associates were similar; they reported that patients with intracapsular metastases tended to have

recurrence at distant sites, whereas patients with extracapsular nodal disease were more likely to have local or groin recurrence.

TREATMENT OF INVASIVE SQUAMOUS CELL CARCINOMA OF THE VULVA

Historical Perspective

In the 1940s, Taussig and Way reported favorable outcomes in carcinoma of the vulva after radical vulvectomy with bilateral inguinal lymphadenectomy performed by en bloc excision. This radical procedure then became the standard therapy applied to most patients. It involved radical removal of the entire vulva, the mons pubis, the inguinofemoral lymph nodes, and often the pelvic lymph nodes. The large surgical defect thus created was generally closed under tension with a high subsequent breakdown rate, significant postoperative morbidity, and marked disfigurement of the genital area. Important concerns with this approach for the treatment of vulvar cancer led to a number of modifications, especially over the past 25 years (Fig. 49.7). Some of these concerns include the high rate and the severity of wound complications and the psychosexual effects of radical removal of the vulvar tissues. Other potential problems related

P.1147

to the en bloc radical resection include urinary or fecal incontinence and vaginal prolapse. The “one-size-fits-all” approach of treating all patients with the same radical vulvectomy and inguinal-femoral lymphadenectomy resulted in overtreatment of many patients and undertreatment of some with inadequate attention to local margin and the risk of lymph node metastasis. The following section provides a more individualized approach based on current literature and extensive surgical experience.

Primary Surgery: Selection of Appropriate Primary Operation

Appropriate Candidates for Primary Surgery

Certain tumor characteristics may preclude an otherwise medically fit patient from undergoing primary surgery. Proximity to important functional structures such as the urethra, clitoris, and anal sphincter must be considered. If adequate surgical margins cannot be obtained without sacrificing such a structure, neoadjuvant treatment with radiation and/or chemotherapy should be considered. Very large primary tumors may leave a large defect after primary resection, which may prove challenging to close. These patients may be candidates for neoadjuvant radiation plus chemotherapy to shrink the size of the primary cancer before surgical resection. The patient’s ability to tolerate a radical resection must also be taken into consideration. Some elderly patients or those with significant comorbidities who may not recover from a radical resection would tolerate a more limited resection after neoadjuvant treatment.

FIGURE 49.8 Modified radical vulvectomy. **A:** Anterior hemivulvectomy. **B:** Right hemivulvectomy with clitoral sparing. **C:** Posterior hemivulvectomy.

Types of Incisions

The most important modification to the classic en bloc excision came after Hacker and colleagues and DiSaia and associates reported that separation of the vulvar and groin incisions resulted in a significant reduction in wound morbidity ([Fig. 49.7B](#)). The report by Hacker and colleagues in 1981 consisted of 100 patients in whom three separate incisions were used to perform the bilateral inguofemoral lymphadenectomy and radical vulvectomy, leaving a bridge of tissue between the incisions and sparing the mons pubis. Major groin wound breakdown occurred in 14 patients, which was a considerable reduction from the 50% or higher groin wound breakdown rate generally seen with the en bloc excision. In this report, there were no isolated recurrences in either the groin or the inguinal skin bridge. There were two recurrences in the inguinal skin bridge associated with other recurrence sites; both patients originally had positive inguinal lymph nodes. In addition to these two patients, there have been other isolated reports of inguinal skin bridge recurrence. However, this still appears to be a rare event. Some authors believe that in the presence of advanced disease or grossly positive inguinal lymph nodes, an en bloc excision of the tumor and the lymph nodes is still the best approach. En bloc excision is certainly warranted at times to obtain an adequate resection of the malignancy.

Modified Radical and Radical Vulvectomy

Modified radical vulvectomy is an ambiguously defined operation that generally refers to radical removal of the portion of the vulva containing the tumor ([Fig. 49.8](#)). In recent

P.1148

years, the extent of the radical vulvectomy has been modified to emphasize wide excision of the primary cancer with adequate skin and deep margins but not necessarily radically resecting the entire (uninvolved) vulva. Recommendations have included 1- to 3-cm skin margins for well-localized, unifocal lesions and to the depth of the inferior fascia of the urogenital diaphragm. The main type of morbidity relating to increasing the radicality of vulvectomy is subsequent sexual dysfunction and disfigurement. Modification of the surgical resection or the use of neoadjuvant chemoradiation should be considered to avoid compromising the function of the anus or urethra. In a 1979 study, DiSaia and colleagues reported complete preservation of sexual function in 17 of 18 patients who underwent wide local excision for early invasive tumors. They also reported that preservation of the mons pubis as well as the major portion of the superior aspect of the vulva resulted in an appreciably more satisfactory cosmetic result.

The chief concerns with decreasing the radicality of vulvectomy are the possibility of an increased risk of local recurrence and later an increased risk of a second primary vulvar cancer. Hacker and colleagues have demonstrated that the extent of the vulvectomy can be decreased as long as careful attention to the margins is observed. They compared radical vulvectomy (56 patients) with wide local excision (28 patients) in the treatment of superficially invasive squamous cell carcinoma of the vulva. The local recurrence rate was identical, 4% in both groups. A later review by Hacker and van der Velden of literature regarding patients with vulvar cancer 2 cm or less in diameter showed a local invasive recurrence rate of 7.2% for 165 patients treated with radical local excision versus 6.3% for 365 patients treated with radical vulvectomy. In a comparative study reported by Hoffman, 45 patients underwent radical vulvectomy and 45 patients were treated with modified radical vulvectomy. The local recurrence rates were 2.2% and 4.4%, respectively. Several additional studies have reported excellent local control with a modified radical vulvectomy ([Table 49.3](#)).

In a GOG study, Stehman and colleagues analyzed recurrences following modified radical hemivulvectomy. The mean time to “relapse” on the vulva was 43.4 months, and 11 of 18 patients had recurrence on the contralateral side from the primary lesion. This suggests a second cancer rather than a true local recurrence. A study by de Hullu and associates also reported a significant number of late recurrences following modified radical vulvectomy. From these results, it is apparent that women undergoing a modified vulvar operation for cancer are at increased risk for later development of a new primary vulvar tumor and require long-term close follow-up.

It appears reasonable to conclude that modified radical vulvectomy is an efficacious treatment for well-localized invasive squamous cell carcinoma of the vulva. Attention should be focused on obtaining a 2-cm gross margin around the tumor while sparing as much vulvar tissue as possible. Most patients with

squamous cell carcinoma of the vulva are candidates for a modified radical vulvectomy via a separate incision from the groin lymphadenectomy. A few patients, however, by virtue of disease extent, require a traditional radical vulvectomy with radical resection of the entire vulva. Whatever the vulvar phase of the operation is called, the aim should be to excise the tumor with a 2-cm gross margin.

Because of tumor proximity, it is occasionally necessary to remove a portion of the urethra to obtain an adequate resection of a vulvar carcinoma. Although several authors have stated that removal of the outer urethra does not result in significant problems with incontinence, there are no substantial confirming data. In one small study, Reid and colleagues did find urinary incontinence to be a problem after resection of the distal urethra or even an excision close to the urethra. If a portion of the urethra is resected, a Foley catheter should be left in place (carefully taped to the leg) for about 1 week postoperatively to facilitate healing and to splint the urethra. A surgical anti-incontinence procedure should also be strongly considered at the time of resection, especially if there is any preoperative stress urinary incontinence or if more than 1 cm of the urethra has to be removed. Increasingly, consideration has been given to treating these patients with neoadjuvant radiotherapy and chemotherapy to minimize or avoid urethral resection.

TABLE 49.3 Modified Radical Vulvectomy Literature: Local Recurrence

There is scant literature concerning the local management of vulvar cancer with perianal involvement ([Fig. 49.9](#)). However, we have noted that about one third of our patients who are referred for vulvar cancer have lesions with perianal or anal involvement. The chief problems in the management of patients with these tumors are the difficulty in obtaining adequate surgical margins while attempting to preserve anal sphincter function and deciding on which patients would be better treated either with a more radical excision and colostomy or with neoadjuvant radiotherapy. In our experience with vulvar carcinoma, partial resection of the external anal sphincter in combination with radical local resection of perianal tissue is associated with a significant rate of subsequent fecal incontinence. Careful sphincter reapproximation and levator muscle plication are done in an effort to minimize incontinence. Other important measures include good bowel preparation preoperatively, prophylactic antibiotics, and careful postoperative bowel management. In addition, we have had

P.1149

good results with the use of cutaneous rhomboid flaps in the reconstruction of the perineum and perianal area. These flaps allow for reconstruction of a perineal body, they bring tissue with a good blood supply into the area that promotes healing, and they allow closure of the wound without tension on the anus. However, if there is concern that these functional structures would be sacrificed in order to obtain margins, strong consideration should be given to neoadjuvant treatment as discussed later in the chapter.

FIGURE 49.9 Invasive squamous cell carcinoma involving the perineum and perianal skin. Note the pigmented lesions of carcinoma in situ adjacent to the ulcerated invasive cancer.

Regional Lymph Nodes

It should be kept in mind that certain vulvar cancers, by virtue of their anatomic extent, may have access to lymphatics that bypass the groins. These include tumors that extensively involve the anus (particularly the anal canal or its surrounding tissue), the rectovaginal septum, the vagina above the lower third, and the proximal urethra. However, for the vast majority of vulvar cancers, the primary metastatic pathway is via the inguinal lymph nodes.

Sentinel Lymph Node Dissection

A large number of reports have been published over the past 25 years on sentinel lymph node detection in various cancers. The concept relies on the presumption that the sentinel lymph node is the initial site of metastatic disease and that lack of metastatic involvement of the sentinel lymph node reflects an absence of metastasis in the rest of the lymph nodes in the basin. Lymphatic mapping is the standard of care in the United States for the surgical treatment of patients with clinically early-stage melanoma and breast cancer.

In the case of invasive squamous cell carcinoma of the vulva, interest in sentinel lymph node was driven by the high incidence and significant morbidity of complications following full inguinal-femoral lymphadenectomy. Though the incidence of groin wound complications has been reduced by separate incisions, it still may occur in up to 30% of patients, and the risk is increased by patient comorbidities and adjuvant chemotherapy or radiation. Therefore, the use of a lesser surgical procedure such as sentinel lymph node dissection is particularly relevant to vulvar cancer.

The concept of sentinel lymph node dissection applies well to vulvar cancer as the tumor location is easily accessible to injection of both radiocolloid and blue dye, and the lymphatic drainage is predictable for most tumors. With lymphatic mapping, the pathologist has only a few lymph nodes to examine, allowing a more detailed examination. Techniques such as serial sectioning, immunohistochemical staining, and reverse transcriptase-polymerase chain reaction analysis can be applied, increasing the sensitivity of the examination and allowing the detection of micrometastases.

When using the combined technique for vulvar cancer patients, lymphatic mapping is nearly always successful in identifying sentinel lymph nodes ([Fig. 49.10](#)). Further, the false-negative rate (based on standard pathology) is very low. A meta-analysis by Hassanzade and colleagues showed that pooled sensitivity of 27 studies was 92% and a negative predictive value of 97%. A phase III trial by the GOG including tumors from 2 to 6 cm showed a sensitivity of 92.1% and a negative predictive value of 97.4% when a combination of blue dye and radiocolloid was used. Another multiinstitutional observational study by van der Zee et al. revealed a sensitivity of 94.1% and negative predictive value of 97.1%. A full inguinal-femoral lymph node dissection is reserved for those patients in which the sentinel node is positive or has not been successfully identified.

Sentinel lymph node mapping is a promising method to substantially reduce the morbidity of inguinal lymphadenectomy. It is widely used in the management of vulvar cancer today. However, many unanswered questions remain, including who the best candidates are for the technique, the role of frozen section, the role of immunohistochemistry, the role of lymphoscintigraphy, the reliability of an isolated lymphoscintigraphy-directed unilateral negative sentinel node with a midline lesion, the role of ultrasound, management of a patient with a microscopically positive sentinel lymph node, the incidence of “skip” metastases, the reliability of lymphatic mapping after prior excisional biopsy, and the optimal lymphatic mapping methodology for vulvar cancer patients.

Modifications on the Extent of Inguinal-Femoral Lymphadenectomy

Various modifications on the extent of lymphadenectomy have been examined. Before the introduction of sentinel lymph node biopsies, a technique involving limited resection of the inguinal lymph nodes in the management of superficially invasive vulvar cancer was reported by DiSaia and coworkers in 1979. The dissection they described is aimed at removal of the superficial lymph nodes above the cribriform fascia, mainly associated with the great saphenous and superficial epigastric veins. These lymph nodes were sent for frozen section analysis. If results were positive, a complete bilateral inguinofemoral lymphadenectomy was performed. In the 1979 study, DiSaia and colleagues also reported 79 cases of invasive squamous cell carcinoma of the vulva treated with radical vulvectomy and bilateral inguinal-femoral lymphadenectomy. In these cases, it was noted that the deep femoral lymph nodes were never positive in the absence of positive superficial inguinal lymph nodes. The purpose of a superficial dissection only is to reduce the morbidity of the groin lymphadenectomy. The dissection is less radical and resulted in only one groin breakdown in the 18 patients in the series of DiSaia and associates. The series was updated in 1989, and they reported no groin recurrences in 50 patients, 42 of whom had been followed for a median of 36 months.

A GOG study specifically studied the issue of superficial inguinal lymphadenectomy in patients with early carcinoma of the vulva. The study group included clinical stage I patients with tumor invasion of 5 mm or less and no capillary or lymphatic space involvement. A modified radical vulvectomy

and ipsilateral superficial inguinal lymphadenectomy were performed, and 121 patients were evaluable. These were compared with a historical control group in the GOG registry who had undergone radical vulvectomy with bilateral inguinofemoral lymphadenectomy. Nine patients in this study, or 7.3%, experienced groin recurrences versus no recurrence in the control group. Six of the groin recurrences were in the ipsilateral groin, and 5 of the 9 patients

died of the recurrent vulvar cancer. The interpretation from this study was that superficial inguinal lymphadenectomy may not be adequate treatment even for early vulvar carcinoma. However, in a number of patients in this study, the tumors approached the midline; there is evidence that more medial tumors may have direct drainage to the deep inguinal lymph nodes. Another area of concern in this study is the high percentage of poorly differentiated tumors—almost twice as many as in the control group. Six of the nine groin recurrences in this study were from the poorly differentiated tumors. Whether poorly differentiated tumors are more likely to metastasize to deep inguinal or contralateral inguinal lymph nodes deserves further study. Subsequent additional retrospective data from large cancer centers also report a 5% to 10% incidence of groin relapse in patients with negative nodes from superficial inguinal lymphadenectomy.

FIGURE 49.10 A: Preoperative lymphoscintigram 60 minutes after intralesional injection of technetium-99. **B:** Intraoperative blue node blue sentinel node in the right groin after injection of isosulfan blue dye into the primary vulvar cancer.

The technique of superficial lymphadenectomy of the inguinal nodes above the cribriform fascia has been largely replaced by sentinel lymph node biopsy, but the occurrences of groin recurrences after apparently negative superficial nodes in these studies remains concerning.

The benefit of sparing versus sacrificing the saphenous vein remains unclear. Various studies have found conflicting results on the reduction of the incidence of lymphedema. A randomized trial by the GOG showed that application of fibrin sealant at time of lymphadenectomy also did not reduce the incidence of lymphedema.

FIGURE 49.11 Unilateral lymphadenectomy in a patient with a focal right-sided small vulvar primary.

Unilateral Groin Lymphadenectomy

Unilateral lymphadenectomy only on the side of a unilateral vulvar tumor has been another modification of surgical treatment that has been used for selected patients (Fig. 49.11). In 1981, Iversen reported on 53 women with unilateral tumors and lymph node metastases. Eighty-three percent of these patients had only one positive ipsilateral node, 15% had bilateral positive nodes, and one patient had contralateral positive lymph nodes only. Other retrospective studies have confirmed these results. It has been the opinion of a number of authors that capillary or lymphatic space involvement by tumor may increase the

risk of contralateral nodal metastases. Patients with tumors approaching the midline or involving more medial structures (perineum, clitoral hood or clitoris, vagina, and labia minora) are at increased risk for contralateral lymph node metastases. The issue of unilateral groin lymphadenectomy was studied to some extent in 1992 by Stehman and associates in a GOG study. Patients with early disease and negative ipsilateral superficial inguinal lymph nodes were treated with ipsilateral superficial inguinal lymphadenectomy and a modified radical vulvectomy. A few patients in this study did have a bilateral inguinal lymphadenectomy because of midline involvement. A total of 121 patients were in the study, and 3 experienced contralateral inguinal lymph node

recurrences. The vulvar lesions of these 3 patients ranged from 0.6 to 2.5 mm in depth of invasion, and all were poorly differentiated. Although lesion location was not given for these 3 cases, a large percentage of patients included in this study had lesions approaching the midline, as defined by involvement of the labia minora. Tumors with capillary or lymphatic space involvement were excluded from this study.

At present, unilateral inguinal-femoral lymphadenectomy appears to be a reasonable approach in a patient with a welllateralized early tumor that is well differentiated, with no capillary or lymphatic space involvement and with negative ipsilateral inguinal lymph nodes.

Pelvic Lymphadenectomy

During the late 1970s and early 1980s, several studies were published showing that carcinoma of the vulva metastasizes to the inguinofemoral lymph nodes before spreading to the pelvic lymph nodes. Extension of the groin lymphadenectomy to include removal of the pelvic lymph nodes continued to be performed in selected patients with positive inguinofemoral lymph nodes. A number of studies also showed that the 5-year survival rate of vulvar cancer patients with positive pelvic lymph nodes is less than 20%. A 1986 study by the GOG directed by Homesley compared pelvic lymph node dissection with groin and pelvic radiotherapy in patients with positive inguinofemoral lymph nodes. The study included 114 patients and showed no difference in morbidity between the two treatment arms and a better 2-year survival rate in the radiotherapy group (68% vs. 54%). The improved survival was seen in those patients with suspicious or grossly positive lymph nodes or those with more than one positive groin lymph node. There was no evidence that groin radiation therapy was beneficial to those patients with occult metastases and only one positive groin node. Review of the pattern of recurrence in that study suggested that adjuvant radiation was more effective largely because groin recurrences were reduced. The value of removing positive pelvic lymph nodes before radiotherapy is unknown. Pelvic lymphadenectomy is now rarely indicated in the treatment of vulvar cancer.

Omitting Groin Dissection for Superficial Disease

Extensive data support the contention that a subset of early vulvar carcinomas (carefully studied pathologically) can be identified that have an extremely low risk of nodal involvement. In a GOG study reported by Sedlis and associates, a subgroup (63 of 272) of patients with early disease was identified as having a zero incidence of lymph node metastases. This subset included nonmidline tumors with no capillary or lymphatic space involvement that were well differentiated or were grade 2 and limited to 2 mm in thickness. Other factors that have been studied for the purpose of identifying a low-risk group include tumor volume (which does not appear to have received further attention since Wilkinson's report in 1985), tumors that are largely carcinoma in situ with very early stromal invasion and with a pushing rather than an infiltrative pattern, tumor diameter, squamous cell type, the presence of an inflammatory response, and tumor ploidy.

There seems to be general agreement that the patients for whom it would be most reasonable to omit the lymphadenectomy are those with tumor invasion less than or equal to 1 mm and less than 2 cm in diameter. However, certain tumors with less than 1 mm of invasion should still be considered for lymphadenectomy. As reported in the literature, three of nine patients with nodal disease or nodal recurrence in association with tumor invasion less than or equal to 1 mm had poorly differentiated cancers ([Table 49.2](#)). Thus, women with suspicious lymph nodes, poorly differentiated tumors, tumors with capillary or lymphatic space involvement, and perhaps those with multiple foci or broad areas of invasion or aneuploidy should still undergo lymphadenectomy. It is important to remember that even with superficial invasion, metastases to the nodes do occur. In the report by Sedlis and colleagues of 272 patients with invasion of 5 mm or less, the groin nodes were positive in approximately 20%.

Operative Technique

Radical Vulvectomy

With the classic en bloc resection, the inguinal specimens are mobilized toward the vulva as just described ([Fig. 49.12](#)). This operation is rarely employed now due to its morbidity and data on favorable oncologic outcomes with less radical surgery. From the point of completion of the inferior inguinal dissections, incisions are continued down along the labiocrural folds on each side and across the perineum, where they meet. A medial mucosal incision is made along the introitus extending through the anterior vestibule and around the urethral meatus.

FIGURE 49.12 Classic en bloc resection of the vulva and inguinal-femoral nodes through one interconnected incision.

When radical vulvectomy is performed through a separate vulvar incision, the same labiocrural, posterior, and mucosal

incisions are used, and the same vulvar tissue is excised (**Fig. 49.13A**). The superior incision extends from the top of the labiocrural folds as an inverted V, with the point above the base of the clitoris. As previously discussed, a variable amount of superior tissue (i.e., mons pubis) is removed, depending on the location and size of the lesion.

FIGURE 49.13 Radical vulvectomy with bilateral inguinal lymphadenectomy done through three separate incisions. **A:** Bilateral inguofemoral lymphadenectomy through separate incisions is completed. Separate incision for radical vulvectomy is marked. **B:** Labiocrural incisions are extended to deep fascia of the urogenital diaphragm. **C:** Dissection proceeds dorsally off of the pubic bone. The vascular base of the clitoris is clamped, followed by transection and ligation. **D:** Perineal body and posterior vulvar tissues are dissected away from the anus.

The radical vulvectomy incisions may be modified somewhat depending on the location and extent of the tumor and the condition of the remaining uninvolved vulvar skin. The surgeon should attempt to attain at least a 2-cm margin of normal-appearing skin or mucosa around the tumor. To accomplish this, it may be necessary to excise a portion of the vagina,

P.1153

anus, or distal urethra. For an anterior lesion, it is reasonable to spare the perineal body; but for a posterior lesion, it is important to incorporate radical resection of this area. For a lesion (especially superficial) in proximity to the urethral meatus or anus, it is reasonable to limit the margin of resection to 1 cm (but not less) to preserve these structures and their function.

FIGURE 49.13 (Continued) **E:** The vascular vestibular tissue along the sides of the vaginal tube is clamped. Transection and suture ligation to follow. **F:** Radical vulvectomy resection is completed. **G:** Closure of the vulvar wound is completed.

The labiocrural incisions are extended to the lateral margins of the deep fascia of the urogenital diaphragm (**Fig. 49.13B**). The internal pudendal vessels are ligated as they are encountered entering the vulva at about the 4 o'clock and 8 o'clock positions. Superiorly, the specimen is dissected off the pubic periosteum and adductor fascia. The vascular base of the clitoris is clamped and transected, and a transfixion suture ligature is placed (**Fig. 49.13C**). If deemed necessary, the attachment of the ischiocavernosus muscles can also be transected at this level. Dissection of the superior portion of the vulva off of the pubic bone and adductor fascia is completed and joined, in the midline, to the transvestibular mucosal incision above the urethra. Inferiorly, a variable portion of the perineum (and in some cases the anus) is dissected upward and cephalad toward the vaginal incision (**Fig. 49.13D**). Care is taken as the vaginal incision is approached above the perineum to avoid injury to the anal canal. Using the index finger or a large Kelly clamp, the surgeon separates the vaginal tube bluntly from the underlying soft tissue cephalad to the vestibular structures. The mucosal incision is then completed, separating the vagina (with the urethra) from the specimen. This dissection can be facilitated by splitting the specimen in the midline anteriorly or posteriorly. The remainder of the dissection off the

P.1154

underlying deep fascia of the urogenital diaphragm is completed. Clamps and transfixion suture ligatures of no. 0 or 2-0 polyglactin are used during transection of the tissue along the side of the vaginal tube in the region of the vestibular bulbs (**Fig. 49.13E**).

After removal of the specimen, the wounds are copiously irrigated with antibiotic solution, and hemostasis is secured (**Fig. 49.13F**). After en bloc resection, the superior abdominal wall flap and the groin and vulvar thigh flaps are further mobilized as necessary to achieve closure of the wounds without tension. Any ischemic-appearing skin is excised. It is very useful, especially if there is an element of vaginal relaxation, to mobilize the lower vagina to facilitate wound closure. Any pelvic relaxation defects (i.e., cystocele, rectocele, loss of the posterior urethrovesical angle) are repaired at this time. To the extent that it is necessary or possible, the perineal body is also reinforced or reconstructed at this time.

The vulvar wound and the perineal area are closed with vertical mattress 2-0 delayed absorbable sutures (**Fig. 49.13G**). Depending on the amount of tissue that has been removed, the superior portion of an en bloc wound may be difficult to close. When done through a separate incision, closure of the vulvar wound is under much less tension, again because of preservation of the inguinal skin bridges. Careful attention must be paid to closure of the periurethral area. The urethra should be secured on a straight course without tension. A hood of skin above the urethra is also avoided because this can obstruct the path of the urinary stream and cause spraying.

Modified Radical Vulvectomy

As previously discussed, it is reasonable in most patients to manage the vulvar lesion locally with a modified radical vulvectomy. This operation consists of radical removal of the portion of the vulva containing the tumor and any skin, which is involved with high-grade VIN. It is performed with the techniques described earlier except that the excision is basically limited to removal of that particular part of the vulva. The lateral and deep tumor margins are not compromised by this operation. After the surgeon carefully demarcates a 2-cm radius of normal skin or mucosa around the tumor, an encompassing incision

is designed that will readily close and be as cosmetically acceptable as possible ([Fig. 49.14](#)).

FIGURE 49.14 Modified right radical vulvectomy and unilateral right inguinal-femoral lymphadenectomy.

P.1155

Lymphadenectomy

Sentinel Lymph Node Dissection

Sentinel lymph node detection is currently accomplished using two methods of lymphatic mapping: blue dye and radiocolloid. One to two milliliters of isosulfan blue dye (Lymphazurin) is injected superficially around the periphery of the primary tumor, and the blue-dyed lymphatic channels are followed. An incision is made over the anticipated location, and the dyed lymph node or nodes that have been stained by accumulating the blue dye are removed. Alternatively, the periphery of the tumor is injected with 400 mCi of technetium-labeled sulfur colloid 2 to 4 hours before surgery. A preoperative technetium scan (lymphoscintigraphy) is done, which may be helpful in confirming lymph node uptake, localization of target lymph nodes, unilateral versus bilateral lymphatic drainage, and identification of the unusual case of predominant drainage to pelvic lymph nodes. An intraoperative gamma counter is used to identify one or more sentinel lymph nodes ([Fig. 49.15](#)). The removed lymph nodes are checked with the gamma counter, and complete removal is assured when the radioactivity in the inguinal area returns to background levels. In practice, the two techniques are complementary and are frequently used together. The removed nodes are sent for frozen section, and the small skin incision in the groin is closed with absorbable sutures. Drains are not required. If the frozen section is negative, no further lymphadenectomy is required. However, if metastatic disease is detected, a complete inguinal-femoral lymphadenectomy is indicated.

Inguinal-Femoral Lymphadenectomy

An incision is made starting about 2 to 4 cm medial and about 2 cm caudal to the anterior superior iliac spine. The incision gradually curves downward just above the superior border of the inguinal ligament medially to the inguinal ring or about 2 cm below and 2 cm medial to the pubic tubercle. Unless there is a large clitoral lesion or palpably suspicious nodes, the mons pubis is spared, and separate incisions with a skin bridge are made as illustrated in [Figure 49.16](#). For anterior lesions, such as those involving the clitoris, a portion of the mons pubis is included in the resection and the lymphadenectomy on one or both sides may be done en bloc with the radical vulvectomy as illustrated in [Figure 49.12](#). From the lateral points, caudal incisions are carried medially so as to excise a strip of skin (optional) 2 to 4 cm in width. Excising an ellipse of the skin may reduce the likelihood of skin necrosis and facilitate more complete dissection of the groin. This incision is designed to extend from just below the fossa ovalis (this can generally be identified clinically as the area just medial to the femoral pulsation in the groin) to the top of the labiocrural fold above a point just medial to the external inguinal ring. In the presence of grossly positive inguinal lymph nodes, a wider resection of both the groin skin and fat is necessary to help ensure adequate tumor clearance. The separate groin skin incision may also be done vertically (with the leg), centered across the fossa ovalis, and about halfway between the femoral artery and pubic tubercle.

FIGURE 49.15 Intraoperative use of the gamma probe to identify the radioactive sentinel node.

FIGURE 49.16 Separate incisions for bilateral lymphadenectomy done with a radical vulvectomy.

Leaving a layer of subcutaneous tissue with the skin, the superior incision is undermined so that the lymph node-bearing adipose tissue above the inguinal ligament and around the superficial circumflex iliac, as well as the superficial epigastric vessels, are included with the resection. These vessels are ligated or electrocoagulated as they are encountered. The superior dissection over the groin area is carried down to the superior border of the inguinal ligament (**Fig. 49.17A and B**). The midline aspect of the superior flap can be mobilized off the pubic bone and rectus fascia at this point to facilitate later closure of the wound without tension. Dissection of the block of inguinal tissue is carried inferiorly off of the inguinal ligament. The lateral corner is dissected medially off of the sartorius fascia. The inferior flap of the lower incision is also mobilized, especially medially, and the saphenous vein is identified as it enters the region of the femoral triangle (**Fig. 49.17C**). Accessory saphenous veins can also be seen entering this area. If it is to be sacrificed, the long saphenous vein is isolated and ligated with a free-tie and a transfixion ligature of 2-0 polyglactin (Vicryl). The vein with its surrounding block of lymph node-bearing tissue is dissected superiorly off of the sartorius and adductor fascia. Dissection of the block of inguinal tissue is continued from the three sides toward the fossa ovalis. As this area is approached, the overlying cribriform fascia is recognized, and the femoral artery pulsation can be palpated in the lateral aspect. En bloc dissection continues and includes the contents of the fossa ovalis (**Fig. 49.17D**). The area under the fascia lateral to the femoral artery should be left undisturbed as the femoral nerve lies lateral. There are no lymph nodes of consequence here, and avoidance of this area prevents injury to the femoral nerve and possibly reduces subsequent

P.1156

lymphedema. Rather, resection of the cribriform fascia begins over the area of femoral pulsation, exposing the underlying femoral vessels. A few small branches of the femoral nerve are sacrificed during this dissection. The sheath of the femoral artery is incised along its anteromedial aspect from somewhere between the base of the fossa ovalis and the apex of the femoral triangle to its emergence from under the inguinal ligament. Branches, such as the external pudendal artery, are ligated as they are encountered. There is no purpose in dissecting under the artery or between the femoral artery and vein. Rather, the dissection that has been performed over the top of the artery is continued over the top of the vein, mobilizing the specimen to the medial aspect of the femoral vein. During this process, the saphenofemoral venous junction is identified, ligated with a 2-0 silk free-tie followed by a suture ligature for security, and transected, thus removing several centimeters of the saphenous vein with the specimen (**Fig. 49.17E**).

FIGURE 49.17 A: Inguinal-femoral lymphadenectomy. The corner of the groin specimen is dissected up from lateral to medially off the sartorius muscle. The lateral portion of fossa ovalis and cribriform fascia are exposed. **B:** The block of lymph node-bearing tissue has been mobilized, and the fatty lymphatic tissue overlying the saphenous vein is clamped.

An alternative method, as long as there are no adherent suspicious lymph nodes, is to dissect the saphenous vein free of the specimen so that it can be preserved, potentially reducing the risk of subsequent lymphedema. Complete dissection of the space medial to the vein is important because this is where most of the femoral groin nodes are located. The specimen is freed from the femoral vein medially, from the inguinal

P.1157

ligament superiorly, and from the underlying pectineal fascia. Dissection is continued toward and off of the adductor longus fascia until the labiocrural fold is reached ([Fig. 49.17F](#)).

FIGURE 49.17 (Continued) **C:** The saphenous vein is identified, isolated, clamped, and divided near its entrance into the femoral triangle. **D:** Dissection of the femoral lymph nodes beginning with the separation of the cribriform fascia and the contents of the fossa ovalis from the anterior aspect of the femoral artery. **E:** The groin specimen containing the fatty nodal tissue above the cribriform fascia and the femoral nodes below the cribriform fascia are reflected medially exposing the femoral vessels and the insertion of the saphenous vein. **F:** The saphenous vein has been divided and ligated. The nodal tissue bundle is then completely excised and removed. The femoral triangle has been cleared of all nodal tissue.

To protect the exposed femoral vessels in the event of subsequent wound breakdown, the sartorius muscle can be transposed over them at this point. Alternatively, the vessels can be covered by a variety of other materials or simple approximation of musculofascial tissues. To accomplish sartorius transposition, the muscle is divided with cautery at its tendinous attachment to the anterior superior iliac spine. The proximal end of the muscle is then mobilized and transposed so that it covers the femoral vessels. It is sutured at this location to the inguinal ligament and pectineal fascia with 0 polyglactin (Fig. 49.18). We have largely discontinued the practice of transposing the sartorius muscles because of the improved healing of these wounds and less radical dissection.

If a superficial inguinal lymphadenectomy has been chosen (also generally done through separate incisions), the same general dissection is done except that the cribriform fascia and underlying femoral lymph node-bearing tissue are left intact. All lymph nodes around the saphenofemoral junction should be included, and any prominent deeper lymph nodes medial to the femoral vein should also be removed. In the absence of clinical suspicion, the only lymph nodes of concern deep to the cribriform fascia are those medial to the femoral vein. There is unlikely to be a significant increase in morbidity by extending the dissection to include removal of these femoral lymph nodes.

If a prominent femoral lymph node can be identified at the most superior aspect of the dissection in the space just medial to the femoral vein (Cloquet node or node of Rosenmüller), this can be used as a sentinel lymph node when evaluating the

P.1158

risk of pelvic lymph node metastases. When such a lymph node is positive, a search may be made for further nodes above this by carrying the dissection up along the femoral artery under the inguinal ligament or the patient may be treated with pelvic radiation postoperatively.

FIGURE 49.18 The transposed sartorius muscle.

Soft, active suction drains are placed in each groin and are brought out through separate stab wounds superolaterally. The lymphadenectomy site is copiously irrigated. When there is anticipated tension in the closure, the groin wound may be approximated with a large mass closure using no. 2 polypropylene vertical mattress retention sutures (**Fig. 49.19A**). Three to five sutures are placed on each side. Each suture starts several centimeters from the edge of the superior flap, with a bite then taken of the underlying inguinal ligament. This is designed to close the dead space under the superior flap. Under the inferior flap, a bite of sartorius, adductor, or pectineal fascia is taken (with care taken to avoid injury to the femoral vessels and nerve), followed by placement of the suture from inside to out through the inferior flap several centimeters from the edge. Again, this is designed to close the dead space of the inferior flap and, once pulled together, to close the dead space of the midline wound. Going back from inferior to superior, a small bite of each skin edge is then taken, which is designed to approximate these edges. The sutures are not tied until all have been placed. The sutures are tied somewhat loosely, with only enough tension to bring the wound together (**Fig. 49.19B**). The skin is further closed with staples (**Fig. 49.19C**). When there has been less extensive dissection, the groin wound may be closed with 2-0 polyglycolic acid suture, approximating first the dead space with interrupted sutures and then the skin with vertical mattress or subcuticular sutures. En bloc groin incisions are closed in an identical manner, but this is delayed until completion of the entire resection. With separate incisions, the medial aspects of the groin wounds are under much less tension and are easily closed because of preservation of the inguinal skin bridge. Separation of the groin and vulvar wounds and especially closure without tension are the factors thought to be largely responsible for the reduced wound complications seen with the three-incision technique.

Vulvar Reconstruction

After radical resection for carcinoma of the vulva, the wounds can generally be closed primarily. This is greatly facilitated when the incisions are modified somewhat (as with sparing of the mons pubis) and especially when separate groin incisions are used. When an extensive resection is necessary, it may not be possible to close the wound primarily or at least not without considerable tension. This is often the case after resection of a recurrent tumor, where previous radical surgery has already left a paucity of tissue. If the area was treated previously with radiotherapy, then closure may be difficult because of the lack of elasticity of the fibrotic tissue and because of radiation-induced healing impairment. Under these various circumstances, closure of the incisions and healing can be facilitated by a variety of reconstructive procedures. Other potential benefits of such reconstruction include maintenance of anal, urethral, and sexual function and a more cosmetically acceptable result. However, packing the wound open is sometimes the best option, and healing by secondary intention is usually quite satisfactory.

Closure of groin and vulvar wounds using reconstructive techniques involves moving a block of expendable tissue (with its blood supply intact) from some nearby site into the deficient area. The mobilized block of tissue is commonly referred to as a flap. Flaps are classified according to what layers of tissue they include and according to their blood supply. The types of flaps that have been useful in reconstruction of the vulva and groin are full-thickness skin (random and arterial based), fasciocutaneous, and myocutaneous flaps. Some flaps remain completely attached at their base and are rotated into the defect, whereas others are partially separated from the base and are transposed as an island of tissue.

Full-Thickness Skin Flaps

A full-thickness skin flap involves rotating an adjacent block of skin with its underlying subcutaneous tissue into the defect. The flap is mobilized from the donor site but remains attached at its base; through this base travels the arterial and venous circulation. The blood supply of the flap may be random, or it may depend on a specifically planned arterial source. A random flap relies on the many small musculocutaneous perforating vessels that are retained through the base. For this reason, the subcutaneous layer must be kept thick, and the length of the flap should not be much greater than the width of the base (1 to 1.5 times greater). This is the type of flap most commonly used for reconstruction of a radical vulvectomy wound. The healing of such flaps is less reliable in patients with impaired wound healing ability, such as those with diabetes, heavy tobacco users, those with vascular disease, and patients who have previously received radiation therapy to the region.

A few specific arterial-based full-thickness skin flaps, sometimes called axial flaps, have been used for reconstruction in vulvar cancer patients. Arterial sources of these flaps have included the internal pudendal, circumflex iliac, superficial circumflex iliac, superficial inferior epigastric, superficial branch of the deep external pudendal, and superficial external pudendal arteries. With some of these arterial flaps, the deep fascia must be carefully mobilized with the subcutaneous tissue to maintain an adequate blood supply. The main advantage of an arterial flap, because of the good arterial blood supply, is that it can

be considerably longer than a random flap. However, these flaps are technically more difficult to construct and have a low margin for error in terms of compromising blood supply.

P.1159

FIGURE 49.19 A: Large block closure of separate groin incisions with vertical mattress sutures. Note the lateral/superior placement of the suction drains. **B:** The mattress sutures are tied somewhat loosely. **C:** The skin closure is completed with staples.

Fasciocutaneous Flap

Full-thickness skin flaps that include the deep fascia off the underlying muscle are known as fasciocutaneous flaps. These are more reliable than random cutaneous flaps because the preserved fascial layer provides additional musculocutaneous perforating vessels along its length. A fasciocutaneous flap can also be relatively long and is transposable as an island of tissue. Some fasciocutaneous flaps have a designated arterial blood supply. Locally useful fasciocutaneous flaps include the pudendal thigh, superior medial thigh, inferior gluteal, and island groin flaps.

Myocutaneous Flap

A myocutaneous flap makes use of an expendable muscle with its intact overlying fascia and cutaneous tissue. The use of these flaps for vulvovaginal reconstruction began after the 1976 report by McCraw and colleagues. A substantial blood supply is preserved through a narrow pedicle connected to the muscle, which allows the flap to be transposed as an island with a wide arc of rotation. Another advantage of a myocutaneous flap is its capacity to bring tissue into the defect that has a blood supply separate and independent from that of the operative site. This makes these flaps particularly valuable in the reconstruction of heavily radiated tissues. These flaps are also somewhat bulky and have the ability to fill a large tissue defect. The main disadvantage of myocutaneous flaps is that they are technically demanding, and the viability of these flaps is somewhat tenuous.

The difficulties resulting from a large wound created by an extensive radical vulvectomy with bilateral inguofemoral lymphadenectomy were previously discussed. Reconstruction of large vulvar wounds with bilateral tensor fasciae latae (TFL) myocutaneous flaps has been reported. The TFL originates from the anterior superior iliac spine. It inserts into the fascia lata and is supplied by the lateral femoral circumflex artery. The base is just lateral to the groin wound, into which the flap is directly rotated. The flaps are easily made long enough to reach and close the often large area created by resection of the mons pubis and anterior vulva. A TFL myocutaneous flap is also useful for reconstruction of the groin after extensive resection for recurrent disease ([Fig. 49.20](#)).

P.1160

FIGURE 49.20 Tensor fasciae latae flap being rotated from the thigh to close a large groin wound.

The rectus abdominis myocutaneous flap, based on the inferior epigastric artery, is also useful for reconstruction of a large groin defect. The block of tissue based on this muscle is taken from the abdominal wall, and the muscle is divided at the superior border of the flap. The island of cutaneous tissue is completely mobilized with its carefully preserved attachment to the muscle, and this is further mobilized inferiorly. This allows the island flap to rotate down easily into the groin (or vulva) through a generous subcutaneous tunnel. The rectus abdominis myocutaneous flap is also suitable for the reconstruction of large vulvar wounds ([Fig. 49.21](#)).

Other Considerations in Reconstruction

Flaps are particularly useful in the reconstruction of vulvar wounds after radical resection of cancer involving the perineal or perianal tissues. Such a resection removes the entire perineal body as well as portions of the superficial muscles and leaves a large defect that is difficult to close ([Fig. 49.22A](#)). Poor healing of this area may significantly compromise both anal and coital function. The use of flaps for such a defect allows closure without tension and brings tissue with a good blood supply into the area, which promotes healing and helps recreate a perineal body. Preventing tension on the anal apparatus helps promote healing of its associated reconstructed musculature and helps preserve its function. Reconstruction of a perineal body separates the vagina from fecal contamination and helps create a smooth and less scarred platform for intercourse. For reconstruction of such defects, we prefer to use local, full-thickness rhomboid skin flaps ([Fig. 49.22B-D](#)). Closure of a larger defect involving the perineal or perianal and vulvar areas may be better accomplished with gluteal thigh fasciocutaneous, gluteus maximus myocutaneous, or gracilis myocutaneous flaps.

FIGURE 49.21 Rectus abdominis myocutaneous flap is brought through a subcutaneous tunnel to close a large perineal wound.

Closure of a heavily radiated wound should be accomplished with a block of relatively unirradiated tissue, the blood supply to which is unlikely to have been significantly compromised by the prior treatment. In general, myocutaneous flaps are better for this purpose.

Many other flaps have been reported to be useful for groin and vulvar reconstruction and may be used depending on the individual situation and preference of the surgeon.

Postoperative Care

Vulvar Wound Care

After closure, silver sulfadiazine (Silvadene, Hoechst Marion Roussel) cream is applied to the perineal wound, and a light dressing is placed. In the recovery room, ice is applied to the vulvar wound, and this is continued off and on for 48 to 72 hours. Depending on the degree of perineal or perianal resection,

several days of bowel rest may be indicated, with or without a constipating agent, followed by a stool softener. On postoperative day 3 or 4, the patient is started on a regimen of cleansing the vulvar wound with a showerhead, followed immediately by complete drying of the area with a hair dryer on the cool air setting. This is done three times a day and as needed (i.e., after a liquid bowel movement) and is continued until the wounds are healed. If moisture in the wound is a problem despite this regimen, other useful measures include placing a roll of gauze between the legs and against the wound between washings, increasing the frequency of washings, not wearing

P.1161

an undergarment, and applying a heat lamp to the area three times a day between washings. All of these efforts are aimed at keeping this normally warm and moist area clean and dry, which reduces the risk of infection and promotes healing. Intermittently leaving the legs slightly apart to air (the immodest position) is also beneficial. The patient should also avoid sitting on the healing wound.

FIGURE 49.22 **A:** Large posterior perineal defect that may be difficult to close primarily. **B:** Planning the rhomboid flap. The defect is divided into two rhomboids. Measurements *A* and *B* are made and marked on the skin of the thigh (*A'* and *B'*). After the flap is mobilized, *1'* will be located at the posterior vaginal introitus (*1*) and *2'* at the anterior anus (*2*). **C:** The bilateral rhomboid flaps are developed. **D:** The flaps have been rotated, and the posterior perineal defect is closed.

If the vulvar wound is left open, postoperative management is the same except that silver sulfadiazine cream is applied after each showerhead, blow-drying until there is good granulation tissue formation. In addition, these women are seen more frequently in the office to ensure good wound care and healing.

The patient is usually immobilized for at least 24 hours after a radical resection. Venous thromboembolic prophylaxis is necessary until the patient is ambulating. If the wounds are closed under tension, ambulation is restricted for 3 to 5 days, and the patient is instructed to avoid leg abduction when getting into and out of bed. A no. 18 Foley catheter is left in place

P.1162

for 3 to 5 days until the patient is easily ambulatory to act as a stent and divert urine while the urethra is healing.

Groin Care and Drains

A closed-suction drain such as a Jackson-Pratt or Blake drain is placed in the groin wounds. Drains are removed when the output has decreased to 30 mL or less per day to prevent lymphocyst formation. Compression boots are continued during this time, and care is taken to avoid marked femoral vein compression.

Especially when lymph node dissection has been extensive or radiotherapy is planned, long-term use of fitted graduated compression stockings may be beneficial.

Surgical Complications

Groin Complications

In published series of large numbers of patients undergoing en bloc radical vulvectomy with bilateral inguinofemoral lymphadenectomy, a high percentage

(overall about 50%) of significant wound breakdown in the inguinal sites has been reported. Extensive undermining of the skin, fluid collections in the wound, and infection are all contributing factors, but the main problem is the considerable tension placed on these wounds during closure. The single most effective method of reducing groin wound breakdown (to around 20%) has been the use of separate incisions, as previously discussed. Suggested but unproven methods of prevention include prophylactic antibiotics, attempts to ligate lymphatic vessels, and prophylactic suction drainage. Modifying the resection by preserving the mons pubis, minimizing undermining of the skin, leaving a layer of fat with the skin, and excising any dark or dusky skin at the end of the operation may also reduce groin wound complications. With more extensive resection, plastic reconstruction (such as with TFL flaps) is also likely to be helpful.

Management of groin wound breakdown is similar to that of other wounds, with debridement and wet-to-dry dressings. During debridement, the surgeon must be cognizant of the femoral vessels. If infection has completely cleared, the wound is clean, and the tissues are pliable, secondary closure may be attempted.

About 10% to 20% of patients develop a clinically evident fluid collection (seroma or lymphocyst) in the groin. When such fluid collections are small and asymptomatic, they should be left alone. The most commonly recommended treatment has been repeated aspirations until resolution. When there is infection, prompt hospitalization with drainage and intravenous antibiotics is necessary. For persistent collections, we prefer reinstitution of suction drainage combined with pressure. Sclerotherapy is another option. If the problem is recalcitrant, the best course of action is to open and pack the cavity.

Femoral nerve injury is a rare but potentially debilitating complication of inguofemoral lymphadenectomy. Not uncommonly, a few sensory branches are sacrificed, resulting in numbness or paresthesia of the anterior thigh. However, surgical injury of a major portion of the nerve lateral to the artery results in significant and potentially permanent difficulty with ambulation. As previously discussed, this complication is prevented by avoiding dissection on the lateral side of the femoral artery.

In the past, large series of patients undergoing en bloc radical vulvectomy with bilateral inguofemoral lymphadenectomy reported a 1% to 2% incidence of severe postoperative hemorrhage from femoral vessel rupture. This was related to the extensive wound breakdown that occurred in a high percentage of these patients, with associated infection and necrosis involving the exposed and denuded femoral vessel walls. Coverage of the vessels by transposition of the sartorius muscle largely prevented this complication. With the use of separate incisions as well as other techniques that have reduced groin wound breakdown, and with avoidance of vessel skeletonization, postoperative femoral vessel rupture is now exceedingly rare.

Lymphedema

After groin node dissection, it is not uncommon for a patient to develop some degree of lower extremity edema. It is most often transient or mild but persists chronically as a significant problem in about 10% of patients. Factors that have been implicated as contributing to this complication include the performance of a pelvic lymphadenectomy, groin or pelvic radiotherapy, major groin wound breakdown, postoperative lower extremity lymphangitis, sartorius muscle transposition, and preoperative lymphangiography. Suggested methods for reducing this problem include limiting the groin dissection to the sentinel lymph nodes when feasible, confining femoral lymphadenectomy to the medial side of the femoral vein, preserving the fascia lata, avoiding pelvic lymphadenectomy, using adjuvant radiotherapy in a more tailored and selective manner, sparing the saphenous vein, wearing fitted support stockings prophylactically for the first 6 months to 1 year after surgery, using a low-dose prophylactic antibiotic to prevent lower extremity lymphangitis, and treating lymphangitis promptly with antibiotics when it occurs. Management of lymphedema begins with patient education, avoidance of trauma to the affected leg, and meticulous skin and nail care. Constricting clothing or jewelry should be avoided. A treatment program with a physical therapist specifically trained in lymphedema management is particularly helpful. Components of management include intermittent leg elevation, manual lymphatic drainage (massage) combined with bandaging, a carefully tailored moderate exercise program, carefully fitted compression stockings, and a carefully fitted pneumatic compression device. There is no effective pharmacologic therapy, and lymphangioplasty remains investigational. Some lymphedema patients occasionally develop lymphangitis, which presents with fever, pain, and redness of the involved extremity. This condition should be treated promptly with an intravenous antibiotic that covers streptococci.

Other Urogenital Complications

Urinary tract infection is common in these patients and generally resolves with antibiotics or catheter removal. However, elderly women sometimes tolerate urosepsis poorly and become profoundly ill. A diligent search for urinary tract infection, treatment of the infection, and removal of the Foley catheter as soon as is practical are important measures in these patients.

Osteitis pubis and osteomyelitis are rare complications that may not become symptomatic until several weeks after radical vulvectomy. The patient reports pain over the pubic bone and difficulty with ambulation, which may become chronic and debilitating. This complication is more likely to develop if the periosteum is traumatized, although this is not always avoidable. Extensive use of the cautery on the periosteum should be avoided. The mainstay of treatment is bed rest and nonsteroidal anti-inflammatory drugs. Even more rarely, frank osteomyelitis of the pubic bone develops. This is a serious condition that requires debridement and drainage of the bone, along with prolonged antibiotic therapy.

Rarely, a rectovaginal fistula develops days to weeks after radical vulvectomy. Prevention of this complication is based

P.1163

on preoperative evacuation of the colon, careful surgical dissection of this area, and prompt recognition of rectal entry. Surgical repair of the fistula is carried out once the area has healed and regained its elasticity.

During follow-up of radical vulvectomy patients, it is not uncommon to discover pelvic relaxation (cystocele or rectocele). This may be related to resection of the perineal body with the attendant loss of its support functions or it may simply be a result of aging. If the patient's medical condition and extent of cancer surgery permit, any stress urinary incontinence or defects in vaginal support should be repaired at the time of radical vulvectomy because they are likely to worsen subsequently.

Spraying or misdirection of the urinary stream is related to poor alignment of the urethra, a hood of periclitoral tissue obstructing the path of the urinary stream, or asymmetry created by a hemivulvectomy. Digital manipulation or the use of an applied collection or directing device is useful, but in some cases, minor surgical revision may offer the best solution.

Rarely, after inguofemoral lymphadenectomy, a femoral or inguinal hernia develops. When a hernia or any apparent weakness of the femoral or inguinal

canal is noted at the time of surgery, it should be repaired at that time. Avoiding incision of the inguinal ligament is also important in the prevention of this complication.

Sexual Function

More studies on sexual function and sexuality after vulvar surgery have been done recently. Generally, the capacity for intercourse remains. However, patients experience a marked sense of disfigurement and a reduction in genital sensitivity, and depression related to negative body image is also seen. A decrease in desire and relationship dissatisfaction are also common in women treated with radical vulvectomy. Dyspareunia can occur as a result of stenosis or scar tissue, and these problems may be surgically treatable. Some patients remain orgasmic. There is evidence to suggest that a modified radical vulvectomy, especially with preservation of the anterior vulvar structures, helps maintain sexual function. It does seem reasonable to assume that sparing of as much normal vulvar tissue as possible is less likely to produce sexual dysfunction and a sense of disfigurement than is radical resection.

Postoperative Adjuvant Treatment

This section deals with adjuvant therapy following radical or modified radical vulvectomy with inguinofemoral lymphadenectomy. Postoperatively, the only adjuvant therapy that appears to be of value is radiotherapy often given together with chemotherapy (see below). This can consist of radiotherapy to the local area of primary tumor resection, to the groins, to the pelvic nodal areas, or to all three. Postoperative radiotherapy administered to the remaining vulvar tissues is rarely indicated but may be considered when an extensive tumor has been resected with positive or close margins that cannot be readily excised further. As discussed later, this type of therapy may be particularly indicated in some Bartholin cancers because they are sometimes difficult to resect widely because of their deep-seated location.

Postoperative adjuvant radiotherapy has been used primarily in patients with metastases to the groin lymph nodes. Substantial data now exist regarding the prognosis and recurrence pattern in these patients. Because vulvar cancer has a recurrence pattern that tends to remain largely locoregional, its use for patients at high risk of recurrence is rational. There are further data to substantiate the benefit of radiotherapy in this setting. When a patient has metastases limited to microscopic involvement of one or perhaps two unilateral groin lymph nodes, the incidence of groin recurrence and pelvic lymph node metastases is very low, the overall prognosis is still reasonably good, and the benefit of postoperative radiotherapy is not great. If, however, there is gross replacement or extracapsular involvement of a lymph node, or involvement of three or more lymph nodes, the risk of groin recurrence and pelvic nodal metastases is substantial and the benefit of adjuvant postoperative radiotherapy is much more evident. A head-to-head comparison of pelvic lymphadenectomy alone versus adjuvant groin and pelvic radiotherapy showed a decrease in recurrence and increase in survival in the radiation group. When such treatment is anticipated, placement of metal clips to localize metastatic sites may aid the radiation oncologist in treatment planning.

Postoperative adjuvant chemotherapy has not been extensively studied, but it is unlikely to be of substantial benefit with use of the currently available agents.

Special Management Techniques

Concurrent Chemoradiotherapy

Combined chemoradiotherapy with or without resection has been used increasingly over the past few decades with promising results in squamous cell carcinomas of several different primary sites. This approach has been particularly successful in the treatment of squamous cell carcinoma of the anus. This type of carcinoma may be somewhat analogous to carcinoma of the vulva in terms of location and, in some instances, preservation of the anus.

The most commonly used chemotherapeutic agents are 5-fluorouracil, mitomycin-C, and cisplatin. Most data have been accumulated over the past 20 years with the use of regimens similar to those used at other sites. There have been no trials of head-to-head comparison between chemoradiotherapy and radiotherapy alone for primary treatment of vulvar cancer. A single trial by Raffeto et al. of 20 cases of recurrent vulvar cancer using both modalities showed only 20% long-term survival in the entire cohort. The addition of cisplatin to radiotherapy in vulvar cancer is largely extrapolated from the literature on cervical cancer. Results suggest a high rate of local control for locally advanced or recurrent disease (Table 49.4). However, an increase in the degree of local morbidity is seen with this type of therapy. Most of these patients develop a moderate amount of mucositis in the vulvovaginal area. This leads to dysuria and generalized pelvic and perineal discomfort. An indwelling catheter (suprapubic in some cases) and the use of various perianal and rectal preparations help ease the discomfort, although treatment interruption is necessary at times. A GOG trial of chemoradiotherapy with cisplatin and gemcitabine in as primary treatment for locally advanced vulvar cancer is ongoing.

Primary or Neoadjuvant Radiotherapy

The role of radiotherapy in the treatment of this malignancy remains unclear. In our experience, teletherapy combined with interstitial needles for locally advanced carcinoma of the vulva appears to be effective but associated with extensive morbidity. With the use of more modern treatment techniques and better definition of the optimal delivery of radiotherapy to the vulva, the role of this modality has been expanded. A modified course of radiotherapy used in combination with other treatment modalities appears to be more efficacious than radiotherapy alone in the treatment of this disease. Combined treatment modalities for this disease present an important form of management. Especially in patients with locally unresectable disease, initial treatment with external radiation therapy combined with chemotherapy appears to be the most reasonable approach. With the guidance of imaging and perhaps random biopsies, an additional treatment course could be planned. Careful planning of how much surgery may be necessary or how much volume needs additional radiation therapy may contribute to an overall decrease in morbidity in these patients.

P.1166

Starting with the work of Boronow and others, data confirm that megavoltage radiotherapy can cause marked regression of even locally advanced vulvar carcinoma to the point at which a more limited resection can be undertaken (often with an improved resection margin) with sparing of organ function and improved quality of life. In an update of his study in 1987, Boronow reported that, of 48 bladders and 48 rectums at risk, 1 bladder and 2 rectums were lost because of local failure, and 1 bladder and 1 rectum were lost because of radiation injury. The report did not mention other types of bladder or bowel morbidity. Of 40 patients who underwent vulvectomy, 17 contained no identifiable residual cancer. There were no reported problems with wound healing. Similar results have been reported in other studies (Table 49.5). In these studies, survival with locally advanced disease so far has been comparable to that with ultra-radical surgery. Again, the optimal radiotherapeutic techniques for such treatment are not well defined. Boronow's group generally used a combination of external beam radiation and intracavitary brachytherapy, delivering a mean vaginal surface maximum dose of 86.26 Gy. His group and others have also used preoperative external beam therapy only, generally delivering a dose of about 50 Gy to the whole pelvis, including the vulva and groins. Surgery has generally been performed 2 to 6 weeks after completion of radiotherapy. Boronow and associates reported 42.5% of vulvectomy specimens and Hacker and colleagues reported 4 of 7 (57%) vulvectomy specimens to be negative for residual tumor.

Management of the regional lymph nodes in the context of combined treatment modalities has been variable and, by necessity, highly individualized.

Complications of Radiotherapy

Acute skin changes are seen almost universally in patients undergoing radiotherapy to the vulva and groin regions. A meta-analysis showed that moist desquamation was the most common complication in patients undergoing radiotherapy to the vulva and groin, and a GOG trial found that half cutaneous complications were severe (grades 3 and 4). Careful skin care, treatment of any associated infection, and even breaks in treatment are sometimes necessary. Adjuvant radiotherapy to the groin also increases the risk of lymphedema, as described in the previous section. Preoperative radiotherapy also increases the risk of surgical complications including necrosis, wound breakdown, abscess, and hematoma. Long-term complications are usually due to radiation fibrosis, which causes loss of tissue elasticity leading to contracture. This is the case in radiation-related urethral stricture, which may require repeated dilation. When the radiation field is extended into the pelvis, there is also the added risk of cystitis and proctitis.

Neoadjuvant Chemotherapy

A large number of pilot studies have reported on the use of neoadjuvant chemotherapy (NACT) in cervical cancer. The planned course of chemotherapy has been followed by surgery, radiotherapy, or both. Reported response rates have been high, and preliminary results with NACT followed by radical surgery are somewhat encouraging.

In 1993, Benedetti-Panici and colleagues reported the results of a pilot study using NACT followed by surgery in patients with locally advanced carcinoma of the vulva. Twenty-one patients with FIGO stage IVA (clinical) were treated. Chemotherapy consisted of cisplatin, bleomycin, and methotrexate plus citrovorum factor rescue. Local control was achieved in 12 of 21 (57%) of the patients (3 to 37 months), and the 3-year corrected survival rate was 24%. The study just discussed does not demonstrate any benefit of NACT over standard treatment approaches. Two European cooperative studies that used bleomycin, methotrexate, and CCNU and included patients with recurrent disease reported similar results. Response rates vary highly according to chemotherapy regimens used, as is survival ([Table 49.6](#)). It is difficult to draw any rational conclusion on the utility of NACT based on these limited data.

Ultra-Radical Surgery

Ultra-radical surgery has been used for patients with clinically resectable vulvar lesions and has generally consisted of a radical vulvar operation extended to include the anorectum and/or the lower urinary tract. This has included resection of bone in a few reports. Inguinofemoral and pelvic lymphadenectomies are usually performed as well.

In some cases, resection can be limited to partial removal of the urethra, anus, or anterior rectal wall. Subsequent incontinence may occur, but this can be prevented to some degree by reconstructive efforts. Reid and associates reported problems with urinary incontinence in 4 of 4 patients who underwent resection of 1 to 1.5 cm of the distal urethra and in 2 of 14 patients who underwent resection within 1 cm of the urethra for carcinoma of the vulva. The value of urethral reconstruction in this setting is uncertain, but it would seem worthwhile. Three recent studies have reported preservation of anal continence after partial sphincter resection and reconstruction for posteriorly located carcinoma of the vulva.

The cumulative literature from 1970 to 2014 includes 227 vulvar cancer “exenteration” patients (Table 49.7). The postoperative mortality rate ranges from 0% to 31%, with a mean of about 5%. The cumulative disease-free survival rate for these patients is 45%. In those series that have included an analysis, the survival has correlated well with the status of the regional lymph nodes. Most studies have not differentiated inguinal and pelvic lymph nodes. There have been very few survivors with positive nodes, either in our series or elsewhere. Some series also suggest that lymphovascular space invasion is an adverse prognostic factor. Although not well addressed in the literature, there is also significant physical and psychological morbidity resulting from these operations as a result of the extensive nature of the surgery and the need for a permanent colostomy and/or urostomy. Neoadjuvant chemoradiotherapy has lead to a decrease in such extensive surgery. Its use is now largely reserved for those patients with locally advanced disease who have previously received radiotherapy to the region.

Conclusion

The management of locally advanced vulvar cancer continues to evolve as reports of small series of these patients accumulate. Considering the relative paucity of data and the rarity and heterogeneity of these tumors, no clear-cut management guidelines can be constructed. It seems reasonable to individualize the management of these patients, carefully considering all of the various treatment modalities available.

POSTTREATMENT SURVEILLANCE

Following completion of treatment for vulvar cancer, longterm follow-up is warranted. It is reasonable to examine these women at least every 6 months for the first 5 years and annually thereafter. Some women are at higher risk for recurrence or have ongoing problems, and more frequent office visits may be warranted.

Follow-up is directed at early detection of recurrence (or later, a new primary vulvar tumor), identification and management of treatment-related complications, and surveillance for associated malignancies. As previously discussed, it is only with local recurrence of vulvar cancer that there is a reasonable expectation for effective salvage treatment.

Approximately 10% to 15% of women treated for vulvar cancer will develop an isolated local recurrence or a subsequent new primary vulvar tumor, well more than half of whom receive effective salvage therapy. During follow-up visits, attention is directed at careful inspection and palpation of the vulvovaginal area and groins. Annual cervical or vaginal cuff cytology is also recommended. Patients are encouraged to do self-examinations and promptly report new symptoms or lesions.

RECURRENT DISEASE

About 15% to 40% of patients with squamous cell carcinoma of the vulva develop recurrence after treatment. As discussed previously, the incidence of recurrence is influenced by a number of factors, most importantly the original stage of the disease, but also the depth of invasion, and the regional lymph node status. For patients with recurrent squamous cell carcinoma of the vulva, the site of recurrence is the strongest predictor of outcome. Only with an isolated local recurrence is there a reasonable expectation of successful salvage therapy ([Table 49.8](#)).

The most common site of recurrence is on the vulva. About 70% of recurrences have a local component, and 55% to 90% of these are isolated local recurrences. This is more likely to occur in the patient with negative lymph nodes at initial treatment. Certain factors predispose the patient to develop local recurrence, including a close resection margin (<1 cm), deep invasion, and a large tumor size. When a patient develops an isolated local recurrence, the reported salvage rate ranges from 40% to 80%. Treatment depends on the individual situation. When feasible, radical resection is performed. Otherwise, the best approach is probably preoperative radiotherapy with or without chemotherapy followed by resection.

The presence of inguinal nodal metastases, especially when multiple, bilateral, or extracapsular spread is seen, predisposes the patient to recurrence within the groin or pelvis and systemically. The prognosis for a patient with regional or systemic recurrence is poor. Regional recurrences do not lend themselves well to salvage resection. Radiotherapy is not very effective against grossly recurrent disease, and there is no effective systemic therapy. A small percentage of patients with groin recurrence can be salvaged with resection followed by radiotherapy.

Distant recurrence carries a dismal prognosis, as vulvar carcinoma is not very responsive to available chemotherapeutic agents. Currently used chemotherapy regiments are largely based on those used for metastatic squamous cell carcinoma of the cervix, with platinum plus a taxane as first line.

P.1169

Response rates are generally less than 20%. Even those patients who respond to chemotherapy have a relatively short progression-free interval. Palliative care referral should be considered for patients with progressive disease or those who are not candidates for chemotherapy.

UNUSUAL VULVAR TUMORS

Vulvar Melanoma

Melanoma is the second most common histologic type of malignancy of the vulva but only accounts for about 10% of all vulvar cancers (Fig. 49.23). This lesion occurs predominantly in white women in the seventh decade, and although the vulva covers only 1% to 2% of the body surface, vulvar melanoma accounts for 3% to 5% of malignant melanomas in women. The most common presenting symptoms are bleeding, a lump or changing mole, and pruritus or irritation. In a small percentage of patients, there is a family history of melanoma. Melanoma of the vulva is uncommon, so most of the literature on the subject consists of retrospective studies of small numbers of patients. However, the behavior of vulvar melanoma appears to be very similar to that of cutaneous melanomas in general.

Therefore, the treatment of vulvar melanoma is individualized based on clinical-pathologic factors, including melanoma microstaging, and modeled using experience derived from cutaneous melanomas in other skin sites.

What Do We Know about Cutaneous Melanoma?

Important areas of information that can be extrapolated from the general melanoma literature include individualization of management based primarily on microstaging, determination of what constitutes an adequate margin of resection, and definition of which groups of patients might benefit from an elective regional lymph node dissection.

FIGURE 49.23 Large vulvar melanoma.

Clark classification has historically been used extensively for the microstaging of melanomas, with division into five levels of invasion. More recently, Breslow classification—based on millimeters of invasion from the upper granular layer of the epidermis to the deepest point of invasion—has become widely used. According to Breslow staging classification, tumor confined to a depth of 0.76 mm or less is generally within the epidermis and behaves as carcinoma in situ. It is generally agreed that melanomas less than 0.76 mm in thickness are associated

P.1170

with a very low risk of lymph node metastases, and elective regional lymph node dissection is not indicated in this group. The dominant prognostic factors for regional spread of melanoma include the number or percentage of metastatic lymph nodes, macroscopic versus microscopic metastases, and the presence of clinical or microscopic satellites around a primary tumor. In patients with distant metastases, the site of metastases, the number of metastatic sites, and an elevated serum lactate dehydrogenase (LDH) level are most predictive of poor survival. In the 2009 revision of AJCC melanoma staging system, tumor mitotic rate was added due to its significant association with survival outcomes.

Vulvar Melanoma

When a vulvar melanoma is suspected, as with any vulvar lesion, the diagnosis is best confirmed by biopsy. Workup of the patient with a clinically localized vulvar melanoma consists of a careful history and physical examination, a serum LDH level, and PET scan for evaluation of possible metastatic disease.

As with squamous cell carcinoma, the main modification in the local management of vulvar melanomas has been to tailor the resection to the individual lesion. A GOG trial demonstrated that centralized vulvar melanomas have a higher risk of nodal metastasis and are associated with a worse prognosis. For most women with vulva melanoma treatment of the primary lesion consists of a wide or radical local excision. For apparently localized lesions amenable to local removal, margin size should probably be that which is appropriate for a cutaneous melanoma, based on the depth of invasion of the melanoma as determined from the biopsy. For melanomas less than 1 mm in thickness, a margin of 1 cm is considered adequate. For those 1 to 4 mm, a 2-cm margin

should be obtained. The excision should contain all layers of skin and subcutaneous fatty tissue. As with vulvar tumors in general, the excision must be tailored to the local vulvar anatomy. The frequent encroachment on midline vulvar structures by the melanoma creates difficulty in obtaining adequate margins while avoiding compromise of urinary or bowel function. Because of the propensity for early hematogenous spread in patients with deeply invasive tumors, ultra-radical resection is rarely, if ever, indicated.

Groin nodal metastasis is an important prognostic factor. Inguinal-femoral lymphadenectomy is not generally recommended for very superficial or deeply invasive vulvar melanoma. Nodal metastases are rarely found in lesions with less than 0.76-mm invasion, and systemic disease is usually present in women with a depth of invasion greater than 4 mm. In melanomas with depth of invasion between 0.76 and 4 mm, the data are unclear, but many experts now recommend sentinel lymph node biopsies for staging and prognostic information. There appears to be no therapeutic benefit from inguinal lymphadenectomy, although excision of isolated, enlarged, and suspicious nodes may be palliative. The overall incidence of lymph node metastases in vulvar melanoma patients is reported to be around 30%. If, during follow-up, isolated metastases appear in a previously undissected groin, they should be excised.

Local recurrence after resection of vulvar melanoma is reported to occur in about one third of patients, and the prognosis for these women is poor. Local tumor control and survival are reduced with more central and deeply invasive tumors. The presence of lymph node metastases also carries a poor prognosis, as previously mentioned. Management of cutaneous melanoma continues to evolve, and effective immunotherapy with BRAF inhibitors has been reported in patients with BRAF mutations. Following surgery, patients with vulvar melanoma should be referred to medical oncologists who specialize in melanoma treatment.

Extramammary Paget Disease

Paget disease is classified, according to location, as mammary or extramammary disease. The original lesion described by Paget is a skin (nipple and areola) lesion related to an underlying invasive ductal adenocarcinoma. Extramammary Paget disease most commonly involves the anogenital region, appearing as a patchy, reddish and whitish, velvety, and eczematous lesion (**Fig. 49.24**). Patients with Paget disease of the vulva are usually white, postmenopausal women who report localized itching and burning.

Paget disease of the vulva is of apocrine origin and is confined to the epithelium in most cases. However, invasive disease is present in about 15% to 25% of cases, either as a result of direct invasion through the basement membrane or, less commonly, because of the presence of an underlying apocrine gland adenocarcinoma. As with all vulvar lesions, biopsy is essential to the accurate diagnosis. Histologically, intraepithelial Paget disease appears as large, pale cells, often in nests at the tips of the rete ridges (**Fig. 49.25**). The cells are often seen infiltrating upward in the epithelium, which is hyperkeratotic. The Paget cells can be located within any of the skin adnexa.

Vulvar Paget disease occurs with other malignancies in about 25% of patients; the most common of these is breast carcinoma. Other commonly associated malignancies are basal cell, rectal, and genitourinary carcinomas. When Paget disease involves the anus, there is a very high incidence of coexisting rectal cancer. Part of the preoperative workup should be directed at screening for these malignancies. Wilkinson and Brown proposed a classification of vulvar Paget disease as primary or secondary (involvement of the vulvar skin by a noncutaneous internal neoplasm). They subclassified primary disease according to the presence of invasive cancer and subclassified secondary disease according to tumor origin. They report that secondary vulvar Paget disease is always intraepithelial.

FIGURE 49.24 Extensive Paget disease of the vulva in a 47-year-old woman. This lesion is so severe and so extensive a total vulvectomy with careful histology is necessary to rule out an associated invasive cancer.

FIGURE 49.25 Histology of Paget disease. Extensive parakeratosis with nests of Paget cells infiltrating the stroma. (Photograph courtesy of Dr. Mokhtar Desouki, Vanderbilt University.)

When a patient is diagnosed with Paget disease of the vulva, the area of involvement should be carefully inspected and palpated to detect any masses or induration, which might be suspicious for invasive cancer. If the disease clinically appears to be intraepithelial, a wide local excision is performed, including a small amount of subcutaneous tissue. A well-known characteristic of intraepithelial Paget disease is histologic extension far beyond that which is clinically apparent. Intraoperative assessment of margins with frozen sections may be helpful. Multiple biopsies around the proposed margins of resection can also be done preoperatively or sent for frozen section in the initial phase of the resection to help guide to extent of the skin removed. Mohs micrographic surgery and fluorescein dye with ultraviolet light have also been used. Colposcopy and toluidine blue staining are not helpful, according to Friedrich and colleagues.

When intraepithelial Paget disease extends far beyond that which is clinically apparent, very extensive excision may be necessary to obtain clear margins. Experienced clinical judgment taking into account the short- and long-term morbidity related to the proposed extensive resection, the patient's age and lifestyle, other comorbidities, and the likelihood of symptomatic recurrence should be included in the discussion and decision about the extent of surgical resection. Primary closure of extensive vulvar excisions is desirable but may not be possible. Reported means of dealing with such cases include skin grafting and laser vaporization of the occult disease (guided by peripheral biopsies). There are a few reports of Paget disease recurring within a skin graft. Topical 5-fluorouracil, imiquimod or bleomycin, administered either preoperatively or postoperatively, has also been used to treat the clinically negative disease with positive margins. If it appears that excision of persistently positive margins may prevent primary closure, it is not unreasonable to close the wound and follow the patient closely.

After excision of intraepithelial Paget disease of the vulva, local recurrence develops in about one third of patients. Because of the difficulty of accurately evaluating the margin status due to the very irregular borders of Paget disease, recurrences are frequently seen in patients with a reportedly "negative" margin. Multiple recurrences over a prolonged period of time are common, and long-term follow-up is required. In some studies, recurrence risk has been correlated with excisional margin status, but it also has been pointed out that the initial disease in some cases is multifocal. Of particular concern are a few reports of patients whose recurrent lesions eventually became invasive. Whether such instances are preventable by diligently eradicating the full histologic extent of the disease is not known.

When vulvar Paget disease is found to contain an invasive component, the treatment is radical surgery, as for squamous cell carcinoma. Overall, these patients have a high incidence of inguinal lymph node metastases with an associated poor prognosis. The role of adjuvant therapy in these patients is unclear.

FIGURE 49.26 Verrucous carcinoma of the left vulva in an 83-year-old woman.

Verrucous Carcinoma

Verrucous carcinoma of the vulva is a rare variant of squamous cell carcinoma, accounting for less than 1% of vulvar carcinomas. This tumor was first described in the oral cavity by Ackerman in 1948 and most commonly occurs in the oral cavity, larynx, and anogenital region. The mean age of the women diagnosed with this malignancy of the vulva is about 50 years. The reported tumors have ranged from 1 to 10 cm in maximum diameter and appear as a slow-growing, cauliflower-like tumor. Characteristically, verrucous cancers have well-demarcated borders that are pushing rather than infiltrating. Verrucous carcinoma can be confused with condyloma ([Fig. 49.26](#)); when

P.1172

an apparent condyloma (especially when large and in an older woman) does not respond to the usual conservative measures, suspicion should be raised for a verrucous carcinoma. About one third of patients with vulvar verrucous carcinoma have a history of genital warts, and HPV has been detected in some lesions, the most common type being HPV-6.

The diagnosis of verrucous carcinoma requires a large (preferably excisional) biopsy that must include the base of the lesion. Verrucous carcinoma can also be confused with so-called warty carcinoma, another variant of well-differentiated squamous cell carcinoma that tends to remain in situ or superficially infiltrating. Differentiation of these two entities is not of great importance because both have a very low incidence of metastases, and treatment is essentially the same.

Verrucous carcinoma is rarely associated with metastatic disease, and many of the reports of such spread have shown histologic evidence of nests of squamous cell carcinoma invading the stroma beneath the tumor. Some authors have suggested that if areas of distinct invasion are found beneath a verrucous lesion, the behavior may be more aggressive, and treatment should be more radical. Inflammatory enlargement of the inguinal lymph nodes has been a frequently reported finding with verrucous carcinoma of the vulva.

It is generally agreed that the main treatment of verrucous carcinoma of the vulva is excision with free margins. How radical this resection should be is unclear, but local recurrences have not been uncommon. Local lesions have had a good initial response to radiation therapy but a high rate of subsequent recurrence and about a 30% incidence of anaplastic transformation with associated aggressive behavior. The few reported cases of metastatic verrucous carcinoma of the genital tract have followed radiotherapy. However, many tumors have been successfully treated with a combination of surgery and radiotherapy; when a tumor is locally advanced, this seems to be a reasonable treatment. Inguinal lymphadenectomy may be indicated in patients with large tumors; in patients with persistence or recurrence of disease, especially after radiotherapy; and in patients with infiltrating cancer beyond very early invasion below the verrucous tumor. Biopsy specimens may be obtained of enlarged lymph nodes thought to be inflammatory.

Verrucous carcinoma of the vulva has been associated with second malignant tumors, most commonly of the cervix, breast, and anogenital skin. Although verrucous carcinoma of the genital tract is a slow-growing tumor that rarely metastasizes, a 1988 review by Andersen and Sorensen reported that 26.1% of the patients with this type of carcinoma had died of disease.

Bartholin Gland Carcinoma

A malignancy can arise from the Bartholin gland or duct. The most common histology is adenocarcinoma, but squamous cell carcinoma is not uncommon. Other much rarer histologic types include transitional cell carcinoma, mixed carcinoma, and sarcoma. Bartholin carcinoma accounts for only 1% to 2% of vulvar malignancies, and, in some cases, a Bartholin origin is not clear-cut. Several criteria have been described to define a primary Bartholin malignancy, including anatomic position consistent with a Bartholin tumor, intact overlying skin, areas of apparent transition from normal to neoplastic elements, involvement of areas of the Bartholin gland with an origin histologically compatible with the gland, and no evidence of any other primary cancer. Although some of these criteria may not be met in an individual case, the tumor should at least be in a location consistent with a Bartholin tumor. As with the other rare types of vulvar malignancy, the available information on Bartholin malignancy is derived from retrospective studies of small series of patients.

FIGURE 49.27 Large right labial cyst in the Bartholin gland. Excisional biopsy is needed to make a definitive diagnosis.

Diagnosis

Bartholin carcinoma should be suspected when a mass is noted in the region of the Bartholin gland, particularly in a woman older than 40 years of age (**Fig. 49.27**). The average age at diagnosis is about 50 years, but there is a wide age range. Many studies report a significant delay in diagnosis, attributed both to the deep-seated location of the tumor and to frequent misdiagnosis and treatment as a Bartholin abscess. When a woman presents with a Bartholin mass, biopsy or excision should be considered if she is older than 40 years of age, if the mass is suspicious, or when an apparently benign process does not resolve promptly with conservative therapy.

Treatment

Because of their deep location in the vulva, Bartholin malignancies tend to invade the ischiorectal fossa, close to the anorectum, or close to the pubic ramus (or all three) before they are diagnosed. These cancers also can erode through the overlying skin. As with other vulvar cancers, surgical resection should be aimed at adequate resection of the tumor. Radical excision with an adequate margin tends to be more difficult with Bartholin malignancies due to their deeper location. Depending on the tumor extent, local resection must consist of at least a radical hemivulvectomy, but it may need to include removal of portions of vagina, levator ani, ischiorectal fat, perineal body, anal sphincter, anorectum, pubic bone, or all of these. In locally advanced but respectable cases, exenterative surgery or multimodality therapy may be necessary.

Due to the difficulty in obtaining an adequate local resection, Copeland and associates reported improved local control with the administration of adjuvant postoperative radiotherapy. This is especially appropriate in the presence of close or

P.1173

positive margins. However, external radiotherapy alone should not be expected to control gross residual disease.

At the time of diagnosis, inguinal lymph node metastases are present in about half of patients with a Bartholin carcinoma. This propensity for lymphatic spread has been attributed to the frequent delay in diagnosis and the more advanced local extent of these tumors. The pattern of lymphatic spread is the same as that for other vulvar malignancies, primarily to the ipsilateral inguofemoral lymph nodes. There are not enough data on which to base a reasonable estimate of the risk of metastases to the contralateral groin nodes. As with other vulvar cancers, if positive nodes are found, dissection of the opposite groin or radiotherapy to the inguinal and pelvic nodal basins, or both, may be warranted. Inguinal lymphadenectomy in these patients appears to be both prognostic and therapeutic.

Local, regional, and distant recurrences are common with Bartholin malignancies, and overall survival rate is lower than that for carcinoma of the vulva in general. Copeland and associates reported on a series of 36 patients with this cancer. The local recurrence rate was 2 of 12 (17%) for patients treated with hemivulvectomy (with or without radiotherapy) and 5 of 24 (21%) for patients treated with radical total vulvectomy.

Basal Cell Carcinoma

Although basal cell carcinoma is the most common malignancy of the skin, basal cell carcinoma of the vulva is a rarely reported tumor. Approximately 250 cases have been reported in the literature, and basal cell carcinoma constitutes 2% to 3% of vulvar cancers. The cause is unknown, but there is frequently a history of chronic vulvar irritation. This lesion shares many features with vulvar squamous cell carcinoma. The average age of patients at diagnosis is 65 years, and there is a predilection for white women. Common symptoms include chronic pruritus vulvae and the presence of a mass. As with squamous cell carcinomas, many authors have repeatedly reported a delay in diagnosis. Most basal cell carcinomas occur on the labia majora and, less commonly, on the labia minora, urethral meatus, and prepuce of the clitoris. The gross appearance is variable. Tumor size has ranged from 0.2 to 13 cm in greatest diameter, averaging 1.5 to 2 cm. There are also reports of multifocal lesions.

Treatment

Most authorities agree that the treatment of choice for vulvar basal cell carcinoma is wide local excision including a generous amount of underlying subcutaneous tissue. For a multifocal lesion, complete vulvectomy may be appropriate. Even when surgical resection margins are positive, local recurrence is not guaranteed. Mulvany and colleagues reported only three recurrences in 10 patients with a positive resection margin. If a malignant squamous component is present, however, then treatment is the same as that for invasive squamous cell carcinoma of the vulva as outlined above. There is little information available on the use of radiotherapy or chemotherapy in the treatment of primary or metastatic basal cell carcinoma of the vulva, but there is one report of a locally advanced lesion that had a complete response to radiotherapy. Close follow-up is essential, because the local recurrence rate has been reported to be 10% to 30%.

Prognosis

The overall prognosis for patients with vulvar basal cell carcinoma is good, but exact figures are difficult to ascertain. In a review by Breen and colleagues, there was a 5-year survival rate of about 64%. However, they were unable to find documentation for a single death directly related to recurrent or residual basal cell carcinoma. Rather, they attributed the deaths to other age-related illnesses and complications of overzealous therapy.

The prognosis for the rare metastatic basal cell carcinoma of the vulva is even more difficult to predict. Sworn and coworkers concluded that the prognosis is similar to that for basal cell carcinoma at other skin sites. With basal cell carcinoma elsewhere on the skin, the mean survival after discovery of metastatic disease has been reported to be 10 to 14 months. However, Conway and Hugo reported prolonged survival if only regional lymph nodes are involved.

Sarcomas

Primary sarcoma constitutes 1% to 3% of all vulvar malignancies. The literature consists of case reports and small series of patients, often with very limited follow-up. In addition, this is a heterogeneous group because of the variety of histologic types and their associated differences in behavior. Hence, the natural history and appropriate treatment of these tumors have not been well defined.

Leiomyosarcoma

The most common histologic type of primary vulvar sarcoma is leiomyosarcoma. Most of these patients are in the age range of 40 to 50 years, but a few are younger. At least four cases of pregnant women with leiomyosarcoma have been reported. According to the descriptions, most patients present with an enlarging mass in the labia majora or Bartholin region. Like tumors at other sites, smooth muscle tumors of the vulva appear to have a range of appearances and behavior, from benign to malignant. Tavassoli and Norris reported 32 smooth muscle tumors of the vulva and attempted to delineate the histologic features that might relate to prognosis. They believed that their analysis was impeded by small numbers of patients in subgroups and by varied adequacy of excision. According to their results, prognosis was best predicted by three main determinants (size, tumor contour, and mitotic activity). Neoplasms greater than 5 cm that have infiltrating margins and five or more mitotic figures per 10 high-power fields are likely to recur unless controlled by total excision. It was also determined that lesions larger than 5 cm with infiltrative margins and prominent mitotic activity have a more aggressive behavior as the number of mitotic figures increases. The significance of mitotic activity could not be fully evaluated because of the small number of cases with intermediate grades of mitotic activity and because of other factors. The degree of cellular atypism did not correlate well with the mitotic activity or with recurrence. In 1996, Nielsen and colleagues proposed similar prognostic criteria but included cytologic atypia. In keeping with a range of behaviors, according to the available reports, vulvar leiomyosarcomas may do well with adequate excision, may follow a slowly progressive course, or may rapidly progress to fatality. Local recurrences are common, and several authors have recommended early radical excision of these tumors to improve treatment results.

As with the other genital tract sarcomas, there is a propensity for hematogenous metastases that may develop early. From the few studies reporting long-term follow-up, it appears that only about half of these patients are 5-year survivors. Information regarding the propensity of these tumors to metastasize to the regional lymph nodes and the prognostic and therapeutic value of inguinal lymphadenectomy is scant. On the basis of general knowledge of the behavior of these types of sarcomas,

P.1174

the regional lymph nodes are probably at minimal risk with a low-grade tumor. In patients with high-grade tumors, removal of regional lymph nodes is probably of prognostic value only, although control of disease in the groin may have palliative value. In a fit patient with a high-risk but apparently localized tumor, inguinal lymphadenectomy seems reasonable. Radiotherapy has been used in only a few cases with mixed results. Postoperative adjuvant radiotherapy to the pelvis (including the perineum) may be worthwhile in selected cases to improve local control. As with other genital tract leiomyosarcomas, chemotherapy has been of limited palliative benefit.

Other Sarcomas

At least 100 cases of *aggressive angiomyxoma* involving the female pelvis or perineum, or both, have been described. Vulvar tumors often present as a pedunculated soft tissue mass. Most patients are aged 30 to 40. A few cases during pregnancy have been reported. It is an unusual tumor derived from fibroblasts or myofibroblasts with nuclei that have no atypical features or mitotic activity. The tumor appears to be locally invasive and spreads by direct extension only. Local recurrences are common, although there have been no reported deaths attributable to this tumor. The mainstay of treatment is wide excision both primarily and for recurrences. Response to gonadotropin-releasing hormone has been reported.

Other histologic types of sarcomas arising in the vulva have been described. These include DermatoFibroSarcoma Protuberans (DFSP), proximal epithelioid sarcoma, malignant fibrous histiocytoma, and variants of fibrosarcoma. These tumors vary widely in their aggressiveness and metastatic potential, but size of the primary tumor and mitotic activity seem to be important prognostic characteristics. Wide local excision with as much margin as possible is indicated, and additional surgery, radiation, or chemotherapy may be desirable based on the histology of the primary tumor, margin status, and metastatic workup.

Although sarcomas constitute only a small percentage of vulvar malignancies in general, they account for most vulvar cancers in children and young women. Overall, pediatric vulvovaginal *rhabdomyosarcoma* has a good prognosis and greatly reduced treatment morbidity because of the efficacy of

combined treatment modalities (especially chemotherapy and brachytherapy). Radical surgery is no longer indicated in young patients with rhabdomyosarcoma. Rhabdomyosarcoma arising in older women and other histologic variants of rhabdomyosarcoma may not be so responsive to chemotherapy.

Isolated reports of a variety of other types of sarcomas arising in the vulva have been published. Treatment of these various sarcomas must be individualized according to the scant literature available, the potential aggressiveness of the malignancy as suggested by the pathologist, and the individual situation.

Merkel Cell Carcinoma

Merkel cell carcinomas are small cell (neuroendocrine) tumors of the skin that occur most commonly in sun-exposed areas (head, neck, and extremities) and behave in an aggressive manner. This malignancy was first described in 1972 by Toker. At least 15 cases of vulvar origin have been reported. The ages of these patients ranged from 28 to 79 years, and the tumors occurred in all regions of the vulva (four in the Bartholin gland). When originating from the vulva, Merkel cell carcinoma has behaved in a highly aggressive manner (even more so than Merkel cell tumors in general), with 11 patients having regional lymph node metastases. At least 8 developed distant metastases and died within 30 months of diagnosis. Surgery and radiotherapy appear to be of value for local control only, and as yet, no effective systemic treatment exists. As in the treatment of small cell carcinoma of the lung, etoposide and cisplatin have been used for a few cases of Merkel cell carcinoma, with good responses. Three of the vulvar cases were treated with this regimen. Two progressed, and one had a partial response of very short duration.

Miscellaneous Tumors

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma accounts for up to 15% of Bartholin gland carcinomas. As seen with electron microscopy, the tumor contains gland-like lumens filled with eosinophilic material derived from basement membrane, so it is of squamous cell origin. The behavior of this rare malignancy appears to be different from that of other Bartholin and vulvar cancers and to be similar to that of adenoid cystic carcinomas arising from other sites, such as the salivary gland. These vulvar tumors have a high local recurrence rate and a propensity for hematogenous metastases usually developing subsequent to local recurrence. Both local recurrences and metastases can be slowly progressive over a period of years but are not very responsive to radiotherapy or chemotherapy. In view of the difficulty in obtaining adequate surgical margins with Bartholin malignancies in general, and the high local recurrence rate and uncertain sensitivity to radiotherapy with adenoid cystic carcinoma in particular, a concerted effort to obtain at least 2-cm margins should be made when resecting this tumor. However, from the 65 cases reported, margin status did not seem to significantly impact recurrence risk. Postoperative adjuvant radiotherapy for close or positive margins did appear to be of possible benefit. From the scant information available, inguinal lymph node metastases occur less frequently with this tumor and have all been ipsilateral. The prognostic and therapeutic value of lymphadenectomy in these patients remains to be defined. The role of adjuvant postoperative chemotherapy for this malignancy also deserves further study.

Supernumerary Mammary Adenocarcinoma

Ectopic breast tissue in the vulva is very rare, but there are at least 26 cases of mammary-type adenocarcinoma arising in the vulvar location have been reported since 1872. These patients ranged in age from 49 to 81 years, and many patients present with an asymptomatic vulvar nodule. The labia majora was the location in 65% of patients according to a review by Abbott et al. Only one of the patients had evidence of primary breast cancer, but rather than representing metastatic disease, the vulvar lesion appeared to be primary from ectopic tissue. The diagnosis of vulvar mammary adenocarcinoma is based primarily on the histologic pattern of the vulvar tumor. Other criteria can include the finding of adjacent normal mammary glandular elements (one case of adjacent in situ malignancy), the presence of estrogen or progesterone receptor positivity, positivity for common breast markers, and ruling out an origin from skin appendages.

One of the reported patients died of disease without treatment 1 month after diagnosis. The patient with coexistent primary breast carcinoma died of widespread metastatic (including cerebral) disease 22 months after the diagnosis. Reports suggest that these tumors follow the same progression and dissemination routes as typical breast cancers via the lymphatics to the inguinofemoral nodes and hematogenously. Given that these tumors are histologically identical to primary breast cancers, most authors advocate application of standard breast cancer adjuvant treatments such as radiation, tamoxifen, and aromatase inhibitors.

P.1175

BEST SURGICAL PRACTICES

- Prognostic factors
 - The dominant prognostic factor for invasive squamous cell carcinoma of the vulva is the status of the inguinofemoral lymph nodes.
 - Primary tumor factors that appear to have prognostic importance include depth of invasion or tumor thickness, tumor diameter, tumor differentiation, lymph-vascular space involvement, and margin status at resection.
- Pretreatment investigation
 - A biopsy confirming the presence of invasive cancer is necessary before any therapy. Because of the frequent advanced age and coexisting medical problems typical of women with vulvar cancer, a thorough preoperative evaluation by internal medicine and anesthesiology consultants should be considered. PET scanning is increasingly used to evaluate patients for evidence of metastatic disease, but it may not be sufficiently sensitive to justify omission of lymphadenectomy if the scan is negative.
- Treatment of invasive squamous cell carcinoma of the vulva
 - *Unilateral groin lymphadenectomy.* Limiting inguinofemoral lymphadenectomy to the ipsilateral side appears to be a reasonable approach in a patient with a well-lateralized early tumor that is well differentiated, with no lymph-vascular space involvement, and with negative ipsilateral inguinal lymph nodes.

- *Sentinel lymph node identification.* An increasing body of evidence indicates that lymphatic mapping with a combination of isosulfan blue dye and technetium-labeled sulfur colloid followed by sentinel lymph node dissection is applicable to a large percentage of women with early invasive squamous cell carcinoma of the vulva. Injection of both substances increase the chance of sentinel node identification compared to either alone. Inguinal-femoral lymphadenectomy can be omitted if the sentinel node(s) are negative for metastatic cancer.
- *Pelvic lymphadenectomy.* Pelvic lymphadenectomy is not indicated in most patients with vulvar cancer. Pelvic radiation therapy is usually administered in patients with positive groin nodes.
- Locally advanced vulvar cancer
 - About 30% to 40% of vulvar cancers are locally advanced. Current approaches to the treatment of locally advanced vulvar cancer include radiotherapy +/- chemotherapy, followed by surgical resection if there is sufficient response and the patient is a good surgical candidate. Ultra-radical surgery such as exenteration is largely reserved for those patients with recurrent disease and prior radiotherapy.
- Recurrent squamous cell carcinoma of the vulva
 - About 15% to 40% of patients with squamous cell carcinoma of the vulva develop recurrence after treatment. Only with an isolated local recurrence is there reasonable expectation of successful salvage therapy (preferably resection).
- Reconstructive techniques for the vulva and groin
 - When an extensive resection of a vulvar malignancy or a groin node metastasis is necessary, it may not be possible to close the wound primarily. Under these circumstances, closure of the incision and healing can be facilitated by a variety of reconstructive procedures. Leaving the wound open is another reasonable option.
- Uncommon histologic types
 - Melanoma, basal cell carcinoma, cancers of the Bartholin gland, invasive Paget disease, and other uncommon or rare vulvar tumors are often managed differently from squamous cell carcinoma. A biopsy of the lesion should identify these lesions to allow special treatment planning.

Chapter 50

Cervical Cancer Precursors and Their Management

L. Stewart Massad

DEFINITIONS

The Bethesda System (TBS)—A classification system originally introduced in 1988 for grading cytologic abnormalities.

Cervical cytology—A diagnostic technique that involves microscopic examination of individual cells or cell clusters scraped, brushed, or washed from the surface of the cervix and stained with Papanicolaou stain. The nuclear characteristics and the nuclear-cytoplasmic ratio are used to diagnose the degree of cervical abnormality present. It is a common screening test for cervical cancer.

Cervical dysplasia—Dysplasia is a pathologic term to indicate noninvasive epithelial atypia that involves various degrees of the cervical epithelium. By convention, in *mild dysplasia*, the nuclear atypia, mitoses, and cellular irregularity involve the lower one third of the squamous epithelium, moderate dysplasia the middle third, and *severe dysplasia* the upper third. Full-thickness dysplasia is termed *carcinoma in situ*.

Cervical intraepithelial neoplasia (CIN)—A cytologic and histologic classification of preinvasive cervical atypias or neoplastic changes. In general, CIN 1 = mild dysplasia, CIN 2 = moderate dysplasia, and CIN 3 = severe dysplasia/carcinoma in situ.

Colposcopy—A diagnostic technique involving visual inspection of the cervix and other areas of the lower genital tract with a low-power (3 to 15×) binocular scope. The surface contour, vascular pattern, and staining pattern of changes seen with dilute acetic acid and Lugol iodine reflect the severity and extent of cervical abnormality and help the clinician to select a location for biopsy confirmation.

Conization—Removal of the cervical transformation zone and part of the endocervix in a cone-shaped specimen. Traditionally performed with a scalpel, it also can be done with laser or wire loops.

Human papillomavirus—One of a family of protein-encapsulated DNA viruses, some of which are the necessary though not sufficient cause of cervical cancer. DNA sequence variations allow distinction of more than 150 genotypes.

Lower Anogenital Squamous Terminology (LAST)—A classification system introduced in 2011 for grading histologic abnormalities while incorporating the impact of papillomavirus infection on disease. Its two tiers mirror TBS terminology, including low- and high-grade squamous intraepithelial lesions. It includes provisions for molecular testing for equivocal lesions.

Loop electrosurgical excision procedure (LEEP)—Also called a large loop excision of the transformation zone (LLETZ). Cone biopsy performed with a thin wire electrosurgical loop electrode 1 to 2.5 cm, usually under local anesthesia.

Squamocolumnar junction (SCJ)—The junction between the squamous and columnar epithelium on the cervix. As columnar epithelium undergoes metaplasia to squamous epithelium on the cervical portion, the SCJ has a dynamic location.

Transformation zone—A colposcopic term for the area of metaplasia that is observed between the original prepubertal (“original SCJ”—lateral edge) and present squamocolumnar junction (medical edge).

Cervical cancer prevention has been very successful because of two important factors. First, preinvasive cervical changes that develop and progress slowly over years have been identified; second, relatively

simple and inexpensive methods to detect and destroy these preinvasive cervical changes have been developed over the past 50 years. In recent years, the cause of these cervical changes has been identified as due to the human papillomavirus (HPV), and this has led to major changes in our understanding and management of both screening and treatment of cervical cancer precursors. Because of the sensitivity of screening tests, which rely on HPV detection and the fact that most women, even with high-risk HPV infection, will *not* progress to invasive cervical cancer, balancing the risk and costs of triage and treatment of these early cervical changes requires a thorough understanding of the natural history of these lesions and the risk and benefits of the triage and treatment options available.

EPIDEMIOLOGY AND ONCOGENESIS

In 1842, Rigoni-Stern noted that cervical cancer was found in married women, but was virtually absent in celibate women, such as Catholic nuns. Subsequent epidemiologic studies reported that number of sexual partners, early age at first sexual

P.1180

intercourse, low socioeconomic status, cigarette smoking, and early age at first pregnancy increased a woman’s risk of cervical neoplasia. More recently, it has become clear that immunosuppression from any cause, including infection with human immunodeficiency virus and therapeutic immunosuppression after organ transplantation, is associated with an increased rate of cervical neoplasia. Oral contraceptive use has been reported to increase a woman’s risk of cervical cancer, especially adenocarcinoma. Cellular changes on Pap smear described as “koilocytosis” have been recognized since the 1940s as correlates of cervical disease, but the human papillomavirus (HPV) was not identified as the etiologic agent in cervical oncogenesis until 1980 by zur Hausen. This discovery and the demonstration that HPV infection is the necessary though far from sufficient cause of cervical cancer won him the Nobel Prize in 2008.

The current understanding of the role of HPV in cervical oncogenesis is illustrated in [Figure 50.1](#). The more than 150 types of HPV are members of a large family of encapsulated DNA viruses known as the *Papovaviridae*. Unlike many viruses that infect humans and that are serotyped by their surface antigens, the papillomaviruses are classified according to their DNA base-pair sequence. The degree of relatedness is determined by the degree of their DNA hybridization homology. HPVs are epitheliotropic viruses that infect virtually all surface epithelia, including the skin and mucous membranes. In addition to cervical cancer, they have been shown to cause significant proportions of vulvar, vaginal, anal, and oropharyngeal cancers and may contribute to malignancies at other sites.

The most prevalent anogenital HPVs can be divided into three groups that are predictive of their ability to produce neoplasia ([Table 50.1](#)). Low-risk HPV types are commonly associated with condylomas and cervical intraepithelial neoplasia (CIN) 1 and some CIN 2 s, but they almost never are associated with true precancer or cancer. HPV types 6 and 11 are responsible for approximately 90% of all condylomas of the lower genital tract. On the other hand, the anogenital HPV types with a high oncogenic risk are mainly types 16, 18, 31, 33, 35, 39, 45, 51, 52, 58, 59, and 68. HPVs in this risk group are overrepresented in high-grade lesions and cancers. HPV types 16 and 18 are highly oncogenic, accounting for two thirds of cancers and about half of precancers. The carcinogenicity of a few HPV types, such as 56, remains uncertain at this time.

TABLE 50.1 Anogenital HPV Types

Low-risk types	6, 11, 26, 40, 42, 43, 44, 53, 54, 61, 68, 72, 73, 81, 82
High-risk types	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59

HPVs infect the cervix by entering basal cells following microtrauma to thin, immature portions of the transformation zone adjacent to the SCJ. Some 80% of sexually active adults appear to have been infected with HPV at some point. When a mitotically active epithelial cell is infected, the virus may remain in the cell in a form termed a *latent infection*. Latent infections can be detected only by molecular techniques and may be undetectable. In most women with an initial HPV infection, the infection clears spontaneously as a result of innate and cell-mediated immunologic host defense mechanisms. About half the women who test positive for HPV will test negative at 6 months later, about 70% will be negative at 12 months, and by 2 years only 8% to 20% continue to test positive. The highly oncogenic types 16 and 18 are more slowly cleared and more commonly persist compared with less oncogenic HPV types. Although women with transient infections may develop cervical epithelial abnormalities that result in abnormal Pap tests and even colposcopic abnormalities, these are usually low- or mid-grade lesions that often clear spontaneously. Approximately 50% of women with CIN 1 will resolve their lesions over 2 years without therapy. Among adolescents, with a more active immune defense system clearance rates approach 90%.

In some individuals, however, for reasons that are not well understood, the latent papillomavirus begins to replicate independent of the host cell cycle, and large numbers of complete virions are produced. This is referred to as a *productive viral infection*. These latent or productive viral infections may be clinically unrecognizable or may be associated with genital warts or CIN 1 or sometimes CIN 2, but they do not result in neoplastic transformation of the infected epithelial cells.

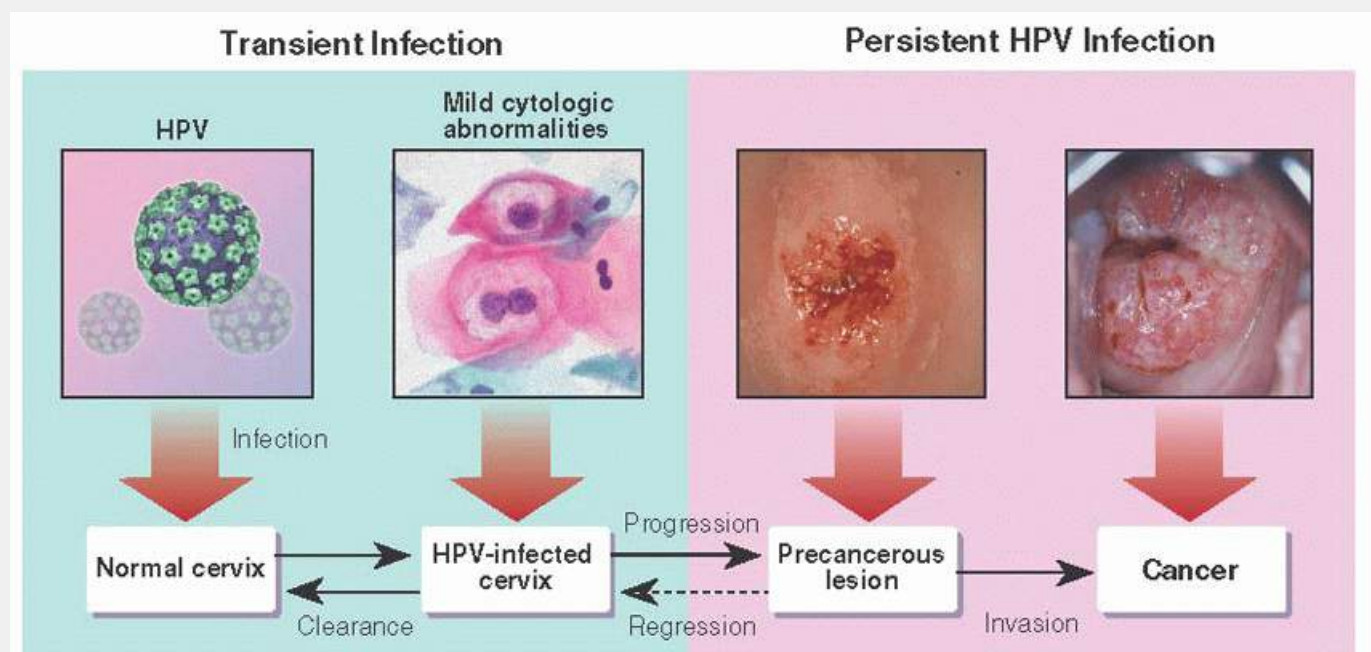

FIGURE 50.1 Natural history of cervical carcinogenesis. (From Schiffman M, Kjaer SK. [Chapter 2: Natural history of anogenital HPV infection and neoplasia](#). *J Natl Cancer Inst Monogr* 2003;31:14-19. interaction critical to the transformation of normal epithelial cells to neoplastic cells. The key alteration seems to be the integration of the viral DNA into host chromosomes. Often, this is associated with loss of regulatory regions of the HPV genome and disruption of a host tumor suppressor gene. The E₇ protein binds to the pRB protein, which in turn triggers E₂F transcription factor and induces p16^{ink4} expression, which leads to DNA synthesis and cell cycling. Other gene products employ host cell synthetic mechanisms to produce new viral DNA and viral proteins. These changes in cellular mechanisms would ordinarily lead to activation of epithelial cell p53 protein, an important protector of the normal cell cycle. However, the HPV E₆ protein targets p53 for proteolytic degradation, allowing oncogenic HPV types to bypass this key cellular control mechanism. Identification of E₆ and E₇ mRNA has been proposed as a more specific marker of epithelial cell transformation leading to cancer than simple HPV detection.

The likelihood of this oncogenic transformation after HPV infection varies by HPV type. In an analysis of HPV screening data of more than 20,000 women in the Portland, Oregon, area, Khan and colleagues found that women who had a negative Pap test and tested negative for any HPV had a less than 1% risk of developing CIN 3 within 10 years of follow-up. This contrasted sharply with women who had a negative Pap but who tested positive for HPV 16 on study entry; those women had a 17.3% risk of developing CIN 3 or a more severe lesion during the next 10 years. At least half of these women developed high-grade CIN within 24 months. For those who tested positive for other HPV types, the risk of developing CIN 3 was only 3%.

Although Rubin recognized “incipient carcinoma” in 1909, it was not until the 1950s that the preinvasive potential of *carcinoma in situ* of the cervix became generally accepted. In their 1952 publication, Galvin, Jones, and Te Linde described their observations of the natural history of carcinoma in situ. Their report confirmed and advanced previous studies by Cullen and by Pemberton and Smith. The concept of a clearly identifiable preinvasive neoplastic change in the cervical epithelium represented a major breakthrough in an understanding of the development and natural history of cervical cancer, but *carcinoma in situ* is clinically occult. Techniques such as the Schiller test with application of Lugol iodine and random four-quadrant biopsy proved imprecise in identifying women with *carcinoma in situ*, and many women with this diagnosis were treated with radical hysterectomy because of the uncertainty of the natural history of this diagnosis and of the risk of concomitant cancer. It was the parallel development of *cervical cytology* by George Papanicolaou and Herbert Trout in the United States after 1941 and of *colposcopy* by Hans Hinselmann in Germany after 1927 that provided techniques that rendered clinically useful the concept of a precancerous cervical lesion whose treatment would prevent the development of invasive cancer. Cytology allowed identification of women at risk, and colposcopy allowed clinicians to identify preinvasive lesions without conization, determine their extent, select sites for biopsy confirmation, and institute fertility-sparing therapy. These developments have led to a 70% reduction in cervical cancer deaths in the United States over the past 50 years. This chapter discusses how these preinvasive lesions evolve, how they can be diagnosed and distinguished from HPV-related lesions destined to clear, and how they can be treated.

TERMINOLOGY

Although *carcinoma in situ* became well recognized as a full-thickness epithelial change without stromal invasion, the terminology and clinical significance of adjacent, less-than-full-thickness atypia was uncertain. In 1956, Reagan and Hamonic introduced the term *dysplasia* to designate these cervical epithelial abnormalities that were characterized by cytologic atypia, increased mitotic activity, and loss of polarity, graded as *mild*, *moderate*, and *severe dysplasia*. The poor reproducibility of the distinction between CIS and severe dysplasia and the clear premalignant nature of the latter led Ralph Richart in 1969 to propound the concept of CIN. CIN 1, CIN 2, and CIN 3 were terms used to describe a continuum of disease, representing basaloid changes extending

into the lower, middle, and upper thirds of the cervical epithelium with CIN 3 incorporating both CIS and severe dysplasia. Modification of the Bethesda cytologic and histologic grading was proposed by Darragh and colleagues in 2012. CIN 1 and other manifestations of HPV infection are labeled as *lowgrade squamous intraepithelial lesions* (LSIL) and CIN 3 s a *high-grade squamous intraepithelial lesions* (HSIL). Since the histologic changes of CIN 2 are heterogenous, including both premalignant and spontaneously regressing lesions, this system encourages use of molecular tests, such as the HPV-related transformation marker p16^{ink4}, to assign mid-grade abnormalities to either the LSIL or HSIL categories. Although the Bethesda System terminology for reporting the results of cervical cytology has been accepted throughout the United States and is used in many other countries, other terminology and definitions are used in Great Britain, Germany, Australia, and other countries, which with different thresholds for colposcopy and treatment creates some difficulty in comparing study results across countries.

The original four- or five-step Papanicolaou cytologic classification, in which “class 1” was normal or benign and “class 5” was suspicious of invasive cancer; the World Health Organization classification of *mild*, *moderate*, or *severe dysplasia* and *carcinoma in situ*; and the Richart CIN terminal have been replaced in the United States by the *Bethesda system* (Table 50.2). Development of this consensus system was driven by several factors, including intraobserver variation and a lack of reproducibility. Multiple classification systems without common diagnostic criteria left clinicians unsure about appropriate management.

The Bethesda system was introduced in 1988 and subsequently updated and revised in 1991 and 2001. While cytology allows the identification of various infections and other nonneoplastic findings, the core of any report is the identification of epithelial cell abnormalities, either squamous or glandular. The Bethesda system combined HPV cytopathologic effects, often referred to as *koilocytosis*, with mild dysplasia or CIN 1 into a category called *low-grade squamous intraepithelial lesion* (LSIL). More significant lesions— including moderate and severe dysplasia and carcinoma in situ, or CIN 2 and 3—were combined into *high-grade squamous intraepithelial lesion* (HSIL). Pap tests with cellular abnormalities insufficient for definitive diagnosis of LSIL were categorized as *atypical squamous cells* (ASC). In 2001, these results were further subcategorized as *of undetermined significance* (ASC-US) or *cannot exclude high grade* (ASC-H). Glandular abnormalities less than cancer have been classified as *atypical glandular cells* (AGC), either *not otherwise specified* (AGC-NOS) or *favoring neoplasia*, and as *adenocarcinoma in situ* (AIS).

In the United States, a typical laboratory that processes cervical cytology from an average, generally low-risk population reports epithelial cell abnormalities in about 5% to 6% of patients. Usually, one half to two thirds of these abnormalities are ASC (2% to 4%), whereas 1% to 2% are LSIL and 0.5% to 1.0% are HSIL diagnoses, with about 0.5% glandular cell abnormalities. The ratio of ASC to SIL diagnoses should

P.1182

be between 2:1 and 3:1 for most cytology laboratories, and roughly half of ASC-US and more than 80% of LSIL should test positive for high-risk HPV. Most cytology specimens are now processed using automated suspensions of exfoliated cells in liquid-based media (liquid-based cytology, LBC) rather than conventional Pap smears. LBC results in fewer unsatisfactory tests and has a greater yield but does not appear to be more sensitive in detecting true premalignant lesions compared to conventional Pap smears. An important advantage of LBC is the possibility of testing for HPV and other biomarkers from the same liquid-based specimen; women with ASC-US cytology who test negative for high-risk HPV types are at low risk for CIN.

TABLE 50.2 The Bethesda System of Cytologic Classification

The 2001 Bethesda System (Abridged)

SPECIMEN ADEQUACY

Satisfactory for evaluation (*note presence/absence of endocervical/transformation zone component*)

Unsatisfactory for evaluation ... (*specify reason*)

Specimen rejected/not processed (*specify reason*)

Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (*specify reason*)

GENERAL CATEGORIZATION (OPTIONAL)

Negative for intraepithelial lesion or malignancy

Epithelial cell abnormality

Other

INTERPRETATION/RESULT

Negative for Intraepithelial Lesion or Malignancy

Organisms

Trichomonas vaginalis

Fungal organisms morphologically consistent with *Candida* species

Shift in flora suggestive of bacterial vaginosis

Bacteria morphologically consistent with *Actinomyces* species

Cellular changes consistent with herpes simplex virus

Other nonneoplastic findings (*optional to report; list not comprehensive*)

Reactive cellular changes associated with inflammation (includes typical repair), radiation, and intrauterine contraceptive device

Glandular cells status posthysterectomy

Atrophy

Epithelial Cell Abnormalities

Squamous cell

Atypical squamous cells (ASC)

Of undetermined significance (ASC-US)

Cannot exclude HSIL (ASC-H)

Low-grade squamous intraepithelial lesion (LSIL)

Encompassing HPV/mild dysplasia/cervical CIN 1

High-grade squamous intraepithelial lesion (HSIL)

Encompassing moderate and severe dysplasia, carcinoma in situ, and CIN 2 and CIN 3

Squamous cell carcinoma

Glandular cell

Atypical glandular cells (AGC) (*specify endocervical, endometrial, or not otherwise specified*)

Atypical glandular cells, favor neoplastic (*specify endocervical or not otherwise specified*)

Endocervical AIS

Adenocarcinoma

Other (*list not comprehensive*)

Endometrial cells in a woman ≥ 40 y of age

Automated Review and Ancillary Testing (Include as Appropriate)

Educational Notes and Suggestions (Optional)

The effectiveness of cytology screening has been demonstrated in organized national screening programs. In the United States, demonstration projects in the 1950s showed cytologic screening identified asymptomatic cancers. In Scandinavian countries, the introduction of national screening programs led to a dramatic decline in cervical cancer. However, screening may not be effective in women before ages 25 to 30. Most women who develop cervical cancer in countries with widespread screening availability have not had regular screening.

Despite its effectiveness in cervical cancer prevention programs, limitations to Papanicolaou test screening exist.

A single Pap test has a sensitivity of only 50% to 60%. This means that a single test will not detect cervical lesions in many women. However, the slow progression of CIN before the development of an invasive cancer provides the opportunity for multiple screening cytologies over a period of years. So even with limited sensitivity, if three consecutive tests are negative, there is less than a 1% chance that the patient will have a highgrade cervical abnormality. Other screening problems include lesions that do not shed cells, do not transfer from the collecting device, or are not sampled by the clinician. Rarely, the slide preparation or staining is unsatisfactory. Another reason for screening failure is that cytotechnicians and cytopathologists may fail to identify abnormal cells or may misinterpret dysplastic cells as reactive or metaplastic. Glandular lesions are more commonly missed than squamous lesions. Women who are diagnosed with invasive cervical cancer after a reportedly “negative” Papanicolaou test often have abnormal cells on review of their slides that are few in number or obscured by blood or inflammatory changes. The threat of a lawsuit when cancer arises after cytology interpreted as negative may cause cytologists and cytopathologists to “overcall” an equivocal diagnosis and the gynecologist to recommend colposcopy and possibly cervical biopsy or even treatment in a patient with any hint of abnormality. This increases not only the anxiety and morbidity associated with cervical cancer screening but also the costs.

First popularized by Hinselmann in Germany, the *colposcope* is a magnifying instrument used to examine the cervix. With the colposcope, vascular changes and other epithelial patterns were recognized and correlated with cytologic and histologic changes. These early neoplastic changes were most prominent adjacent to the squamocolumnar junction (SCJ); this area was called the *transformation zone*, the area of the cervix that had undergone metaplasia from the prepubertal columnar epithelium to mature squamous epithelium. With time, colposcopic patterns associated with the developing stages of dysplasia and early invasive cancer were described. Adoption of colposcopy in North America was limited by cumbersome German terminology and the association of colposcopy with Nazi experimenters, including Hinselmann’s associate Eduard Wirths. However, by the 1970s, colposcopy with directed biopsy had generally replaced cone biopsy as the triage test for women with cytologic abnormalities.

Following the announcement of the 2001 Bethesda System terminology for reporting the results of cervical cytology, the American Society of Colposcopy and Cervical Pathology has sponsored consensus conferences to develop and update management guidelines, expanding recommendations to cover

P.1183

results of cotesting. The guidelines are based on 5-year risk of CIN 3+ and prescribe similar management for problems with similar risks. They also incorporate cotesting into follow-up to improve sensitivity of surveillance for persistent or recurrent lesions, with longer intervals between follow-up tests to minimize the risk of identifying transient lesions. When cytology, colposcopy, and histology findings are discordant, expert review may be in order. Multiple biopsies minimize the likelihood of missing CIN 3+.

Once the importance of HPV in cervical oncogenesis had been demonstrated, other investigators suggested that a vaccine might prevent infection and perhaps even eliminate the HPVs in already infected individuals. Koutsky and colleagues tested immunization against HPV type 16 in a clinical trial, prospectively randomizing almost 2,400 young women who tested negative for HPV type 16 infection to three doses of a vaccine made from synthetic capsule protein or placebo. This and other trials showed that vaccinated HPV-naïve women develop essentially 100% immunity to targeted HPV types, with substantial reduction in subsequent CIN. Currently approved prophylactic HPV vaccines are targeted against L₁ capsid proteins and thus are HPV-type specific. The quadrivalent vaccine targets the high-risk HPV types 16 and 18, as well as low-risk types 6 and 11, while the bivalent vaccine targets only HPV 16 and 18. Minor side effects are common and include injection site pain and fever. Serious side effects are rare, but anaphylaxis and vagal reactions have been reported. Vaccines appear only prophylactic, with little or no effect on established infections. Multivalent and therapeutic vaccines

are in development.

Screening for Cervical Neoplasia

The goal of cervical cancer prevention is the identification and destruction of precancer before the development of invasive disease that threatens life, health, and reproductive capacity. This must be balanced against the harms of screening, including stigmatization from the identification of HPV as a sexually transmitted infection, fear of cancer, and the potential for bleeding, local injury, and preterm delivery after treatment when lesions identified through screening are not destined to lead to cancer. For this reason, screening should not begin until age 21, since the risk of cancer in teens is negligible, and although precancers do occur earlier, they are unlikely to progress to invasion prior to detection in subsequent screening rounds. Similarly, cancer late in life is unlikely among women with long negative screening histories, so screening should cease in such women at age 65. The sensitivity of screening appears sufficient to allow 3-year intervals between Pap tests and 5-year intervals between Pap and HPV cotests. These screening recommendations were revised in 2013 (www.ASCCP.org).

A variety of devices have been devised for cervical sampling, including spatulas, brooms, and brushes. The spatula is rotated with gentle pressure twice around the cervix with the longer lobe in the os to enhance sampling. A broom is also rotated against the ectocervix. An endocervical brush is placed in the cervical canal with some bristles visible and rotated 90 to 180 degrees; deeper penetration and more vigorous rotation increase bleeding without improving cell collection. Cells should be transferred to slide or vial according to manufacturer's instructions; inadequate cell transfer may result in uninterpretable results.

Visual Inspection

Although colposcopy has been used instead of or in addition to cytology for cervical cancer screening in some areas of Europe and South America, it is time-consuming, requires well-trained clinicians, and is expensive. Simple visual inspection of the cervix after application of acetic acid (VIA) or Lugol iodine (VILI) has been studied in resource-poor settings for cervical cancer screening, alone or in combination with HPV testing. Areas of cervical dysplasia turn white after application of acetic acid and turn yellow after application of iodine. Inspection of the cervix using handheld low-power magnifying lenses can identify many lesions. Although these techniques have proved useful and cost-effective in resource poor settings, they are not appropriate for developed countries because of limited sensitivity and specificity. In most settings, VIA and VILI remain investigational.

Human Papillomavirus Testing

Primary HPV screening promises greater sensitivity but lower specificity than screening cytology. However, without longitudinal testing, HPV tests cannot distinguish the majority of women with transient infections from those few with persistent infections, which can progress to cancer. Current technology can identify DNA or mRNA from one or more high-risk HPV subtypes. Testing for low-risk HPV has no role in cervical cancer screening and should be discouraged. HPV testing can be automated and requires no interpretation, in contrast to the Pap test. These advantages must be weighed against its lack of specificity for high-grade lesions. Several approaches have been suggested to improve the specificity of HPV testing. Because the prevalence of HPV infection in most populations decreases around age 30, HPV screening should be more specific for cervical neoplasia in an older population. Despite promising studies conducted outside the United States, the appropriate triage test after a positive HPV screen is unclear. Recently, a type-specific HPV test for primary cervical cancer screening has been approved by the Federal Drug Administration for use in the United States. Experience with primary HPV testing for cervical cancer screening outside of a clinical study is limited. Cotesting that combines Pap and HPV testing increases sensitivity while preserving the familiarity of a Pap result is well suited for women 30 to 64 years of age. Since women with HPV types 16 and 18 are at increased risk for precancer, genotyping tests that identify these types can be used to identify women who need immediate assessment.

EVALUATION OF ABNORMAL SCREENING TESTS

Cytology

Collection of cervical cytology specimens depends on full visualization of the cervix, including the cervical os. This may require use of a variety of different specula. Graves specula, with their flared blades mirroring the vaginal fornices, are best adapted for reproductive age women. The straight blades of Pedersen specula are more suited to postmenopausal women or some young nulligravid women. After visual inspection confirms absence of gross lesions, cervical sampling is undertaken. A variety of different instruments are available, with little clinically meaningful difference among them in screening effectiveness. For spatulas and brooms, the instrument should be rotated at least twice. With the Ayre spatula, the longer lobe is placed within the endocervix. Cervical brushes, when employed, should not be inserted beyond the last bristles and should not be rotated more than 180 degrees to minimize bleeding. Samples should be placed in liquid media according to manufacturers' instructions.

P.1184

Colposcopy

The earliest and most severe epithelial changes on the cervix occur adjacent to the cervical SCJ. The location of the SCJ migrates inward during a woman's life. After vaginal acidification at puberty, columnar cells on the exocervix are transformed into squamous cells by a process called *metaplasia*. The area between the prepubertal and current SCJ where this metaplastic change has occurred is called the *transformation zone*. This epithelium can be recognized as a circumferential, pale white, translucent ring around the SCJ. These metaplastic cells are especially susceptible to coital trauma and HPV infection. As CIN develops, vascular changes occur, and these may be recognized as punctation or mosaic. If the lesion progresses, nonbranching vascular changes become visible. These atypical vessels have grossly abnormal architecture and are the colposcopic hallmarks of invasive cancer.

A standard colposcopic examination involves inspection of the cervix with both low- and high-power magnification after application of normal saline and then 3% to 5% acetic acid. Both optical and video colposcopes are available. The onset of acetowhitening peaks after 1 to 2 minutes, so some delay between acetic acid application and inspection is important. Low-grade lesions lose acetowhitening faster than high-grade lesions; repeated application of acetic acid may be required. After examination with the standard white light, a green filter may be used on the light source to increase the contrast of the red blood vessels and help clarify any vascular changes and the margins of acetowhite epithelium that may be present. Lugol iodine solution also may be used after inspection with acetic acid to clarify areas of dysplasia, metaplasia, or columnar epithelium. Manipulation with an endocervical speculum or cotton-tipped applicators may help to expose the SCJ and lesions within the endocervix. Large swabs may be needed to inspect the vaginal fornices, where low- and high-grade lesions may otherwise be hidden, especially when the cervix appears colposcopically normal.

Colposcopic terminology was updated by the International Federation for Cervical Pathology and Colposcopy in 2011. All of the squamous epithelium must be visualized for the examination to be *adequate* or satisfactory. An inadequate exam means that cancer cannot be excluded with confidence, and diagnostic excision is required when cancer risk. Once the adequacy of the examination has been evaluated, a careful systematic evaluation of the cervix and upper vagina is performed, concentrating on the *transformation zone* adjacent to the SCJ. Areas of white epithelium, punctation, and mosaic are noted. The severity of any lesions seen are graded based on the whiteness of the epithelium, the intercapillary distance in vascular lesions, the sharpness of the lesion border, and the surface contour (flat, ulcerated, or raised). Application of Lugol iodine can inform the grading of equivocal lesions, as normal epithelium stains dark brown, low-grade lesions are mottled yellow and brown, and high-grade lesions are yellow with sharp borders.

Traditionally, colposcopic grading was used to identify the most severely abnormal area or areas for a colposcopically directed biopsy. Lesions assessed as grade 1 (minor) have vascular changes such as mosaicism or punctation that are fine in caliber and are associated with thin acetowhite epithelium with irregular borders. Grade 2 (major) colposcopic lesions have denser, more long-lasting acetowhite epithelium in association with coarse vascular change and the presence of inner borders and ridging.

However, recent US studies have shown that while colposcopic grading reflects a true spectrum of disease, grading is imprecise and poorly reproducible, even among experts. Colposcopic assessment may be more accurate in young women and those with larger lesions. With colposcopy alone, some high-grade lesions will be missed, and some low-grade lesions will be overcalled. For this reason, a histologic diagnosis based on one or more colposcopically directed cervical biopsies is the gold standard for determining the final diagnosis of the cervical lesion. Random biopsy of normal appearing areas of the cervix is not standard for US women with abnormal cytology, but achieving maximal sensitivity for precancer requires biopsy of all acetowhite areas. A recent prospective study by Wentzensen and colleagues showed improvement in colposcopic sensitivity for high-grade disease as biopsy number increased up to four, regardless of the level of colposcopist training, lesion size, or antecedent Pap grade.

Colposcopic biopsies are obtained using punch forceps, commonly Tischler or Kevorkian-Younger forceps. As colposcopists have embraced taking multiple biopsies, use of smaller biopsy forceps has increased to minimize pain. Unfortunately, local anesthetics and oral nonsteroidal analgesics are ineffective in decreasing pain.

Endocervical curettage can identify disease within the canal. However, it can be contaminated by inadvertent sampling of ectocervical lesions, and yield is low. It offers greatest benefit among older women with inadequate colposcopy exams and high-grade cytology. When indicated, endocervical curettage is undertaken with a Kevorkian curette, whose multiple sharp surfaces allow endocervical sampling with either a rotating in-and-out motion using the tip as a cutting edge or rotating lateral motion using the longer lateral blades of the curette. With either technique, the endocervical sample should include both tissue fragments adherent to the curette and those in the clot of mucus and blood developed by curettage. Some experts prefer vigorous sampling with an endocervical brush, with the sample submitted for histologic rather than cytologic analysis.

In 2007, the National Cancer Institute proposed risk-based concepts for cervical cancer screening prevention and the frequency of screening and the indications for treatment are based on the women's risk of cervical cancer or CIN 3. Since risk cannot be reduced to zero despite intensive screening, women with a low risk are observed at intervals. Long intervals are appropriate for women at lowest risk. For example, women with negative results on Pap and HPV testing and no prior abnormalities can be observed with repeat cotesting in 5 years. In contrast, women with CIN 2, women with CIN 3, and those with HPV-positive HSIL cytology merit treatment. Women with other results, such as those from biomarker or HPV genotyping tests, that raise risk for CIN 3 close to 50% also may merit immediate treatment. For women with intermediate risk, colposcopy with biopsy of all acetowhite areas allows triage to treatment or observation.

Using this risk-based concept, colposcopy is indicated for women with ASC-H, LSIL, HSIL, and AGC cytology. Women with ASC-US cytology should undergo colposcopy when ASCUS is persistent or associated with high-risk HPV infection. Colposcopy is also indicated when high-risk HPV persists or when HPV types 16 or 18 are found regardless of the cytologic diagnosis. Some evidence suggests that negative cytology and an abnormal molecular marker, such as p16^{ink4a}, may also be an indication for colposcopy. Colposcopy may be useful for the more detailed assessment of the nature and extent of visible cervical lesions. These general guidelines should be helpful in most cases, but there are many special situations—including the evaluation of young, pregnant, and postmenopausal women—in which alternative management plans may be more suitable. More detailed management guidelines are available on the American Society for Colposcopy and Cervical

Pathology Web site, www.asccp.org, where the most recent guidelines are available. Delay in colposcopy may allow regression of abnormalities, but is not recommended because of the risk for progression.

Abnormal Papanicolaou Results in Pregnancy

The goal of evaluation of the pregnant patient with CIN is to rule out invasive cancer, since CIN is unlikely to progress to cancer during pregnancy and treatments jeopardize both fetus and mother. CIN is not treated in pregnancy but is followed up until the postpartum period, when the patient is reevaluated and managed as indicated by the biopsy results and her social situation. The pregnant woman with significant cytologic abnormality generally is evaluated by colposcopic examination and directed biopsy, although colposcopic assessment of those with ASC-US and LSIL can be deferred until the woman is postpartum. During pregnancy, biopsy is advisable when high-grade colposcopic features are present, and it is acceptable for lesser colposcopic lesions. In clinics where biopsy was limited to women with colposcopic features of invasion, invasive cancers were missed. The pregnant cervix is quite vascular, especially in the last trimester, so a biopsy may bleed profusely, and cervical trauma can initiate uterine contractions. Use of mini-Tischler forceps minimizes bleeding. Multiple biopsies are usually not well tolerated. ECC is contraindicated in pregnancy, because of the risk of rupturing the membranes.

Rarely, diagnostic excision is required in pregnancy to rule out invasive cancer suspected cytologically, colposcopically, or on biopsy. This can be a difficult and potentially bloody procedure and should be undertaken by an experienced gynecologist only after all other avenues to rule out invasion have been exhausted. Because of bleeding risk, excisional procedures during pregnancy should be performed only in settings where transfusion is available, usually in an operating room. Placement of a circumferential suture near the cervicovaginal junction can evert the SCJ and minimize bleeding. When the goal is to identify deep invasion rather than to treat microinvasive cancer or CIN, the size of the excision can be limited to the colposcopically apparent lesion, and treatment of the remainder of the transformation zone can be deferred until after postpartum involution is complete. Because of the eversion of the transformation zone during pregnancy, deep cone-shaped excisions are usually unnecessary, and a “coin” biopsy that is shallow and flat may be more appropriate. Electrosurgical excision with a loop electrode or straight wire rather than knife conization during pregnancy may reduce blood loss.

MANAGEMENT OF CERVICAL INTRAEPITHELIAL NEOPLASIA

Although high-grade cervical neoplasia can regress, cervical treatments designed to destroy premalignant lesions in the transformation zone are standard for women at high risk. CIN 3 is recognized as true precancer, and CIN 2 is a mix of precancerous lesions and benign HPV infections. However, because the natural history of CIN 2 is difficult to predict with current technology, it has become the threshold for treatment. Despite low risk for cancer, CIN 1 also may be treated to speed reversion to normal epithelium and minimize the morbidity, inconvenience, and expense of repeated Pap tests and colposcopies, but only when it is persistent. Persistent HPV infection and atypical or low-grade cytology without CIN 2+ should not be treated, as the relevant HPV infection may not be in the transformation zone. Recent consensus suggests that when assessment indicates a risk of CIN 2+ of 50% or more, treatment is indicated. Within each cytologic grade, concomitant detection of high-risk HPV confers a higher risk of CIN 2+. Diagnostic excision is also indicated if there is a significant discrepancy between cytologic, colposcopic, and histologic findings, although review of these findings by experts may avoid overtreatment. Increased risk for later preterm delivery is a risk for all cervical therapies, in proportion to the amount of cervix destroyed, and in addition to risk of CIN, the patient's desire for future childbearing may influence treatment decisions. Regression of HPV-related disease is more common in younger women, and age may influence treatment decisions as well. For example, a 32-year-old mother of three with a tubal ligation and a

two-quadrant CIN 2 lesion should probably be treated, whereas the same lesion in a 24-year-old unmarried nulligravida might well be watched in expectation of regression. The most recent treatment guidelines can be found on the Web site of the American Society for Colposcopy and Cervical Pathology, www.asccp.org.

Treatment Techniques

In general, treatment techniques can be divided into ablative and excisional. Ablative methods such as cryotherapy, CO₂ laser ablation, and electrocautery rely on an accurate colposcopically directed biopsy diagnosis to exclude invasive cancer because no tissue specimen is provided by the treatment procedure. For this reason, ablative treatments are contraindicated when endocervical curettings contain CIN, when colposcopic examination is inadequate, when the biopsy and cytology results are discordant, and when cancer is suspected on cytology, colposcopy, or biopsy. In these circumstances, diagnostic excisions using scalpel, laser, and electrosurgical needle or loop all provide a specimen, so these techniques are both diagnostic and therapeutic.

Cryotherapy

Cryosurgery is a destructive technique that was introduced to gynecologists in the late 1960s to treat CIN. It has since been superseded for many indications by office excisional techniques. The cryosurgical instruments use nitrous oxide or carbon dioxide as a refrigerant to lower the temperature of the tissue below -22°C. This produces cell death by intracellular and extracellular water crystallization. The refrigerant is applied to the cervix with a cryoprobe, which is covered with lubricant gel to enhance thermal transfer and placed in contact with the cervical epithelium. As the gas is circulated through the cryoprobe, it withdraws heat from the cervix until freezing temperatures occur. The cervix and cryoprobe generally reach a steady state after 3 to 5 minutes of freezing, at which time the amount of heat brought to the cervix by the vascular supply balances the amount of heat withdrawn from the cervix by the evaporating cryogenic gas. Many experts advise doublefreeze cryotherapy, with a second freeze after a 5-minute thaw with the cryoprobe removed. Visible ice must extend at least 5 mm past the edge of the cryoprobe, and the cryoprobe must cover the transformation zone. This is best defined with acetic acid or Lugol iodine prior to applying the cryoprobe. The need for multiple probe placements to cover a large lesion is a relative contraindication to cryotherapy.

Patients treated with cryotherapy may experience minor cramping during the procedure, but otherwise the treatment is not painful, so anesthesia is not needed. During the 2 weeks after cryosurgery, about 20% of patients experience a profuse watery discharge that may require wearing a pad. Some patients experience light spotting, particularly 12 to 15 days after cryotherapy, when the eschar begins to separate from the treated area; pelvic rest through this period will minimize the

P.1186

risk of heavy bleeding. Infections, including endometritis or tuboovarian abscess, following cervical cryotherapy are rare but can occur, especially in women who already have a subclinical cervicitis.

Long-term complications of cryotherapy are minimal and consist principally of cervical stenosis in 1% to 4% of patients. Several studies have reported that there is no change in fertility and that pregnancy complications seldom occur, except in patients who have excessive cervical fibrosis and in whom cervical dystocia may be a problem. Postcryotherapeutic healing is generally completed within 12 weeks. Cryoprobes with deep endocervical extensions may lead to a higher rate of cervical stenosis. In many patients, the SCJ will not be visible after the cervix has healed following cryotherapy.

Carbon Dioxide Laser

The CO₂ laser is another useful treatment modality for the management of CIN lesions, most often for ablation. The CO₂ laser produces a high-intensity collimated light beam that can be focused with high-power density. Absorption of laser energy at the site of light impact results in flash boiling of cells, vaporizing the tissue.

Increasing the power density and narrow focusing of the beam allows the CO₂ laser to cut tissue. Defocusing the laser beam to lower-power density results in coagulation rather than flash boiling. This can be used focally as a hemostatic technique, but inadequate power density results in serious stromal injury that may increase preterm delivery risk.

The CO₂ laser has the following advantages: it can be used for either cutting or ablation; therapy can be targeted individually, based on the extent of the transformation zone and the lesion being treated; the healing after laser surgery is rapid; and there are minimal side effects, including limited vaginal discharge. Because depth control is relatively straightforward, laser ablation is especially useful for lesions that extend onto the vaginal walls, where excisional treatments risk injury to bladder, rectum, and vasculature. Patients treated with the CO₂ laser generally have minimal cervical scarring and a lower stenosis rate than those treated with cryotherapy. Few obstetric complications have been reported after laser ablation, though deep laser conization like other techniques can predispose to preterm delivery. The major disadvantages of the laser are (a) its acquisition expense; (b) the time required to acquire and maintain laser skills, particularly for excisional laser conization; and, (c) the relatively high maintenance cost of the instrument. Use of the CO₂ laser for the management of CIN has decreased dramatically since the introduction of the loop electrosurgical excision procedure (LEEP).

To perform CO₂ laser ablation, the cervix is visualized after placement of a matte speculum with smoke evacuation tubing attached. Matte instruments are important, because their surfaces will scatter laser light that strikes them accidentally, dispersing the laser energy and reducing the risk for inadvertent injury. The perineum should be protected by draping with wet towels, and use of potentially flammable paper drapes avoided. The cervix is injected with a vasoconstrictive agent, either epinephrine as in local anesthetics or vasopressin. The cervix is visualized using a colposcope at 3 to 10× magnification. The laser is set to achieve a power density of 750 to 1,250 W/cm² by adjusting the input power and the spot size. Ablation is carried out to cover the entire transformation zone and any lateral lesion, as focused ablation is associated with a lower success rate. In the transformation zone, the depth of ablation should extend beyond the 5-mm depth of cervical glands or about 7 mm. Over the vagina, ablation should not extend beyond 2 mm. An endocervical button should be preserved to facilitate regrowth of cervical epithelium with minimal risk of stenosis. This should not obstruct ablation of any visualized lesion, as ablation is only acceptable when the SCJ is fully visible. If bleeding occurs, rapid defocusing of the beam will allow coagulation, or suturing may be accomplished.

Laser conization can be done with the beam tightly focused. Tailored excision is done under colposcopic guidance using matte hooks to manipulate the specimen. Again, bleeding is controlled with rapid defocusing of the beam.

Loop Electrosurgical Excision

LEEP was introduced as the large loop excision of the transformation zone, by Prendeville, who modified a small electrosurgical wire loop biopsy instrument developed by Cartier. LEEP was introduced in North America in the early 1990s and rapidly became the procedure of choice for the management of CIN. Unless anatomy or anxiety contraindicate, it is done under local anesthesia as an outpatient procedure.

LEEP takes advantage of the properties of electrosurgical generators coupled with loop electrodes made with a thin stainless steel or tungsten wire to excise portions of the cervix (**Fig. 50.2**). In contrast to ablative procedures, LEEP provides a tissue specimen that is assessed for early invasive cancer and unsuspected AIS. Some 0.5% of cases diagnosed as CIN by colposcopy, punch biopsies, and ECC in fact have invasive cancer or AIS in the LEEP specimen.

FIGURE 50.2 Loop electrosurgical excision procedure. Endosurgical loop is passed through the cervix from right to left. Note cut surface of cervical stroma from the 12-o'clock to the 6-o'clock position.

LEEP begins with the insertion of an insulated speculum; the insulation prevents inadvertent contact with a live electrode from creating a vaginal epithelial injury or shock. The largest tolerable speculum is placed and is opened maximally both in the fornices and at the yoke. Obese women and those with vaginal laxity may benefit from insertion of a sidewall retractor prior to speculum placement, but some women are unable to tolerate placement of both. A local anesthetic with epinephrine is injected to reduce bleeding. This is used for its vasoconstrictive action, even if the patient is having general or regional anesthesia. The injection is made subepithelially, not into the deep stroma, and blanching of tissues should be apparent. Potocky needles allow precise subepithelial injection but

P.1187

increase cost. Loops should be selected to excise the transformation zone, and excision should be accomplished under 3 to 10× colposcopic magnification after application of 3% to 5% acetic acid or Lugol iodine to ensure that all at-risk epithelium is excised. Power settings vary with the generator and should follow manufacturer's instructions. The LEEP electrode diameter is commonly 15 to 25 mm and is selected based on the size of the cervix and the extent of the transformation zone. Since CIN can extend into glands, the depth of the ectocervical excision should extend more than 5 mm beneath the surface, usually 7 to 8 mm. If the transformation zone is wide and cannot be removed intact with a single pass of the electrode, the first pass should encompass the cervical os. Because most highgrade disease will lie at or near the SCJ, every effort should be made to excise this area intact so that the histologic orientation of the tissue will not be damaged by physical or thermal injury. An intact, adequate specimen of the SCJ will allow the pathologist the best opportunity to correctly diagnose invasive disease and the measure depth of invasion if the basement membrane is breached. Additional lateral or anterior or posterior passes can be made to encompass the outer portions of the transformation zone. The central pass can be made from side to side or bottom to top; excision from top to bottom allows the partially excised specimen to fall forward, obstructing the operator's view and making completion of the posterior excision difficult. Edges should be beveled slightly to avoid sharp angles that cannot be fulgurated. Since loop electrodes cut by sparking that causes flash boiling of tissue, the electrode should be activated immediately prior to

contacting the cervix, and the wire should be passed gently through the tissue with the insulated support just above the epithelium. Current should be maintained until excision is complete. Loss of current during the procedure stops the cutting wave of sparks and requires either reactivation of the electrode in place, with increased thermal artifact, or reinitiation of excision in the opposite direction, with potential for increased bleeding at the jagged edge where the two excisional passes meet. When the lesion extends into the endocervix, especially when colposcopy is inadequate, an additional, deeper, specimen ("top hat") with a 10 × 10-mm or 15 × 10-mm loop can excise a deeper area of the endocervical canal. This specimen should encompass tissue at least 5 mm lateral to the canal to include gland crypts. A postprocedure endocervical curettage can provide prognostic information, suggesting the presence or absence of residual CIN.

FIGURE 50.3 Diagram of approach to loop excision of small portion of lesion, which can be removed by a single pass (A) of the 2-cm × 7 to 8-mm loop. B: Note the shallow dish configuration of the removed tissue. If squamous epithelium remains in the canal, it can be removed by a second pass with a smaller loop (C).

An alternative to LEEP is the cone biopsy excisor, a straight wire mounted on a right-angled base that is inserted into the endocervix and rotated. Indications and results are similar to LEEP. The cone biopsy excisor may be most appropriate for central and endocervical lesions and less suitable for lateral lesions or when there is anatomic asymmetry.

Once excision is complete, electrofulguration of the cautery bed should be carried out using a 5-mm cautery ball. Fulguration within the endocervical excision bed after top hat excision can be done with a 3-mm ball, but cautery near the endocervical canal should be kept to a minimum to allow eversion of endocervical epithelium with healing. A large swab may be useful in absorbing blood so cautery can be applied directly to the excision bed. Bleeding points can be controlled with direct coagulation rather than fulguration (contacting tissue rather than sparking onto it). Bleeding from the cervix can also be temporally controlled by clamping the cervical lip with a ring forceps. In some cases, suturing is required, either for control of brisk cervical bleeding or from vaginal lacerations that result from contact between an active wire and the vaginal wall. For those situations, the clinic should be equipped with a 12-inch needle holder, 12-inch toothed tissue forceps, and 0-gauge delayed absorbable suture on a 1-inch curved, taper-point needle, which should always be available in an outpatient area where LEEP is done. In rare cases, packing may be required. Monsel paste should be applied after hemostasis has been achieved.

Because LEEP is easy to learn, easy to teach, and relatively easy to perform, it can be used to treat patients with highgrade CIN without the disadvantages and greater cost of coldknife or laser conization. The major advantage of LEEP over conventional cold-knife conization is that the procedure can be performed in the

outpatient setting under colposcopic control. The advantage over outpatient ablative procedures is the fact that LEEP produces a tissue specimen of the entire transformation zone for pathologic examination. Invasive disease can be identified and excision margins evaluated. Women with positive margins can be managed with observation or reexcision; hysterectomy may be indicated when reexcision is not feasible and childbearing is complete. However, margins are less predictive for LEEP than for knife conization, especially when the specimen is removed in slices.

For LEEP to be used effectively, the extent of excision and the choice of electrodes must be tailored to the size and distribution of the lesion ([Fig. 50.3](#)). The use of extremely large

P.1188

electrodes (e.g., 20 × 20 mm) may lead to inadvertent cervical amputation; injury to vaginal walls, rectum, and bladder; and significant obstetric morbidity. These large loops should be used only by those who have mastered more standard excision using loops 15 to 20 mm in width and 7 to 12 mm in depth. They are best suited for women with microinvasive squamous cell carcinoma in situ and AIS, when a large, intact specimen is needed to assess need for hysterectomy.

Infection in the cervix or an ascending endometritis, parametritis, or salpingitis can be seen following LEEP, but they are rare and usually represent a flare-up of an already existing subclinical infection. Long-term complications include cervical incompetence and cervical stenosis.

Although cervical incompetence leading to premature cervical dilation and delivery in subsequent pregnancies has been a well-known complication of traditional cold-knife cone biopsy for many years, the risk of pregnancy complications after LEEP was only recognized after 2000. LEEP appears to roughly double risk of preterm delivery, although most patients will deliver at term and most preterm deliveries occur between 34 and 36 weeks' gestation, with little long-term morbidity. Risk for preterm delivery appears related to greater depth and number of excisions, and commonly employed 20 mm by 7 or 8 mm excisions may have minimal impact. Women with cervical dysplasia have a higher incidence of prematurity than the general population, and some authors have suggested that the association of LEEP with preterm delivery reflects confounding. Prospective trials are unlikely, and prudence suggests that for fertile women LEEP should be undertaken only when the risk of precancer is substantial.

Because LEEP is a simple procedure that can be used for both diagnosis and treatment during a single office visit, its use has been recommended in the so-called "see-and-treat" mode. With this application, LEEP is performed for patients with HSIL cytology after colposcopic assessment for suitability and the absence of evident invasive cancer. The patient does not first have to undergo cervical biopsies and an ECC. This approach is especially valuable in clinics with high no show rates and is unsuitable for young women wishing to minimize risk to future pregnancies. It is not indicated for women with minor cytologic abnormalities or HPV infection with normal cytology.

Cervical Conization

Traditional cold-knife conization has been used successfully for generations to excise lesions that extend into the endocervical canal and to rule out invasive cancer. Hot cautery was used in the past to remove a cone-shaped piece of tissue from an inflamed, hypertrophic, chronically infected cervix. A standard surgical scalpel is more appropriate for the excision of CIN, and, thus, the term *cold knife* was introduced to differentiate these two procedures. Cone biopsies can be excised from the cervix using a sharply focused laser beam or an electrosurgical needle as well as a scalpel. The laser is more expensive and requires considerable operator experience to be used effectively. The electrosurgical wire is quite effective and hemostatic. Both techniques result in some thermal artifact, which may make interpretation of the surgical margins difficult. Cold-knife conization does not have that drawback, making it ideal when management depends on knowing whether the

lesion excised extends to the margin of excision, as with endocervical glandular lesions and suspected microinvasion. The cone usually is performed in an operating room under anesthesia; thus, it is more expensive than outpatient excision.

Conization can be tailored to lesion location, with coneshaped excisions for lesions encompassing both endo- and ectocervix, flattened “coin” biopsies for ectocervical lesions, and cylindrical excisions for endocervical lesions. Although most glandular lesions are located within a few millimeters of the SCJ, a cone biopsy for a glandular abnormality should extend deeply into the cervical canal. Colposcopic examination and Lugol iodine staining may help the surgeon determine the size and location of the lesion to be excised.

After a careful examination under anesthesia, a gentle vaginal prep is done. The cervix should not be scrubbed vigorously to avoid denuding the surface epithelium containing the intraepithelial lesion. To decrease blood loss, the cervix is injected with a vasoconstrictive agent, commonly a commercially available mixture of local anesthetic (lidocaine) with 1:100,000 epinephrine. Acute hypertension can be caused by this drug, and its use should be considered and discussed with the anesthesiologist. Approximately 1.5 to 2 mL is injected directly into the cervix, at 12, 2, 3, 6, 8, and 10 o'clock outside the planned incision line, for a total of 9 to 10 mL. Injection should cause some “ballooning” up and blanching of the cervix. Although deep lateral sutures in the side of the cervix at 3 and 9 o'clock have been said to decrease blood loss by ligating the descending branches of the uterine arteries, there is no evidence that this reduces bleeding with a cone biopsy. These sutures may assist in manipulation of the cervix.

The cervix is then re-stained with Lugol iodine to outline the lesion, and a scalpel is used to cut the cone. The cervix can be stabilized with a tenaculum placed high on the anterior lip away from the anticipated line of excision. Sometimes, two tenacula are better, or the lateral stay sutures described above may be used if the cervix is large or the vagina small. A pointed no. 11 scalpel blade is preferred, but a large no. 10 blade or a smaller no. 15 blade can be used. Some experts use an electrosurgical needle or thin pointed electrosurgical blade. As the cone is cut, the cervix is retracted to the opposite side to provide visibility at the base of the incision. Manipulations that may strip epithelium should be avoided. Once the incision has extended well into the cervical stroma, Allis clamps can be used to grasp the specimen's outer cut edges, and further traction will expose bands of fibrous stroma that can be cut to release the specimen. If possible, the cone should be symmetrical around the endocervical canal with the apex in the canal. It is desirable to remove the specimen intact and to mark it with a suture at 10 or 6 o'clock so that the pathologist can orient any positive margins or foci of invasive cancer.

There are several ways to manage the cone bed once the specimen has been removed. If bleeding is minimal, the cone bed may be cauterized and left open to granulate. This may result in a visible SCJ more frequently than if the bed is sutured. If this fails to control bleeding, the cone bed can be closed with a running locked suture placed from just lateral to the cone edge to deep in the cervical stroma by the canal. This is run circumferentially around the cervix. Finally, the classic Sturmdoff suture can be employed, as illustrated in [Figure 50.4](#). The anterior and posterior cervical mucosa are pulled in to cover the cone defect. This is the most aesthetically pleasing closure, but in many cases, the SCJ cannot be seen after the cervix is healed.

Complications of cold-knife cone biopsy are similar to but perhaps somewhat more common than those with LEEP because the specimen is larger. Significant bleeding may occur in the first 24 hours or 10 to 21 days after surgery as the sutures dissolve. Five to 10% of patients will require reevaluation, packing, or suturing after cold-knife cone biopsy, and occasional patients will require transfusion. Cervical stenosis occurs in about 3% of patients. This is more common in postmenopausal women. The risk of premature labor and delivery caused by an excisional cone biopsy has already been discussed in the section on LEEP. The depth of the cone is related to the risk of premature labor.

FIGURE 50.4 **A:** Mattress suture is placed as in Sturmdorf tracheloplasty. **B:** Method of action of suture in drawing the flap into the canal. **C:** The lower flap has been pulled into position. **D:** Anterior and posterior flaps have been drawn into the canal. Lateral mucosa wounds are being sutured.

Posttreatment Outcomes and Assessment

The overall “cure” rate for most cervical treatment is 90% to 95%. With all treatments, persistence is related to lesion size, lesion grade, and extension into the endocervical canal, but the incidence of persistent disease is related to the anatomy of the lesion. For excisional procedures, a positive excision margin predicts persistent CIN, although it does not appear independent of other factors. However, even with a histologically involved margin, immediate reexcision is not required unless invasive cancer is suspected above the excision line. Healing of the treatment bed often results in destruction of small areas of residual dysplasia. Women treated for CIN remain at risk for recurrence and cancer for at least 20 years and should be followed with cytology or Pap and HPV cotesting.

BEST SURGICAL PRACTICES

- The identification of a preinvasive lesion that precedes the development of invasive cancer of the cervix and development of screening tests and diagnostic procedures that allow the clinician to screen for, diagnose, and treat these precursor lesions has greatly reduced the incidence of cervical cancer worldwide.
- Persistent cervical infection with certain genotypes (especially type 16 and 18) of human papillomaviruses (HPV) has been identified to be the cause of cervical cancer.
- Most HPV-related lesions will regress with relatively low potential for cancer. Risk-based management of women with screening abnormalities and cancer precursors allows clinicians to prevent most cervical cancers while minimizing cervical trauma and focusing resources on patients with greatest need.
- Colposcopy is indicated for most women with ASC-US cytology and associated HPV infection, as well as for most other women with abnormal cytology.
- Colposcopy identifies most precancers, but colposcopic grading cannot be used reliably to direct treatment, even in expert hands. Cervical biopsy is required. Up to four biopsies will result in increased accuracy of identifying a high-grade lesion. Endocervical curettage has relatively low yield but is indicated when colposcopy is inadequate.

P.1190

- Excision and ablation have similar cure rates, but ablation is contraindicated unless cancer has been excluded. Treatment is recommended for most women with CIN 2 or CIN 3, although pregnant women and those under age 25 with CIN 2 may be monitored. Deep excision can result in injury and can predispose to preterm delivery.
- LEEP begins with activation of the electrode before contacting tissue, and current flow should continue till excision is complete. Sharp angles in the incision bed make hemostasis difficult, so angles should be beveled or rounded. Fulguration provides hemostasis with minimal deep coagulation injury, although direct coagulation of active bleeding points is effective.
- Traditional cold-knife cone biopsy of the cervix or large loop excision should be used for women with suspected microinvasive cancer or glandular lesions. For these women, excision should provide a single large, deep specimen that can be well oriented and has a better chance for a clear margin.

Kaled Alektiar

Dennis S. Chi

DEFINITIONS

FIGO staging—The International Federation of Gynecology and Obstetrics (FIGO) has defined staging of gynecologic cancers for more than 50 years. The cancer stage defines the extent of disease at diagnosis before treatment. FIGO staging is used worldwide to compare clinical experience and results of treatment.

Lymphovascular space invasion (LVSI)—Small endothelial-lined vessels within the cervical stroma may be either lymphatic vessels or small capillaries. On histologic examination of a surgical specimen, tumor cells or clusters of tumor cells are sometimes seen in these vessels. Tumor invasion or involvement of these lymphovascular spaces is generally believed to increase the risk of nodal metastases and worsen prognosis.

Parametrium—Connective tissue lateral to the cervix and uterus within the broad ligament.

Pararectal space—The avascular space in the posterolateral pelvis. It is bounded medially by the rectum, laterally by the pelvic wall, posteriorly by the presacral fascia, and anteriorly by the broad ligament and cardinal ligament. During pelvic surgery, we commonly define the boundaries of the pararectal space as follows: laterally, the internal iliac system and medially, the ureter and mesoureter.

Paravesical space—The avascular space in the anterolateral pelvis is bounded by the bladder medially, the pelvic sidewall laterally, and the broad ligament and cardinal ligament posteriorly. During pelvic surgery, we define the paravesical space into two spaces—the lateral paravesical space components are bound laterally by the external iliac vessels and medially by the obliterated umbilical artery. The medial paravesical space is bound medially by the bladder and laterally by the obliterated umbilical ligament. Opening this medial paravesical space facilitates the identification of the uterine artery at its origin from the internal iliac vessel.

SEER database—The Surveillance, Epidemiology and End Results Database is managed by the U.S. National Cancer Institute. It collects data from population-based tumor registries around the country that represent a cross section of 23% of the population.

Sentinel lymph node—The sentinel node is the first node involved in lymphatic metastases from the primary cancer. The sentinel node concept holds that lymph node metastasis occurs in an orderly, stepwise progression so that if the first, or *sentinel node*, is negative, then the ensuing nodes are unlikely to be involved with metastatic cancer. Because cervical cancer is a midline tumor that may spread to either pelvic side and perhaps by more than one lymphatic pathway, these sentinel nodes are bilateral, and frequently, more than one node is identified on either side of the pelvis.

In the first half of the 20th century, more women died from cervical cancer in the United States than from any other cancer. With the introduction of the Papanicolaou (Pap) smear in the 1940s, the early detection and treatment of preinvasive disease became possible. Consequently, both the incidence and mortality rates due to invasive cervical cancer in the United States declined approximately 75% by the end of the 20th century. In the United States, approximately 11 to 12 thousand women will be diagnosed with new invasive cervical cancer annually. It is also estimated that approximately 3 to 4 thousand women will succumb to the disease annually. Based on these figures, cervical cancer currently ranks as the third most common female genital tract malignancy in the United States (behind uterine corpus and ovarian cancer).

Worldwide, however, the burden of this disease remains large, with estimates of 300–400 thousand new cases annually and approximately 200 thousand deaths per year. This makes cervical cancer not only the most common gynecologic malignancy but also the third most frequently diagnosed cancer in women (behind breast and colorectal cancer). In general terms, the disease is much more common in developing countries, with 80% of worldwide cases occurring in these areas. In developing countries, cervical cancer accounts for 15% of female malignancies, carrying a lifetime risk of approximately 3%. In contrast, the cervical cancer lifetime risk is approximately 1% in developed countries. The highest incidence rates are observed in Latin America, the Caribbean, sub-Saharan Africa, and Southern and Southeast Asia. This geographical disparity is often attributed to the presence or absence of effective screening and treatment programs, since epidemiologic and biologic studies have not shown significant differences in tumor biology in countries with high rates of cervical cancer.

STAGING OF CERVICAL CANCER

In 1937, the Health Organization of the League of Nations adopted a clinical classification system for cervical cancer, making it the first cancer to be classified so. In 1950, this classification was modified to include preinvasive (in situ) cervical cancer, which was designated stage 0. New recommendations for the clinical classification of carcinoma of the cervix were adopted by the General Assembly of the International Federation of Gynecology and Obstetrics (FIGO) in 1961, and several other modifications have been made since. The general use of this classification abroad and in the United States has been extremely helpful in reporting and comparing results of various modalities of therapy. Descriptions of the clinical stages in carcinoma of the cervix uteri as updated by FIGO in 2009 appear in [Table 51.1](#) and [Figure 51.1](#).

The major redefinition and refinements involve stage I disease. Microinvasive (stage IA) carcinoma has been subdivided into stage IA1 and IA2 based on the depth of cervical stromal invasion by carcinoma. Stage IB has been subdivided into stage IB1 and IB2 based on the size of the clinical lesion.

P.1193

TABLE 51.1 Staging of Carcinoma of the Cervix Uteri (FIGO Committee on Gynecologic Oncology, 2009)

Stage I	The carcinoma is strictly confined to the cervix (extension to the corpus would be disregarded).
---------	--

IA	Invasive carcinoma that can be diagnosed only by microscopy, with deepest invasion ≤ 5 mm and largest extension ≥ 7 mm
IA1	Measured stromal invasion of ≤ 3.0 mm in depth and extension of ≤ 7.0 mm
IA2	Measured stromal invasion of > 3.0 mm and not > 5.0 mm, with an extension not > 7.0 mm
IB	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than stage IA ^a
IB1	Clinically visible lesion ≤ 4.0 cm in greatest dimension
IB2	Clinically visible lesion > 4.0 cm in greatest dimension
Stage II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina.
IIA	Without parametrial invasion
IIA1	Clinically visible lesion ≤ 4.0 cm in greatest dimension
IIA2	Clinically visible lesion > 4 cm in greatest dimension
IIB	With obvious parametrial invasion
Stage III	The tumor extends to the pelvic wall and/or involves the lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney. ^b
IIIA	Tumor involves the lower third of the vagina, with no extension to the pelvic wall.
IIIB	Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney
Stage IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to stage IV.
IVA	Spread to adjacent organs
IVB	Spread to distant organs

^aAll macroscopically visible lesions—even with superficial invasion—are allotted to stage IB carcinomas. Invasion is limited to a measured stromal invasion with a maximal depth of 5.00 mm and a horizontal extension of not > 7.00 mm. Depth of invasion should not be > 5.00 mm taken from the base of the epithelium of the original tissue—superficial or glandular. The depth of invasion should always be reported in mm, even in those cases with “early (minimal) stromal invasion” (~ 1 mm).

The involvement of vascular/lymphatic spaces should not change the stage allotment.^bOn rectal examination, there is no cancer-free space between the tumor and the pelvic wall. All cases with hydronephrosis or nonfunctioning kidney are included, unless they are known to be due to another cause.

HISTOPATHOLOGY

The principal histologic type of invasive cervical cancer, occurring in approximately 80% of cases, is the *squamous (epidermoid)* lesion. In 1923, Martszloff classified these squamous tumors into three main histologic subtypes and grades. Grade 1 tumors contain well-differentiated cells, keratin, and squamous pearls (Fig. 51.2A). Grade 2 tumors, the most common, are predominantly composed of transitional cells of the large cell nonkeratinizing type (Fig. 51.2B). Grade 3 tumors, the least common, are poorly differentiated small basal cell-type tumors (Fig. 51.2C). The classification of Martszloff did not prove to be clinically useful, mainly because biopsies taken from different areas of the same tumor often show different degrees of differentiation and different predominant cell types. Martszloff's work did inspire Broders, Wentz and Reagan, and others to continue to categorize the histologic types and degree of differentiation of squamous cell cervical tumors and to study their clinical behavior and response to treatment. The histologic classification of squamous cell tumor types introduced in 1959 by Wentz and Reagan is sometimes used in pathology reports. However, Willen and coworkers were unable to confirm a predictive value for survival from the Wentz-Reagan classification. Similarly, most recent studies, including those by the Gynecologic Oncology Group (GOG), have shown that grading squamous carcinomas has little predictive value.

A rare form of squamous cell cancer of the cervix is a *verrucous carcinoma*. It is a very well-differentiated squamous cell carcinoma with extensive keratinization that usually presents as a large bulky tumor of the cervix and often is confused with giant condylomas, such as those seen on the vulva. There is a sharp line between the tumor and underlying cervical stroma. Verrucous carcinoma, like most cervical cancers, has been shown to be associated with human papillomavirus (HPV) infection. Although metastatic disease is rare, this tumor has been noted to become more virulent if treated with irradiation. Goldberger and coworkers reported an unusually aggressive verrucous carcinoma of the cervix. According to deJesus and coworkers, at least 49 cases of this tumor have been reported in the female genital tract, sometimes as verrucous carcinoma and sometimes as squamous papillary tumor.

FIGURE 51.1 FIGO classification of carcinoma of the cervix. **A:** Stage IB: Carcinoma confined to the cervix, exophytic. **B:** Stage IB: Carcinoma is confined to the cervix, “cauliflower” lesion. **C:** Bulky stage IIA lesion with involvement of the vaginal fornix. **D:** Stage IIA: Carcinoma extends into the upper vagina or fornix. **E:** Stage IIB: Carcinoma extends into the parametrium but does not extend to the pelvic wall.

P.1195

FIGURE 51.1 (Continued) F: Stage IIIA: Carcinoma involves the anterior vaginal wall, extending to the lower third. **G:** Stage IIIB: The parametrium is infiltrated, and the carcinoma extends to the pelvic wall. **H:** Stage IVA: The bladder base or rectum is involved.

Adenocarcinomas of the cervix are becoming more common, especially in younger women. In a review of the Surveillance, Epidemiology, and End Results (SEER) Cancer Incidence Public-Use database from 1973 to 1996, Smith and colleagues reported that although the age-adjusted incidence rates per 100,000 for all invasive cervical cancers and squamous cell cancers decreased by 37% and 42%, respectively, the rates for adenocarcinoma of the cervix increased by 29% during the study period. These results suggest that current screening practices may be insufficient in detecting a significant proportion of adenocarcinoma precursor lesions.

Approximately one half of cervical adenocarcinomas are exophytic, usually polypoid, or papillary; others diffusely enlarge or ulcerate the cervix. Approximately 15% of patients have no visible lesion because the epicenter of the carcinoma is within the endocervical canal. Even without visible signs or symptoms, the lesion may infiltrate deeply into the cervix. Drescher and colleagues reported a higher frequency of uterine corpus invasion and nodal metastasis in 26 patients with cervical adenocarcinoma compared with 139 cases of squamous cell carcinoma. More recent studies have reached contradictory conclusions regarding the prognostic significance of this histology compared to the squamous counterpart. In general, most practitioners would treat stage I cervical cancer of squamous or adeno histology in a similar manner, without much regard to the histology. This is drastically different from the approach to stage I small cell neuroendocrine tumors and other rare tumors, such as adenoma malignum, which tends to be much more lethal.

P.1196

FIGURE 51.2 A: Grade 1: Well-differentiated epidermoid carcinoma of the cervix. High-power view of spinal cell type. The tumor cells contain abundant keratin that forms epithelial pearls. **B:** Grade 2: Moderately differentiated epidermoid carcinoma of the cervix, transitional cell type. The tumor cells are characterized by a moderate amount of cytoplasm but are without pearl formation. Extensive pleomorphism and mitosis are evident. The tumor is frequently classified as being of large cell, nonkeratinizing type. **C:** Grade 3: Poorly differentiated epidermoid carcinoma of the cervix, fat spindle or basal cell type. The tumor cells have little cytoplasm, numerous mitoses, and no keratin or epithelial pearls.

In addition to pure (endocervical) adenocarcinoma (Fig. 51.3), cervical adenocarcinomas can exhibit a variety of patterns and can be composed of diverse cell types. Other histologic patterns include *endometrioid*, *clear cell*, *serous*, *mesonephric*, and *adenoma malignum*. Different histologic patterns and cell types often appear in the same cervical tumor. Because mixtures are common, the designation of tumor type is based on the predominant component. In general, if a second histologic type constitutes 20% or more of the tumor, the lesion is designated as a *mixed cell type*, but pathologists also use various criteria to distinguish mixed lesions. Not infrequently, an adenocarcinoma and squamous cell carcinoma coexist in the same tumor, and these lesions are referred to as *adenosquamous carcinomas*. The so-called glassy cell adenocarcinoma of the cervix is rare and considered a variant of poorly differentiated adenosquamous carcinoma. It is known to be clinically

P.1197

aggressive, with frequent early distant metastasis. *Clear cell adenocarcinoma* of the cervix can occur in the presence or absence of intrauterine exposure to diethylstilbestrol (DES). Saigo and coworkers found that the endometrioid pattern was associated with a more favorable prognosis than any was other histologic type of cervical adenocarcinoma; however, other authors believe that the subpatterns have no prognostic significance. DES-related neoplasia is rarely seen by most practitioners, but clear cell neoplasia of the cervix unrelated to DES is occasionally encountered.

FIGURE 51.3 Adenocarcinoma of the cervix.

The early classifications of squamous cell carcinoma of the cervix proposed by Martszloff and others divided these tumors into three categories: keratinizing squamous cell carcinoma, large cell nonkeratinizing squamous cell carcinoma, and small cell carcinoma. Over the years, however, it became apparent that the subgroup designated as *small cell carcinoma* was composed of a heterogeneous group of tumors, many of which displayed neuroendocrine differentiation. Recent changes in the nomenclature have led to the subdivision of these *neuroendocrine tumors* into four categories: carcinoid, atypical carcinoid, large cell neuroendocrine carcinoma, and small cell carcinoma. Typical carcinoid and atypical carcinoid tumors are rare in the cervix; therefore, their clinical and pathologic features have not been well characterized. Large cell neuroendocrine and small cell carcinomas are highly aggressive neoplasms, with a propensity to metastasize early and widely. Usual methods of therapy incorporate systemic chemotherapy to treat potential distant metastasis, even in apparent clinical stage I disease.

Various *cervical sarcomas* have been described by Rotmensch and coworkers. These tumors constitute less than 0.5% of all cervical cancers and include adenosarcomas, leiomyosarcomas, carcinosarcomas, and rhabdomyosarcomas. Melanoma may also develop in the cervix and upper vagina and is often highly lethal. It is extremely rare for a lymphoma to develop primarily in the cervix, but lymphoma in the cervix is more likely to represent evidence of generalized lymphomatous disease.

CLINICAL PRESENTATION

Invasive cervical cancer is more likely than are its intraepithelial precursors to cause symptoms such as *abnormal vaginal bleeding* (menorrhagia, metrorrhagia, postcoital bleeding, or postmenopausal bleeding) or discharge. Many patients describe a profuse and often malodorous discharge, especially when the disease is advanced. Thus, any patient with abnormal vaginal bleeding or discharge should have a pelvic examination, including a speculum examination with visualization of the cervix. Failure to examine and visualize the cervix in a patient with abnormal vaginal bleeding or discharge could result in failure to diagnose cervical cancer.

Pain is not a common symptom in patients with cervical cancer, unless the disease is locally advanced and has invaded the adjacent pelvic structures, including pelvic nerves. In more advanced stages, patients may report bladder and rectal symptoms. When the disease involves lumbosacral and sciatic nerve roots and the lateral pelvic sidewall, chronic pelvic pain radiating down the leg can be excruciating and indicative of advanced disease. Edema of the lower extremities likewise indicates tumor obstruction of lymphatic and/or venous drainage and is a sign of advanced disease. Palpable supraclavicular or inguinal adenopathy may indicate distant spread and should be evaluated to exclude nodal spread. Ascites is uncommon in cervical cancer. Peritoneal dissemination is uncommon in early stages and is highly lethal regardless of histologic subtype.

Unfortunately, the physician cannot rely on the presence of symptoms to lead to a diagnosis of early carcinoma of the cervix. Many women remain without symptoms for many months. Approximately one third of patients with advanced-stage (III or IV) disease report symptoms for less than 3 months. The only way to diagnose cervical cancer in the earliest possible stages is to routinely apply special diagnostic procedures to large groups of women with and without gynecologic symptoms. This means screening the adult female population with Pap smears and cervical HPV testing at set intervals.

Invasive cervical lesions can be exophytic, infiltrative, ulcerative, or occult. The size of the visible lesion on the cervix may correlate with the depth of stromal invasion, but exceptions do occur with superficial exophytic lesions ([Fig. 51.4](#)).

An everted exophytic carcinomatous growth may be friable. Bits of tissue may break off on the examining fingers. On inspection, the friable exophytic cancer shows a rough, granular bleeding surface that can be sloughing and infected, with a foul-smelling discharge.

A tumor that develops beneath the mucosa of the ectocervix and infiltrates the cervical stroma usually causes cervical enlargement (expansion). The surface of the cervix may still feel smooth, but the cervical consistency to palpation is firm, hard, or nodular. It is characteristic of cervical cancers that develop in the endocervical canal to cause cervical enlargement and a firm cervical consistency before breaking through the mucosa of the exocervix to cause a visible lesion on speculum exam. This also is characteristic of some cervical cancers that develop in postmenopausal women. In fact, it is possible, although uncommon, for a cervical cancer that is developing from an epicenter high in the endocervical canal to invade the parametrial tissue and even obstruct the ureters before causing a visible cervical lesion. An ulcerative lesion can look like a large punched-out ulcer, but more commonly, it is an irregular crater with a necrotic bleeding base and a foul-smelling discharge. The normal contour of the cervix is absent in these ulcerative cases, and complete loss of a significant portion of the ectocervix is common.

FIGURE 51.4 Squamous cell carcinoma, cervix uteri, FIGO stage IIA.

Any grossly visible lesion of the cervix should be considered suspicious for cancer, and biopsy should be performed. Good visualization with a speculum and adequate illumination are essential. A Pap smear can be performed, even though it can be less accurate in the presence of a grossly visible cervical lesion, but the main diagnostic procedure should be a biopsy.

Colposcopic examination is neither needed nor particularly effective for a gross cervical lesion but can be helpful when there is a small surface lesion to identify the most abnormal area for directed biopsies. The primary benefit of colposcopy is in visualizing noninvasive, precursor, or minimally invasive lesions that cannot be visualized without magnification.

Cervical biopsy techniques are discussed in another chapter. Biopsies can be undertaken with any of a number of special instruments: The Kevorkian ([Fig. 51.5](#)), Younge, or Gaylor biopsy forceps are particularly functional for taking an adequate biopsy specimen. It is important to obtain a sufficient specimen where frank stromal invasion can be demonstrated. Surgical conization under anesthesia is unnecessary when a grossly visible lesion is present. Iodine (Schiller) staining can be used to demarcate the vaginal margins of a neoplastic area from adjacent normal epithelium. All of these procedures, as well as the popular loop diathermy conizations (LEEP), can be done in the outpatient setting. It is rarely necessary to take the patient to the operating room to diagnose cervical cancer. If an anesthetic is deemed necessary for some other reason, a careful pelvic examination under anesthesia, biopsy of any vaginal lesions, cervical and uterine sounding, cystoscopy and proctoscopy (if warranted), and even uterine curettage can be done; therefore, useful information to plan treatment can be obtained.

FIGURE 51.5 Kevorkian square-jawed cervical biopsy forceps.

PROGNOSTIC FACTORS

Several factors have been reported to affect prognosis in cervical cancer. However, the most important determinant of prognosis remains FIGO clinical stage. Based on studies by Piver and colleagues, van Nagell and associates, Delgado and coworkers, and numerous others that have demonstrated the prognostic significance of depth of cervical stromal invasion (DSI) and clinical or histologic tumor size in early-stage disease, FIGO incorporated these factors into its current clinical staging system by subdividing stage I. The 5-year survival rates by stage as reported by FIGO are shown in [Table 51.2](#).

In addition to FIGO stage, other reported prognostic factors include regional (pelvic) and distant (para-aortic) lymph node metastases, lymphovascular space invasion (LVSI), and select histologic subtypes, such as the small cell neuroendocrine tumors mentioned earlier.

Uterine corpus and endometrial cavity extension from primary cervical cancer was originally deemed a poor prognostic factor. The original League of Nations classification of 1937 included such lesions in the stage II category. Over the years, classification of the disease based on extension to the uterine corpus or endometrial cavity has gradually been discounted. These lesions, classified as stage IC in 1950, were included in

P.1199

the broad category of stage IB in 1961. Despite the change in classification, there is still some concern about patients whose tumor extends into the corpus of the uterus; this is of paramount importance in fertility-sparing radical trachelectomy cases. Evidence from Washington University reported by Perez and coworkers showed that tumor extension into the endometrial cavity lowers the 5-year survival rate of stage IB and IIA lesions by 10% to 20%. Lesions that involve the corpus also were found to have a twofold greater incidence of distant metastases compared with lesions without corpus extension. Similar observations have been reported by Prempre and coworkers from 82 cases of stage I and II disease with endometrial extension. The absolute 5-year cure rates of 68% for stage I and 62% for stage II disease with endometrial extension reflect the higher risk of metastases: 20% for stage I cases and 24% for stage II cases. Such reports must be studied with consideration of the difficulty of establishing a diagnosis of endometrial extension by using microscopic study of endometrial curettage specimens. The curettage specimen is frequently contaminated by the cervical tumor, making it difficult to be certain about endometrial extension. Treatment planning is not altered by such observations, nor is a fractional curettage recommended as part of pretreatment evaluation.

TABLE 51.2 Five-Year Survival by Figo Stage

STAGE	NUMBER OF PATIENTS	5-YEAR SURVIVAL RATE (%)
Ia1	860	98.7
Ia2	227	95.9
IB1	2,530	88.0
IB2	950	78.8
IIA	881	68.8
IIB	2,375	64.7
IIIA	160	40.4
IIIB	1,949	43.3
IVA	245	19.5
IVB	189	15.0

From International Federation of Gynecology and Obstetrics.

FIGURE 51.6 Squamous cell carcinoma, cervix uteri, FIGO stage IIA, with gross metastatic tumor in a right parametrial lymph node.

Lymph node metastases, either regional (pelvic) or to higher-level (common iliac and paraaortic) lymph nodes, have proven to be one of the most reliable prognostic factors for patients with cervical cancer ([Fig. 51.6](#)). The frequency of metastases to pelvic lymph nodes is approximately 0% to 1% for patients with stage IA1, 7% to 9% for stage IA2, 12% to 20% for stage IB, 20% to 38% for stage IIA, 16% to 36% for stage IIB, and greater than 35% for stage III and IV disease. Historically, preoperative detection of positive pelvic and paraaortic lymph nodes was unreliable; however, with the advent of newer radiologic imaging techniques, such as positron emission tomography (PET) scan, radiologic imaging has significantly improved the detection of nodal metastasis. Nevertheless, detection of positive lymph nodes is best made by pathologic evaluation and more accurately determined when lymphadenectomy or sentinel lymph node (SLN) mapping is used in preoperative staging or treatment. Although Kolstad showed that when intraoperative lymphography is used, 15% to 25% more patients with stage IB disease are found to have positive regional lymph nodes, this technique is rarely used nowadays and is mostly of historical relevance. The development of cervical injection techniques for SLN mapping has become a more accepted strategy in conjunction with pelvic lymphadenectomy to map early cervical cancer and determine nodal status.

When patients with stage IB cervical cancer are primarily treated with radical hysterectomy and pelvic lymphadenectomy, the 5-year cure rate is approximately 90% if there are no lymph node metastases. However, if metastatic disease to lymph nodes is detected, the 5-year cure rate falls to approximately 65% to 80%. The number of positive nodes also influences prognosis. In a review of the literature before the current standard of postoperative concurrent chemoradiation therapy,

Hoskins reported an 83% survival rate for patients with stage IB and IIA disease who had negative lymph nodes at the time of radical hysterectomy and pelvic lymphadenectomy. The survival rate decreased to 57% in patients with one to two positive nodes and 31% in those with more than three positive nodes.

Metastatic disease to paraaortic lymph nodes occurs in 4% to 7% of patients with stage I disease, 15% to 20% with stage II disease, 25% to 30% with stage III

disease, and 30% to 50% with stage IVA disease. Most studies confirm that metastasis to paraaortic nodes occurs more frequently when positive pelvic nodes also are present. The rarity of patients found to have isolated positive paraaortic nodes when pelvic nodes are negative raises the question: How well sampled and/or sectioned were the pelvic nodes? With more incorporation of SLN mapping and pathologic ultrastaging of pelvic nodes, it is likely that the incidence of isolated aortic nodal metastasis will be even less than previously reported. Even with extended-field radiation therapy, the 5-year survival rate for patients with metastases to the paraaortic nodes is only approximately 25% to 35%. Combined modality chemoradiation is a standard of care in many countries for node-positive cases. The addition of more chemotherapy after definitive chemoradiation has been investigated and is gaining popularity as a consolidation strategy in advanced cases.

Historically, tumor grade has been reported to affect prognosis. Early studies by Chung and coworkers and van Nagell and colleagues demonstrated a poorer prognosis among patients with poorly differentiated tumors. However, more recent studies by Zaino and the GOG have shown the grading of squamous tumors to be of little predictive value in cervical carcinoma. Shingleton and Orr reviewed nine publications that reported on 3,761 patients with predominantly squamous cell carcinoma. Twenty-eight different factors were evaluated for prognostic significance. *On multivariate analysis, tumor volume, lymph node metastasis, parametrial invasion, and LVSI were found to be significant independent prognostic factors, but patient age and tumor grade were not.*

On the other hand, tumor differentiation may have a significant prognostic role in adenocarcinoma of the cervix. Shingleton and Orr also reviewed eight studies of 577 patients with adenocarcinoma of the cervix. As with squamous cell carcinoma, the strongest independent prognostic variables were tumor size and nodal metastasis. However, unlike with squamous cell carcinoma, tumor grade appeared to have prognostic significance.

Several investigators, including Swan and Roddick, Wheeless and Graham, and Julian and coworkers, have drawn attention to the fact that when there is a mixture of adenocarcinomatous and squamous elements—so-called adenosquamous tumors—the prognosis is poor and the incidence of pelvic lymph node metastases is high. Histologic combinations should be considered when comparing the prognoses of adenocarcinoma and squamous cancers of the cervix. The literature is mixed on the overall issue of whether adenocarcinoma in general and adenosquamous cancers specifically are more virulent and less curable than are their squamous counterparts. Stehman and colleagues performed a multivariate analysis of prognostic variables for 626 patients with locally advanced cervical carcinoma treated with radiation therapy on three GOG protocols. Histologic cell type was not found to be a significant prognostic factor. A national pattern of care and evaluation study of the American College of Surgeons also failed to report statistically different 5-year survival rates for squamous and adenocarcinoma, regardless of type of therapy chosen.

In a landmark GOG prospective study of 645 patients with stage IB squamous cell carcinoma of the cervix treated with radical hysterectomy and pelvic lymphadenectomy, Delgado and colleagues identified three independent risk factors in relation to disease-free survival: the depth of invasion, the size of the tumor, and LVSI. The disease-free interval was 89% for patients without LVSI compared with 77% for those with LVSI. Although not all studies have found LVSI to be an independent prognostic factor, as stated, in a review of nine studies (including the study by Delgado et al.) of 3,761 patients, Shingleton and Orr found LVSI to be a significant independent prognostic factor on multivariate analysis. The incidence of LVSI in early-stage lesions varies widely, depending on multiple factors, including the number of sections of the cervix prepared, the depth of stromal invasion, and the interest of the examining pathologist. Observations from Austria and Germany indicate that there is considerable variation in the frequency with which LVSI is recognized by the pathologist. In a combined study of more than 1,000 patients at three different reference centers (Graz, Munich, and Erlangen), Burghardt and associates reported that the frequency with which LVSI was identified ranged from 9% in Munich, where only blood vessel involvement was so classified, to 43% in Graz, where it was classified as capillary-like space involvement. At the third center, Erlangen, the corresponding value was intermediate at 23%. Such variations in histopathologic criteria may well contribute to some of the controversy that exists regarding the prognostic significance of LVSI. LVSI in itself, although a risk factor for nodal metastasis, is not a contraindication to consider and offer fertility-sparing surgery, such as radical trachelectomy.

To this point, this discussion of prognostic factors has included only anatomic and morphologic factors. Peipert and associates emphasized that cancer, including cervical cancer, has both form and function. Accordingly, other clinical variables, such as the patient's symptoms, symptom severity, and comorbidity, affect the survival rate of patients with invasive cervical cancer. Unless these variables are suitably included such as in nomograms, prognostic estimates based on morphology alone are imprecise, and therapeutic evaluations can be misleading. According to Rutledge and associates, there is no consistent effect of age on survival rate in patients treated for cervical cancer. Younger patients with early-stage disease seemed to survive longer than did older patients, but the tendency reversed when disease was advanced.

PRETREATMENT EVALUATION AND STAGING

When a diagnosis of invasive cervical cancer has been established, the clinician should perform an evaluation of relevant pelvic organs to determine whether the tumor is confined to the cervix or has extended to the adjacent vagina, parametrium, bladder, ureters, or rectum. To determine clinical stage, a pelvic exam with palpation, inspection, and estimation of tumor involvement and measurements is allowed; in addition, a conization is also allowed as a staging tool in occult early-stage lesions. According to FIGO guidelines for clinical staging, diagnostic studies may include intravenous urography (IVU), cystoscopic examination of the bladder and urethra, a proctosigmoidoscopic study, a barium enema (BE), and in the case of early-stage disease, a colposcopic study of the vagina and the vaginal fornices. Colposcopic findings may be used for assigning a stage to the tumor (for instance, FIGO stage IIA), but the results must be confirmed by biopsy. Standard x-rays,

P.1201

such as a chest x-ray and routine bone films, are allowed for staging. Chest radiographs and electrocardiographic studies are also used to determine cardiopulmonary disease, particularly in the older patient. Advanced imaging modalities with pelvic MRI, computerized tomography (CT), and whole-body PET scan, although very useful to help triage treatment, are not available to the majority of women in developing nations.

When studies detect ureteral obstruction, a tumor is classified as a stage IIIB lesion, regardless of the size of the primary lesion. Ureteral obstruction, either hydronephrosis or nonfunction of the kidney, is well established as an indicator of poor prognosis, as recognized in the FIGO classification system. Retrograde pyelography can be performed after the ureteral obstruction is located for further evaluation, and stenting of the blocked ureter is frequently considered. Kidney function studies such as serum creatinine and creatinine clearance provide important baseline information before treatment; complete urinalysis is useful for detecting the presence of albumin or white and red blood cells and renal tubular casts. The majority of women with advanced cervical cancer will be candidates for chemotherapy, and maintaining good renal function is important in these patients.

In women with bulky or advanced-stage tumors, the bladder mucosa also should be inspected cystoscopically for possible bullous edema, which indicates lymphatic obstruction within the bladder wall. Evidence of tumor in the bladder must be confirmed by biopsy before the lesion can be classified as stage IVA. Urine cytology is usually not sufficient to make that diagnosis. Rectal mucosal lesions from cervical cancer are infrequent and also require a biopsy via proctosigmoidoscopy, because they can be related to an inflammatory or other neoplastic process rather than to the cervical tumor.

A pelvic examination must be performed as part of the staging process, and it may be necessary to have the patient completely relaxed by general anesthesia for a satisfactory exam. In as many as 20% of patients, the initial clinical classification of the disease based on office evaluation has been proven to be incorrect based on findings at the time of pelvic examination under anesthesia. Such an examination can reveal a more advanced stage of the disease than was originally found; additional biopsies (if indicated) or fractional curettage can be done, as well as colposcopy, cystoscopy, and proctosigmoidoscopy. In today's health care climate, however, the cost of a separate examination under anesthesia may need to be reserved for only the most problematic cases. Moreover, the advancements in pelvic MRI quality are giving gynecologic oncologists better information about the extent of locally advanced cervical neoplasia.

A main goal of tumor staging is to define prognostic groups, to enable clinicians to compare disease status, screening efficacy, treatment results, and other health care outcomes. The present form of the FIGO cervical cancer staging system is in principle a series of definitions of the most important prognostic features of cervical cancer, and it has been used in treatment protocols for generations. However, in the present form of the system, some of the stages do not refer to the presence or absence of paramount prognostic features that are recognized as definition criteria for lower (previous) stages. For example, stage IIA is defined as vaginal vault spread of the disease. Stage IIB does not contain information about the disease involvement of the vaginal vault (presence or absence of criteria for stage IIA), although extensive tumor spread to the vaginal vault seems to be at least as significant a prognostic factor as parametrium involvement (definition of stage IIB). Likewise, stage IIIB does not describe the presence or absence of a condition described in stage IIIA, although extensive tumor spread to the lower parts of the vagina (criteria of stage IIIA) is indeed a severe prognostic sign that should be considered in treatment planning. Similar weaknesses of the staging system include the lack of tumor size description in stage IIB and upper stages. (This problem was recognized by the new staging system, which differentiates between stage IIA1 and IIA2.)

The introduction of a more complex system of stages might better define prognostic groups, but inevitably, it would be more difficult to use and would make it difficult to collect large enough patient cohorts in a given substage for research. However, considering these weaknesses of the FIGO staging, a descriptive combination of the FIGO stages might be used in daily practice. For example, a patient with a bulky tumor involving the vaginal vault, inner half of the parametrium with hydroureter, should be defined as stage IIIB disease (based upon the ureter compression). But the disease (prognosis) might be better defined by adding information about criteria of previous stages, stating, for example, this is stage IIIB disease, with features of stage IIA2 and IIB, that is, no lower vaginal invasion or pelvic sidewall invasion.

Using an extension or combination of findings from lower stages might help to better define prognostic groups, explain results, and create treatment suggestions for special conditions without the need for creating a completely new and more complex staging system.

Pretreatment pedal lymphangiography has been used in the past to detect pelvic and paraaortic lymph node metastases, but the procedure is tedious and associated with many false-negative and false-positive findings. When compared with lymphadenectomy, positive lymphangiograms have an accuracy rate of less than 75% and a false-negative rate as high as 50%. Furthermore, a lymphangiogram only detects metastatic lesions when the parenchyma of the lymph node has become distorted, by which time the lesions are macroscopic. The procedure is therefore not recommended for routine use in the pretreatment evaluation of cervical cancer patients and is mostly mentioned nowadays for historical value.

Surgical experience from pelvic lymphadenectomy has confirmed an error rate of 15% to 25% in the clinical staging of patients with stage IB or II lesions. In 10% to 30% of cases with stage II or III tumors, in addition to positive findings of occult pelvic lymph nodes, other metastases may be found in the paraaortic nodes. Unfortunately, pelvic examinations and clinical staging as defined by FIGO cannot detect such metastases. Consequently, there is a growing body of literature showing the superiority of cross-sectional imaging (CT, MRI, and PET) over clinical staging in delineating the extent of disease in patients with cervical cancer. As stated earlier, official FIGO guidelines do not incorporate the use of advanced imaging, such as PET and MRI, into the staging of cervical cancer. This is due to FIGO's determination to create guidelines with universally available staging methods so that staging can be a standardized means of communication between different institutions worldwide. However, as knowledge of prognostic factors and the value of cross-sectional imaging have accumulated, its use in treatment planning has increased despite the lack of change in the official FIGO clinical staging guidelines, and in developed countries, MRI and PET scans are frequently performed as a routine part of the workup and management of suspected advanced cervical cancer.

In a Patterns of Care Study conducted between 1978 and 1988, Montana et al. reported a decrease in the use of IVU (86% to 42%) and BE (58% to 32%) in the staging of cervical cancer patients. During the same time period, the use of CT scan increased from 6% to 70%. In another Patterns of Care Study in the United States recently reported by Amendola

P.1202

and colleagues, the use of lymphangiography, IVU, and BE had fallen to 1% in the pretreatment evaluation of patients with clinical FIGO stage IB1 or greater cervical cancer who were scheduled for surgery.

The greatest value of a CT scan in the pretreatment evaluation of patients with cervical cancer is in the assessment of advanced disease (stage IB2 and greater) and in the detection and biopsy of suspected lymph node metastasis and possible ureteral obstruction. The treatment plan for patients with locally advanced disease must be modified if retroperitoneal lymph node involvement and/or distant metastasis is discovered. A meta-analysis by Schneider et al. reported a positive predictive value of 61% for CT scan in the pretreatment evaluation of nodal disease in cervical cancer. Moreover, in experienced hands, fine needle aspiration of retroperitoneal nodes with CT scan guidance has an accuracy rate of 80% to 95%. When the aspiration study unequivocally shows malignant cells, a surgical biopsy need not be performed. This information is most valuable in patients who have metastasis to the paraaortic nodes, because these patients would need the pelvic radiation fields extended to incorporate the involved region if there is no other evidence of distant metastasis. The use of laparoscopy and robotic surgery to "surgically stage" the paraaortic nodes is common in many practices, and pathologic evaluation of these nodes remains the most reliable strategy to exclude disease despite advances with imaging, such as PET scan. Recent studies have shown that even with a negative PET scan in the paraaortic region, a nodal dissection may identify a 10% to 15% nodal positivity on microscopic examination.

SURGICAL TREATMENT OF EARLY-STAGE CERVICAL CANCER

Based on the pretreatment evaluation of the patient, including the prognostic factors of tumor size, clinical stage of the disease, and risk of pelvic node metastases, a treatment schema can be developed for invasive cervical cancer, as shown in [Table 51.3](#). Almost all patients are treated with either primary surgery or primary radiation therapy with concurrent chemotherapy. Some patients are appropriately treated with combinations of all three. The standard management of patients with early cervical carcinoma is surgical removal of the cervix and pelvic nodal evaluation. The extent of resection of the surrounding tissue depends on the stage, size of the lesion, and the depth of cervical stromal invasion.

Stage IA1 Disease

The exact definition of early-stage cervical cancer has been debated for several decades. This is illustrated by the fact that FIGO changed the definition of early-

stage cervical cancer at least five times since 1960. In 2009, FIGO made its most recent revision to the stage IA cervical cancer staging system. After an extensive evaluation of the data in the literature, as well as seeking advice from specialty societies and individuals worldwide, FIGO changed the definition of stage IA1 disease to lesions that invade the cervical stroma ≤ 3 mm in depth and ≤ 7 mm in width. Stage IA2 includes patients with >3 mm but <5 mm invasion and ≤ 7 mm lateral extent.

In an exhaustive review of the literature, Ostor identified 31 studies spanning the years 1976 to 1993 that reported on 3,598 patients with squamous cell carcinoma of the cervix and ≤ 3 mm stromal invasion. Although not all patients had lymph nodes removed as part of their treatment, the calculated incidence of lymph node metastasis in this group of patients was less than 1%.

TABLE 51.3 General Treatment Schema for Invasive Cervical Carcinoma^a

DISEASE STAGE	TREATMENT
Stage IA1	Simple hysterectomy, abdominal or vaginal, or cervical conization If there is LVI, consider sentinel node mapping or pelvic lymphadenectomy
Stages IA2 ^b , IB1, and nonbulky IIA	Radical (type C) ^c hysterectomy or trachelectomy, ^d bilateral pelvic lymphadenectomy (consider sentinel node mapping) with postoperative irradiation, \pm concurrent chemotherapy in selected high-risk patients
Stages IB2 and bulky IIA ^e	Full external and intracavitary pelvic irradiation with concurrent chemotherapy (\pm extrafascial hysterectomy) or radical abdominal hysterectomy and pelvic (\pm periaortic lymphadenectomy)
Stages IIB to IVA ^f	Full external and intracavitary pelvic irradiation with concurrent chemotherapy
Stage IVB	Palliative chemotherapy

^aFor individual patients, recommendations for treatment can vary, depending on the clinical circumstances.

^bSome authorities recommend modified (type B) radical hysterectomy, bilateral pelvic lymphadenectomy for stage IA2 disease.^cRefer to [Figure 51.7](#).^dIn highly selected cases.^eSome authorities recommend simple hysterectomy in addition to radiation/chemotherapy for stage IB2 and bulky stage IIA disease.^fA patient with a stage IVA lesion that extends only in the anterior or posterior direction may be a candidate for pelvic exenteration.

Diagnosis

Microinvasive carcinoma cannot be diagnosed from a punch biopsy because adjacent areas may contain more advanced tumor; conization is required for definitive diagnosis in this situation. The accuracy of the diagnosis depends on the adequacy of the cone and the adequacy of the pathologic examination of the cone. The entire cone should be blocked so that an adequate number of histologic sections can be taken from each block. If the diagnosis is still not ascertainable, more sections should be made. Although some experts can obtain a large tissue specimen with negative margins using loop electrosurgical excision techniques for a satisfactory diagnosis of microinvasive cancer, a traditional cold-knife cone biopsy in the operating room under anesthesia is often preferable. This is thoroughly discussed in another chapter.

Treatment

In 1996, the National Institutes of Health (NIH) invited an international panel of experts to develop a consensus conference statement on cervical cancer. After an extensive literature review and presentation of the scientific evidence, they concluded that patients who have squamous cell carcinoma

P.1203

of the cervix with ≤ 3 mm stromal invasion and negative conization margins have virtually a 100% cure rate when treated with simple hysterectomy or conization alone. However, for patients treated by conization alone, both the internal conization margin and the postconization endocervical curettage must be negative for cancer and dysplasia, because the risk of residual invasive cancer is significantly increased if either the margin or the curettage is positive. The definition of a negative margin remains debatable, and whether no tumor at the inked margin is sufficient versus a 1- to 3-mm tumor-free margin remains to be determined, but it is preferable to have a nonfragmented specimen for evaluation of margins. The choice of therapy should also be influenced by the patient's desire to maintain fertility. Although LVSI generally is considered to be an adverse prognostic factor in cervical cancer, its prognostic significance in stage IA1 disease is uncertain. Because of this uncertainty, some clinicians suggested that the presence of LVSI in stage IA1 disease might be more appropriately treated with radical hysterectomy and pelvic lymphadenectomy. SLN mapping is gaining increasing credibility in early-stage cervical cancer, and stage IA1 cases with LVSI are reasonable candidates for SLN injection and mapping as a strategy to evaluate pelvic nodes.

Recurrence in the vaginal vault may be the result of failing to accurately define the extent of the lesion and the presence of involvement of adjacent vaginal mucosa. This usually can be prevented with a careful colposcopic examination before hysterectomy. If vaginal fornices are involved, partial vaginectomy may be easier to perform with hysterectomy if the operation is done vaginally ([Fig. 51.7](#)). Alternatively, if the woman is not a good surgical candidate, radiation therapy (usually in the form of brachytherapy alone) can be selected.

Increased infection morbidity has been reported with intracavitary irradiation of a recently coned cervix. The cervix must be allowed to heal completely before intracervical irradiation. The survival rates for microinvasive disease (all treatments) should reach 98% to 99% if patients are adequately studied and properly treated.

Several studies of microinvasive adenocarcinoma of the cervix have been done. Webb and colleagues recently reviewed the SEER public-use database to

identify 131 cases of cervical adenocarcinoma with 3-mm or less stromal invasion. Fifty patients had a radical hysterectomy and pelvic lymph node dissection, and none were found to have lymph node metastasis. Furthermore, there were no deaths among the 54 patients treated with simple hysterectomy alone. Others have reported a 0% rate of lymph node metastasis with depths of stromal invasion of up to 5 and 12 mm. However, bilateral pelvic lymph node metastases have been reported with as little as 2.5 mm of stromal invasion. Furthermore, Elliot and associates reported a case of lymph node metastasis with cervical adenocarcinoma with less than 1-mm invasion and a second case of recurrence and death after radical hysterectomy and pelvic lymphadenectomy in a patient with 1.8 mm of stromal invasion. From a clinical standpoint, stage IA1 adenocarcinoma is treated similarly to its squamous counterpart, except gynecologic pathology consultation is highly recommended in all cases of early cervical cancer to accurately determine the diagnosis and stage and to identify any LVSI. In summary, stage IA1 disease is highly curable with conization or trachelectomy or hysterectomy. The need to evaluate pelvic lymph nodes is appropriate to consider in women with LVSI or if higher stage is suspected and may be accomplished with SLN mapping or pelvic lymphadenectomy. Parametrectomy is being decreasingly utilized in true stage IA1 disease, and fertility-sparing surgery has become a standard of care with favorable oncologic and obstetrical outcomes in many women with early-stage cervical cancer.

FIGURE 51.7 Vaginal hysterectomy and partial vaginectomy specimen from a patient with squamous cell carcinoma, cervix uteri, FIGO stage IA1, with extension to adjacent vaginal fornix. Note uniform width of vaginal cuff.

If simple hysterectomy is subsequently chosen as the definitive surgical treatment after a conization, the hysterectomy should be done within 48 hours of the conization or delayed until the cervix has healed, usually about 6 weeks later. If the hysterectomy is done after 48 hours and before the cervix has healed, the risk of postoperative infectious morbidity is increased. However, a radical abdominal hysterectomy and bilateral pelvic lymphadenectomy can be done at almost any time after cervical conization, even before the cervix is completely healed. The reason for this difference is not clear, but may be related to the fact that indurated and possibly infected paracervical and parametrial tissue is actually removed when a radical hysterectomy is done.

Stages IA2, IB1, and Nonbulky (≤ 4 cm) IIA Disease

The recommended treatment by the NIH Consensus Conference for patients with stage IA2 disease is primary radical or modified radical hysterectomy with bilateral pelvic lymphadenectomy or primary radiation therapy, because the risk of nodal metastases is 4% to 10% in these patients. Again, the diagnosis of both stage IA1 and IA2 diseases should be based

P.1204

on microscopic examination of removed tissue, preferably a conization or large loop excision specimen, which must include the entire lesion. For stage IA2 disease, the depth of invasion should not be more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates. The second dimension, the horizontal spread, must not exceed 7 mm. Vascular space involvement, either venous or lymphatic, should not alter the staging but should be specifically recorded. The remaining stage I cases should be allotted to stage IB. All grossly visible lesions are defined as stage IB.

FIGURE 51.8 The cardinal ligament is excised medially in women with microscopic lesions (class II operation) or laterally in those with larger-volume lesions (class III operation). (Modified from Piver MS, Rutledge F, Smith JP. Five classes of extended hysterectomy for women with cervical cancer. *Obstet Gynecol* 1974;44:265, with permission.)

TABLE 51.4 Comparison of Extent of Resection for Surgical Procedures to Treat Early-Stage Cervical Cancer

TISSUE	CERVICAL CONIZATION	TOTAL ABDOMINAL/VAGINAL HYSTERECTOMY	MODIFIED RADICAL HYSTERECTOMY (TYPE B)	RADICAL ABDOMINAL HYSTERECTOMY (TYPE C)	RADICAL VAGINAL TRACHELECTOMY (TYPE B)	RADICAL VAGINAL HYSTERECTOMY (TYPE C)
Cervix uteri	Partially removed	Completely removed	Completely removed	Completely removed	Majority removed	Completely removed
Corpus uteri	Preserved	Completely removed	Completely removed	Completely removed	Preserved removed	Completely removed
Ovaries and tubes	Preserved	Preserved	Preserved	Preserved	Preserved	Preserved
Parametria and paracolpos	Preserved	Preserved	Removed at level of ureter	Removed lateral to ureter	Partially removed	Removed at level of ureter
Uterine vessels	Preserved	Ligated at level of cervical internal os	Ligated at level of ureter	Ligated at origin from hypogastric vessels	Descending cervicovaginal branch ligated	Ligated at level of ureter
Uterosacral ligaments	Preserved	Ligated at uterus	Divided midway to rectum	Divided near rectum	Partially removed	Partially removed
Vaginal cuff	Preserved	None removed	1-2 cm removed	≥2 cm removed	1-2 cm removed	≥2 cm removed

For stage IA2 disease, standard treatment is a type C1 (class III) nerve-sparing radical hysterectomy with bilateral pelvic lymphadenectomy; however, some authors recommend a type B (class II) modified radical hysterectomy ([Fig. 51.8](#)). The type B, or class II, hysterectomy removes the medial half of the cardinal and uterosacral ligaments, ligating the uterine artery at the ureter. This more conservative operation has been used by some authors in the past 3 decades to excise small primary tumors while reducing the partial bladder denervation associated with the complete excision of the cardinal and uterosacral ligaments required for a type C, or class III, hysterectomy. Five-year survival rates of 97% to 98% have been reported for patients with small cervical lesions treated with a type B, class II, hysterectomy. The role of the class II modified radical hysterectomy was recently evaluated in a randomized, prospective study reported by Landoni and colleagues. Two hundred forty-three patients with FIGO stages IB and IIA were randomized to either class II or III hysterectomy. The recurrence-free and overall survivals were similar between the two groups. Patients treated with type II radical hysterectomy had a statistically significant reduction in operative time and postoperative morbidity, particularly bladder dysfunction. However, given the relatively high cure rate for early cervical cancer treated by radical hysterectomy, larger trials are necessary to prove equivalence in survival between the two types of hysterectomy. As stated by Rose, larger trials are required before we can accept these results as the new standard of care. The estimated extent of tissue resection in surgical procedures for early cervical cancer is summarized in [Table](#)

RADICAL HYSTERECTOMY

Historical Points in the Development of Radical Surgery for Cervical Cancer

Radical hysterectomy for cervical cancer was performed by John Clark while still a resident trainee at the Johns Hopkins Hospital in Baltimore in 1895; however, earlier reports describe the radical hysterectomy performed in 1888 by the Czech surgeon Pavlik. The procedure is linked in perpetuity to Wertheim of Vienna, who reported his series of 500 cases of radical extended abdominal hysterectomy and partial lymphadenectomy performed from 1898 until 1911. Despite the skill and enthusiasm of Wertheim, Schauta (who developed the vaginal radical hysterectomy in 1901), Okabayashi, and others, radical pelvic surgery was fraught with significant operative morbidity and mortality. Therefore, the introduction of radium brought irradiation to the forefront of primary treatment for carcinoma of the cervix for the next several decades.

In the United States, Joe V. Meigs reintroduced radical hysterectomy as the treatment of choice, publishing a series of 344 cases in 1945. Until formalization of training fellowships in gynecologic oncology in the early 1970s, many outstanding gynecologic surgeons in the United States (Parsons, Ulfelder, Green, and many others) made important contributions and modifications to the radical surgical approach that have markedly decreased complications while preserving the cure rate. Proficient performance of the radical hysterectomy remains a benchmark of the gynecologic oncology surgeon.

Patient Selection for Radical Hysterectomy

Simple hysterectomy is not adequate treatment for stage IB cervical cancer. In 1943, Jones and Jones reported a 5-year survival rate of only 41.6% in patients who had been treated for stage I cervical cancer with simple hysterectomy only. Such poor results also have been reported by Schmidt and others. When more than FIGO stage IA1 invasive cervical cancer is a surprise finding in a simple hysterectomy specimen, additional therapy—usually radiation therapy with or without chemotherapy—should be given postoperatively. Suggested indications for radical abdominal hysterectomy are summarized in [Table 51.5](#).

Although radical hysterectomy and pelvic lymphadenectomy occasionally are used to treat patients with adenocarcinoma of the endometrium with involvement of the cervical stroma (stage IIB) and, rarely, patients who have a small cervical cancer that persists or recurs in the cervix after primary radiation therapy, in this chapter, emphasis is given to the use of the operation as primary treatment for invasive cervical cancer.

In most institutions, the majority of patients with stages IA2, IB1, and nonbulky IIA cervical cancer are offered radical abdominal hysterectomy and bilateral pelvic lymphadenectomy as primary treatment.

Patients with bulky stage IB disease (currently FIGO stage IB2) have traditionally been treated with radical hysterectomy and bilateral pelvic lymphadenectomy or primary radiation therapy, with equivalent survivals. However, patients with these larger lesions treated surgically have a very high risk of having lymph node metastasis or close resection margins or local tumors risk factors, such as deep stromal invasion with LVSI, which are often reasons for postoperative pelvic radiation treatment. Landoni and colleagues performed a randomized trial of radical hysterectomy and pelvic lymphadenectomy versus pelvic radiation therapy for stage IB to IIA cervical cancer. Patients randomized to the surgery arm who had pathologic risk factors, such as lymph node metastasis, received adjuvant radiation therapy. Of the 55 patients with tumors greater than 4 cm, 46 (84%) required postoperative irradiation. The disease-free and overall survival rates for these patients treated with surgery and radiation therapy were the same as those for patients with bulky tumors treated with radiation therapy alone; however, the combination therapy significantly increased morbidity. Subsequently, a randomized trial performed by the GOG has demonstrated the benefit of the addition of cisplatin chemotherapy to pelvic radiation followed by extrafascial hysterectomy in this group of patients. Therefore, many experts feel that patients with FIGO stage IB2 and bulky IIA cervical cancer are best treated with concomitant cisplatin chemotherapy and radiation therapy with or without completion extrafascial hysterectomy.

TABLE 51.5 Indication for Radical Abdominal Hysterectomy

INDICATION	EXTENT OF DISEASE
Invasive cervical cancer	Stage IA1 with lymphovascular invasion
	Stage IA2
	Stage IB1
	Stage IB2 (selected)
	Stage IIA (selected)
Invasive vaginal cancer	Stage I-II (limited to upper one third of vagina, usually involving posterior vaginal fornix)
Endometrial carcinoma	Clinical stage IIB (gross cervical invasion)
Persistent or recurrent cervical cancer after radiotherapy	Clinically limited to cervix or proximal vaginal fornix

In the United States, patients with stage IIB invasive cervical cancer usually are excluded from primary treatment with surgery. They are usually treated with concomitant radiation therapy and chemotherapy. However, it should be noted that select stage IIB cases have traditionally been considered in some countries (Japan, Germany, Hungary, and other European countries) as an indication for primary radical hysterectomy. Recent studies from Japan demonstrated equal overall survival with a favorable quality-of-life outcome of radical hysterectomy compared to primary chemoradiotherapy in this stage of the disease. The question about radical hysterectomy indication in select stage IIB patients cannot be considered resolved; thus, although radical hysterectomy treatment of stage IIB

cervical cancer is not suggested in this book, it should be considered as an acceptable alternative concept in the appropriate hands and clinical setup.

The clinical significance of parametrial involvement dates to the early studies of Kundrat and Sampson. Kundrat, working in Wertheim's clinic, studied more than 21,000 serial microscopic sections of the parametrium, finding that the parametrium of one or both sides was involved in 44 of 80 patients. In a similar study at the Johns Hopkins Hospital, Sampson pointed out that the parametrium could feel indurated and yet show no evidence of cancer. Also, the parametrium can feel normal and yet contain cancer. Sampson emphasized that only

P.1206

by the microscope can the surgeon exclude cancer involvement of the parametrium. More recently, Inoue and Okumura found parametrial extension in 7% of stage IB patients and in only 34% of stage IIB patients. Burghardt and Pickel found true parametrial involvement in only 19% of stage IIB patients. Matsuyama and coworkers found no parametrial cancer in 58% of stage IIB patients. These studies were based on careful examination of microscopic sections and reemphasize the difficulty of being certain about parametrial extension from pelvic examination alone, emphasizing the shortcomings of a clinical staging system. Inoue and Okumura studied 628 operative specimens from patients treated with radical hysterectomy and lymphadenectomy and found that parametrial extension is an important factor in the number of positive lymph nodes found and in patient survival. If there is suspicion of spread into the parametrial tissues by examination, CT scan, or MRI scan, it is reasonable to offer radiation therapy with concomitant chemotherapy as primary treatment (despite the fact that the official FIGO stage should remain unchanged).

The major point to be emphasized is that the gynecologic surgeon should not attempt to treat a patient with a large cervical tumor with primary radical surgery unless there is reasonable assurance that the operation will result in the complete removal of the central tumor with an adequate margin of tumor-free tissue around it. The surgeon should not operate on patients with the idea that radiation therapy with or without chemotherapy can be used postoperatively to eliminate residual fragments of tumor tissue after incomplete resection. Such patients usually are better treated with concurrent pelvic radiation and chemotherapy from the beginning.

Primary radical surgical treatment is not contraindicated in any histologic type of cervical cancer. Shingleton and coworkers have suggested that the survival of patients with stage I adenocarcinoma of the cervix is better with surgery than with irradiation. Patients with stage I adenosquamous cancer, clear cell cancer, and undifferentiated adenocarcinoma have a poorer prognosis, regardless of the method of treatment chosen, and therefore are often considered for adjuvant radiation therapy and/or chemotherapy after primary surgery.

Patients considered for radical hysterectomy must be acceptable candidates for an operation and free of serious medical problems that contraindicate extensive surgery. In former years, some institutions limited radical surgery as primary treatment to premenopausal women so that ovarian function might be conserved. As experience has accumulated, it has become apparent that the operation is also well tolerated by older women. In a study of 45 women aged 65 years and older with cervical cancer, Fuchtnier and associates concluded that age alone should not be a contraindication to extensive hysterectomy in the elderly patient with American Society of Anesthesiologists physical status I to III. Kinney and coworkers reported their experience with the Wertheim operation in a geriatric population. Thirty-eight selected women between 65 and 89 years of age (median age, 69 years) were compared with 320 patients younger than age 65. The survival rates were almost identical in the two groups. Perioperative morbidity was minimally increased in the geriatric group. Geisler recently compared the outcomes after radical hysterectomy and pelvic lymphadenectomy of 62 patients older than age 65 to 124 matched controls age 50 or younger. Even using this relatively younger cohort for comparison, there were no significant differences in operative mortality or morbidity. However, to achieve such excellent results in older women, Kinney and coworkers pointed out that "meticulous surgical technique, high-quality ancillary services, and support from internal medicine and anesthesia services" are required. Such extended supportive care is not available in every hospital.

Extreme morbid obesity presents especially difficult technical problems when radical surgery is chosen for primary treatment. Not only is the performance of the operation more challenging and possibly less satisfactory, but also there may be an increased risk of wound complications, postoperative infection, intraoperative hemorrhage, pulmonary embolus, pulmonary atelectasis, and anesthesia-related and other problems. Unfortunately, primary treatment with radiation therapy with or without chemotherapy also is frequently less than satisfactory in extremely morbid obese patients. The introduction of robotic minimally invasive surgery may play a role in treating select obese women with early cervical cancer, avoiding the need for laparotomy.

Studies by Soisson and Levraut compared outcomes after radical hysterectomy for cervical cancer in obese versus nonobese women. They found that survival was not compromised, and the incidence of serious complications was not increased in obese patients. However, in obese women, the authors reported that the operative technique is more difficult, the procedure lasts longer, and the surgery is associated with greater blood loss. Cohn and colleagues recently reported their results with radical hysterectomy for cervical cancer in 46 obese women. The median body mass index was 36 kg/m², and the median weight was 95 kg. Nine patients (20%) experienced postoperative morbidity, mostly related to wound complications. No patient developed a fistula. Massi and associates have reported that the Schauta-Amreich vaginal hysterectomy can be used as an alternative to the radical abdominal hysterectomy in the presence of obesity or elevated surgical risks.

According to Shingleton, primary treatment with radical surgery paradoxically also can be riskier in very thin patients because of a higher incidence of fistula. It is speculated that easy exposure and lack of excess fatty tissue in these patients may result in removing essential vasculature around the ureters and bladder, resulting in ischemic necrosis. A thin patient has less fat around the pelvic vessels and in the lymph fields; thus, the surgeon should be satisfied to remove less tissue in an operation that will still be adequate in a thin patient.

The management of the *pregnant patient* diagnosed with invasive cervical carcinoma is more challenging. First, a decision must be made to either save the pregnancy or treat the cancer. Pregnancy is not a contraindication to primary treatment of stage IB or IIA carcinoma of the cervix with radical surgery (Fig. 51.9). In 1974, Sall and coworkers reported on 29 patients with stage IB carcinoma of the cervix in pregnancy treated with radical hysterectomy and pelvic lymphadenectomy. At the time of publication, 28 patients were alive and well, and 23 patients had been followed for more than 5 years. There were no fistulae or major complications. Others have confirmed 5-year survival rates of 85% to 95% for patients treated with radical surgery for stage IB cervical cancer in pregnancy. Funnell and associates, operating on 17 pregnant patients, suggested that the associated pregnancy changes facilitated the surgical dissection. Sood and colleagues performed a case-control study comparing the outcomes after radical hysterectomy and pelvic lymphadenectomy for 26 pregnant versus 26 nonpregnant patients. Operative times and postoperative complication rates were similar between the two groups. There was a statistically significant increase in blood loss at the time of surgery for pregnant patients; however, there was no difference in the frequency of blood transfusion. Eleven patients underwent surgical treatment in the third trimester of pregnancy, with a mean planned delay in therapy of 16 weeks. None of the patients with the planned delay in therapy developed recurrent disease. The authors concluded that surgical management of early cervical cancer is safe during pregnancy. In select obstetric patients who desire to maintain

P.1207

their pregnancies, Sood and colleagues agreed with the conclusions of Greer and coworkers that planned delay in therapy to increase the likelihood of fetal maturity is safe for early-stage I squamous cell cancers diagnosed in the late second and early third trimester. All other patients should be treated promptly in an attempt to cure the cancer.

FIGURE 51.9 Squamous cell carcinoma, cervix uteri, FIGO stage IB with intrauterine pregnancy, 16 weeks (lymphadenectomy specimen not included).

Finally, based on data from Orr, Chapman, and others, extensive parametrectomy and pelvic lymphadenectomy appear to be appropriate management for selected patients found to have *unexpected invasive cancer of the cervix on pathologic examination of a uterus removed for benign conditions*. Low morbidity rates and acceptable rates of long-term disease-free survival have been reported. However, pelvic irradiation is usually recommended for these patients.

Advantages of Radical Surgery as Primary Treatment for Invasive Cervical Cancer

The most important considerations in choosing a method of therapy for any cancer are, first, effectiveness of the treatment in curing the disease and, second, mortality and morbidity rates associated with the treatment plan. For the indications listed previously, the cure rates of primary radiation therapy and primary extensive surgery are about equal. The modern mortality rates also are about equal. Both modalities of therapy have a list of complications unique to each that seem about equal. There are, however, important major and minor advantages of primary radical surgery over irradiation for early-stage disease, some of which are discussed in the following sections.

Accurate Evaluation of Extent of Disease

The findings at operation and from careful pathologic examination of the surgical specimen can be immensely helpful in selecting high-risk patients for adjuvant postoperative radiation therapy, chemotherapy, or both. Most patients with FIGO stages IA2, IB1, and nonbulky IIA disease are not found to have high-risk factors and thus are spared the potential morbidity associated with whole pelvic radiation therapy. Furthermore, the findings at operation and careful pathologic examination of the surgical specimen can be helpful in determining prognosis and in identifying patients at greatest risk for persistence or recurrence of disease. Such high-risk patients may require additional therapy.

In addition to an accurate assessment of the extent of the cervical cancer, primary surgical treatment allows for discovery of other intra-abdominal incidental conditions and diseases entirely unrelated to the cancer. Ovarian malignancies, pelvic tuberculosis, sigmoid diverticulitis, cholelithiasis, and other diseases and conditions may be encountered at the time of operation.

Preservation of Ovarian Function

When primary radiation therapy with or without chemotherapy is used to treat invasive cervical cancer in premenopausal women, premature loss of ovarian function is an unfortunate and inevitable result. When primary surgery is used instead, the function of normal ovaries can be conserved. Sutton and associates analyzed the incidence of ovarian metastasis for 991 patients with stage IB carcinoma of the cervix treated with radical hysterectomy and pelvic lymphadenectomy on a prospective GOG protocol. Ovarian spread was found in 4 of 770 patients (0.5%) with squamous cell carcinoma and in 2 of 121 patients (1.7%) with adenocarcinoma. The difference was not statistically significant. All six patients with ovarian metastases had other evidence of extracervical disease. This study confirmed that ovarian metastasis is rare in patients with stage IB cervical cancer and extremely rare in the absence of other evidence of extracervical disease.

Although the incidence of ovarian metastasis is slightly higher in women with adenocarcinoma of the cervix as compared with squamous cell carcinoma, ovarian conservation should still be considered, especially in young women. Brand and Berek reported no ovarian metastases in more than 60 patients with adenocarcinoma of the cervix treated with radical surgery. Angel and associates found no ovarian metastases in 41 patients with adenocarcinoma of the cervix who underwent oophorectomy. Greer and coworkers treated 55 patients with stage IB adenocarcinoma of the cervix with radical hysterectomy and pelvic lymphadenectomy. Ninety-one percent had ovarian preservation, and there was no evidence that this contributed to tumor recurrence. Hopkins and coworkers found that the best cumulative 5-year survival rate (93%) with cervical adenocarcinoma was in patients treated by radical hysterectomy without bilateral salpingo-oophorectomy and concluded that "ovarian conservation seems to be an acceptable alternative to bilateral salpingo-oophorectomy" in young patients.

Some authors have advocated transposing the ovaries into the paracolic gutters at the time of radical hysterectomy in premenopausal women to protect the ovaries from radiation damage should postoperative pelvic radiation therapy be needed. The technique used for ovarian transposition was described by Hussein-zadeh and coworkers. However, in the series reported by Chambers and coworkers, there was a threefold increase in symptomatic benign ovarian cyst formation with lateral ovarian transposition compared with those who did not have their ovaries transposed. Furthermore, Anderson and coworkers reported that only 4 of 24 patients (17%) who had ovarian transposition retained ovarian function after postoperative radiation therapy. Moreover, after transposition, 17.6% of

patients required surgical treatment for ovarian-associated pain or cysts. These data raise the question of whether paracolic gutter transposition actually achieves its goal of protecting the ovaries.

Sexual Function

Studies of the effect of surgical and radiation treatment for cervical carcinoma on sexual function have been published by Seibel and coworkers from Emory University and by others. Among patients treated with radiation, there are decreases in sexual enjoyment, ability to attain orgasm, frequency of intercourse, and desire for intercourse. Marked alterations can be seen and felt in the upper vagina and paravaginal tissues. The vagina usually is shorter from stenosis. The upper vagina is less pliable. Tissues are fixed and firm. The vaginal mucosa is thin, smooth, and dry, with a tendency to split and bleed with slight trauma. Some of these changes are made more pronounced in young women because of hypoestrogenism from radiation-induced premature menopause. They are not completely reversed by intravaginal or oral administration of estrogen. Such functional and anatomic changes are not seen nearly as frequently in patients treated with primary extensive surgery. Even if the vagina has been surgically shortened by several centimeters with primary surgery, it remains soft, pliable, moist, and functional. Unfortunately, in women who undergo postoperative adjuvant pelvic irradiation, some of these characteristics are lost.

Fewer Late Complications

Late complications after treatment for cervical cancer are rarely seen after primary radical surgery. They occur more often when patients are treated with primary radiation therapy. Because of the gradual and progressive obliterative endarteritis produced by irradiating tissue, complications resulting from ischemic changes (e.g., cystitis, proctitis, enteritis, colpocleisis, pyelonephritis) can be seen many years after radiation treatment. Late onset of complications after primary radical hysterectomy and pelvic lymphadenectomy are unusual. These points are especially important when selecting a method of primary treatment for young women.

Psychological Benefits

There are probably important psychological benefits of primary treatment with radical surgery compared with radiation therapy. Most patients prefer to have the tumor removed and are especially encouraged when the surgeon can report that “the cancer is out” and that no evidence of metastatic disease was found at operation. Radiation therapy carries an unfortunate connotation in some patients who feel that it is the treatment of last resort, that the tumor is still there (albeit treated), or that irradiation will cause other cancers. All gynecologic surgeons have heard the disappointment patients express when they are told that they cannot be treated with an operation. Some patients continue to request an operation even after they have completed radiation therapy. It is paramount to counsel patients thoroughly and outline the many advantages modern radiation therapy may provide in select cases.

Justification for Pelvic Lymphadenectomy

Historically, there was competition between gynecologic surgeons who advocated radical vaginal hysterectomy without lymphadenectomy and those who advocated radical abdominal hysterectomy with lymphadenectomy. The advocates of extensive vaginal hysterectomy without lymphadenectomy (the Schauta-Amreich-Navratil operation) argued that their patients had fewer postoperative complications (especially urinary fistulae), a lower operative mortality rate, and a cure rate that was almost equal to that achieved by an abdominal operation that included lymphadenectomy. Furthermore, they pointed out that pelvic lymphadenectomy is an incomplete operation, at best, in that the removal of all pelvic lymph nodes that can possibly be involved with metastatic tumor is technically not feasible in many cases. This is especially important for those inferior gluteal nodes that are located in the region of the ischial spine, as pointed out by Reiffenstuhl. However, even Navratil stated in 1965 that “indications for the Schauta operation must take the lymph node problem into account.” Later, he performed extraperitoneal pelvic lymphadenectomy with the Schauta operation in all stage I and II cases that were locally advanced, as did Mitra, the Indian gynecologist who performed the pelvic node dissection through a bilateral extraperitoneal abdominal incision after radical vaginal hysterectomy.

In recent years, the operative mortality and complication rates in patients who have undergone radical abdominal hysterectomy and bilateral pelvic lymphadenectomy have significantly decreased. Operative mortality and fistulae occur in less than 1% and approximately 2% of patients, respectively. Therefore, one purported disadvantage of radical hysterectomy (high morbidity) has essentially been removed, and the surgeon can concentrate on the question of whether lymphadenectomy adds anything to the possibility of cure. If a pelvic lymphadenectomy is not done in patients who have a radical hysterectomy for cervical cancer, at least 15% to 20% of patients (those with positive nodes) will be inadequately treated for their disease (unless perhaps all patients receive postoperative pelvic irradiation). In our judgment, it is better to do a pelvic lymphadenectomy in all eligible patients and then give postoperative radiation therapy selectively than to avoid a lymphadenectomy and give postoperative radiation therapy to all patients.

It is the opinion of some that pelvic lymphadenectomy is of no value in those 80% to 90% of patients who have negative lymph nodes. We believe that lymphadenectomy is helpful in achieving an adequate central dissection around the cervical tumor, the most important part of the operation. This is especially true of that part of the lymphadenectomy that involves removal of tissue from around the hypogastric vessels, from the obturator fossa, and from the lower presacral region. Admittedly, dissection of lymph nodes from the common iliac vessels and from the paraaortic region does not add to the completeness of the central dissection. Removal of these and other nodes, however, is helpful in prognosis and in identifying patients at greater risk for persistent disease who might receive adjuvant postoperative radiation therapy to the pelvis and perhaps to extended fields along the aorta. Although we seldom dissect and remove the highest paraaortic lymph nodes, we do remove the lower paraaortic nodes around and just above the aortic bifurcation. If pelvic lymph nodes involved with tumor are found during the operation, a concerted effort is made to do a more complete paraaortic dissection. Although it is possible for paraaortic nodes to be directly involved without involvement of pelvic nodes, this is rare. For the group of patients who usually would be chosen for treatment with primary radical surgery,

P.1209

routine extensive paraaortic lymph node dissection would not result in a therapeutic benefit very often. Podczaski and coworkers found positive paraaortic lymph nodes in 7 of 52 patients (13.4%) with stage IB and IIA disease. Twenty-eight of the 52 patients, however, had bulky tumors greater than 5 cm in greatest diameter. Currently, such patients are considered by many gynecologic oncologists not to be appropriate candidates for treatment with primary radical surgery. Patsner and coworkers performed paraaortic lymph node sampling in patients with small (tumor ≤ 3 cm) stage IB cervical cancer. Only 2 of the 125 patients who underwent radical hysterectomy, bilateral pelvic lymphadenectomy, and paraaortic node sampling had metastases to the paraaortic nodes. No patient had gross paraaortic nodal involvement, and both patients with microscopic paraaortic nodal metastases had grossly positive pelvic nodal involvement. These investigators recommended that paraaortic sampling in patients with small stage IB cervical tumors be restricted to patients with suspicious or positive pelvic or paraaortic nodes. The paraaortic region should be carefully palpated and any enlarged or firm nodes removed, but the gynecologic surgeon should be aware of the added morbidity associated with comprehensive paraaortic lymphadenectomy.

A study reported by Downey and colleagues provides indirect evidence that postoperative pelvic irradiation is more effective in controlling disease after pelvic lymphadenectomy has removed clinically positive lymph nodes that contain metastatic tumor. The amount of irradiation required to eliminate tumor in lymph nodes is directly related to the volume of tumor present ([Table 51.6](#)). Thus, removing the larger nodes involved with tumor increases the probability of control of

tumor with irradiation. Patients in this study who underwent resection of large positive pelvic nodes followed by postoperative extended-field irradiation had a surprisingly high 5-year recurrence-free survival rate of 51%. The advantages of surgical debulking of positive lymph nodes also were discussed by Potish and coworkers in a later study from the same center. No patient with unresectable pelvic nodes survived 5 years. In 84% (49/58) of cases with grossly positive pelvic nodes, the nodes were able to be debulked. The 5-year actuarial relapse-free survival rates were the same for patients with only microscopically involved pelvic node metastases (56%) and for patients with grossly involved but surgically resected pelvic node metastases (57%). All patients with positive pelvic nodes received postoperative irradiation to the pelvis and paraaortic nodes. These authors believe that surgical debulking of grossly involved pelvic lymph nodes to microscopic residual disease may improve the chance of control with postoperative irradiation.

PERTINENT PELVIC ANATOMY ARTERIAL AND VENOUS ANATOMY

Although the lower portions of the aorta and vena cava are frequently incorporated into the operative field of the pelvic lymphadenectomy, the major operative dissection includes the common iliac, external iliac, and hypogastric (also known as the internal iliac) arteries and veins and their various branches and tributaries. The abdominal aorta emerges through the aortic hiatus of the diaphragm at the lower border of the last thoracic vertebra and descends along the ventral surface of the vertebral column, where it bifurcates into the left and right common iliac arteries at the fourth lumbar vertebra (Fig. 51.10). This is an important anatomic landmark because the bifurcation at L4 lies directly beneath the umbilicus in most cases. Therefore, an abdominal midline incision that provides surgical exposure to the lower aorta needs to be extended somewhat above the umbilicus. The right common iliac artery crosses the upper portion of the left common iliac vein at the aortic bifurcation. This segment of the venous drainage of the left side of the pelvis

P.1210

joins with the right common iliac vein to form the vena cava, which lies directly along the right side of the aorta and on the right lateral side of the bodies of the lumbar vertebrae in its retroperitoneal course through the abdomen.

FIGURE 51.10 Abdominal and pelvic anatomy, showing the anatomic relations of the aorta, vena cava, iliac vessels, and ureters. Note the arteriovenous crossing of the right common iliac artery and the left iliac vein.

Both common iliac arteries continue along the medial border of the psoas muscle to the pelvic brim, where they divide into external iliac and hypogastric vessels. As shown in **Figure 51.10**, this important vascular division marks the site where the ureters enter the pelvis from the abdomen, usually overlying the terminal end of the common iliac artery on the left and commonly crossing the actual bifurcation of the artery on the right. Both external iliac arteries pass beneath the inguinal ligament to proceed into the leg as the femoral artery. The external iliac artery makes no direct vascular contribution to the pelvis, although there is a fairly consistent arterial branch to the ureter from the midportion of the common iliac artery.

FIGURE 51.11 Anatomy of the arterial blood supply to the female pelvis showing relations of pelvic musculature, divisions of hypogastric artery, and lumbosacral and sacral nerve plexuses. Note that the anterior division of the hypogastric artery provides the blood supply to the pelvic viscera.

The external iliac vein emerges from beneath the inguinal ligament, where it courses along the lateral pelvic brim on the medial side of the artery until it reaches the proximal segment. Here, the vein passes directly beneath the artery at the bifurcation of the common iliac artery and then passes along the lateral side of the upper half of the artery. It then joins the left common iliac vein to become the inferior vena cava at the fifth lumbar vertebra. In dissecting the lymph nodes along the external iliac vessels, these anatomic landmarks are important to avoid trauma to the wall of the vein as it deviates from the medial to the lateral side of the arterial tree.

The hypogastric artery provides the major blood supply to the pelvic viscera. For descriptive purposes, it is conveniently divided into an anterior and a posterior division. The important branches of the hypogastric artery are shown in [Figures 51.11](#) and [51.12](#).

P.1211

FIGURE 51.12 Anatomy of hypogastric vein. (From Thompson JD. Extensive hysterectomy and bilateral pelvic lymphadenectomy. In: Coppleson M, ed. *Gynecologic oncology*, 2nd ed. New York, NY: Churchill Livingstone, 1992, with permission.)

A fairly consistent arterial branch to the ureter arises from the hypogastric artery near the common iliac bifurcation. This vessel passes medially to the ureter and should be preserved, if possible, during the dissection of the hypogastric vessels. The posterior division of the hypogastric artery continues beneath the

coccygeus muscle through the ischiorectal fossa, where it becomes the internal pudendal artery to supply the perineum and vulva.

The major blood supply to the pelvic viscera is derived from the anterior division of the hypogastric artery. **Figure 51.11** shows the anterior division, which gives off the uterine artery before continuing along the posterolateral pelvic wall to supply the superior and inferior vesical branches to the bladder. The anterior division then continues as the obliterated umbilical artery as it passes cephalad along the inferior surface of the rectus muscle to the umbilicus. In dissecting along the hypogastric artery in a caudad direction, the uterine artery is the first vessel encountered; it emanates from the medial side of the vessel. Passing more inferiorly and medially is the middle hemorrhoidal artery, which supplies a major segment of the rectum and communicates with the superior hemorrhoidal (from the inferior mesenteric) and the inferior hemorrhoidal (from the internal pudendal) arteries.

The hypogastric vein and its tributaries course along the pelvic floor and medial side of the artery to drain the pelvis in close relation to the arterial blood supply. Its extensive anatomic variations and its location along the pelvic sidewall and floor place these tortuous, thin-walled veins in a precarious and vulnerable position for trauma during deep dissection of the pelvis. As shown in **Figure 51.12**, the delicate tributaries of the trunk of the hypogastric vein extend into sacral foramina and pass beneath nerve fibers and muscles within the pelvis, so that their visualization during the dissection of the pelvis frequently is obscured. The continuation of the hypogastric vein, in association with the artery, beneath the coccygeus muscle is a frequent site of bleeding when dissection is undertaken along the pelvic floor. When this occurs, it is difficult to identify the vessel because it retracts beneath the margins of the muscle.

The profuse collateral blood supply to the ureter is an important anatomic safeguard that protects its pelvic segment from ischemic necrosis as a result of radical hysterectomy (**Fig. 51.13**). The ureter has the advantage of a multiple-source blood supply. This favorable collateral circulation permits interruption of small arteries and veins deep in the pelvis during extensive dissection of the base of the broad ligament without producing a significant incidence of ischemic necrosis and fistula formation. The freely anastomosing arterial and venous network that courses along the longitudinal surface of the ureter in its adventitial layer is supplied in its superior segment by branches from the renal and ovarian arteries. The middle segment of the ureter derives its blood supply directly from aortic branches and from a vessel from the common iliac artery. As the ureter enters the pelvis and courses along the lateral pelvic wall, it receives arterial branches from the uterine, vaginal, middle hemorrhoidal, and vesical arteries. As it approaches the trigone of the bladder, it has a rich arteriovenous collateral circulation from the arterial branches to the vagina and base of the bladder. Protection of this important vascular network is important for the integrity of the terminal ureter during extensive dissection of the cardinal ligament. Preservation of the lateral aspect of the posterior segment of the vesicouterine ligament has been recommended to ensure adequate vascularity to the terminal segment of the ureter, but we have encountered no difficulty in removing this tissue and have no hesitation in doing so to enhance the adequacy of the central dissection.

Lymphatic Anatomy

The lymphatic drainage of the pelvis follows the course of the arterial and venous blood supply. Although there are multiple variations in the lymphatic anatomy of the pelvis, in general, lateral, superior, medial, and inferior lymph nodes and communicating lymphatic channels surround the common iliac, external iliac, and hypogastric vessels. One of the important pathways of the pelvic nodes and thin-walled lymphatics that drain the upper vagina, cervix, and uterus courses along the posterior aspect of the endopelvic fascia. Here, the pelvic nodes pass through the uterosacral ligament area and terminate in lymph nodes along the lateral aspect of the sacrum. These nodes communicate freely with lymphatic channels from the bifurcation of the common iliac artery near the lateral sacral and ischiosacral fossae. These can be difficult nodes to resect because they are closely attached to the thin-walled tributaries of the hypogastric vein. In dissecting the nodes from the

P.1212

bifurcation of the common iliac vessels, care must be taken to avoid injury to the hypogastric vein, which extends from beneath the artery on the medial side in this area.

FIGURE 51.13 Blood supply of the ureter showing multiple sources of collateral arterial circulation.

The most direct lymphatic drainage of the cervix and upper vagina is through the lateral parametrium (cardinal ligament) to the hypogastric and obturator

lymphatics. Because of the presence of obscure obturator veins and multiple venous tributaries from the hypogastric vein along the pelvic floor, the obturator dissection can be associated with troublesome venous bleeding. Injury also can occur to the obturator nerve, which arises from the anterior division of the second, third, and fourth lumbar nerves; enters the pelvis through the psoas muscle; and runs along the lateral pelvic wall in the obturator fossa to exit the pelvis through the obturator foramen along with the obturator vessels. It is a motor nerve to the adductor muscles of the thigh and is the only motor nerve that arises from the lumbar plexus without innervating any of the pelvic structures. Damage to the obturator nerve produces not only motor impairment to the adductor muscles but also sensory loss along the medial aspect of the thigh (**Fig. 51.14**). Deep dissection posterior to the obturator nerve can be complicated by bleeding from the tributaries of the hypogastric and obturator veins, so dissection in this area must be done with great care, using clips or vessel sealers on the small vessels and compression for troublesome venous bleeding.

Reiffenstuhl, in his classic study of the lymphatics of the female genital organs, described efferent lymph channels from the cervix to the interiliac lymph nodes, the lateral and medial external iliac lymph nodes, the lateral and medial common iliac lymph nodes, the sacral lymph nodes, the subaortic lymph nodes, the aortic lymph nodes, the superior gluteal lymph nodes, the inferior gluteal lymph nodes, and the rectal lymph nodes. Of these, the inferior gluteal nodes are not technically possible to remove with the standard approach. This is because the nodes lie around the ischial spine in proximity to the inferior gluteal artery and pudendal artery and nerve. An imposing network of veins also surrounds the inferior gluteal nodes. They are thin walled, easy to damage, difficult to expose, and difficult to control when damaged. Reiffenstuhl's concepts of the lymphatic drainage of the cervix are partially shown in **Figure 51.15**.

FIGURE 51.14 Obturator nerve (L2 through L4): motor and sensory innervation.

Sentinel lymph node studies in women with cervical cancer are also adding greatly to our knowledge of the lymphatic drainage in vivo (**Fig. 51.16A**), and identification of SLNs with blue dye (**Fig. 51.16B**), fluorescent indocyanine green (ICG) (**Fig. 51.16C**), and technetium injections is feasible, with very low morbidity. These SLNs can be submitted for ultrastaging with immunohistochemistry staining and may help in the postoperative management of cases. Further evaluation and validation of SLN techniques is leading many investigators to recommend the routine use of SLN with pelvic nodal dissection and even consider an SLN algorithm as a comprehensive strategy to evaluate nodal metastasis. Recent studies have strongly suggested that SLN identification can potentially replace complete pelvic lymphadenectomy in select early-stage (I) cervical cancer. The SLN algorithm may help reduce the total operative time as well as some perioperative complications and long-term complications, such as postoperative leg lymphedema, which is occasionally seen in patients undergoing pelvic lymphadenectomy. The most common injection sites for SLN mapping are shown in **Figure 51.16D**.

EVOLUTION OF THE CLASSIFICATION SYSTEMS OF RADICAL HYSTERECTOMY AND PELVIC LYMPHADENECTOMY

There are several variations of hysterectomy used in the management of cervical carcinoma. The description of the five classes of hysterectomy by Piver and colleagues has found general acceptance and was used for many years. The first three classes are used in the primary treatment of cervical carcinoma, whereas the last two classes are generally reserved for patients

P.1213

with recurrent disease. The class I hysterectomy is a simple extrafascial total hysterectomy. It is used as primary treatment for stage IA1 disease and after concurrent chemotherapy and radiation therapy for stage IB2 and bulky stage IIA cervical carcinoma. The class II hysterectomy (**Fig. 51.8**), also known as a modified radical hysterectomy, removes a more generous vaginal cuff, ligates the uterine artery on the medial side of the ureter (but does not dissect the ureter from the vesicouterine ligament), and removes the inner one third to one half of the cardinal ligament. As previously stated, some authors recommend the performance of the class II hysterectomy for stage IA2 cervical carcinoma. The class III operation is the classic Meigs procedure, with removal of all of the parametrium and paravaginal tissue in addition to the pelvic lymph nodes (**Fig. 51.8**). A more extensive procedure is performed in the class IV radical hysterectomy, in which the ureter is completely dissected from the cardinal and vesicouterine ligaments, the superior vesical artery is sacrificed, and three fourths of the vagina is removed, as well as the uterus and parametria, along with a complete lymphadenectomy. A far more extensive procedure is done with the class V radical hysterectomy, in which the terminal ureter or a segment of the bladder or rectum is removed along with the uterus, parametria, adnexa, and pelvic lymph nodes.

FIGURE 51.15 The regional lymph node stations of the uterine cervix. Channels 8, 9, and 10 (indicated by especially heavy lines) lead to those regional lymph node stations most frequently reached by the efferent lymph vessels of the cervix. Nonetheless, it is necessary to remember that carcinoma cells also can reach the pelvic lymph nodes by way of channels 1 through 7, without previous interruption, to (1) rectal, (2) subaortic (promontorial), (3) aortic, (4) medial common iliac, (5) lateral common iliac, (6) lateral external iliac, (7) sacral, (8) superior gluteal, (9) interiliac, and (10) inferior gluteal lymph nodes. (From Reiffenstahl G. *The Lymphatics of the female genital organs*. Philadelphia, PA: JB Lippincott, 1964, with permission.)

Although many techniques emphasize a more or less extensive dissection in one phase of the operation or another, the management of the parametria and the dissection of the pelvic lymph nodes appear relatively uniform. Because the most serious complication of this procedure is related to ureteral fistulae and stenosis, many modifications have been undertaken to ensure an adequate blood supply to the terminal ureter. We agree that the terminal ureter must have a good blood supply and believe that this can be accomplished without jeopardizing the adequacy of the central dissection. The classic radical hysterectomy with wide resection of the parametrium, dissection of the terminal ureter from the vesicouterine ligament, and wide resection of the uterosacral ligaments, upper 2 to 3 cm of vagina, and paravaginal tissues, along with a thorough pelvic lymphadenectomy, is the traditional procedure that is used in our institution.

The major focus of the operation is the adequacy of the central dissection. The central cervical tumor must be removed with an adequate margin of uninvolved normal tissue around it. This is the most crucial point in the success of the operation and has been emphasized by many of the famous pelvic surgeons of former years, especially Parsons and Navratil. The central dissection can be facilitated by developing the pelvic spaces and using proper planes for dissection. Correct

P.1214

dissection along natural rather than artificial connective tissue planes and correct development of the pelvic spaces (paravesical, pararectal, vesicocervical, and rectovaginal) avoid unnecessary injury to pelvic vessels, keep blood loss to a minimum, and facilitate an adequate central dissection (**Fig. 51.17**). The central dissection also is facilitated by a complete removal of the contents of the obturator fossa (except the obturator nerve) so that branches of the hypogastric artery and vein in the cardinal ligament are clearly visible and can be dissected away from their attachments to the lateral pelvic sidewall.

FIGURE 51.16 **A:** Most common sites of involved nodes in women with cervical cancer. **B:** Following a cervical injection of dye, the most common location of SLN is medial to the external iliac, ventral to the hypogastric, and superior part of the obturator nodes. **C:** Less common SLN drainage and location. If the lymphatic trunks are following the mesoureter look for the SLN in the common iliac presacral region. **D:** This picture demonstrated the most common injection sites for cervical neoplasia. Reproduced with permission from Memorial Sloan Kettering Cancer Center.

The importance of an adequate central dissection also was emphasized by Girardi and coworkers. By studying surgical specimens processed according to the giant-section technique of Burghardt and Pickel, parametrial lymph nodes were found in 280 (78%) of the 359 surgical specimens from radical hysterectomies. Metastases to parametrial nodes were found in 63 (22.5%) of these 280 specimens. The lymphatic drainage from the cervix to the pelvic lymph nodes runs through the parametrium, and deposits of tumor often are found there. An adequate central dissection must include removal of a wide margin of parametrial tissue around the central tumor and total removal of the parametria from the bladder, the rectum, and the lateral pelvic wall because positive lymph nodes can be found in the lateral as well as medial parametrium.

P.1215

FIGURE 51.17 Cross section of pelvis showing paravesical and pararectal space. The base of the broad ligament (cardinal ligament) extends to the lateral pelvic wall and contains the major lymphatics draining the cervix.

When a large vaginal cuff must be removed because of a bulky cervical tumor or involvement of adjacent vaginal mucosa, starting the operation from below may facilitate the central dissection. Sometimes, a bulky lesion is excised and fulgurated transvaginally. The formation of the vaginal cuff is done in a manner

similar to that in the Schauta-Amreich procedure. The vaginal incision is made around the entire circumference of the vagina, mobilizing the vaginal cuff from paravaginal tissue. Further dissection into the paravesical space, vesicocervical space, and rectovaginal space from below may be easier than from above.

Superior to the midcommon iliac arteries and in the paraaortic region, lymph nodes are sampled in selected patients (usually stage IB1 and IIA). A special effort is made to remove any nodes that look or feel suspicious. The paraaortic lymph nodes then are sent for frozen section analysis. Approximately 5% to 10% of stage IB patients have paraaortic lymph node metastasis. Metastasis to the paraaortic lymph nodes is considered by many gynecologic oncologists as a contraindication to radical hysterectomy. These patients are currently being treated with extended-field radiation therapy with concurrent chemotherapy.

In recent years, Querlu and Morrow suggested a modernization of the classic classification system, with a main emphasis on the role of a nerve-sparing radical hysterectomy (type C1) and on three-dimensional topography of radical pelvic surgery. Simply put, a type B resection is equivalent to a class II hysterectomy, a type C1 resection is equivalent to a class III hysterectomy with nerve sparing, and a class C2 hysterectomy is equivalent to a more radical class III operation with disregard to hypogastric and pelvic splanchnic nerves.

RADICAL ABDOMINAL HYSTERECTOMY SURGICAL TECHNIQUE

Preoperative Evaluation and Preparation

After the initial history and physical examination have indicated the possibility of primary treatment with radical hysterectomy and pelvic lymphadenectomy, the usual preoperative evaluation common before any extensive operation is indicated. We also recommend a chest x-ray to screen for cardiac or pulmonary disease as well as the very low risk of pulmonary metastases.

Contrary to the frequent practice of doing all possible tests on every patient, it is our practice to be selective and to do only those tests and procedures that are expected to yield useful information. It is not necessary (and indeed may be inappropriate) to subject every patient to a long list of preoperative procedures that are expensive and exhausting and have little, if any, expectation of providing useful information. Indeed, it is most unfortunate when a test or procedure yields questionable or suspicious findings that require one or more additional studies that, after delay, discomfort, and expense, turn out to be negative or even perhaps nondiagnostic. Good judgment from an experienced clinician is usually the most helpful.

A young, healthy patient with a small cervical lesion requires an admission history and physical examination, chest radiograph and routine laboratory studies, and anesthesia consultation. If the patient is older, has medical complications, or has a larger or undifferentiated cervical lesion, the preoperative workup and preparation may be more involved and thorough. Although an intravenous pyelogram provides good visualization of the course and number of ureters, if radiologic evaluation of the abdomen and pelvis is being considered, most surgeons obtain a CT scan of the abdomen and pelvis with contrast, which also shows the course and number of ureters and also may provide additional information about nodal or other metastases. However, because of the uncertainty of enlarged nodes on CT scan, patients with clinical stage IB1 disease and enlarged pelvic nodes on CT scan would not make us cancel the surgical approach in favor of radiation therapy. These nodes need to be evaluated further, possibly with a surgical resection, biopsy, or PET scan.

Larger lesions or those more likely to have metastases may be investigated by pelvic and abdominal CT scan or magnetic resonance scans, but we have rarely found those to be helpful in women with small cervical cancers. They may be most helpful when the clinician is undecided regarding whether primary surgery or radiation is the best management option—a clean, normal study may be reassuring that primary surgery is the way to go, whereas suspicious, enlarged nodes in a woman with a 4-cm cervical lesion help make the decision to recommend radiation. Likewise, cystoscopy or proctoscopy is rarely indicated or helpful in the preoperative evaluation of early-stage cervical cancer. As much as possible

P.1216

should be done on an outpatient basis before admission to the hospital.

Bowel Preparation

In our institution, patients are asked to start a liquid diet 24 hours before surgery. They also are given a mechanical bowel preparation if significant peritoneal adhesions are anticipated or there is a history of previous major pelvic surgery or radiation. An intestinal tube for suction is not necessary.

Positioning and Incision

Multiple approaches to performing a radical abdominal hysterectomy and bilateral pelvic lymphadenectomy have been described. The traditional transperitoneal approach has been used in our institution for many years, with satisfactory results. The transverse Maylard or Cherney incision is used by some, whereas others prefer midline incisions. Orr and Scribner have reported shorter hospital stays when a Pfannenstiel incision is used. Currie has presented and published a technique using a transverse cosmetic incision with vertical fascial entry for selected patients.

After anesthesia is induced, some surgeons prefer that the patient be placed comfortably in stirrups, with the buttocks brought to the edge of the “broken” table. Pneumatic compression devices are placed on both lower extremities, and the knees are separated approximately 90 degrees. The thighs are elevated only 15 to 20 degrees relative to the abdomen. Care is taken to avoid pressure on the peroneal nerves in the legs. Proponents of this position claim several advantages. There is less strain on the patient's lumbosacral spine when the thighs are slightly flexed. This is especially important for patients with lumbosacral back problems. It is possible to have a second assistant stand at the foot of the table between the patient's legs. His or her participation in the operation is greatly facilitated by being closer to the operative field. Finally, in this position, the urethral orifice, vaginal introitus, and anal orifice are all available for instrumentation in case this is necessary to clarify anatomy.

After the patient is positioned on the operating table, a careful rectovaginal-abdominal pelvic examination is done. This can be followed by cystoscopy or proctosigmoidoscopy if desired. If hair needs to be removed, it is preferable to use an electric hair trimmer rather than a razor. The skin is prepared from the rib margin to the midthigh, with special attention given to the umbilicus, perineum, and vagina. The patient is draped, a transurethral Foley catheter is inserted into the bladder, and the operation is begun. If an SLN injection is planned, the injection is done at the time of exam under anesthesia just before the patient is prepped and draped.

When operating abdominally, the exposure achieved depends on the choice of incision, the method of retracting, the placement and intensity of overhead lights, and the participation of willing and skillful assistants. Suction should be available to keep the field dry. Dry sponges are likely more traumatic to delicate serosal surfaces and other tissues. It usually is possible (and always desirable) to keep the number of clamps in the operative field to an absolute minimum. If the field is cluttered with clamps, the operator cannot see well to operate. There is sometimes a tendency for gynecologic surgeons to use instruments that are too short. Pedicle clamps, tissue forceps, dissecting scissors, needle holders, and all other instruments must be longer when operating deep in the pelvis and when operating on obese patients. The handles of the instruments must come all the way out and above the level of the incision so that they do not interfere with the

operator's vision.

Evaluation at Laparotomy

As stated, the operation is initiated through a low-transverse (Maylard, Cherney, Pfannenstiel) or low midline incision; the same exploratory strategy should apply if a minimally invasive approach is being utilized. In most patients, the umbilicus identifies the location of the bifurcation of the aorta; therefore, extension of the incision approximately 2 to 3 cm above the umbilicus is recommended for adequate exposure of this area if a lower midline incision is used. The midline incision is protected by a moist pack beneath each arm of the self-retaining retractor to avoid excessive compression of the epigastric vessels that course beneath the rectus muscles. In case of a lengthy operative procedure, the mechanical retractors are released at periodic intervals to improve circulation through the abdominal musculature. The bladder is decompressed by an indwelling catheter throughout the procedure to facilitate exposure and maintain an accurate record of urine output.

Before initiating the pelvic procedure, the abdominal viscera and parietal peritoneum of the abdominal cavity are evaluated meticulously for possible evidence of metastatic tumor. The superior and inferior surfaces of the liver are carefully palpated, as is the region of the celiac plexus. The undersurface of the diaphragm is particularly vulnerable to metastases, especially the right hemidiaphragm, where the paraaortic lymphatics pass from the abdominal cavity into the mediastinum. The mesentery of the large and small bowel and the serosal surface of the bowel along with the omentum should be examined carefully for evidence of metastatic tumor. The kidneys are examined, and the retroperitoneal space along the aorta and vena cava is palpated assiduously because these are the major sites of extrapelvic spread of cervical cancer. It is well known that 15% or more of paraaortic node metastases are occult; therefore, even the most unsuspecting node should be removed and evaluated histologically by frozen section study for possible metastatic tumor. If there is histopathologic evidence of unsuspected, metastatic tumor in a paraaortic lymph node, we generally do not proceed with a radical hysterectomy, and the operation is abandoned. These patients are currently being treated with concurrent chemotherapy and extended-field radiation therapy.

Peritoneal washings for cytologic examination usually are not obtained because the yield is low and the prognostic significance is undetermined.

At this point in the procedure, any adhesions in the pelvis are lysed, and the intestines are placed in the upper abdomen and held there with moist packs. A suitable self-retaining retractor can be used. If Bookwalter, Turner-Warwick, or Balfour retractor is used in a lower midline incision, care must be taken to avoid compression of the femoral nerves by the lateral blades.

An evaluation of the extent of the pelvic tumor is undertaken at this time by examining the course of the lymphatic drainage of the pelvis, which is carefully palpated along the pelvic vessels. When enlarged or clinically suspicious nodes are found, they are removed and immediately sent for frozen section study while further evaluation of the pelvis is undertaken. The paravesical and pararectal spaces are important anatomic landmarks. When developed, they provide an opportunity for thorough exploration of the intervening base of the broad ligament (**Fig. 51.17**). Tumor can extend into the base of the broad ligament without detection of anatomic evidence of disease before operation. This step, therefore, is a safeguard in determining the possible extension of tumor beyond the cervix and into the immediate paracervical tissues. When there is evidence of extracervical disease, we may abandon the surgical

P.1217

procedure unless there is clear evidence that the disease can be removed cleanly. In either case, full pelvic irradiation is indicated. Certainly, the lateral pelvic wall must be free of tumor. When the central tumor is clearly resectable, we do not hesitate to complete the operation, even if there is evidence of metastatic disease in the pelvic lymph nodes.

A decision must be made about conservation or removal of the tubes and ovaries before the pelvic planes and spaces are developed. If normal ovaries are conserved in premenopausal patients, the tubes usually may be removed. After the round ligaments are clamped, cut, and ligated, the utero-ovarian ligaments and medial fallopian tubes are clamped and doubly ligated. The infundibulopelvic ligaments are carefully mobilized, and the adnexal organs are packed out of the operative field with the intestines.

Development of Paravesical Space

The anterior leaf of the broad ligament forms the roof of the *paravesical space* and blends with the bladder peritoneum medially and the parietal peritoneum laterally. This deep fossa beneath the peritoneal covering is composed of loose connective tissue and fat. It occupies the area between the bladder and the retropubic space medially, with the pelvic sidewall and obturator muscle forming the lateral boundaries. The superior boundary is formed by the cardinal ligament, whereas the floor is composed of the levator ani muscle. After clamping and ligating the round ligament about midway along its course, the anterior leaf of the broad ligament is opened in an inferior direction, passing well into the pelvis before diverting the incision medially to reflect the bladder peritoneum from the lower uterine segment (**Fig. 51.18A**). The paravesical space can be entered without difficulty with gentle digital pressure, making certain that the dissection is initiated between the external iliac vein laterally and the obliterated hypogastric artery (lateral umbilical ligament) medially. The dissection is carried all the way down to the levator ani muscle (**Fig. 51.18B**). There are no major blood vessels in this potential space, although occasionally, an aberrant obturator vessel emerges from the inferior epigastric artery and courses along the posterior aspect of the pubic bone to the obturator space. With gentle digital dissection, the pelvic floor can be palpated and the posterior aspect of the space can be identified, including the anterior margin of the cardinal ligament.

FIGURE 51.18 A: Opening the anterior leaf of the broad ligament after ligation of the right round ligament and infundibulopelvic ligament. **B:** Development of paravesical space.

Development of Pararectal Space

The *pararectal space* lies beneath the pelvic peritoneum and extends between the cardinal ligament laterally and the uterosacral ligament medially. It can be entered by extending the incision in the anterior leaf of the broad ligament in a cephalic direction along the lateral margin of the infundibulopelvic ligament ([Fig. 51.19A](#)). By retracting the infundibulopelvic ligament and displacing the uterus medially, the uterosacral ligament is placed on a stretch, and the pararectal space is widened. Dissection of this space is much more precarious than that of the paravesical space. Unskilled dissection in this area frequently is associated with troublesome bleeding. The medial border of the fossa is bounded by the uterosacral ligament and rectum, and the lateral border is formed superiorly by the piriformis muscle and inferiorly by the levator muscle. The sacrum forms the posterior margin of the space, and the ureter is attached to the peritoneum along the roof of the space before entering the medial aspect of the cardinal ligament. The hypogastric artery and vein are located in the deeper aspect of the pararectal space along the levator ani muscle.

P.1218

The cardinal ligament forms the caudal and lateral borders of this important area. Entry into the pararectal space must be made cautiously ([Fig. 51.19A](#)) with medial displacement of the ureter and its attached peritoneum. A point between the ureter, which is attached to the medial leaf of peritoneum, and the hypogastric artery is selected. Blunt dissection should be used in this area, and careful handling of tissue is imperative to avoid unnecessary damage to small veins deep in this fossa. When the examining finger reaches the pelvic floor and levator ani muscle, the fossa narrows, and care must be taken to avoid damage to the lateral sacral and hemorrhoidal vessels. The dissection is carried vertically downward for a short distance. The further development of the space then changes to an inferior and caudad direction lateral to the rectum. If the development of the space is difficult, it should be delayed until a later time in the operation. When the paravesical and pararectal spaces have been dissected ([Fig. 51.19B](#)), the pelvic floor and cardinal ligament easily can be identified and palpated. In the absence

P.1219

of demonstrable tumor extension, the case is considered operable, and the lymph node dissection is initiated at this time.

FIGURE 51.19 A: Extending the incision in the anterior leaf of the broad ligament in a cephalic direction along the lateral margin of the right infundibulopelvic ligament. **B:** Paravesical and pararectal fossae, with intervening base of broad ligament attached to pelvic floor and lateral pelvic wall.

Pelvic Lymphadenectomy

If an SLN mapping is planned, the SLNs are removed first. Dissection of the lymphatic tissue along the iliac vessels can begin in the region of the bifurcation of the common iliac artery and extended superiorly to the bifurcation of the aorta and inferiorly to the inguinal ligament and deep circumflex iliac vein, or it can begin at another point along the course of the iliac vessels. The opening of the posterior peritoneal leaf of the broad ligament must be extended to the area of the pelvic brim, where the ureter is easily identified as it enters the pelvis at the bifurcation of the common iliac artery. This dissection is made easier if the infundibulopelvic ligament has been ligated and divided; however, the ligament and ovarian vessels can be retracted medially if the adnexa are preserved. The ovary and tube also can be detached from the uterine corpus and gently tucked beneath the retractor above. In dissecting the presacral area in the angle of the bifurcation of the aorta, care must be taken to avoid bleeding from the middle sacral vessels as well as from the proximal part of the left external iliac vein, which courses through this retroperitoneal space. It is best to occlude the middle sacral vessels with smaller vascular clips as they are identified, and if traumatized, the venous bleeding can be controlled with positive pressure against the sacrum and with vascular clips. The lymphatic tissue along the common iliac vessels is removed by sharp dissection with the points of the Metzenbaum scissors directed upward, while special care is taken to avoid trauma to the ureter ([Fig. 51.20](#)). The ureter is reflected medially during the dissection of the common iliac vessels and left attached to the parietal peritoneum to maintain its blood supply.

FIGURE 51.20 Pelvic lymphadenectomy with dissection of right common iliac vessels and their branches, including the external iliac and hypogastric arteries and veins. Note attachment of ureter to parietal peritoneum. The genitofemoral nerve courses along the psoas muscle.

It is important to remove the loose areolar tissue and fascial sheath from the iliac vessels; however, to avoid trauma to the intima or wall of the vessels (particularly the veins), the surgeon should not attempt to skeletonize the pelvic vessels to the point of producing a pearl-white vascular tree. If there is tumor in the adventitia of the vessel wall, the patient probably will not be cured by this procedure; consequently, such compulsive surgical efforts produce far more complications than benefits. It is important to rotate the vessels medially and laterally with a vein retractor during the dissection of the common and external iliac trunks to obtain the posterior

P.1220

lymphatic chain behind the vessels along the psoas muscle. The genitofemoral nerve, which is seen lateral to the external iliac vessels, should be preserved, if possible, because damage to this peripheral nerve occasionally produces postoperative discomfort in the groin and medial aspect of the thigh.

The external iliac vessels are carefully dissected down to the point where the deep circumflex iliac vein crosses over the external iliac artery. At this point, care must be taken to avoid injury to the inferior epigastric artery and vein, which arise from the anterior and medial side of the iliac vessels and course along the anterior peritoneum onto the lower abdominal wall. Removal of the distal external iliac or circumflex iliac nodes cephalad to the Cloquet node likely increases the risk of leg lymphedema. The surgeon also must be cognizant of the anomalous obturator artery and vein, which can arise from the lower portion of the external iliac or inferior epigastric vessels and course over the pelvic sidewall into the obturator space. If accidentally traumatized, they should be ligated at their point of origin from the artery or vein. To avoid bleeding in the obturator space, these vessels are frequently occluded with small vascular clips as they pass through the obturator space, regardless of their origin. Clips also can be used to occlude the lymphatic channels coming into the pelvis from the leg.

The obturator space is entered by reflecting the external iliac vessels medially away from the psoas muscle and freeing the areolar tissue that lies directly between these vessels and the lateral pelvic wall (**Fig. 51.21A**), usually with blunt dissection. Once the space has been entered and the adjacent tissue cleaned from the external iliac vessels, the artery and vein are released and gently retracted laterally with a vein retractor, and the obturator space is clearly exposed. The lymphatic and areolar tissue are dissected from the obturator space to the region of the pelvic floor, with particular care taken to avoid trauma to the obturator nerve and vessels (**Fig. 51.21B**). The dissection is continued by removing all of the nodes below the bifurcation of the iliac vessels, including the hypogastric nodes and the nodes in the obturator fossa. A lymph node may be encountered in the angle formed by the external iliac and hypogastric arteries and must be carefully dissected out, avoiding trauma to the adjacent hypogastric vein.

Retraction of the common iliac artery and vein medially exposes a group of lymph nodes that should be removed carefully. These lymph nodes are the lateral common iliac nodes. There is danger of venous bleeding in this area. When this area has been cleared, the surgeon can see the obturator nerve entering the obturator fossa through the body of the psoas muscle. The nerve roots of the lumbosacral plexus also are exposed. Particular care must be exercised in the dissection of the lateral sacral and sacroiliac plexus, just medial to the hypogastric artery and vein, near their origin. The rich arcade of small arteries and veins increases the risk of bleeding in this area. When the vessels retract into the sacral foramen, control of bleeding becomes difficult.

The obturator artery can be identified as it courses along the lateral pelvic wall adjacent to the obturator nerve. The nerve, artery, and vein advance toward the obturator foramen, through which they leave the pelvis. Care must be taken to avoid trauma to all of the structures, particularly the obturator veins, which have a rich anastomotic network against the lateral pelvic wall and communicate freely with the adjacent hypogastric veins. It is best to ligate or clip the obturator vessels, but if uncontrolled bleeding occurs in this area, hemostasis is best obtained by packing the space tightly with a hot pack and providing adequate time for a fibrin clot to develop. If excessive bleeding occurs on one side of the pelvis, dissection can continue on the opposite side in the interim after pressure packing.

Dissection of Hypogastric Artery, Uterine Artery, Bladder, and Ureter

The hypogastric artery is dissected with identification of the visceral branches of the anterior trunk, which include the uterine; superior, middle, and inferior vesical; vaginal; and middle hemorrhoidal arteries. The anterior division of the hypogastric artery continues along the paravesical fossa to become the obliterated lateral umbilical ligament beneath the anterior abdominal wall. If the superior vesical artery is damaged, it can be ligated without serious compromise to the blood supply of the bladder. At this point, we ligate the uterine artery at its origin from the hypogastric artery. Some authors believe that a more adequate central dissection is achieved by ligating the anterior division of the hypogastric artery just distal to the point of origin of its posterior division rather than ligating the uterine artery individually. Whichever vessel is chosen, after double ligation, the distal branches traversing the cardinal ligament are removed with the specimen. No attempt is made to remove the hypogastric vein. The other, adjacent veins should be ligated to avoid brisk bleeding in this area.

The bladder then is reflected off the lower uterine segment by incising the bladder peritoneum from its attachment to the uterus. The fascial adhesions of the base of the bladder are released from the cervix and upper vagina by electrocautery or sharp scissors dissection, and the vesicocervical space is developed inferiorly and laterally. The ureter tunnels between the anterior fascial bundles of the base of the broad ligament, commonly called the vesicouterine ligament. This fascial tunnel is carefully opened by sliding the Metzenbaum scissors or an Adson right angle clamp, with concave surface pointed upward, along the anterior and medial surface of the ureter, and by gently spreading the blades, as shown in [Figure 51.22A](#). The uterine artery and vein course along the fascial roof of this ligament. As shown in [Figure 51.22B](#), the anterior sheath of the vesicouterine ligament is opened by doubly clamping and incising this tissue. Each of the fascial bundles is suture ligated for control of bleeding, and the ureter is dissected free of its attachment to the posterior leaf of the vesicouterine ligament. As with the pelvic vessels, care must be taken to prevent damage to the adventitia and muscular wall of the ureter, which contain nutrient vessels from the collateral circulation. In the event that the blood supply to the ureter is compromised by thrombosis or trauma to the veins, fistula formation is a serious and frequent complication. The ureter is gently retracted with an umbilical tape or vein retractor. If forceps are used to handle the ureter, they should gently grasp only the adventitia.

Dissection of Cardinal Ligament

The base of the broad ligament (the cardinal ligament) then can be excised from its attachment at the lateral pelvic wall. The technique of clamping and ligating the vascular cardinal ligament varies, depending on the circumstances. Sometimes, part of the ligament can be included in a single clamp. Sometimes, it is better to ligate or clip individual vessels. The ligament is excised with sharp scissors dissection and ligated with 2-0 delayed absorbable suture. A series of clamps are placed until the dissection is completed to the pelvic floor and along the paravaginal tissues ([Fig. 51.23](#)). If serious bleeding occurs in this region owing to trauma to the pelvic floor veins, hemostatic control is best obtained by firm packing of the pelvis and shifting the dissection temporarily to the opposite side.

P.1221

FIGURE 51.21 A: Entry into obturator space by medial reflection of external iliac vessels. **B:** Dissection of obturator fossa, demonstrating obturator nerve with areolar tissue attached superiorly to external iliac vessels.

The uterosacral ligaments originate from a posterolateral position on the cervix, where they are thickest, and run posteriorly to the anterolateral aspect of the rectum. As the ligaments approach the rectum, they broaden so that they have a wider attachment to the rectum than to the cervix. The uterosacral ligaments are stretched by sharply drawing the uterus forward. The peritoneal reflection of the cul-de-sac of Douglas then is incised, leaving a small segment of peritoneum attached to the anterior surface of the rectum. Care must be taken to avoid injury to the ureters, which are attached to the peritoneum just lateral to the uterosacral ligament ([Fig. 51.24A](#)). The rectovaginal space is opened by sharp scissors dissection and deepened by blunt and sharp dissection ([Fig. 51.24B](#)). This procedure separates the posterior reflection of the endopelvic fascia from the lateral wall of the rectum, which includes the more superficial uterosacral

ligaments. The entire fascial bundle of the uterosacral ligament is identified, clamped as far posteriorly and close to the anterior rectal wall as possible, and cut and ligated (**Fig. 51.24C**). No attempt is made to divide the attachments to the sacrum. Using modern vessel-sealing devices to transect both the cardinal and uterosacral ligaments is advocated by some authors to significantly reduce operating time and blood loss, without any adverse effects on complication or tumor recurrence

P.1222

rates. Continuation of this plane of dissection along the posterior endopelvic fascia frees the posterior aspect of the cervix from the pelvic floor. Trimbos and colleagues have described a “nerve-sparing” radical hysterectomy that involves a less radical dissection of the uterosacral ligament, which reduces the incidence of bladder dysfunction, without compromising cure rates.

FIGURE 51.22 A: Metzenbaum scissors inserted above the ureter in the vesicouterine ligament or ureteral tunnel of the broad ligament. Note ligated uterine artery in anterior fascial sheath of tunnel. **B:** Roof of tunnel is opened between clamps.

It is important to dissect the paravaginal fascia to obtain all of the microlymphatic channels that communicate between the cervix and upper vagina (**Fig. 51.25**). The bladder then is dissected further from the upper portion of the vagina by sharp and blunt dissection, making certain to avoid trauma to the blood supply of this organ. It is important, therefore, that sharp dissection, rather than blunt trauma, be used to free the base of the bladder from the anterior vagina to avoid forceful tearing of the blood vessels and musculature of the bladder. When the specimen is ready to be removed, a long right-angled Wertheim clamp is placed across the vagina below the cervix (not shown) to avoid gross spillage of tumor cells into the pelvis. The specimen then is removed by dividing the vagina above clamps placed on the lateral vaginal angles (**Fig. 51.26**).

Closure

The vaginal angles are suture ligated separately to secure hemostasis, and then the remaining cuff is closed in an anteroposterior direction using a continuous or interrupted 2-0 or no. 0 absorbable suture. No additional attempt is made to support the vaginal vault because all of the fascial support of the uterus and vagina has been removed. The remaining vagina, which has been shortened by about 2 to 3 cm, is well supported by its attachments to the levator ani muscles and urogenital diaphragm and mainly by the effects of postoperative fibrosis during the healing phase.

At the end of the procedure, some surgeons place suction catheters in the obturator fossae and along the lateral pelvic walls and bring them out through stab wounds in the lower

P.1223

abdomen. After the abdomen is closed, these catheters are connected to intermittent, low-suction drainage units. Traditionally, these drains were thought to be effective in preventing pelvic infection and fistula and lymphocyst formation. However, recent retrospective and prospective studies have demonstrated that the incidence of these complications is minimal and the same whether or not drains are used. Therefore, many gynecologic oncologists no longer routinely use pelvic drains.

FIGURE 51.23 **A:** Clamping and incision of lateral portion of cardinal ligament adjacent to the lateral pelvic wall. **B:** Excised ligament showing pelvic floor and levator muscles. Dissected obturator nerve is seen in obturator space.

No attempt is made to suspend the ureters to the hypogastric artery, as suggested by Green and coworkers, or to place the terminal ureter on the inside of the peritoneal surface, as recommended by Novak. Furthermore, there appears to be no benefit to reperitonizing the pelvis as described by Symmonds and Pratt.

If the ovaries are to be transposed out of the pelvis, a tunnel is dissected beneath the peritoneum laterally and superiorly toward each lateral gutter. An incision in the peritoneum

P.1224

is made as high as possible at the top of the tunnel. The adnexal structures are guided through the tunnel and through the incision at the top of the tunnel, making absolutely certain that the ovarian vessels in the infundibulopelvic ligament are not twisted. Permanent suture material is used to suture the tubo-ovarian pedicle as high as possible to the peritoneum and underlying muscle. Two large metal clips also are placed across the pedicle to later identify the location of the ovaries with an abdominal radiograph. This ovarian suspension is done when there is a reasonable chance that a patient will need postoperative pelvic irradiation, and recent studies suggest that at minimum, the ovary should be placed 1.5 cm cephalad to the iliac crest based on planar radiology films ([Figs. 51.27](#) and [51.28](#)). In most operations, however, the tubes and ovaries can be left in their natural positions in the pelvis. If the ovary is to be transposed, it is reasonable to remove the tube and fimbriae; this may decrease the formation of future benign and malignant tubal disease and likely has limited compromise in the vascular perfusion to the remaining ovary.

FIGURE 51.24 **A:** Cutting the cul-de-sac peritoneum as it reflects onto the rectum. Ureters course laterally, devoid of peritoneum. **B:** Dissection of the rectovaginal septum with development of rectal stalks (uterosacral ligaments). **C:** Clamping the uterosacral ligament. The ureter is gently retracted to avoid trauma.

FERTILITY-SPARING RADICAL ABDOMINAL TRACHELECTOMY

Historically, the recommended surgical treatment for a stage IA2-IB1 cervical cancer is a total radical hysterectomy and pelvic lymphadenectomy. This operation is very effective at treating early-stage cervical cancer; however, infertility is one of the serious and inevitable consequences of treatment. Partial radical organ resection has been accepted in many solid tumors, such as partial gastrectomy, nephrectomy, pneumonectomy, and colectomy to treat malignancies affecting these organs. In gynecologic oncology, partial organ resection with radical abdominal or vaginal trachelectomy and pelvic lymph node dissection are relatively new techniques used in women with early cervical cancer who wish to retain fertility ([Table 51.7](#)). This operation and technique are to be distinguished from the radical abdominal trachelectomy, which is occasionally used for resection of retained cervical stump malignancy following a previous supracervical hysterectomy in the setting in which fertility preservation is not an issue. The first reports of abdominal trachelectomy came from Europe in the 1950s by two separate gynecologists—F. Novak and E. Aburel; however, it is the work of D. Dargent in radical vaginal trachelectomy in the early 1990s that revived interest in the abdominal approach, with several investigators, namely, the Budapest team lead by L. Ungar, who started routinely performing the abdominal operation in adult women in 1997. The operation also appeared suited for pediatric cases with cervical cancer in whom the vaginal approach was not feasible; this approach was pioneered by a combined effort of the gynecology and pediatric surgery teams at Memorial Sloan Kettering Cancer Center in New York in 2004.

Technique

A laparotomy and a bilateral complete pelvic lymphadenectomy are performed in a similar manner to a radical abdominal hysterectomy. The limits of nodal dissection are the deep circumflex iliac vein caudally and the proximal common iliac artery cephalad. Any suspicious lymph nodes are sent for frozen section analysis. It is our intent to abandon a fertility-sparing approach if positive lymph nodes are identified. SLN biopsy following a structured algorithm is also a reasonable option and may allow for pathologic ultrastaging of these SLNs. The removal of paraaortic nodes is also considered for select lesions stage **IB1** or greater.

P.1228

FIGURE 51.29 Diagrammatic representation of the tissue renewed at radical abdominal trachelectomy.

The intent of the radical abdominal trachelectomy is to resect the cervix, upper 1 to 2 cm of the vagina, parametrium, and paracolpos in a similar manner to a type C1 nerve-sparing radical abdominal hysterectomy while preserving the uterine fundus or corpus ([Figs. 51.29](#) and [51.30](#)).

The procedure is begun by developing the paravesical and pararectal spaces and dissecting the bladder caudal to the midvagina. The round ligaments are divided (some surgeons preserve the round ligaments), and large Kelly clamps are placed on the medial round ligaments to manipulate the uterus. Care is taken not to destroy the cornu or the utero-ovarian pedicles. The infundibulopelvic ligaments, with ovarian blood supply, are kept intact. Care is also taken not to injure the fallopian tubes or disrupt the utero-ovarian ligament.

FIGURE 51.30 The intent of the radical abdominal trachelectomy is to resect the cervix, upper 1 to 2 cm of the vagina, parametrium, and paracolpos in a similar manner to a type III radical abdominal hysterectomy but sparing the uterine corpus.

The uterine vessels are then ligated and divided at their origin from the hypogastric vessels. The parametria and paracolpos with uterine vessels are mobilized medially with the specimen, and a complete ureterolysis is performed similar to a type C1 radical abdominal hysterectomy. The posterior cul-de-sac peritoneum is incised and the uterosacral ligament divided; similarly, the parametria and paracolpos are divided. Using a vaginal cylinder (Apple Medical Corporation; Marlborough, MA), the desired length of vaginectomy is performed, and the specimen is completely separated from the vagina and placed in the midpelvis, keeping its attachment to the utero-ovarian ligaments.

The lower uterine segment is then estimated, and clamps are placed at the level of the internal os (**Fig. 51.31**). Using a knife, the radical trachelectomy is completed by separating the fundus from the isthmus or upper endocervix at approximately 5 mm below the level of the internal os, if possible (**Figs. 51.32** and **51.33**).

The uterine fundus with preserved attachments to the uteroovarian ligaments, placed in the superior part of the pelvis, and the specimen, consisting of radical trachelectomy and parametria with suture marking the vaginal cuff at 12 o'clock, are sent for frozen section evaluation of its endocervical margin. The uterine fundus is inspected, and curettage of the endometrial cavity is performed as well as a shave disc margin on the remaining cervical tissue, which is sent for frozen section analysis (**Fig. 51.34**). This is performed to ensure that the reconstructed uterus to the vagina is disease free. A frozen section analysis is also obtained on the distal vaginal margin, if clinically indicated.

If all frozen sections tested are benign and at least a 5-mm clear margin is obtained on the endocervical edge, a permanent cerclage with no. 0 Ethibond or no. 0 GoreTex suture (knot tied posteriorly) may be placed before the reconstruction (**Fig. 51.35**). Some surgeons do not recommend cerclage. The uterus is then reattached to the upper vagina with six to eight no. 2-0 absorbable sutures (**Figs. 51.36, 51.37** and **51.38**). No drains are placed. Standard antibiotic prophylaxis and routine postoperative care is prescribed. We do not routinely place a stent or IUD into the uterus, but some investigators suggest it may help reduce the risk of postoperative stenosis; however, neocervical stenosis can occur beyond 6 weeks postsurgery, and such short-term devices used in the immediate post-op weeks are unlikely to affect that outcome. Use of vaginal dilators starting at 6 weeks post-op may help reduce the extent of upper vaginal agglutination around the neocervix.

P.1229

P.1230

FIGURE 51.38 The reconstructed fundus with remaining blood supply from the intact utero-ovarian ligaments: uterine serosa without evidence of fundal ischemia.

An alternative approach to performing the operation, similar to what Aburel described, is to separate the fundus from the cervix before the colpotomy, pack the fundus with the intact utero-ovarian blood supply in the upper pelvis, place retraction clamps on the cervix, and perform the radical trachelectomy. The role of cystourethroscopy with bilateral temporary ureteral catheterization is optional.

LAPAROSCOPICALLY ASSISTED RADICAL VAGINAL HYSTERECTOMY (SCHAUTA)

History

The “extended” hysterectomy performed vaginally for the treatment of cervical cancer was invented by Schauta in Austria in 1901. A few years earlier, in 1898, also in Austria, Wertheim had reported on the abdominal extended hysterectomy. The mortality and morbidity of the Wertheim method was initially much higher, but it had the advantage of including a pelvic lymphadenectomy, which is now appreciated as an important and necessary part of the procedure. Because the initial Schauta operation did not include the lymph node assessment, it gradually became less popular. In 1959, Mitra combined the Schauta operation with a retroperitoneal approach for the pelvic lymphadenectomy. This was a clever idea, but it did not gain a lot of acceptance because it necessitated bilateral flank incisions. More recently, in 1987, Dargent revived the Schauta operation by combining it with laparoscopic surgery, allowing thorough and complete pelvic

lymphadenectomy. The Schauta operation preceded by a laparoscopic pelvic lymphadenectomy is thus a perfect example of the recent trend toward minimally invasive surgery in gynecologic oncology.

Technique

Laparoscopic Part of the Surgery

Pelvic Lymphadenectomy

The procedure begins with a complete laparoscopic pelvic lymphadenectomy using a 4-trocar technique, as detailed in the laparoscopic surgical staging section below. In the future, if SLN mapping proves acceptable to gynecologic oncologists, the extent of the lymphadenectomy may be further minimized to the removal of only the SLNs.

Division of the Uterine Artery

Caudally to the crossing point of the uterine artery, an opening is created bluntly just under the superior vesical artery, which is then retracted laterally in such a way that the uterine vessels lie between the two openings created. Once the uterine artery is divided, the stump can be retracted medially and freed gently from the ureter. This will facilitate the dissection of the uterine artery vaginally. Of note, several collaterals of the uterine artery are frequently encountered and should be clipped, excised, or cauterized individually to avoid bleeding. The vaginal branch of the uterine artery is also frequently seen appearing under the excised uterine artery. It can be divided now or later during the vaginal excision of the parametrial tissue. Lastly, the uterine veins are usually located under the artery and again should be managed individually. On occasion, uterine veins cross over the ureter and can be the source of bleeding during the vaginal part of the surgery.

Vaginal Part of the Surgery

The vaginal part of the surgery can be divided into five steps: (a) vaginal cuff preparation, (b) anterior phase (opening of the vesicouterine space and paravesical space and mobilization and dissection of the ureter), (c) posterior phase (opening of the cul-de-sac and pararectal space and excision of the paracolpos), (d) lateral phase (excision of the parametrium), and (e) excision of the specimen and closure.

Vaginal Cuff Preparation

Because the radical vaginal hysterectomy is primarily offered to women with cervical lesions less than 3 cm, it is rarely necessary to remove more than 1 cm of vaginal mucosa. A rim of vaginal mucosa is delineated circumferentially clockwise around the cervix with six to eight straight Kocher clamps placed at regular intervals, about 1 cm below the cervix ([Fig. 51.39](#)).

To reduce bleeding from the edges of the vaginal mucosa, a 10- to 20-mL solution of xylocaine 1% mixed with epinephrine 1:100,000 is injected between each Kocher clamp, and then a circumferential incision is made with the scalpel just above the Kocher clamp ([Fig. 51.40](#)). The anterior and posterior edges of the vaginal mucosa are grasped with four to six Chrobak clamps to completely cover the cervix.

Anterior Phase (Described for the Patient's Right Side)

OPENING OF THE VESICOUTERINE SPACE

While pulling the specimen slightly downward with the Chrobak clamps, a single-tooth forceps is used to hold and retract the anterior vaginal mucosa, which usually creates a triangular fold indicating where to cut ([Fig. 51.41](#)). The vesicouterine space is opened with Metzenbaum scissors held perpendicular to the cervix in the midline to avoid bleeding from the bladder pillars laterally. The space is further defined and stretched by gentle dissection with the index finger. Care is taken not to enter the anterior peritoneum as in a simple vaginal hysterectomy as

P.1231

it makes identification of the bladder base and ureters more difficult. If entered correctly, the space should be avascular, and the anterior surface of the endocervix and isthmus should be easily identified without resistance. If resistance is encountered, it usually means that the plane of dissection is either too posterior and that the surgeon is digging into the endocervix, or too anterior, which carries a risk of damage to the bladder. For that reason, the bladder base should be carefully delineated. In patients who have had a recent conization, there may be substantial fibrosis and scarring between the cervix and the bladder base. The opening of the vesicouterine space may be particularly difficult in those cases. In such situations, a metal bladder catheter introduced in the urethra may be used to locate the bladder base and facilitate its mobilization. Once clearly identified, the vesicouterine space is stretched upward with a narrow Deaver retractor, showing the intact peritoneum ([Fig. 51.42](#)).

FIGURE 51.39 A vaginal cuff is prepared to remove about 1 to 2 cm of vaginal mucosa.

OPENING OF THE PARAVESICAL SPACE

To open the right paravesical space, the Chrobak clamps are slightly pulled toward the patient's right side. Straight Kocher clamps are placed onto the vaginal mucosa at 11 and 9 o'clock and stretched out (this is where the 12-o'clock mark made earlier is useful). This maneuver defines a triangle formed by the bladder pillars, the vaginal mucosa, and the Chrobak clamps. An areolar opening is seen just medial and slightly anterior to the 9-o'clock clamp, indicating where to enter to define the paravesical space. The space is blindly entered by opening and closing Metzenbaum scissors, with the tips pointing upward and outward in an oblique axis. If entered correctly, the space should be avascular and the scissors should slide inside easily. Once entered, the space is widened by rotating the scissors under the pubic bone in a semicircular, rotating motion to the patient's left side. A small Breisky retractor is then placed in the space. This step is unquestionably the most "scary" part of the procedure as it is a blind maneuver. Having defined the paravesical space laparoscopically facilitates the entry of the scissors.

FIGURE 51.40 Section of the anterior vaginal mucosa, with the 12-o'clock mark (*arrow*).

IDENTIFICATION AND MOBILIZATION OF THE URETER

To palpate the ureter, the Chrobak clamps are pulled to the left of the patient, and the surgeon's right index finger is placed in the vesicouterine space while a Breisky retractor (or the back of the scissors) is placed in the right paravesical space. By pulling down and "rubbing" the finger against the Breisky retractor, the "click" of the ureter rolling under the finger should be heard and felt. This maneuver orients the surgeon as to the location of the ureter in relation to the bladder pillars. Next, with the Breisky retractor placed in the right paravesical space and the narrow Deaver retractor placed in the vesicouterine space, the bladder pillars

are clearly identified. The knee of the ureter is normally located on the lateral aspect of the bladder pillars (**Fig. 51.43**).

Once the ureter has been precisely located by palpation, the bladder pillars are excised midway between the bladder base and the endocervix. (Bipolar scissors are useful to decrease bleeding from the bladder pillars.) With the scissors, the medial and lateral pillars of the bladder pillars should be separated first before cutting (**Fig. 51.44**). The most proximal fibers of the pillars can then be excised, and normally, the knee of the ureter should appear anteriorly. At that point, a Babcock clamp is extremely useful to grab the ureter to allow a good traction on it and to constantly keep it under direct visualization. Once the ureter is clearly identified, the medial and lateral bladder pillars are safely excised. If the ureter is not seen unequivocally, it should be palpated again to relocate its position before cutting the pillars.

P.1232

FIGURE 51.41 Opening of the vesicouterine space, with the Chrobak clamps pulling the vaginal cuff.

FIGURE 51.42 The vesicovaginal space is open, showing the intact peritoneum (*arrow*).

FIGURE 51.43 The right bladder pillars separate the vesicouterine (1) and the right paravesical (2) spaces.

FIGURE 51.44 The ureter is localized by opening the bladder pillars.

P.1233

DISSECTION OF THE URETER

Once the ureter is clearly identified and placed under traction with a Babcock clamp, it is possible to dissect the ureter. (It is easier if part of the unroofing has been done laparoscopically.) The uterine vessels are usually seen just under the knee of the ureter ([Fig. 51.45](#)). With a Kelly clamp, the vessels are pulled down from under the ureter, while at the same time, Metzenbaum scissors are used to free the filmy attachments and allow mobilization of the ureter upward. The uterine artery can be drawn completely into the operative field along with the clips (if they have been used laparoscopically to divide the uterine artery).

Posterior Phase (Described for the Patient's Right Side)

OPENING OF THE CUL-DE-SAC

Chrobak clamps are sharply angulated anteriorly, and the posterior cul-de-sac is opened using Metzenbaum scissors as for a simple vaginal hysterectomy. Once entered, the space is stretched laterally to allow placement of a retractor.

OPENING OF THE PARARECTAL SPACE AND EXCISION OF THE UTEROSACRAL LIGAMENTS

Using Metzenbaum scissors, the pararectal space is defined by opening a space just lateral to the peritoneal folds of the uterosacral ligaments. The medial or rectouterine fibers of the uterosacral ligaments are separated and excised.

FIGURE 51.45 After dissection of the ureter (U), the uterine vessels are seen underneath (arrow).

EXCISION OF THE PARACOLPOS

To complete the posterior phase preparation, the paracolpos is excised. The paracolpos is the inferior border of the parametrium. With the Chrobak clamps rotated to the left, the paracolpos is clamped just medial to the vaginal mucosa, excised, and ligated.

Lateral Phase (Excision of the Parametrium)

Before clamping the parametrium, the paravesical space and the ureter should be relocated. The space is verified by palpation with the finger, and a Breisky retractor is replaced in the paravesical space. The ureter should be readily visible and placed under traction with a Babcock clamp. While the Chrobak clamps are pulled and rotated to the patient's left side, a curved Heaney clamp is placed proximally on the parametrium, and then a second clamp is placed higher and more lateral to obtain wider parametrium. The second Heaney clamp should be placed at the contact of the knee of the ureter, which can be further dissected if needed ([Fig. 51.46](#)). The parametrial tissue is excised and ligated.

Once completed on the other side, the uterus can now be tilted backward and should only be held by the ovarian ligaments (if the adnexae are preserved) or by residual peritoneal attachments. These can be clamped, excised, and ligated. The specimen is removed ([Fig. 51.47](#)).

Closure

In general, an attempt is made to include the anterior and posterior pelvic peritoneum along with the vaginal mucosa. Interrupted figures-of-eight of Vicryl 2-0 sutures are used for the closure, starting with the lateral angles. No drains are left in place, except for the Foley catheter.

FIGURE 51.47 Specimen with parametrium and uterine arteries.

Results

Over the last two decades, data have been accumulating in the literature to indicate that the laparoscopically assisted radical vaginal hysterectomy is a safe procedure, with an overall low morbidity rate. Several studies—including those of Jackson and associates, Malur and colleagues, Nam and coworkers, Renaud and associates, Roy and colleagues, and Steed and coworkers—compared laparotomy versus laparoscopically assisted vaginal route. In general, the data suggest that the operative time is longer for the laparoscopically assisted vaginal group, but blood loss, transfusion rate, and hospital stay are significantly lower. The lymph node yield is similar between the two groups. Malur even reported a higher lymph node count in the laparoscopically assisted vaginal group. The intraoperative complication rate appears to be higher in the laparoscopically assisted vaginal group, probably related in part to the initial learning curve. In the study by Steed and coworkers, most of the complications were related to bladder and ureteral injuries. However, postoperative complications, such as wound infection and bleeding, tend to be higher in the laparotomy group. Jackson and associates reported the incidence of bladder and bowel dysfunction to be less in the laparoscopically assisted vaginal group, whereas Steed and coworkers found the opposite. Renaud and associates reported that the conversion rate to laparotomy is low. Importantly, there does not appear to be a statistically significant difference in recurrence rate and overall survival, suggesting that the radicality of the vaginal approach is adequate. However, Nam and coworkers noted a higher recurrence rate in the laparoscopically assisted vaginal group in patients with larger tumor volume and concluded that the vaginal approach should be restricted to patients with small tumor (<2 cm).

For larger-sized lesions, Possover and colleagues and Querleu have described a technique to provide extended radicality comparable to that of a type III radical hysterectomy with the idea that it may reduce long-term lateropelvic recurrences. However, the more radical the hysterectomy, the more side effects on bladder and bowel function. In recent years, attention has been paid to this matter, and laparoscopic nervesparing surgical techniques have been developed by Querleu and associates to reduce these side effects. However, this extensive paracervical and parametrial dissection is of limited value in patients with small lesions (measuring <2 cm), as the risk of lateropelvic recurrence is low.

LAPAROSCOPICALLY ASSISTED RADICAL VAGINAL TRACHELECTOMY (DARGENT PROCEDURE)

History

In 1987, Dargent proposed a modification of the Schauta-Amreich radical vaginal hysterectomy to preserve the body of the uterus and thus the reproductive function. The procedure, the radical vaginal trachelectomy, today known as the *Dargent procedure*, implies the removal of the cervix along with the proximal portion of the parametrium and is preceded by a complete laparoscopic pelvic lymph node dissection. After nearly three decades, the accumulating experience worldwide summarized by Plante and coworkers suggests that the oncologic outcomes with this conservative procedure are comparable to those obtained following a radical hysterectomy for similarly sized lesions. Obstetrical outcomes are also very encouraging.

Indications

Eligibility criteria for this conservative procedure were initially proposed by Roy and Plante in 1998 and, for the most part, have remained unchanged.

1. Desire to preserve fertility
2. No clinical evidence of impaired fertility (relative contraindication)
3. Lesion size lesser or equal to 2 cm
4. FIGO stage IA1 with presence of vascular space invasion, IA2 and IB1
5. Squamous cell or adenocarcinoma
6. No involvement of the upper endocervical canal as determined by colposcopy or MRI
7. No metastasis to regional lymph nodes

The procedure can be offered to women older than age 40, understanding that the fertility potential is obviously reduced, or to women who already have children, as they may wish to have more children in the future. Sonoda and colleagues reviewed the Memorial Sloan Kettering Cancer Center experience over the course of 10 years and noted that 43% of their patients who underwent a radical hysterectomy for early-stage cervical cancer were younger than 40 years old; of those, 48% would have met the eligibility criteria for a radical trachelectomy. Therefore, a substantial proportion of young women with cervical cancer are potential candidates for this fertility preservation alternative.

Technique

The technique described in this chapter is based on the original technique developed by D. Dargent with modifications by M. Roy. The laparoscopic part of the procedure is identical to that of the Schauta, except that the uterine arteries are obviously not excised. The first three steps of the vaginal part of the surgery are also identical to the Schauta operation (vaginal cuff preparation, anterior phase, and posterior phase). The initial part of the lateral phase—that is, excision of the parametrium—is also identical; however, only the descending branch of the uterine artery is excised. The excision of the trachelectomy specimen and closure also differ from the Schauta operation and will be detailed here.

Lateral Phase (Described for the Patient's Left Side)

Ligation of the Cervicovaginal Artery

As opposed to the Schauta operation, in which the uterine artery is clamped at

P.1235

its origin, pulled down, and unroofed from under the ureter, the cross of the uterine artery is actually preserved in the case of a trachelectomy to maintain optimal vascularization of the uterus in the event of a future pregnancy. Therefore, only the cervicovaginal or descending branch of the uterine artery is excised. So, after precise localization of the isthmus and the cross of the uterine artery, the cervicovaginal artery is clamped with a right angle clamp placed at 90 degrees and directly applied to the isthmus ([Fig. 51.48](#)); then it is sectioned and ligated.

FIGURE 51.48 A clamp is applied just under the arch of the left uterine artery (*arrow*). The uterine isthmus area is visible (*X*).

FIGURE 51.49 Section of the cervix 1 cm below the isthmus. The endocervical canal is visible (*arrow*).

FIGURE 51.50 A, B: The specimen with its parametrium. The superior endocervical canal is shown (*arrow*).

Excision of the Specimen and Closure

The uterine isthmus and endocervix are precisely located by palpating the uterus anteriorly and posteriorly. The cervix is amputated with a scalpel held perpendicular to the specimen about 1 cm distal to the isthmus (**Fig. 51.49**). As the specimen is excised, the cervical os appears gradually, and the anterior lip can be grasped with a straight Kocher clamp. Care is taken not to angulate the scalpel to avoid removing too much cervix posteriorly. The specimen is completely excised in one piece to facilitate the pathologic evaluation of the margins.

P.1236

Ideally, the specimen should be at least 1 to 2 cm wide, with 1 cm of vaginal mucosa and 1 to 2 cm of parametrium (**Fig. 51.50A, B**). When there is no clinical evidence of residual tumor, a frozen section analysis is not performed. The specimen is kept intact for final analysis and will be processed as a cone specimen. However, in patients with a visible lesion, the trachelectomy specimen is sent for immediate frozen section analysis to assess the level of the tumor in relation to the endocervical resection margin. At least 8 to 10 mm of tumor-free tissue should be obtained between the level of the tumor and the endocervical resection margin; otherwise, additional endocervix should be removed or the trachelectomy should be completed by a radical vaginal hysterectomy (Schauta). It is thus extremely important to ask the pathologist to do a frozen section analysis of the cervix with a section made longitudinally from the ectocervix to the endocervix to evaluate the distance between the most cephalad edge of the tumor and the endocervical resection margin. A permanent cerclage is placed at the level of the isthmus using a nonresorbable Prolene or Ethibond 0 suture starting posteriorly at 6 o'clock to have the knot lying posteriorly. The sutures should not be placed too deeply into the cervical stroma, as the cerclage can eventually erode into the endocervical canal and be expelled. When tying the cerclage knot, a uterine probe can be placed in the cervical os to avoid tightening the knot too much, as this may cause cervical stenosis (**Fig. 51.51**).

The Dargent procedure is completed by reapproximating the edges of the vaginal mucosa to the new exocervix. This is accomplished with interrupted figures-of-eight sutures of 2-0 Vicryl. It is easier to begin with the sutures at 12 and 6 o'clock first. The lateral sutures are then placed separately to include the anterior and posterior vaginal mucosa only. Although easy to do, the closure of the vaginal mucosa is an extremely important step of the procedure, and care should be taken not to bury the cervical opening into folds of redundant vaginal mucosa (**Fig. 51.52**). The new exocervix should remain accessible for monitoring with colposcopic examination and cytology.

FIGURE 51.51 A cerclage is put in place and ligated posteriorly with a dilator (*arrow*) in the cervical canal.

FIGURE 51.52 Suturing the vaginal mucosa to the cervical stroma. A clamp (*arrow*) indicates the endocervical canal.

At the end of the trachelectomy procedure, laparoscopy is performed to verify hemostasis in the pelvis and the integrity of the pelvic structures. No drains or packings are left.

Oncologic Outcome of Radical Trachelectomy

Data are accumulating worldwide indicating that the oncologic outcome following the radical trachelectomy is comparable to the outcome following a radical hysterectomy for similar-sized lesions. It should also be emphasized that adenocarcinoma histology and the presence of LVSI are NOT contraindications to offer or consider a fertility-sparing approach. Indeed, several large series consistently report a large percentage of adenocarcinoma cases with LVSI and a recurrence rate of less than 4% and a death rate of less than 2% ([Table 51.8](#)). Plante and colleagues have noted that the size of the lesion (≥ 2 cm) and the presence of LVSI seem to be the most important risk factors for recurrences. The recent work of Hertel and coworkers also suggests that adenocarcinomas may carry a higher risk of recurrence, but this is not uniformly agreed upon.

Morice and associates noted unusual sites of recurrences, such as in the vesicovaginal septum and in the bladder, which suggests that very meticulous surgical technique should be observed to avoid entering the wrong planes of dissection and

P.1237

potentially disseminating tumor cells at the time of the procedure. Piketty recently reported a recurrence in the ovary in a patient with an adenocarcinoma. Few recurrences have been reported on the residual cervix itself. The first, which occurred nearly 7 years following the initial surgery, was reported by Bali. It is unclear, however, whether it was a recurrence or a new primary. The other was reported by Bader and coworkers; it occurred 6 months after an abdominal trachelectomy and was picked up on a routine Pap smear. A radical hysterectomy was performed and disclosed a 3-mm recurrence (or persistence) in the cervix.

^aExcluding one case of neuroendocrine tumor. ^bAbdominal radical trachelectomy.

Ungar and associates and del Priore and colleagues reported two recurrences following the abdominal radical trachelectomy procedure, and both were in patients with bulky lesions: One had a 3.8-cm lesion, and she recurred within 4 months of the surgery with a 6-cm lesion; the other had a 5-cm glassy cell adenocarcinoma and recurred 14 months after surgery. Strict selection criteria are extremely important to lower the risk of recurrences. Further experience will determine if the abdominal radical trachelectomy is safe in bulky lesions. Another alternative for patients with larger lesions is the use of neoadjuvant chemotherapy to reduce the size of the tumor followed by a fertility-preserving radical trachelectomy. Plante and coworkers have recently published their preliminary experience with three cases. All have had a complete pathologic response to the chemotherapy with no residual cancer in the surgical specimen. Obviously, this approach is currently experimental, but it has potential merits and deserves further investigation.

Shepherd recommends regular follow-ups after trachelectomy, including a colposcopic examination, cytology, and rectovaginal examination every 3 to 4 months for the first 2 to 3 years, every 6 months for the next 2 years, and yearly thereafter. Unfortunately, colposcopy and cytologies are frequently unsatisfactory after trachelectomy because the squamous columnar junction is often not visualized and the cytology frequently contains only squamous cells. Conversely, atypical glandular cells from the lower uterine segment are commonly picked up on the smear and misinterpreted as suspicious for recurrence. Singh and coworkers reported their experience with nearly 200 smears posttrachelectomy and concluded that a high proportion of the smears were unsatisfactory; 2% of the smears were reported as suspicious and, in fact, represented atypical endometrial cells, but two patients recurred and retrospectively had abnormal smears long before the recurrence was diagnosed. Reports of cytology posttrachelectomy should thus be interpreted with caution. Shepherd and coworkers recommend the use of an endocervical cytobrush for the cytology and an MRI at 6, 12, and 24 months postsurgery. The superb work by Sahdev and associates emphasizes the fact that radiologists interpreting those MRIs should be very well aware of the anatomical changes posttrachelectomy, as some of the changes may be misinterpreted as cancer recurrences.

Obstetric Outcome

The collected data on obstetric outcome are also very promising. As seen in [Table 51.9](#), there have been hundreds of pregnancies reported from the same groups of investigators, mostly with the vaginal but increasingly with the abdominal approach. In general, the rate of first-trimester miscarriage does not seem to be higher than in the general population, at approximately 16%. It is interesting to note that even though women undergoing a radical trachelectomy do so to preserve their fertility, there is a surprising 4% rate of elective pregnancy termination. The rate of second-trimester losses is higher than in the general population (8%). Overall, 66% to 75% of all pregnancies reach the third trimester. Of those, approximately 15% will end with significant prematurity at less than 32 weeks of gestation. Luckily, less than 10% will deliver before 28 weeks, when most of the severe neonatal morbidities and mortalities occur. Of note, multiple pregnancies appear to be at a particularly high risk of severe prematurity posttrachelectomy, and this should be taken into consideration when discussing in vitro fertilization in patients with infertility. Overall, 85% of the pregnancies reaching the third trimester will evolve normally beyond 32 weeks, and the majority will actually deliver at term (>37 weeks of gestation). The work of Klemm and colleagues suggests that there is no evidence that birth weight of newborns delivered from women who had a trachelectomy is lower. They showed that the vascular flow to the uterine artery before and after vaginal trachelectomy is well preserved.

The etiology of the second-trimester losses and the preterm deliveries is considered mechanical and/or infectious. Indeed, the short cervix probably does not offer as much support to the lower uterine segment. As the uterus enlarges and gets heavier, the cervix is more likely to dilate prematurely. However, the main etiology is felt to be infectious. Indeed, the shortened cervix after the trachelectomy procedure seems to prevent the formation of an efficacious mucus plug. The mucus plug is thought to play an important role as a physiologic barrier between the vaginal flora and the membranes to prevent ascending infections. Hence, the subclinical chorioamnionitis is thought to be responsible for the premature rupture of membranes and premature labor. Plante and associates proposed some guidelines for the follow-up of these high-risk pregnancies. A consultation with a specialist in fetal-maternal medicine is recommended. The value of prophylactic antibiotic coverage—as well as steroid injections to accelerate fetal lung maturity near term—is unclear, although Shepherd and colleagues strongly recommend it. The work of Berghella and coworkers showed that serial transvaginal ultrasound is the best modality for the follow-up of cervical length in the general obstetric

P.1238

population and has been used in the follow-up of pregnant women posttrachelectomy. If the pregnancy evolves normally, delivery is planned at 38 to 39 weeks of gestation. Because of the permanent cerclage, women should be delivered by elective cesarean section.

Outcomes of pregnancy following an abdominal trachelectomy also appear promising. Although the numbers are smaller, Ungar and coworkers reported 10 pregnancies, with results comparable to pregnancies after the vaginal approach. There was concern that ligating the uterine arteries at the time of the procedure might have an impact on the vascularization of the uterus and potentially lead to intrauterine growth retardation. So far, the data seem reassuring in that regard, particularly after a recent publication by Wethington of an international series of abdominal trachelectomy with robust fertility outcomes, similar to those of the vaginal approach.

Conclusion

Based on the collected data available, the radical trachelectomy truly offers a valuable alternative to young women with small, early-stage cervical cancer who wish to preserve their fertility. Oncologic outcomes are comparable to standard radical hysterectomy for similar-sized lesions, and the complication rate is low. Pregnancies are possible after this procedure, and overall obstetrical outcome is good despite the rate of second-trimester loss and premature delivery. In the last three decades, there has been a tremendous shift toward minimally invasive surgical techniques in gynecologic oncology. Laparoscopic, robotic, and radical vaginal/abdominal fertility-sparing surgeries have revolutionized the surgical management of cervical cancer. The radical trachelectomy (Dargent operation) is unquestionably the most important surgical development in the treatment of early-stage cervical cancer in the last century. Importantly, in 2013, the NCCN cervical cancer management guidelines began dedicating a full panel for the surgical treatment options of women with stage IA1-IB1 cervical cancer who wish to preserve fertility and included a conization or trachelectomy as a standard of care in select women.

TOTAL LAPAROSCOPIC AND ROBOTIC RADICAL HYSTERECTOMY WITH LYMPHADENECTOMY

Laparoscopic radical hysterectomy with pelvic and aortic lymph node dissection was first reported by Nezhat in 1992. This technically challenging procedure initially was received with caution by gynecologic oncologists who have used the abdominal radical hysterectomy as the traditional approach for decades. So far, there have not been any reported randomized trials to compare these two surgical approaches; however, such a trial is currently ongoing, and there have been hundreds of reported cases worldwide, with encouraging results. Well-recognized, pioneer work was undertaken by Spirtos and associates, who described 78 consecutive patients, all with early cervical cancer and a Quetelet body mass index less than 35, who underwent the procedure. In all, 94% of the procedures were completed laparoscopically, with an average operative time of 205 minutes and an average blood loss of 225 mL, with only one patient (1.3%) requiring transfusion. There was one ureterovaginal fistula documented. The average lymph node count was 34, with 11.5% of patients having positive lymph nodes. Three patients (3.8%) had close or positive surgical margins, and 5.1% recurred with a minimum of 3 years of follow-up. [Table 51.10](#) summarizes reports on laparoscopic radical hysterectomy with pelvic and aortic lymphadenectomy.

Total Laparoscopic or Robotic Radical Hysterectomy

One technique of the laparoscopic radical hysterectomy is well described by Spirtos and associates and Chen and colleagues. The laparoscopic approach uses different surgical instruments and techniques than the classic approach to accomplish the same procedure performed via laparotomy. The technique of laparoscopic radical hysterectomy described in this section relies on the use of the monopolar electrosurgical devices and vessel-sealing instruments or bipolar traditional graspers. The robotic platform brought much improvement in ergonomics and visualization and helped popularize the use of laparoscopy in radical hysterectomy, but the energy sources and technology remain similar to the laparoscopic counterpart and all pneumoperitoneum-based surgery. Four to six trocars are needed, with the camera near the umbilical site. The retroperitoneum is opened and the round ligaments coagulated. The paravesical and pararectal spaces are developed with monopolar devices, and the ureter is clearly identified. Resection of the adnexa is managed on an individual basis as per the open approach. The uterine artery is identified after developing the pararectal and paravesical spaces, and the umbilical ligament is isolated. The uterine artery and vein are sealed and divided. The bladder flap is then developed. The posterior cul-de-sac peritoneum is incised and the rectouterine ligaments exposed. The ureter is then unroofed from the parametria by placing medial traction on the stapled uterine artery stump, and the bladder is dissected further inferiorly. The uterosacral/rectouterine ligaments are divided, and the ureter is retracted laterally to resect the desired length of parametria. Anterior colpotomy is performed at the desired vaginal length. A vaginal probe facilitates stretching the vagina for easier incision. The remaining parametria and paracolpos are resected with monopolar devices. The specimen is removed vaginally with a single-tooth tenaculum, and the vaginal cuff is closed laparoscopically with endoscopic sutures. The placement of ureteral catheters or stents to facilitate ureteric manipulation is optional. The pelvic and aortic lymphadenectomy is performed, as described. Pelvic drains usually are not necessary, and a suprapubic catheter is optional.

P.1240

LAPAROSCOPIC SURGICAL STAGING

Currently available clinical staging methods and imaging studies are not completely accurate in the detection of pelvic and aortic lymph node metastasis from cervical cancer, and pathologic evaluation of retroperitoneal lymph nodes remains the gold standard for establishing metastasis. In addition, identifying retroperitoneal nodal metastasis may alter the overall therapeutic approach and affect the patient's prognosis.

Laparoscopic surgical staging with pelvic and aortic lymph node dissection for cervical cancer was initially reported by Querleu in France. Since that initial report, many investigators have adopted the laparoscopic pretreatment surgical approach and continue to modify the technical details of the procedure. It is well established at this point that transperitoneal or extraperitoneal laparoscopic pelvic and aortic lymph node dissection for cervical cancer, in experienced hands, is feasible, yields similar results as the open approach, and is associated with low morbidity. Furthermore, this approach may provide valuable information that is not available using clinical staging techniques. Computed tomography was able to detect retroperitoneal nodal metastasis in only 17% to 57% of cervical cancer patients staged laparoscopically. [Table 51.11](#) summarizes selected reports on laparoscopic pelvic and aortic lymph node dissection in the management of stage I to IV cervical cancer.

Laparoscopic Surgical Staging Technique

The technique of laparoscopic surgical staging continues to evolve as experience with this minimally invasive approach increases; the introduction of the robotic approach has added to this evolution, although the principles of this procedure are similar to those of the laparoscopic approach, except whether the nodes are approached transperitoneally or extraperitoneally. Therefore, these are the two main approaches: the transperitoneal approach and the extraperitoneal approach (popularized by Querleu and Dargent from France). For the transperitoneal approach, four laparoscopic trocars usually are needed (Fig. 51.53): 10-mm trocars in the umbilical and suprapubic regions and 5-mm trocars just medial to the iliac crest on each side. For the aortic nodal dissection, the laparoscope is placed in the suprapubic region, and the monitors are moved cephalad. For the pelvic lymphadenectomy, the laparoscope is placed in the umbilical region, and the monitors are placed caudal. A variety of endoscopic tools may be used with similar results. The selection usually is based on the surgeon's preference and experience. Both monopolar and bipolar currents are available, and a wide variety of endoscopic dissecting instruments, clip appliers, and specimen retrieval devices are available. A retroperitoneal nodal dissection may be satisfactorily completed in the majority of cases with the aid of a tissue grasper and an endoscopic clip applier or vessel-sealing device.

P.1241

The right aortic nodal tissue is approached via a retroperitoneal incision over the right common iliac artery. The right ureter and ovarian vessels are identified, and the nodal tissue over the inferior vena cava is removed. The left aortic nodal tissue may be approached via the same incision. The inferior mesenteric artery, left ureter, and left ovarian vessels are identified, and the nodal tissue over the left aortic region is removed.

FIGURE 51.53 The transperitoneal minimally invasive approach for laparoscopic surgical staging. Four laparoscopic trocars usually are needed. (Figure © MSKCC, 2002.)

Dissection above the inferior mesenteric artery to include the infrarenal nodal regions may be accomplished through a similar approach, and a left-sided laparoscopic suprarenal retrocrural paraaortic lymphadenectomy in advanced cervical cancer has been described, but the resection of infrarenal aortic nodes using the transperitoneal approach is technically challenging, particularly in obese patients. Robotics may improve on the popularization of paraaortic minimally invasive lymphadenectomy.

PATHOLOGIC EXAMINATION OF THE OPERATIVE SPECIMEN

Considerable useful information about the extent of the disease can be obtained by a careful pathologic examination of the operative specimen. This is helpful in determining prognosis but is also absolutely essential to the identification of patients at greater risk for persistent disease so that additional therapy and close surveillance can be provided. Even though the operator may be fatigued at the end of the operation, in cases where there is a major critical decision based on the specimen, the surgeon should consider accompanying the specimen to the pathology laboratory, where it can be examined with the pathologist before it is placed in fixative and sectioned. Another alternative is to call the pathologist to the operating room for a joint examination of the specimen while the surgical incisions are being closed. The gynecologic surgeon then can indicate worrisome parts of the specimen; such information assists the pathologist in taking sections. Critical margins of dissection can be pointed out and stained with India ink so that they can be seen on microscopic slides. The primary cervical tumor should be measured as accurately as possible so that at least an estimate of its size and volume can be recorded. Numerous microscopic sections of the cervix with adjacent vaginal cuff; lower uterine segment; and paravaginal, paracervical, and parametrial tissue should be examined to show the cell type, degree of differentiation, depth of stromal invasion, and presence or absence of invasion of lymphatic and vascular spaces. It is important to know not only the depth of invasion but also the thickness of the uninvolved fibromuscular stroma of the cervix, as pointed out by Kishi and coworkers. These authors found that the nodal metastasis and 5-year cancer death rates were 7% and 8%, respectively, in patients with uninvolved fibromuscular stroma thickness greater than 3 mm, and 37% and 26%, respectively, in patients with thickness less than 3 mm. Furthermore, the GOG has demonstrated that the percentage of invasion of tumor into the cervical stroma is an independent prognostic factor and is used to help determine the need for postoperative adjuvant treatment.

Unfortunately, the exquisite giant section technique of pathologic examination used by Burghardt and coworkers is not available in any US pathology laboratory. These authors measured ratio of tumor size to the size of the cervix. The incidence of lymph node involvement increased with tumor size, reaching a maximum of 68.3% in the group with a ratio from 70% to 80% of cervical anatomic involvement. Surprisingly, direct spread into the parametrium seldom was found, even when large tumors were found to occupy the entire cervix. This finding is contrary to that of Bleker and coworkers, who found 16.8% unrecognized parametrial tumor involvement in patients with stage IB and IIA lesions. The 5-year survival rate fell with parametrial involvement.

Thorough examination of the lymphadenectomy specimens must be done. Tumor metastasis to lymph nodes affects patient survival adversely and is an indication for postoperative adjuvant therapy. In patients with positive nodes, the pathologic examination should report whether the metastatic disease is microscopic or macroscopic, single or multiple, and unilateral or bilateral. The location of lymph nodes positive for tumor also should be reported because the prognosis is especially poor in patients with positive common iliac or paraaortic nodes. The usual standard technique of pathologic examination of lymphadenectomy specimens involves removal of visible and palpable nodes from fatty tissue, with bisection of each node for microscopic examination. This standard technique may not be adequate for an accurate assessment of lymph node metastases. A significant increase in positive findings can be obtained if special pathologic examination techniques are used, as demonstrated by To and coworkers, Ahrens and Tschoke, and Wilkinson and Hause. With their technique of dissection of lymph nodes at multiple levels before paraffin embedding, To and coworkers showed that 9% of patients originally reported to have negative nodes actually had positive nodes.

An accurate assessment of the extent of disease by a careful pathology examination of the operative specimen is imperative in deciding whether additional treatment is needed. Indeed, it is such an important component in the surgical management of patients with cervical cancer that these patients should be operated on only in hospitals where such expert specimen evaluation is available.

POSTOPERATIVE COMPLICATIONS

Bladder

Neurogenic Dysfunction

A non-nerve-sparing radical hysterectomy substantially denervates the bladder and upper urethra; the more extensive the dissection, the greater the degree of interference with their function. Therefore, a type C1 nerve-sparing resection has

P.1242

been popularized. Parasympathetic and sympathetic nerve fibers to and from the bladder and urethra are removed, along with paracervical, paravaginal, cardinal ligament tissues and pelvic lymph nodes. All patients have some degree of bladder dysfunction; the incidence of significant bladder dysfunction can be as high as 50%.

Studies have demonstrated that the bladder initially can be hypertonic, with decreased bladder capacity, increased resting pressure, and increased residual urine volume. Many patients have difficulty initiating micturition and experience a loss of sensation of bladder fullness. Using sensitive urodynamic instrumentation, Scotti and coworkers found a variety of abnormalities, including obstructive voiding patterns, immediate and delayed loss of compliance, sensory losses, and genuine stress incontinence. Some patients had complete absence of bladder contractions during voiding. Although these findings are quite compelling, Lin and associates recently reported normal preoperative urodynamic findings in only 17% of 210 patients with cervical cancer scheduled to undergo radical hysterectomy.

Mundy and Sasaki and coworkers have suggested that the posterior part of the cardinal ligament (pars nervosa) contains the major part of the parasympathetic and sympathetic nerve supply to the bladder and urethra and that its removal is responsible for postoperative bladder dysfunction. Sasaki and coworkers demonstrated that removal of the anterior cardinal ligament (pars vasculosa) with preservation of the pars nervosa reduces the incidence of postoperative bladder dysfunction. The work of Kadar and coworkers and that of Asmussen and Ulmsten suggests that the nerve supply to the bladder and urethra can be spared without compromising the necessary extensive dissection and tissue removal around the central disease, thus sparing many patients the loss of urethrovaginal function. Kuwabara and colleagues recently reported a decrease in bladder dysfunction by using a technique of intraoperative electrical stimulation to identify and preserve the vesical nerve branches. These nerve-sparing modifications have not been widely adopted by gynecologic oncologists in the United States because of a concern that this same cardinal ligament tissue also carries lymphatic channels draining the cervix and should be removed in a complete central dissection. However, Trimbois and colleagues, from the Netherlands, reported no increase in recurrence or decreased survival in a series of patients treated with nerve-sparing radical hysterectomy.

Techniques of managing the postoperative bladder have varied widely. Duration of catheter drainage, suprapubic versus transurethral drainage, the value of self-catheterization, and the value of cystometric studies have all been debated, as described by Bandy and coworkers. These authors also found that patients receiving postoperative adjunctive pelvic radiation had significantly more contracted and unstable bladders than patients treated with surgery alone. Proper management of the bladder in the first several weeks after operation is essential to avoid overdistention. The duration of postoperative bladder catheterization

has decreased in recent years. Chamberlin and investigators reported a contemporary median indwelling catheter duration of 6 days compared with 30 days in historical controls, with no increase in complication rates.

Although some clinicians leave an indwelling catheter or suprapubic tube in place 2 to 3 weeks, we prefer continuous transurethral catheter drainage until 7 days after surgery. Early postoperative intravenous pyelography (IVP) in the absence of intraoperative urinary tract injury or clinical symptoms suggestive of injury is not indicated; moreover, an abnormal early IVP is not predictive of subsequent urinary tract dysfunction. When the catheter is removed, postvoid residuals are checked with a bladder ultrasound scan (transurethral catheterization also can be used). If the postvoid residual volume is below 50 to 75 mL and the volume of urine spontaneously voided is greater than the postvoid residual, then the patient is allowed to leave the hospital without an indwelling catheter. She must be thoroughly schooled in the importance of not allowing her bladder to become overdistended. Allowing the bladder to overdistend, especially in the early postoperative recovery period, can result in a flaccid bladder from stretching and decompensation of the detrusor muscle, prolongation of bladder dysfunction with high residual urine volumes, and the likelihood of urinary infections. Patients who have unacceptable postvoid residuals are best managed with intermittent self-catheterization or prolonged indwelling catheter drainage for several weeks before attempting removal. If a serious episode of overdistention of the bladder ever occurs, continuous indwelling catheter drainage should be reinstituted, sometimes for 1 to 2 weeks, with the hope that permanent impairment of bladder function can be avoided. Urinary tract infections can occur in conjunction with bladder dysfunction and should be looked for with periodic urinalysis and culture and treated with appropriate antibiotics. Patients should be encouraged to maintain a urine output above 2,000 mL per day to avoid urinary tract infection.

In most patients, a satisfactory voiding pattern can be established within several months. Urodynamic studies, however, can show some evidence of slight and persistent chronic bladder dysfunction for several years. Fraser stated that 20% of his patients continued to report changes in bladder sensation 5 to 15 years after operation. In many patients who have had properly performed radical hysterectomy and pelvic lymphadenectomy, it is inevitable that bladder function will never be completely normal again. With proper postoperative bladder care and rehabilitation, however, function should be satisfactory in most patients at the end of the first year. According to Fishman and coworkers, 35% of patients continued to express unhappiness at the extent and effect of their postoperative urinary dysfunction.

Vesicovaginal Fistula

In the absence of prior pelvic irradiation, bladder ischemia and vesicovaginal fistula are infrequent complications of this procedure. Vesicovaginal fistulae occur in less than 1% of patients (Table 51.12). Nearly one third of urinary tract fistulae following surgery heal spontaneously, compared with none if adjuvant radiation therapy is given. The management of vesicovaginal fistulae is discussed in Chapter 39.

Ureter

Clark, working at the Johns Hopkins Hospital, published one of the first descriptions of radical hysterectomy for cervical cancer in 1895. Sampson, working in the same institution during the same time, recognized that injury to the ureter was the most serious problem associated with primary radical surgery for this disease. His publications on ureteral anatomy and blood supply and the relation between the ureter and gynecologic disease are classic and pertinent today. Devascularization and ischemic necrosis of the wall of the terminal ureter has proven to be one of the more serious complications of this operation. Wertheim found this complication to be one of the more serious sequelae. In Meigs's clinic, there was a 12.5% significant ureteral complication rate, including an 8.5% incidence of ureterovaginal fistulae and a 4% incidence of ureteral stricture.

For many years, gynecologic surgeons have attempted to lower the rate of ureteral complications with special techniques. Novak, from Yugoslavia, reduced the incidence of ureteral fistulae to 2% after primary radical surgery by placing the dissected pelvic ureter on the inside (peritoneal surface) of the pelvic peritoneum and by preserving the lateral mesentery to the terminal ureter. Green and coworkers suggested that the terminal ureter should be lifted out of the accumulated fluid in the retroperitoneal space by suturing it to the obliterated hypogastric artery. Ohkawa developed a procedure that attempted to elevate and isolate the ureter from the infected retroperitoneal fluid and also to develop a new blood supply to the terminal ureter by placing it in a peritoneal envelope from the pelvic brim to the bladder. Blythe and coworkers compared this technique with simple retroperitoneal suction drainage first advised by Symmonds and Pratt. They found that ureteral obstruction and ureterovaginal fistulae occurred twice as often and that the operative time was extended 45 minutes to 1 hour with the Ohkawa technique. More recently, Patsner and others have recommended the routine use of the omental J-flap (omentopexy) at the conclusion of radical hysterectomy and pelvic lymphadenectomy as an effective means of minimizing urinary tract fistulae.

Given a normal unirradiated ureter, we believe that the incidence of ureteral fistulae and permanent stenosis can be kept below 1% with meticulous intraoperative management of the ureter by a technically skillful operator who can prevent vascular trauma to the periureteral sheath and injury to the muscularis of the ureter.

P.1244

Some temporary postoperative changes in ureteral function are an almost inevitable result of radical hysterectomy, as pointed out by Gal and Buchsbaum. Using special static and cinefluoroscopic IVP techniques, these authors found ureteral dilation in 87% of patients in the first week after surgery. In most cases, by 6 weeks after surgery, the dilation had regressed and the pyelograms had returned to normal. Peristalsis was altered in the distal ureter, which appeared as a rigid conduit during the first postoperative week. Peristalsis had returned 1 month later. These changes may explain the increased frequency of urinary tract infections after radical hysterectomy, and the possibility of permanent ureteral stenosis if radiation, serious infection, or lymphocyst formation is superimposed.

Table 51.12 shows the frequency of urinary fistulae in a collected series of 7,473 nonirradiated patients treated by radical hysterectomy as compiled by Shingleton and Orr. The management of ureterovaginal fistulae is discussed in [Chapter 39](#).

Lymphocyst Formation

Traditionally, a closed system of constant suction was placed in the retroperitoneal spaces on each side at the end of the procedure. These drains were thought to be effective for reducing the risk of pelvic infection, fistula, and lymphocyst formation. However, recent retrospective and prospective studies have demonstrated that the incidence of these complications is not decreased in patients who have retroperitoneal drains placed compared with those who do not. Furthermore, the drains may actually increase infectious complications. Therefore, we do not routinely place drains in the retroperitoneal spaces.

Whether drains are placed or not, a small percentage of patients will develop lymphocysts. A lymphocyst becomes obvious by symptoms and examination in the weeks after radical hysterectomy and pelvic lymphadenectomy. It may be small and asymptomatic. Most patients with large lymphocysts report lower abdominal discomfort on the same side with radiation to the back, hip, or thigh. Some edema of the lower extremity on the same side may be present and mistaken for postoperative chronic lymphedema due to nodal dissection, but it is more likely due to acute pressure obstruction of lymphatics with the large sidewall lymphocyst and may improve after cyst drainage. Evidence of ureteral obstruction may be found on IVP or CT urogram.

Small lymphocysts that do not cause ureteral obstruction can be observed without treatment. Large symptomatic lymphocysts and those that cause ureteral obstruction should be aspirated. CT-directed needle aspiration can be done with local anesthesia and repeated as needed. The fluid should be submitted for cytologic examination and culture. It is seldom necessary to perform open drainage of a lymphocyst. Mann and coworkers reported successful sclerosis of a recurrent lymphocyst by injection of a solution of tetracycline. Others have used povidone-iodine sclerosis.

Infection

Historically, patients were treated with antibiotics only if postoperative infection occurred. However, antibiotic prophylaxis has been associated with decreased febrile morbidity and decreased rates of serious infection in women undergoing radical abdominal hysterectomy. Furthermore, Orr and colleagues have demonstrated that a single dose of prophylactic antibiotic is as effective as a multiple-dose regimen and lessens patient exposure and cost. Thus, the prophylactic use of broad-spectrum antibiotics with both aerobic and anaerobic coverage has proved to be a useful addition to the surgical armamentarium.

We initiate single-agent broad-spectrum antibiotic coverage immediately before surgery. The administration of the drug is timed to allow adequate distribution before incision. During an extended operation, if the antibiotic given has a short half-life, a second dose is administered.

When secondary infection occurs despite the use of prophylactic antibiotics, the appropriate cultures are obtained, and bacteria-specific antibiotic therapy is chosen.

Venous Thrombosis and Pulmonary Embolus

Patients who undergo radical pelvic surgery fulfill the components of Virchow's triad and are at high risk for the development of venous thrombosis of the lower extremities and thromboembolic phenomena. Factors such as postoperative alteration of blood coagulation, trauma to the vein wall, and venous stasis are recognizable features of this type of surgery. In particular, pelvic lymphadenectomy invariably produces some trauma to the vein wall during the mobilization of the vessel and resection of the adherent lymphatic tissue. One of the biologic effects of radical surgery is the occurrence of local tissue necrosis during healing. This results in the release of tissue thromboplastin into the circulation, which contributes to venous thrombosis by acceleration of the clotting mechanism. The release of thromboplastin from the intima of the vein wall also provides an excellent nidus for the formation of fibrin, particularly in an area of the venous system where there is alteration in venous flow with stagnation of blood. This is frequently seen behind the valves of the veins of the lower extremity, where silent thrombosis is common. Prolonged immobilization of the lower extremities during a lengthy operative procedure is responsible for intraoperative venous stasis and clot formation. There is evidence to document that postoperative thrombosis of the lower extremity is a result of the surgical procedure in more than 50% of cases. The prevention, diagnosis, and treatment of venous thromboembolic events are extensively discussed in another chapter.

Efforts to decrease the frequency of this complication initially used prophylactic low-dose heparin, 5,000 U subcutaneously, three times daily, beginning 2 hours before surgery, and given every 8 hours thereafter for the subsequent 5 postoperative days. By using perioperative heparin alone, the incidence of deep vein thrombosis in a study by Kakkar and associates was decreased from 24.6% in the untreated control group to 7.7% in the heparin-treated group of surgical cases. More impressive was the observation in a subsequent study by the same investigators that 16 patients in the control group, compared with only 2 patients in the heparin-treated group, were found on autopsy study to have died of acute, massive pulmonary embolism.

We use intermittent pneumatic calf compression beginning in the operating room and continuing whenever the patient is in bed until she is discharged. These compression boots are used not only in our patients undergoing radical hysterectomy but in all our patients undergoing major gynecologic surgical procedures. In very high-risk patients, we add prophylactic low molecular weight heparin.

Approximately 3% to 5% of patients with occult venous thrombosis of the lower extremities develop pulmonary emboli. Unfortunately, more than half of the cases of fatal pulmonary embolism occur in patients with silent venous thrombosis and without any clinical evidence of this complication before the acute pulmonary catastrophe. When evidence of

P.1245

venous thrombosis of the lower extremity is verified, full anticoagulation therapy is required for prevention of pulmonary embolism. However, the decision about how soon after radical surgery it is safe to fully anticoagulate a patient may be very difficult. In the rare case that a pulmonary embolus occurs after full anticoagulation has been achieved, it is necessary to prevent further migration of clot to the lung by either inferior vena cava ligation or the use of an intracaval Silastic umbrella. These complications are rare, but the sinister effects of thromboembolism must be carefully evaluated on a daily basis, and a high index of suspicion needs to be maintained in this high-risk group of patients.

Hemorrhage

Intraoperative and postoperative pelvic hemorrhages also are discussed in another chapter.

Intraoperative Bleeding

Despite the surgeon's adequate technical skills and careful dissection, serious hemorrhage can suddenly appear, especially during retroperitoneal dissections on the lateral pelvic sidewalls and around the sacrum. When it happens, it is hoped that the operative field will not be cluttered with clamps; exposure, lighting, and suction will be adequate; the patient's condition will be stable; and anesthesia will be sufficient to maintain good relaxation. If the bleeding vessel cannot be clamped quickly, the simplest and most effective method of controlling the bleeding is provided by pressure applied by the index finger of the gloved hand. With cessation of bleeding, the operative site can be cleared of accumulated blood by suctioning, exposure of the area can be improved, and the surgeon can gain a few moments to evaluate the situation and choose the best possible course of action. Arterial bleeding is easy to identify and control with clips, clamps, or ligatures. The difficult problem with hemorrhage in the pelvis comes from lacerations of deep pelvic veins that are fragile, tortuous, distended, sometimes hidden or retracted from view, and sometimes held open by attachment of the vein wall to surrounding tissue. Blood returning through the lacerated vein can come from multiple sources unavailable for ligation. Placing clamps or sutures blindly is dangerous and can even make the problem worse. Sometimes, digital pressure for at least 5 minutes is the most effective procedure to control venous bleeding. Sometimes, additional careful dissection in the area is required to free the vessel above and below the bleeding point to allow more precise clipping or suture ligation. A cardinal rule in dissecting in the pelvis is to avoid creating a deep hole, the bottom of which cannot be exposed in case a deep vein is lacerated. This is the reason that dissection of the pararectal space, for instance, should not be forced if it does not develop easily.

Whenever an extensive pelvic dissection is anticipated, preparations should be made in advance in case severe intraoperative bleeding is suddenly encountered. Adequate quantities of blood should be available to replace lost volume. More blood should be requested in advance of its need, if possible. A responsible member of the operating team or anesthesia team should be assigned the task of monitoring blood loss, blood replacement, and urine output. When bleeding is profuse, in the excitement of the moment, it is possible to lose count of the number of units of whole blood, blood components, crystalloids, and other fluids that have been given and how much blood has been lost. A dependable route for administering blood must be maintained. Without it, rapid blood replacement is not possible. If massive hemorrhage occurs or if even a possibility of its occurrence exists, a Swan-Ganz or similar catheter should be placed for better monitoring of physiologic functions and blood replacement. In extreme cases in which no other vessels are available for rapid intraoperative blood volume replacement, transfusions can be given under pressure directly into the common iliac artery, with the needle pointed in the direction of the heart.

The most frequent site of troublesome intraoperative bleeding during radical hysterectomy occurs from the pelvic floor veins in the dissection of the cardinal ligament and the hypogastric vessels. The collateral venous circulation of the hypogastric veins is an ever-present source of potential hemorrhage owing to difficulty in identification of these vessels as they course among muscle bundles and fascial planes on the pelvic floor. The pararectal fossa, cardinal ligament, and presacral and paraaortic areas are frequent sites of venous bleeding. Therefore, meticulous dissection is important to avoid these complications. When venous bleeding does occur, it can be difficult to identify the site of the lacerated vein. In these circumstances, it is important to use compression of the pelvic floor veins by either a sponge stick or finger held in place for several minutes or to use an abdominal pack placed firmly against the site of bleeding for a similar

length of time. In these cases, it is advisable to keep pressure on the vein until full control of the bleeding has been established, in the meantime dissecting in other places in the pelvis. Only when the wall of a major pelvic vein has been severely traumatized and has retracted out of the operative field is there a serious problem in reestablishing hemostasis. In contrast to arterial bleeding, hemorrhage from deep pelvic veins is seldom improved by hypogastric artery ligation, owing to the extensive collateral venous circulation to the pelvis from the lower extremity and vena cava. It occasionally is beneficial to ligate the anterior division of both hypogastric arteries to determine whether interruption of the major arterial blood supply to the pelvis can reduce the venous bleeding. When more extensive trauma to the wall of the external or common iliac vein has occurred, it is necessary to place vascular clamps above and below the area of injury and to repair the defect with fine vascular sutures.

Postoperative Hemorrhage

This condition is a rare complication of radical pelvic surgery. Because all of the blood supply to the pelvis has been skeletonized as part of the operative procedure, it is exceedingly rare for secondary hemorrhage to occur unless there has been uncontrolled bleeding at the completion of the operation. In these cases, the pelvis usually is packed with multiple gauze packs, with one end exteriorized through the open vagina. Tamponade of the pelvis by means of an umbrella or parachute gauze pack and external ring (see [Chapter 19](#)) has been advocated by some when there is persistent venous oozing in the pelvis at the completion of the operation. Pelvic packs should be advanced within 24 to 48 hours and removed shortly thereafter to avoid ascending infection from the vagina. In certain cases of postoperative hemorrhage, selective embolization by invasive radiographic techniques can prevent reoperation.

Neuropathies

Nerve injury with radical hysterectomy was reviewed by Hoffman and coworkers, who reported its infrequent occurrence. The most important injuries are to the femoral, obturator,

P.1246

peroneal, sciatic, genitofemoral, ilioinguinal, iliohypogastric, lateral femoral cutaneous, and pudendal nerves. Awareness of the anatomic location of these nerves in the operative field, careful surgical technique in dissection and securing hemostasis, careful placement of self-retaining retractors, and careful positioning of patients in stirrups prevent most nerve injuries. Fortunately, most nerve injuries are not associated with serious or permanent disability. However, injury to the obturator nerve can lead to difficulty with adduction of the lower extremity. Obturator nerve injuries are the most common neurologic injuries, and they occur most frequently during the removal of the obturator lymph nodes from the obturator fossa. If the nerve is transected, it should be repaired as described by Vasilev.

Rectum

Although much less frequently reported than bladder dysfunction, both acute and chronic rectal dysfunction may occur following radical hysterectomy. The rectal dysfunction is characterized by difficulty with defecation and loss of defecation urge and constipation. Barnes and associates reported that postoperative anorectal manometry studies were abnormal in all patients studied, suggesting disruption of the spinal reflex arcs controlling rectal emptying, possibly secondary to partial denervation of the rectum. Nerve-sparing radical surgery will hopefully abbreviate and reduce the burden of this complication. Dietary fiber modifications and rectal stimulation with suppositories over several weeks or months are effective in addressing these problems.

ADJUVANT THERAPY IN CONJUNCTION WITH RADICAL SURGERY

Postoperative Pelvic Irradiation

External beam radiation therapy is used in the postoperative period as an adjunct to radical abdominal hysterectomy and bilateral pelvic lymphadenectomy in selected cases. It is given selectively to patients considered to be at high risk for persistent disease based on operative findings and careful study of the surgical specimens. Previously, if only one or two lymph nodes showed micrometastases, postoperative irradiation may not have been given. However, when several nodes are involved, the risk of persistent disease is greater, and postoperative irradiation is usually given; it can be extended as high as T12 if proximal common iliac or paraaortic nodes are involved with metastatic disease. However, nodal metastasis is not the only risk factor for recurrence, and other local tumor-related factors may be indicators of high-risk tumors that may warrant adjuvant radiation therapy.

Sedlis and associates—in a GOG randomized trial of pelvic radiation therapy versus no further therapy in selected patients with stage IB carcinoma of the cervix with negative lymph nodes after radical hysterectomy and pelvic lymphadenectomy—evaluated the benefits and risk of adjuvant pelvic radiation therapy aimed at reducing recurrence in this group of patients. In this study, 277 eligible patients were entered with at least two of the following tumor-related risk factors: greater than one-third stromal invasion, capillary lymphatic space involvement, or large clinical tumor diameter. [Table 51.13](#) summarizes the eligibility criteria: Of the 277 patients, 137 were randomized to pelvic radiation therapy and 140 to no further treatment. Twenty-one patients (15%) in the radiation therapy group and 39 (28%) in the no-further-treatment group had a cancer recurrence, 18 and 27 of which were vaginal/pelvic, respectively. Life table analysis indicated a statistically significant (47%) reduction in risk of recurrence (relative risk = 0.53, $p = 0.008$, one tail) among the radiation therapy group, with recurrence-free rates at 2 years of 88% versus 79% for the radiation therapy and no-further-treatment groups, respectively. Toxicity was generally acceptable, with severe or life-threatening urologic adverse effects occurring in four (3.1%) in the radiation therapy group and two (1.4%) in the control group. The authors concluded that adjuvant pelvic radiation therapy following radical surgery in selected women with stage IB cervical cancer reduces the number of recurrences at the cost of 6% grade 3 and 4 adverse events versus 2.1% in the control group.

TABLE 51.13 Eligibility Criteria for Radiation Therapy after Radical Hysterectomy in Node-Negative Patients (Sedlis Criteria)

CLVI	STROMAL INVASION	TUMOR SIZE (CM)
+	Deep one third	Any
+	Middle one third	≥2
+	Superficial one third	≥5

From Sedlis A, Bundy BN, Rotman MZ, et al. A randomized trial of pelvic radiation therapy versus no further therapy in selected patients with stage IB carcinoma of the cervix after radical hysterectomy and pelvic lymph adenectomy: a Gynecologic Oncology Group Study. *Gynecol Oncol* 1999;73:177-183, with permission.

Many physicians use these data to identify node-negative patients with local cervical risk factors following radical hysterectomy and pelvic lymphadenectomy to prescribe adjuvant radiation therapy.

If invasive cervical cancer is unexpectedly found after a simple hysterectomy has been done, postoperative pelvic radiation therapy is recommended. Survival rates in these patients have improved with the advent of megavoltage irradiation, as reported by Andras and coworkers, Davy and coworkers, and Papavasiliou and coworkers. Heller and coworkers reported 35 patients with invasive cervical carcinoma discovered in uteri removed for benign conditions. All patients received postoperative radiation therapy; patients with presumed stage IB disease had a corrected 5-year survival rate of 78%, and those with presumed stage IIB disease had a corrected 5-year survival rate of 67%.

Postoperative Adjuvant Chemoradiation

After radical surgery in high-risk, early-stage cancer of the cervix, Peters and colleagues reported a phase III trial of adjunctive concurrent chemotherapy and pelvic radiation therapy compared with pelvic radiation therapy alone. In all, 243 assessable patients with clinical stage IA (2), IB, and IIA carcinoma of the cervix, initially treated with radical hysterectomy and pelvic lymphadenectomy, and who had positive pelvic lymph nodes and/or positive margins and/or microscopic involvement of the parametrium were evaluated. Patients were randomized to receive platinum-based chemoradiation or radiation only. Patients in each group received 49.3-Gy

P.1247

radiation therapy in 29 fractions to a standard pelvic field. Chemotherapy consisted of cisplatin 70 mg/m² and a 96-hour infusion of fluorouracil 1,000 mg/m² day every 3 weeks for four cycles, with the first and second cycles given concurrent to radiation therapy.

Progression-free and overall survivals were significantly better in women receiving chemoradiation. The projected progression-free survival at 4 years was 63% with radiation therapy alone and 80% with chemoradiation. The projected overall survival rate at 4 years was 71% with adjuvant radiation therapy and 81% with adjuvant chemoradiation. However, grade 3 and 4 hematologic and gastrointestinal toxicity were more frequent in the chemoradiation group.

The authors concluded that the addition of concurrent cisplatin-based chemotherapy to radiation significantly improves progression-free and overall survival for high-risk, early-stage patients who undergo radical hysterectomy and pelvic lymphadenectomy for carcinoma of the cervix and are found to have positive pelvic lymph nodes and/or positive margins and/or microscopic involvement of the parametrium. Although the data from this study are compelling, use of this regimen should be undertaken only with understanding of the toxicities encountered.

The data from this randomized trial and the Sedlis trial currently provide practical guidelines for eligibility of patients for adjuvant chemoradiation following primary radical hysterectomy or trachelectomy and pelvic lymphadenectomy.

Postoperative Extended-Field Irradiation or Chemoradiation

In selected cases, with multiple positive pelvic nodes, metastasis to common iliac nodes, or aortic nodal metastasis, patients are treated with pelvic and extended-field radiation to include the paraaortic lymph chain. To numerous previous studies can be added two studies from Japan that describe the results of paraaortic nodal irradiation in the treatment of cervical cancer. Inoue and Morita (1988) administered extended-field radiation after extensive surgery to 76 patients with aortic nodal metastases. Two patients developed severe intestinal complications that required reoperation. Postoperative extended-field irradiation improved the survival rate of patients with four or more positive nodes from 39% to 69% as well as the survival rate of patients with unresectable nodes from 0% to 44%. The authors concluded that postoperative extended-field irradiation can control the distant spread by way of lymphatic routes and can increase the survival time of patients. In addition, 86 patients with cervical cancer were treated with paraaortic nodal irradiation by Horii and coworkers (1988). None of the patients developed severe complications from the treatment. Based on their selection criteria for paraaortic nodal irradiation, the authors found a statistically significant improvement in the prognosis for the treated group.

In 1987, Jones reported on a collected series of 332 patients with paraaortic lymph node metastases who received extended-field radiation. Twenty-six percent were long-term survivors. Although it is true that most patients with positive paraaortic lymph nodes die of their disease (probably because systemic disease is already present), it also is clear that some patients are curable with extended-field radiation or chemoradiation, especially if the nodes are involved with only microscopic disease. The surgeon must anticipate a 10% incidence of enteric complications even with doses limited to 5,000 cGy. Again, micrometastatic disease is more likely to be eradicated by a dose of paraaortic radiation that can be tolerated by the patient. Patients with paraaortic nodes that contain a large volume of tumor are not likely to be cured, even with a dose of paraaortic radiation that exceeds 5,000 cGy, unless the bulky nodes are excised before the irradiation.

Extended-field chemoradiation also may be used. The GOG reported on a multicenter trial of chemoradiation therapy to evaluate the feasibility of extended-field radiation therapy with 5-fluorouracil (5-FU) and cisplatin and to determine the progression-free interval, overall survival, and recurrence sites in patients with biopsy-confirmed paraaortic node metastases from cervical carcinoma. In all, 86 evaluable stage I to IV patients with aortic metastases were reported. Radiation therapy doses were 4,500 cGy to paraaortic nodes, and concomitant chemotherapy consisted of 5-FU 1,000 mg/m² per day for 96 hours and cisplatin 50 mg/m² in weeks 1 and 5.

Initial sites of recurrence were pelvis alone, 20.9%; distant metastases only, 31.4%; and pelvic plus distant metastases, 10.5%. The 3-year overall and progression-free survival rates were 39% and 34%, respectively, for the entire group. Overall survival was stage I, 50%; stage II, 39%; and stage III/IVA, 38%.

GOG grade 3 and 4 acute toxicity was gastrointestinal (18.6%) and hematologic (15.1%). Late morbidity actuarial risk of 14% at 4 years primarily involved the rectum. The authors concluded that extended-field radiation therapy with 5-FU and cisplatin chemotherapy was feasible in a multicenter clinical trial, that a progression-free survival of 33% at 3 years suggests that a proportion of patients achieve control of advanced pelvic disease, and that not all patients with paraaortic metastases have systemic disease. This points to the importance of assessment and treatment of paraaortic metastases.

Adjuvant Postoperative Chemotherapy

Few studies of adjuvant chemotherapy following radical hysterectomy have been done. Wertheim et al. from Memorial Sloan Kettering Cancer Center in 1985

reported on a pilot study of adjuvant chemotherapy with cisplatin and bleomycin and pelvic radiation therapy in patients with cervical cancer at high risk of recurrence after radical hysterectomy and pelvic lymphadenectomy.

The continuous disease-free survival rate for the 32 evaluable patients was 84% at a median follow-up time of 28 months. In addition, the complications of this treatment program were not significantly greater than those observed in prior studies using the combination of surgery and adjuvant radiation therapy without chemotherapy. When compared with the results from historical controls in a large series of similar patients at the same institution, the results in this pilot study were encouraging and appeared to justify a randomized prospective clinical trial.

Two randomized trials have attempted to clarify the role of adjuvant postoperative chemotherapy. In 1992, Tattersall and colleagues reported a randomized trial comparing standard pelvic radiation therapy versus three cycles of combination chemotherapy with cisplatin, vinblastine, and bleomycin followed by pelvic radiation therapy. No difference in disease-free or overall survival emerged between the two treatment groups. Relapse was more common in patients with nonsquamous tumors (44%) and in those with metastases in several pelvic lymph nodes.

In 1996, Curtin et al. from MSKCC reported on a prospective multicenter randomized phase III trial of adjuvant chemotherapy versus chemotherapy plus pelvic irradiation for

P.1248

high-risk stage IB to IIA cervical cancer patients after radical hysterectomy and pelvic lymphadenectomy. The objective was to compare the clinical efficacy of adjuvant chemotherapy alone versus chemotherapy plus whole pelvic radiation therapy on recurrence rates, patterns of recurrence, and survival of patients after radical hysterectomy and pelvic lymphadenectomy for cervical cancer at high risk for recurrence.

Risk factors included deep cervical invasion, tumor greater than 4 cm, parametrial involvement, nonsquamous histology, and/or pelvic lymph node metastasis. Chemotherapy consisted of cisplatin and bleomycin alone or in combination with whole pelvic radiation therapy. Eighty-nine patients were entered, 19 had recurrences, and 16 died. Nine of 44 (20%) patients receiving chemotherapy alone recurred compared with 10 of 45 (22%) patients receiving chemotherapy and radiation ($p = \text{NS}$). Patterns of recurrence were statistically similar between the two treatment arms, even among the subgroup of patients with more than three risk factors. In addition, both regimens were well tolerated. The authors concluded that recurrence rates and patterns of recurrences (local, regional, or distant) were not influenced by the addition of radiation therapy.

However, in view of the more recent randomized trial of adjuvant chemoradiation, most high-risk patients with nodal metastasis will probably be offered adjuvant platinum-based chemoradiation. Whether weekly cisplatin or other platinum-based regimens are the optimal choice remains to be determined.

FOLLOW-UP AFTER RADICAL SURGERY FOR CERVICAL CANCER

Despite carefully planned and executed radical surgery for early-stage cervical cancer, 5% to 20% of patients in various series show evidence of recurrent or persistent tumor. About half occur in the first year after treatment. Almost all occur within the first 3 years. Few occur later. Recurrences many years later are extremely rare after primary surgical treatment and are more likely to be seen in patients treated with primary radiation therapy.

Persistent or recurrent disease after primary radical surgery may represent incomplete resection of the central tumor undetected at operation or by the pathologist's examination of the surgical specimen. Microscopic metastatic involvement of lymph nodes may be undetected by incomplete pathologic examination, or these nodes may be left behind by incomplete lymphadenectomy. Viable tumor cells in small numbers may escape by way of lymphatics or vascular channels to distant sites and overcome host resistance. Probably in as many as 10% of patients with persistent disease, recurrence may result from continued growth of unrecognized intraperitoneal spread of tumor.

After the immediate postoperative recovery is completed, patients are scheduled for regular follow-up examinations, which vary depending on circumstances. Patients who are at greater risk for recurrence should be followed especially closely at frequent intervals. These usually are the same patients who have been given postoperative therapy, including patients with metastatic disease in lymph nodes and/or parametria, close surgical margins, large-volume cervical tumors, deep cervical stromal invasion, and lymphatic and/or vascular channel involvement. The frequency of examination varies somewhat from patient to patient. Most patients are seen every 3 to 6 months during the first 3 years after primary treatment, every 6 months during the 4th and 5th years, and annually thereafter. Patients are instructed to immediately report unusual signs or symptoms (e.g., vaginal bleeding or discharge, leg swelling or discomfort, discomfort in the pelvis, difficulty with urination or defecation, enlarged neck or groin nodes). Krebs and coworkers, however, reported that 25% of their patients did not have symptoms when persistent disease was diagnosed. In the study reported by Larson and coworkers, 37% did not have symptoms.

A follow-up examination should include palpation of the neck for enlarged lymph nodes, abdominal and leg examination, and a speculum and bimanual rectovaginal pelvic examination. A vaginal cytology smear is performed with each visit. Computed tomography or MRI scan of the abdomen and pelvis, PET scan, proctosigmoidoscopy, cystoscopy, and biopsy (needle, punch, or both) of any suspicious lesions may be required, depending on the patient's symptoms and examination findings. These special diagnostic procedures are not done routinely as part of postoperative follow-up surveillance in patients without symptoms. Positive findings are rare, unless the patient has symptoms. For example, IVP seldom shows ureteral obstruction in a patient who does not also have symptoms of persistent pelvic sidewall disease and is, therefore, not routinely done at specific intervals. It is in the patient's best interest to have follow-up examinations done in the same center in which her treatment was administered. Findings at each visit must be compared with previous information all the way back to her original presentation.

Soisson and coworkers reported a comparison of symptoms, physical examination, and vaginal cytology in the detection of recurrent cervical carcinoma after radical hysterectomy. The study group consisted of 203 women with stage IB and IIA cervical cancer followed at the Duke University Medical Center. Thirty-one (15%) patients developed recurrence. For the detection of recurrent tumor, vaginal cytology had a sensitivity and specificity of 13% and 100%, pelvic or general physical examination 58% and 96%, and the presence of suspicious symptoms 71% and 95%, respectively. Ninety-four percent of all patients with recurrent tumor had at least one abnormal surveillance index. Another Duke study by Weber and associates found that MRI correctly demonstrated the extent of recurrence in 18 of 21 cases.

Regular pelvic examinations and vaginal cytology smears may detect a central pelvic recurrence early. This can be a great advantage. Just as it is important to detect the original cancer in the earliest stage possible so that the patient can have the best possible chance of cure, it also is important to detect persistent disease at the earliest possible moment for the same reason. For example, Jobsen and coworkers reported on the use of radiation therapy to treat local-regional recurrence of carcinoma of the cervix after primary surgery. The overall 5-year survival rate was 44%. Response to radiation therapy was strongly correlated with tumor volume, providing additional supportive evidence to the idea that persistent disease should be diagnosed as early as possible and, it is hoped, when the volume of persistent tumor is still small and responsive.

Patients with recurrent or persistent cancer of the uterine cervix after initial radiation therapy can have radical surgery provided the disease is limited and judged

to be surgically resectable. Usually, some type of pelvic exenteration is required to resect the recurrent tumor with negative margins. In carefully selected patients with centrally recurrent disease, 5-year survivals of 40% to 60% have been reported. Pelvic exenteration is discussed in another chapter.

Tumor ulceration in the upper vagina can produce vaginal discharge and spotting, a palpable tumor mass, and induration and nodularity of tissue extending to the pelvic sidewalls. Pain may not be present unless the tumor involves nerve roots. Symptoms related to urination and defecation can result from pressure, infection, or tumor involvement of the bladder and rectum. Either unilateral or bilateral edema of the lower extremities or unilateral or bilateral hydronephrosis can be an ominous sign of persistent disease, but these also can be the result of a combination of the effects of radical surgery and postoperative irradiation. When initially diagnosed, recurrences are central in about one fourth of patients, involve the pelvic sidewall in one fourth, and involve distant sites in one fourth; the remaining one fourth of patients have multiple sites of involvement.

Approximately 20% to 25% of patients with recurrence after primary radical surgery still can be cured. The best chance of cure is in patients who had no postoperative radiation treatment and no metastatic disease to pelvic lymph nodes and in whom persistent disease is limited to the central pelvis. A combination of total pelvic irradiation plus vaginal brachytherapy can be effective in controlling the disease. The addition of concurrent platinum-based chemotherapy also should be considered.

Chemotherapy can be given for palliation when there is evidence of unresectable persistent disease in the pelvis in patients who have already received postoperative pelvic radiation or when there is metastatic disease in distant sites.

Because recurrence or persistence of cervical cancer after treatment is difficult but important to detect as early as possible, attempts have been made to use a serum marker that would monitor the course of the disease. Kato and Torigoe isolated a squamous cell carcinoma antigen from cervical carcinoma tissue. A squamous cell carcinoma antigen radioimmunoassay kit developed by Abbott Laboratories (Abbott Park, IL) has been tested, but the role of this antigen in the follow-up of patients with cervical carcinoma is yet to be determined.

Although the early detection of persistence is the primary purpose of and justification for follow-up visits, assessment of urinary tract function also is important. Particular attention should be paid to bladder function and maintaining a satisfactory voiding pattern. Urinary tract infection should be diagnosed and treated promptly. If ureteral stenosis impairs renal function, early intervention can be successful in avoiding nephrectomy. This is more likely to be seen in patients who receive a combination of radical surgery and irradiation as primary treatment.

Rehabilitation of sexual function after surgical therapy for cervical cancer usually is easily done by the patient and her partner but is more difficult if the vagina and paravaginal tissues have received heavy doses of radiation or if the patient has lost ovarian function as a result of treatment. The gynecologic surgeon should inquire about sexual problems and should give advice and permission when needed. Counseling, including instruction in the technique of alternative means of sexual gratification, may be needed. If ovarian function has been lost as a result of treatment, estrogen replacement therapy should be provided, even though symptoms of hypoestrogenism are not present. If normal ovaries were conserved, their function should be monitored with periodic follicle-stimulating hormone and estrogen levels so that estrogen replacement can be discussed when ovaries cease functioning in future years. There may be other contraindications to estrogen replacement therapy in patients treated for cervical cancer, but a history of treatment for cervical cancer is not one of them.

And finally, patients who have been treated for cervical cancer are at greater risk for developing other primary cancers at different sites, especially if their treatment included irradiation. Detection of other primary cancers should be part of posttreatment follow-up. This subject has been studied by Hoffman and coworkers, Buchler, and others. Axelrod and coworkers reported that 3.9% of patients with invasive cervical cancer had second primaries. In 1987, Arneson and Kao reported that 61 new primary cancers were detected among 718 patients with invasive cervical cancer who had been studied from 1955 to 1979.

RADIATION THERAPY

Although radical hysterectomy is generally recommended for women with early-stage cervical cancer who can tolerate the surgery, women with stage IIB or more advanced disease are usually treated with radiation therapy. Radiation is also appropriate for women who are poor surgical candidates because of medical conditions or age.

Ionizing radiation can destroy tumor and cure cancer effectively. Radiation therapy for cervical cancer is usually delivered by two techniques. *Intracavitary therapy* or *brachytherapy* is administered by placing a radioactive element— such as radium, cesium, or iridium—in close contact with the tumor. This produces a very effective, high-dose local treatment, but the dose rate delivered falls off very sharply as the distance away from the radioactive source increases. This is called “the inverse square law.” The radiation dose delivered to a given point is equal to 1 divided by the square of the distance away from the radiation source (dose = 1/distance²). Because of the rapid decrease in the dose, it is necessary to treat potential pelvic lymph node metastases and large primary cervical cancer with *external beam radiation*. This type of radiation was originally produced by modified diagnostic x-ray machines, but now, special high-energy linear accelerators or betatrons are used. These machines are capable of delivering a uniform dose of radiation across the whole pelvis or even an extended field to include the paraaortic lymph nodes.

The use of radiation for the treatment of cervical cancer followed very shortly after the discovery of radium by Marie and Pierre Curie. Beginning in 1903, several methods of intracavitary therapy were developed, including the Stockholm technique from the Radiumhemmet; the Paris technique, designed at the Curie Foundation; and the Manchester technique from England. The Stockholm radium technique consisted of high-intensity central irradiation, repeated two or three times within 3 weeks, whereas the Paris technique used low-intensity central irradiation, continuously delivered over 1 week. The Manchester technique, derived from the Paris method, used low-dosage rates that required at least two separate intracervical insertions of radiation sources. Other radioactive elements, including cesium and iridium, have replaced radium in central brachytherapy for cervical cancer.

The traditional brachytherapy systems for cervical cancer have been low-dose-rate systems delivering 0.4 to 2 Gy per hour, and typical implants have been of 24- to 72-hour durations. More recently, high-dose-rate systems have been employed capable of delivering dose rates of more than 0.2 Gy per minute, thereby allowing treatments of only a few minutes' duration and adaptable to the outpatient—rather than the inpatient—setting. A comparison of 5-year survival rates of the two systems by clinical stage documents the usefulness of the newer system (Table 51.14).

With the establishment of the roentgen as a defined unit of radiation exposure (Stockholm, 1921), it became possible to measure the quantity of irradiation delivered to the tumor. Although many clinicians are most familiar with the dosing measure of rads, modern therapy is calculated in grays (Gy) [1 Gy = 100 rads; 1 centigray (1 cGy) = 1 rad]. Highenergy, external beam radiation sources, ranging to 25 mV for the betatron and linear accelerator, have significantly reduced the complication rates after radiation therapy and have improved the cure rates. An intracavitary pelvic dosage derived from the gamma rays of radium or cesium is complementary to the megavoltage external beam irradiation to ensure tumoricidal dosages to the cervix, broad ligaments, and lateral pelvic walls. Extended fields of external radiation can deliver therapy to common iliac and aortic nodal tissues.

The balance between enough radiation to destroy the tumor and too much radiation (which results in damage to adjacent normal tissues such as the bladder,

vagina, or rectum) is sometimes difficult to achieve. It requires using the correct combination of brachytherapy with external radiation therapy. Treatment planning has been enormously improved in recent years because of the integration of imaging techniques (such as CT scanners) with computer programs that can calculate the dose to the tumor volume and adjacent normal tissues, which helps the radiation oncologist maximize the tumor dose while minimizing the damage to nearby organs.

Survival rates of irradiation and primary surgery can be compared by analyzing the reports from patients treated for stage I cervical cancer. Patients treated by irradiation have an average 5-year survival rate essentially identical to the survival rate for those who undergo radical surgery (Table 51.15).

In the United States, radical hysterectomy generally is recommended for women with stage IA2 and IB1 cervical cancer who are good operative risks, especially if they are premenopausal. Women with larger tumors and those who are at risk for surgical complications generally are referred for radiation therapy.

SUMMARY

Many improvements have been made in the operative technique of the radical hysterectomy and lymphadenectomy since its original description. The incidence of complications after this procedure has decreased during the past 75 years, and the survival rates have increased. The operation has achieved its peak of clinical usefulness during this period and is now considered the principal method of treatment of early invasive carcinoma of the cervix. Among the better surgical institutions, the meticulous execution of this operative procedure has reduced the incidence of complications to an acceptable and infrequent occurrence. In medical centers in which the operation is performed well, the 5-year cure rate for stage IB1 carcinoma of the cervix is greater than 90%. Newer laparoscopic approaches are gaining acceptance, with comparable cure rates and the potential to retain fertility in carefully selected patients. Radical trachelectomy has proven safe and effective for selected patients with stage I tumors who wish to preserve their fertility.

Comparative studies with primary radiation therapy have demonstrated an equal cure rate with primary radical surgery in the treatment of early-stage disease. However, the complications of irradiation are more difficult to manage than are those of primary surgery. In young women, when preservation of

P.1251

ovarian function is important, primary surgery is a preferable choice of treatment.

The major limiting factor in the long-term surgical cure of cervical cancer is related to the spread of the disease at the time of initiation of treatment. Historically, in cases in which pelvic lymph nodes were positive for metastatic tumor, the 5-year cure rate was reduced to approximately 60%. However, numerous recently reported prospective, randomized trials have demonstrated the benefit of concurrent chemotherapy and radiation therapy in various settings. In the management of high-risk patients after radical hysterectomy and pelvic lymphadenectomy, including those with positive nodes, the reported 4-year disease-free survival is 80%.

It is important to understand that it is the individual surgical expertise that offers the highest cure rate and lowest incidence of complications to the patient with invasive carcinoma of the cervix. One of the greatest errors in clinical judgment is made by the gynecologist who attempts a radical hysterectomy and pelvic lymph node dissection without adequate surgical training and experience. Unless the pelvic surgeon is performing this type of surgery regularly in a well-staffed medical center with trained assistants, he or she would be well advised to refer the patient to an established cancer center. From the patient's point of view, the initial treatment, whether primary surgery or irradiation, provides the best chance for long-term cure of this disease. It would be to her advantage to have the treatment conducted in the most expert hands because secondary treatment for recurrent disease offers only limited potential long-term cure.

BEST SURGICAL PRACTICES

- Invasive cancer of the cervix is predominantly of squamous histology. Adenocarcinoma is increasingly common in many practices and now accounts for up to 20% to 50% of the lesions in some series. Adenosquamous, clear cell, and small cell neuroendocrine histology are seen infrequently. Tumor grade in squamous lesions is not prognostically significant, but grade may be important in adenocarcinoma lesions.
- Although most women with early-stage cancer are asymptomatic, patients with larger tumors may have vaginal discharge, vaginal bleeding (especially postcoital bleeding), and eventually pelvic or low back or hip pain. Leg edema and ureteral obstruction are signs of advanced disease.
- A careful and thorough staging workup should be done after a diagnosis is made. This evaluation of the extent of disease is very important for treatment planning and prognosis. FIGO staging should be used, but the metastatic workup should not be limited by FIGO's restrictive guidelines. MRI and PET scans provide very important information to guide treatment even though they are not part of the FIGO staging system.
- Patients with microinvasion (stage IA1) are generally treated with cone biopsy or simple hysterectomy. Patients with stage IA2 disease should be treated by radical hysterectomy or trachelectomy with pelvic lymphadenectomy. Most of these patients can be adequately treated by a modified radical hysterectomy (type B), but women with larger tumors and LVSI may benefit from a traditional (type C1) radical hysterectomy. Expert gynecologic pathology review is essential for correct diagnosis.
- In the United States, most women with stage IB1 and stage IIA cervical cancer are treated with radical surgery. Women with larger, higher-stage tumors are usually treated with radiation therapy plus adjuvant chemotherapy. Women who are poor surgical risks are also usually treated with radiation \pm chemotherapy. The main advantage of surgery compared with radiation is the preservation of ovarian function, which is most advantageous in younger patients. There is also less risk of upper vaginal stenosis and dyspareunia following surgery. Bladder and rectal dysfunction and, rarely, fistulae occur with both surgery and radiation. Surgical complications tend to occur in the perioperative period, whereas complications and side effects from radiation are often delayed and long lasting.
- Radical surgery for cervical cancer requires training, experience, and good ancillary support. This means well-trained operating room personnel; surgical assistants, and anesthesia staff, as well as adequate radiology, intensive care, and consulting physicians need to be a regular part of the patient care team.
- In a radical hysterectomy for stage IB cervical cancer, we do not routinely do a paraaortic lymphadenectomy, but any suspicious nodes are removed and sent for frozen section. The surgical procedure is usually abandoned if aortic lymph node metastases are identified.
- Radical hysterectomy for cervical cancer can be done using the classic abdominal approach, a vaginal approach (Schauta), or a total laparoscopic or robotic approach. There are advantages and disadvantages to each of these techniques, but overall survival appears to be similar. The basic technique is the same.
- Fertility-sparing radical trachelectomy with lymphadenectomy has become a standard of care in many practices. Women with stage IA and early IB1 tumors who wish to preserve fertility have been treated successfully, and the cure rates are comparable to radical hysterectomy. SLN mapping techniques for operable stage I cervical cancer are gaining popularity worldwide and have become a standard of care in many practices.

Chapter 52

Endometrial Cancer

Marta Ann Crispens

INTRODUCTION

The management of endometrial cancer has changed significantly over the last 40 to 50 years. During the 1970s, endometrial cancer was clinically staged. Patients with early-stage disease were treated with preoperative packing of the endometrial cavity with radiation sources, Heyman capsules, followed by hysterectomy. In 1988, the International Federation of Gynecology and Obstetrics (FIGO) approved a surgical staging system for endometrial cancer. This acknowledged the shift to surgery as primary therapy, with pelvic radiotherapy being used postoperatively as adjuvant therapy for women at increased risk for recurrence. The FIGO staging system for endometrial cancer was again revised in 2009 to reflect our improved understanding of the prognostic factors for this disease. The role of lymphadenectomy and postoperative radiotherapy in the treatment of patients with endometrial cancer remains controversial. Laparoscopic surgery, particularly robotic-assisted laparoscopy, is becoming more important in the treatment of this disease.

In 1983, J.V. Bokhman described two pathogenetic types of endometrial cancer. Type I tumors account for approximately 90% of endometrial cancers and are associated with exposure to unopposed estrogen from either internal or external sources. They are typically of endometrioid pathology, low grade, diagnosed at early stage, and have an excellent prognosis. Type II tumors are high grade and often have papillary serous or clear cell pathology. They tend to be diagnosed at a later stage, but have a poor prognosis even if diagnosed at an early stage. There is a clear difference in the molecular biology of these tumors. Type I tumors may be associated with a number of genetic changes, including microsatellite instability (20% to 45%), inactivation of the PTEN tumor suppressor gene (57% to 83%), PIK3CA mutation (up to 50%), PIK3R1 mutation (20% to 40%), EGFR overexpression (38% to 46%), E-cadherin loss (6% to 57%), mutational activation of the K-ras oncogene (22% to 43%), BAF250a loss (29% to 39%), and gain of function mutation of the β -catenin gene (14% to 47%). Type II tumors are characterized by aneuploidy. Overall, 9% to 54% of type II tumors exhibit inactivating mutations of p53 gene locus. However, in serous endometrial cancers, over 90% demonstrate p53 inactivation. Type II endometrial cancers may show other mutations, such as PIK3CA (30%), PIK3CA amplification (45%), HER2 amplification (17% to 50%), EGFR overexpression (35% to 56%), E-cadherin loss (41% to 87%), and BAF250 loss (18% to 26%).

EPIDEMIOLOGY

According to American Cancer Society (ACS) estimates, endometrial cancer remains the most common of the gynecologic malignancies in the United States, with 52,630 new cases anticipated in 2014. This makes it the fourth most common cancer occurring in women, behind only breast, lung, and colorectal cancer. It is estimated that there will be 8,590 deaths

P.1258

due to endometrial cancer in the year 2014. That most women with newly diagnosed endometrial cancer can expect a good prognosis is due to the fact that endometrial cancer is usually diagnosed at an early stage, when it is readily treatable with surgery alone. However, there remain a few patients with endometrial cancer who present with high-risk histologic subtypes or advanced stage disease, in whom the prognosis is more guarded.

Table 52.1 shows the stage distribution and survival of patients diagnosed with endometrial cancer from 1999 to 2001, as reported in the 26th annual FIGO report.

TABLE 52.1 Stage and Survival of Endometrial Cancer

STAGE	PATIENTS	5-YR SURVIVAL
I	70%	89.6%
II	13%	78.3%
III	14%	61.9%
IV	3%	21.1%

The 2009 FIGO staging system for endometrial cancer as described by Pecorelli et al. is shown in [Table 52.2](#). Tumor grade and depth of myometrial invasion are important prognostic features for endometrial cancer. In the 1988 surgical staging system, tumors confined to the uterine corpus had been divided into three groups: (a) those with no invasion, (b) those with less than 50% myometrial invasion, and (c) those with greater than 50% myometrial invasion. Because FIGO data demonstrated no significant difference in 5-year survival between patients with grade 1 or grade 2 tumor without myometrial invasion as compared to patients with grade 1 or grade 2 tumor with less than 50% myometrial invasion, these two groups were combined.

The 2009 FIGO staging system for endometrial cancer no longer upstages a patient for extension to the endocervical glands. Stage II tumors are now defined as those that invade the cervical stroma. Tumors involving the endocervical glands only are classified as stage I and subdivided according to the depth of myometrial invasion.

The 1988 FIGO staging system had defined patients with positive peritoneal washings as having stage IIIA disease. Positive peritoneal washings are associated with a worse prognosis only in patients with other adverse prognostic features. The presence of malignant cells in the peritoneal washings has been demonstrated not to be an independent adverse prognostic variable. Thus, it has been removed from the staging system. Peritoneal washings should still be performed and reported on every patient with endometrial cancer. Extension to the parametrium has been added to vaginal metastases in stage IIIB.

Stage IIIC previously encompassed metastases to the pelvic and/or paraaortic lymph nodes. Many studies suggest a worse prognosis with spread to the paraaortic lymph nodes. Thus, stage IIIC has been subdivided into IIIC1, pelvic lymph node involvement only, and stage IIIC2, paraaortic lymph node involvement with or without pelvic lymph node involvement.

TABLE 52.2 FIGO Staging of Carcinoma of the Corpus Uteri, 2009

Stage I	Tumor Confined to the Corpus Uteri
IA	No or less than half myometrial invasion
IB	Invasion equal to or more than half of the myometrium
Stage II	Tumor invades cervical stroma, but does not extend beyond the uterus

Stage III	Local and/or regional spread of tumor
IIIA	Tumor invades the serosa of the corpus uteri and/or adnexa
IIIB	Vaginal and/or parametrial involvement
IIIC	Metastases to pelvic and/or paraaortic lymph nodes
IIIC1	Positive pelvic lymph nodes
IIIC2	Positive paraaortic lymph nodes with or without positive pelvic lymph nodes
Stage IV	Tumor invades bladder and/or bowel mucosa and/or distant metastases
IVA	Tumor invasion of bladder and/or bowel mucosa
IVB	Distant metastases, including intraabdominal metastases and/or inguinal lymph nodes
Positive cytology has to be reported separately without changing the stage.	
Histopathology: Degree of Differentiation	
Grade 1	5% or less of a solid growth pattern
Grade 2	6%-50% of a solid growth pattern
Grade 3	More than 50% of a solid growth pattern
Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade 1 or grade 2 tumor by 1.	
Uterine papillary serous carcinomas and clear cell carcinomas of the endometrium are always high-grade tumors, by definition.	

Uterine sarcomas account for less than 10% of all uterine cancers. The more common histologic types of uterine sarcoma include leiomyosarcoma, endometrial stromal sarcoma, high-grade undifferentiated sarcoma, and adenosarcoma. Prior to the revision of the FIGO staging system in 2009, uterine sarcomas had been staged using the same staging system as endometrial cancers. However, uterine sarcomas and endometrial cancers have significantly different patterns of spread and prognostic features. In the revised 2009 staging system, FIGO introduced a separate staging system for uterine sarcomas ([Table 52.3](#)). Carcinosarcoma, also known as malignant mixed müllerian tumor, was previously classified as a sarcoma but is now understood to be a poorly differentiated endometrial carcinoma. Therefore, malignant mixed müllerian tumors are staged according to endometrial cancer staging system.

TABLE 52.3 FIGO Staging of Uterine Sarcomas, 2009*Leiomyosarcomas and ESS^a*

Stage definition

I	Tumor limited to uterus
	IA ≤5 cm
	IB >5 cm
II	Tumor extends beyond the uterus, within the pelvis
	IIA Adnexal involvement
	IIB Involvement of other pelvic tissues
III	Tumor invades abdominal tissues (not just protruding into the abdomen)
	IIIA 1 site
	IIIB >1 site
	IIIC Metastases to pelvic and/or paraaortic lymph nodes
IV	Tumor with
	IVA Bladder and/or rectum invasion
	IVB Distant metastases

Adenosarcomas

Stage definition

I	Tumor limited to uterus
	IA Tumor limited to endometrium/endocervix with no myometrial invasion
	IB ≤ half myometrial invasion

IC > half myometrial invasion

II Tumor extends beyond the uterus, within the pelvis.

IIA Adnexal involvement

IIB Involvement of other pelvic tissues

III Tumor invades abdominal tissues (not just protruding into the abdomen).

IIIA 1 site

IIIB >1 site

IIIC Metastases to pelvic and/or paraaortic lymph nodes

IV Tumor with

IVA Bladder and/or rectum invasion

IVB Distant metastases

Carcinosarcomas

Carcinosarcomas should be staged as carcinomas of the endometrium.

^a*Note:* Simultaneous endometrial stromal sarcomas of the uterine corpus and ovary/pelvis in association with ovarian/pelvic endometriosis should be classified as independent primary tumors.

RISK FACTORS

There are no clear risk factors for type II endometrial cancers. Type I endometrial cancers are usually related to exposure to unopposed estrogen, whether exogenous or endogenous. Risk factors for type I tumors are summarized in **Table 52.4**. Endometrial cancer incidence increases with age, until about 70 years, when rates begin to decline. Living in North America or Northern Europe is associated with an increased risk of endometrial cancer.

Reproductive factors are associated with an increased risk of endometrial cancer. Endometrial cancer risk is increased in women who are nulliparous or infertile or have menstrual irregularities. Early onset of menarche or late age at menopause is also associated with an increased risk of endometrial cancer.

Exogenous exposure, such as estrogen replacement therapy, has been shown to be associated with an increased risk of endometrial cancer in a number of studies. A meta-analysis that combined data from both case-control and cohort studies found a 2.3-fold increased risk of endometrial cancer among women who had ever used estrogen replacement therapy as compared to never users. The risk increases with increasing estrogen dose and increasing duration of estrogen use. In the same meta-analysis noted above, the relative risk of developing endometrial cancer rose to 9.5 among women who had used estrogen replacement therapy for 10 or

more years as compared to never users. The risk can be reduced by the concurrent use of cyclic or continuous progestin.

TABLE 52.4 Risk Factors for the Development of Endometrial Cancer

Increased risk

Increasing age

Residence in North America or Northern Europe

Higher socioeconomic status

Higher level of education

White race

Nulliparity

Infertility

Menstrual irregularities

Early menarche

Late menopause

Treatment with unopposed estrogen

Tamoxifen use

Anovulatory disorders, such as polycystic ovarian syndrome

Estrogen-producing tumors, such as granulosa-theca cell tumors

Obesity

Hypertension

Diabetes

High fat diet

Hereditary nonpolyposis colon cancer syndrome

Decreased risk

Oral contraceptive use

Nonmedicated plastic or copper IUD use

Consumption of some phytoestrogens, such as isoflavones and lignans

Diet rich in fruits, vegetables, and fiber

Physical activity

Cigarette smoking

The use of tamoxifen by postmenopausal women for the prevention or treatment of breast cancer is associated with an approximately twofold increased risk of endometrial cancer as well as an increased risk of uterine sarcoma. However, this small increased risk of uterine cancer is outweighed by the survival benefit of tamoxifen use among women with breast cancer. As compared to other endometrial cancers, tamoxifen-related endometrial cancers are not associated with an increased incidence of adverse prognostic features. Although tamoxifen acts as a weak estrogen in the postmenopausal endometrium, it has predominantly antiestrogenic effects in the premenopausal endometrium. Thus, there is no increased risk of endometrial cancers among premenopausal women using tamoxifen. The use of aromatase inhibitors for the treatment of breast cancer has not been associated with an increased risk of endometrial cancer.

Patient metabolic factors such as obesity are associated with an increased risk of endometrial cancer and an increased risk of mortality from the disease. Weiderpass et al. found that as compared to women of normal body mass index (BMI), women with a **BMI** of 30 to 33.99 had a threefold increased

P.1260

risk of endometrial cancer that rose to a sixfold increased risk among women with a BMI greater than 34. In the Million Women Study, the relative risk of developing endometrial cancer was 2.73 and the relative risk of dying of endometrial cancer was 2.28 among women with a BMI ≥ 30 as compared to women with a normal BMI. Likewise, in a large prospective study of the effect of obesity on the risk of death from cancer, Calle et al. found that the relative risk of death from endometrial cancer was increased over sixfold among women with a BMI ≥ 40 as compared to those with a normal.

In the past, the increased risk of endometrial cancer among obese women has been attributed to increased levels of unopposed estrogen due to peripheral conversion of androgen to estrogen by the aromatase enzyme in adipose tissue. More recently, the roles of proinflammatory adipokines, which are cytokines produced in the adipose tissues, and of insulin and insulin-like growth factor on stimulating endometrial cancer development have begun to be elucidated.

The ovaries may be a source of unopposed estrogen in women with anovulatory disorders, such as polycystic ovarian syndrome (PCOS). In a retrospective study of 128 women with endometrial cancer, Pillay and colleagues found that among women less than 50 years old, PCOS was significantly more prevalent among women with endometrial cancer than among normal controls. They observed no relationship between PCOS and endometrial cancer in postmenopausal women.

Fearnley et al. conducted a case-control study of the incidence of endometrial cancer in 156 women with PCOS as compared to 398 controls. They identified a statistically significant fourfold increased risk of endometrial cancer among women with PCOS. After controlling for BMI, the difference in endometrial cancer risk did not remain significant. Therefore, some experts contend that PCOS, per se, is not a risk factor for endometrial cancer. They emphasize that women with PCOS have multiple other risk factors for endometrial cancer, including chronic anovulation, centripetal obesity, and diabetes. Premenopausal women with PCOS should be counseled on the risk of endometrial cancer and the importance of maintaining regular withdrawal bleeding cycles. The optimal treatment regimen is unknown (ACOG Practice Bulletin 108). Estrogen-producing tumors, such as granulosa cell tumors of the ovary, may be another source of endogenous, unopposed estrogen, and endometrial hyperplasia or cancer is common in women with estrogen-producing tumors.

The risk of endometrial cancer is increased in patients with diabetes. This risk is further increased in obese diabetic patients. Similarly, the risk of endometrial cancer is increased in patients with metabolic syndrome. Of the components of the metabolic syndrome, elevated BMI is the factor most strongly associated with endometrial cancer risk.

Factors that decrease exposure to unopposed estrogens decrease the risk of endometrial cancer. The Cancer and Steroid Hormone Study demonstrated that 12 months of oral contraceptive use decreased the risk of endometrial cancer by 40%, and the effect persisted for at least 15 years after the cessation of use. A large, Chinese case-control study demonstrated a 50% decrease in the risk of endometrial cancer after 3 years of oral contraceptive use.

Smoking also decreases the risk of endometrial cancer. The exact mechanism is unknown. It may be due to alterations in sex hormone metabolism, a reduction in body weight among smokers, or an earlier age at menopause among smokers. Obviously, the overall detrimental health effects of smoking far outweigh any benefit related to decreased endometrial cancer risk.

A number of studies have suggested a protective effect of IUD use on the risk of endometrial cancer. Tao's large case-control study of 2,416 women in Shanghai, China, demonstrated an approximately 50% reduction in the risk of endometrial cancer among women who had ever used an intrauterine device (IUD). The type of IUD was not specified. Case-control studies by Castellsague in patients using unspecified type of IUDs and by Hill in patients using nonhormonal IUDs demonstrated a similar approximately 50% decreased risk of endometrial cancer in IUD users as compared to nonusers.

Gardner et al. conducted a randomized controlled trial of levonorgestrel IUD versus observation in 122 postmenopausal women with breast cancer who were being treated with tamoxifen. The mean follow-up time was 26 months, range 14 to 36 months. They were able to demonstrate benign endometrial changes and a decrease in the development of endometrial polyps in the IUD users as compared to nonusers. This study was unable to assess the effect of IUD use on the development of endometrial cancer. Nor could this study assess the safety of levonorgestrel-containing IUD use in women with breast cancer.

Endometrial cancer is one of the components of the Lynch syndrome. This autosomal, dominant cancer risk syndrome is caused by inactivation of one of several genes involved in DNA mismatch repair. A personal and/or family history of colon, endometrial, ovarian, ureteral, or smallbowel malignancy should prompt the clinician to consider referral of the patient for genetic counseling and possible genetic testing. Diagnosis of an endometrial or ovarian cancer often triggers the identification of a family with Lynch syndrome.

The lifetime risk of endometrial cancer in women with Lynch syndrome is 40% to 60%. Patients with Lynch syndrome may consider chemoprevention with OCPs, although there are no clear data to support this approach. A woman with Lynch syndrome may consider increased surveillance with annual endometrial biopsy beginning at age 30 to 35, although there is no definitive evidence to support this approach. Patients should be counseled to

promptly report and be evaluated for any abnormal uterine bleeding. Risk-reducing surgery with hysterectomy and bilateral salpingo-oophorectomy (BSO), performed after the completion of childbearing, has been demonstrated to reduce the risk of endometrial cancer in patients with Lynch syndrome.

PROGNOSTIC FEATURES

The prognostic features for endometrial cancer have been well defined ([Table 52.5](#)). These include age, race, FIGO stage, tumor grade, histologic subtype, depth of myometrial invasion, cervical or adnexal involvement, positive peritoneal cytology, metastasis to pelvic or paraaortic lymph nodes, and presence of lymphovascular space invasion.

Among women with stage I endometrial cancer, risk factors that adversely affect survival include increasing age, grade 2 to 3 histology, the presence of lymphovascular space invasion, and invasion to the outer third of the myometrium. Using these factors, patients with “*high-intermediate risk*” for recurrence can be identified. These patients have an approximately 27% chance of recurrence at 48 months. The GOG defines high-intermediate risk endometrial cancer as (a) any age with greater than or equal to 3 or more risk factors; (b) age greater than or equal to 50 but less than 70 with greater than or equal to 2 or more risk factors, and (c) age greater than or equal to 70 with greater than or equal to 1 or more risk factors (Keys). Many experts suggest that these are the patients who should be targeted for surgical staging and/or postoperative adjuvant therapy.

the uterus.

SCREENING FOR ENDOMETRIAL CANCER

The ACS guidelines for the early detection of cancer recommend that for average-risk, asymptomatic individuals, endometrial cancer screening should consist of education of women at the time of menopause regarding the risks and symptoms of endometrial cancer. Women should be strongly encouraged to report any unexpected bleeding or spotting to their physician.

Even women at increased risk for endometrial cancer due to a history of unopposed estrogen therapy, tamoxifen use, late menopause, nulliparity, infertility, anovulation, obesity, diabetes, or hypertension do not benefit from routine screening for endometrial cancer, beyond the reporting of symptoms. The ACS recommends that women at high risk for endometrial cancer, such as women known or at substantial risk to be a carrier of a Lynch syndrome mutation, should be offered annual screening with endometrial biopsy by the age of 35, in addition to being informed about the symptoms of endometrial cancer. Patients should be counseled regarding the potential benefits, risks, and limitations of endometrial cancer screening. These recommendations are based on expert opinion. There is no current evidence that this approach will result in earlier diagnosis or improved outcomes for these women.

EVALUATION OF THE SYMPTOMATIC PATIENT

Abnormal uterine bleeding is the most common presenting symptom of endometrial cancer. In a review of the pathologic findings among women with postmenopausal bleeding, Gredmark and colleagues found that the risk of adenomatous endometrial hyperplasia or cancer in a woman with postmenopausal bleeding is approximately 18%. The risk of malignancy increased with increasing age, with the peak incidence of endometrial cancer occurring in women between 65 and 69 years of age. The most common cause of postmenopausal bleeding was endometrial atrophy, which was identified in 50% of the patients. All patients with postmenopausal bleeding should undergo evaluation for possible endometrial cancer.

Endometrial cancer can also occur in premenopausal women and may present with heavy or irregular vaginal bleeding. The American Congress of Obstetricians and Gynecologists recommends that any women aged 45 or older with abnormal bleeding should have endometrial sampling performed. Younger women with risk factors for endometrial cancer, such as obesity or anovulation, who have failed hormonal treatment, or who have persistent abnormal uterine bleeding should also undergo endometrial sampling. A 25-year-old woman who experienced menarche at age 12, is obese, and has PCOS will already have experienced more than 10 years of exposure to unopposed estrogen.

There are several options for the evaluation of a woman with postmenopausal bleeding. The ACOG Committee Opinion on the assessment of postmenopausal bleeding recommends either transvaginal pelvic ultrasonography or office endometrial biopsy as the initial approach, but not both together ([Fig. 52.1](#)).

Transvaginal pelvic ultrasound to evaluate the endometrial stripe thickness is one of the options for primary evaluation of postmenopausal bleeding. Several meta-analyses have been published evaluating the use of transvaginal pelvic ultrasound in the triage of women with postmenopausal bleeding. The most referenced meta-analysis, performed by Smith-Bindman et al., evaluated 35 studies performed between 1966 and 1996 that included 5,892 patients. Women with a pretest probability of cancer of 10% had only a 1% risk of having cancer following a transvaginal ultrasound result showing 5 mm or less endometrial stripe.

Gupta et al. performed a subsequent meta-analysis that assessed 57 studies in 9,031 postmenopausal women. Only four studies using a cutoff of less than or equal to 5 mm were of adequate quality to be included in the analysis. They found that among women with an endometrial stripe thickness of 5 mm or less, the risk of

endometrial cancer was approximately 2.5%.

Timmermans et al. performed a meta-analysis using original datasets from 13 studies including 2,896 patients. They calculated receiver operating characteristic curves of endometrial thickness. The commonly used cutoff values of 4 and 5 mm were found to have a sensitivity to detect endometrial cancer of 95% and 90%, respectively. These authors recommend the use of a 3-mm cutoff value, which yielded a sensitivity of 98% for the detection of endometrial cancer.

ACOG recommends that endometrial sampling is not required in a patient with postmenopausal bleeding and an endometrial stripe thickness of less than or equal to 4 mm. If the

P.1262

endometrial stripe thickness is greater than 4 mm or if the endometrial stripe thickness cannot be assessed, then further evaluation with endometrial biopsy, sonohysterography to rule out endometrial polyps or submucosal fibroids, or office hysteroscopy is indicated.

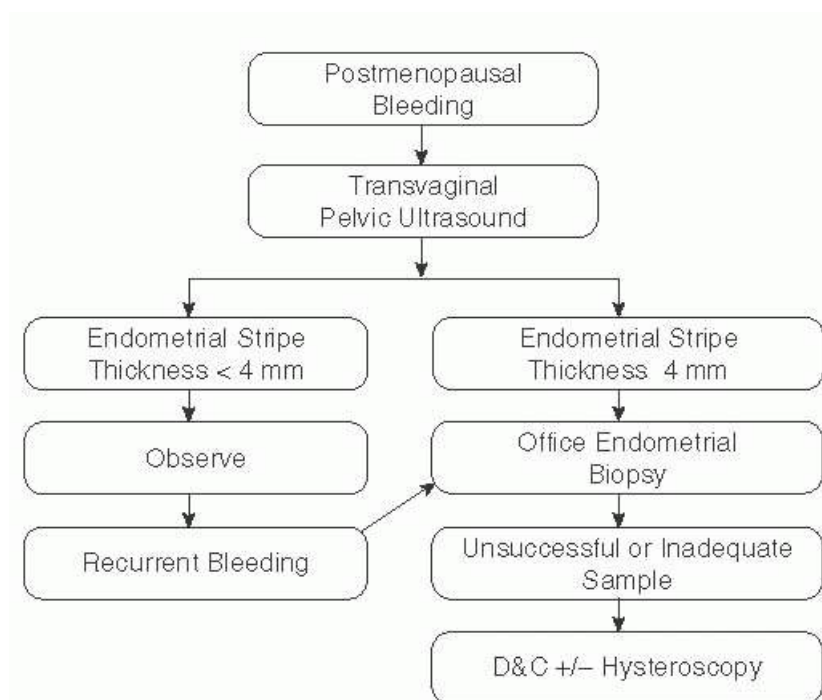

FIGURE 52.1 Algorithm for the evaluation of postmenopausal bleeding. (Adapted from Moodley M, Roberts C. Clinical pathway for the evaluation of postmenopausal bleeding with an emphasis on endometrial cancer detection. *J Obstet and Gynaecol* 2004;24:736-741, with permission. Copyright © 2004, Informa Healthcare.)

Another option for the initial evaluation of postmenopausal vaginal bleeding is to proceed directly to office endometrial biopsy. This is typically accomplished with a Pipelle instrument, which is a disposable plastic catheter that can be placed through the cervix into the endometrial cavity for the aspiration of endometrial cells. Its use occasionally may require the placement of a single-toothed tenaculum on the cervix for countertraction or gentle cervical dilatation.

In a meta-analysis comparing endometrial sampling techniques, the Pipelle was found to be the most accurate. Among postmenopausal women, the sensitivity for the detection of atypical endometrial hyperplasia was 81% and for the detection of endometrial cancer was 99.6%. The sensitivity of the device for the detection of endometrial cancer among premenopausal women was 91%. The specificity of the Pipelle device for the diagnosis of endometrial hyperplasia or malignancy was 98%.

Up to 54% of patients will have failure of endometrial sampling. Farrell and coworkers have reported a 20% incidence of uterine pathology after an “insufficient” endometrial biopsy, with 3% of these patients having

malignancy. These patients may be further evaluated with transvaginal pelvic ultrasound. If the stripe thickness is ≤ 4 mm, then the risk of malignancy is low (Farrell).

Dilatation and curettage (D&C) in the operating room is considered the “gold standard” for endometrial sampling. However, even D&C fails to sample the entire endometrial cavity. Stock and Kanbour performed pre hysterectomy D&Cs and found that in approximately 60% of patients, less than half of the endometrium had been sampled. There are limited data regarding the sensitivity and specificity of D&C for the diagnosis of endometrial hyperplasia and malignancy. Women with persistent postmenopausal bleeding despite a negative prior workup should undergo reevaluation.

Both Pipelle endometrial biopsy and D&C are limited for the evaluation of focal endometrial lesions. Studies differ as to whether adding hysteroscopy may improve the diagnostic accuracy of D&C. Patients with endometrial cancer who undergo hysteroscopy are more likely to have positive pelvic peritoneal washings than those who do not undergo hysteroscopy, which may be due to insufflation of the uterus with fluid during hysteroscopy. There is currently no evidence that this results in an increased risk of recurrence or decreased survival. This conclusion is limited by the small number of patients with recurrent disease and short follow-up intervals.

ENDOMETRIAL HYPERPLASIA

Endometrial hyperplasia is a proliferation or overgrowth of the endometrium caused by exposure to unopposed estrogen. Kurman et al. further classified endometrial hyperplasia into four groups, simple hyperplasia with and without atypia and complex hyperplasia with or without atypia. Simple hyperplasia is characterized by an increase in the number of endometrial glands, which may be dilated with little crowding or may have irregular outline and exhibit crowding. Complex hyperplasia is characterized by glands with irregular outline that demonstrate marked structural complexity and back-to-back crowding. Atypical hyperplasias demonstrate cytologic atypia and loss of cellular polarity. These criteria were adopted by the World Health Organization for the classification of endometrial hyperplasia in 1994.

More recently, Mutter and colleagues have introduced a two-tier system for the classification of premalignant lesions of the endometrium, the endometrial intraepithelial neoplasia system. This system uses morphometric analysis to differentiate between monoclonal, premalignant lesions as compared to polyclonal and not premalignant lesions. In this system, the lesion must exceed 1 mm, the area of glands exceeds that of the stroma, and the cytology differs between the architecturally crowded focus and the background endometrial glands. Cytologic atypia is associated with an increased risk of progression to endometrial cancer. In Kurman's series of 170 women with endometrial hyperplasia not treated with progesterone, progression to cancer occurred in 1% of patients with simple hyperplasia without atypia, 3% of patients with complex hyperplasia without atypia, 8% of patients with simple hyperplasia with atypia, and 29% of patients with complex hyperplasia with atypia during a mean follow-up time of 13.4 years. In another study by Horn et al., among women with complex hyperplasia without atypia, only 2% progressed to cancer and 10.5% progressed to complex atypical endometrial hyperplasia. Among women with complex hyperplasia without atypia treated with progestin therapy, 128 of 208 (61.5%) regressed. Progression to cancer occurred in 58 of 112 women (52%) with complex atypical hyperplasia. Of the seven patients with complex atypical endometrial hyperplasia treated with progestins, four had persistent disease and three progressed to cancer.

Endometrial hyperplasias without atypia are typically treated with some form of progestin therapy. Common regimens include medroxyprogesterone acetate 10 to 20 mg daily or cyclically for 14 days per month, depot medroxyprogesterone 150 mg intramuscularly every 3 months, megestrol acetate 40 to 160 mg daily, or the levonorgestrel-containing IUD (Trimble).

Complex atypical hyperplasia of the endometrium is a premalignant condition, which is typically treated with hysterectomy with or without BSO. Approximately 40% of women with complex atypical endometrial hyperplasia

diagnosed by biopsy will have the finding of endometrial cancer in the hysterectomy specimen. The risk of change in diagnosis from hyperplasia to cancer may be slightly higher with preoperative Pipelle endometrial biopsy (46%) than with D&C (27%).

Progestin therapy can be considered for women with complex atypical endometrial hyperplasia or in selected women with grade 1 endometrial cancer who are either poor operative candidates or who wish to retain their fertility. Gunderson and colleagues performed a systematic review of 45 published studies including a total of 391 women, 111 with complex atypical endometrial hyperplasia and 280 with grade 1 endometrioid adenocarcinoma of the endometrium who were treated with progestin therapy. The median age of the patients was 31.7 years in trials for which patient age was reported. Median follow-up was 39 months. The most common progestins used were medroxyprogesterone in 49%, megestrol acetate in 25%, and levonorgestrel-containing IUD in 19%. The complete response rate was 65.8% in women with complex atypical endometrial hyperplasia and 48.2% in women with endometrial cancer. The median time to complete response was 6 months. Recurrence was diagnosed in 23.2% of women with hyperplasia and 35.4% of women with cancer. There were 117 live births among the 391 women in this study.

Before progestin therapy is considered in a young woman with complex atypical endometrial hyperplasia or grade 1 endometrial cancer who is attempting to retain her fertility, a thorough evaluation of the endometrial cancer by D&C should be performed. If endometrial cancer is confirmed, then transvaginal pelvic ultrasound and magnetic resonance

P.1263

imaging (MRI) of the pelvis should be performed to rule out myometrial invasion and any ovarian pathology. Chest x-ray or chest computed tomography (CT) with CT of the abdomen and pelvis should be performed to evaluate for the possibility of metastatic disease. Patients with hyperplasia or cancer who are being treated with progestins should have endometrial sampling every 3 months to evaluate response to therapy. They should be extensively counseled regarding the risks of this approach. There is a case report describing progression to grade 2 endometrioid adenocarcinoma of the endometrium metastatic to the lymph nodes in a 40-year-old patient with complex atypical hyperplasia who was treated with progestin.

SURGICAL STAGING AND TREATMENT

Rationale

Endometrial cancer is surgically staged and treated. The procedure includes thorough exploration of the peritoneal contents, pelvic washings, hysterectomy, and BSO. The role of bilateral pelvic and paraaortic lymph node dissection remains controversial. Laparotomy has been the principle surgical approach to hysterectomy and staging for endometrial cancer. Laparoscopy and robotically assisted laparoscopy are increasingly being used for endometrial cancer surgery. Since laparoscopic hysterectomy and lymph node dissection techniques are discussed in detail elsewhere in this text, the discussion below will focus on open techniques.

Type I endometrial cancers have three main patterns of spread, by direct extension, to regional lymph nodes, and hematogenously. The most common mechanism of spread for type I endometrial cancer is by direct extension, invading into the myometrium or by extension to the adjacent cervix. Hematogenous metastasis tends to occur late in the course of the disease. Type II endometrial cancers, particularly uterine papillary serous carcinomas, may also metastasize within the peritoneal cavity, similar to ovarian carcinomas.

Endometrial carcinoma spreads through three separate lymphatic pathways: Paracervical and parametrial lymphatics drain to the pelvic lymph nodes, ovarian lymphatics drain to the paraaortic lymph nodes, and round ligament lymphatics drain to the inguinal lymph nodes ([Fig. 52.2](#)). The lymphatic drainage of the uterine fundus and cervix directs most of the metastases to the pelvic lymph nodes. Although the paraaortic lymph nodes may be primary metastatic sites via spread through the infundibulopelvic ligament lymphatics, it is rare for an

endometrial cancer patient to have isolated paraaortic lymph node metastases without concomitant pelvic lymph node metastases. The incidence of isolated paraaortic lymph node metastases is approximately 1% to 1.5%.

Performance of pelvic and paraaortic lymphadenectomy for the staging of endometrial cancer remains controversial. Kilgore and colleagues retrospective study suggested that lymphadenectomy might have a therapeutic effect for patients with endometrial cancer. They evaluated the outcomes of 649 patients surgically managed for endometrial cancer. In this study, 212 patients had pelvic lymph nodes sampled from at least 4 separate sites (multiple-site lymph node sampling), 205 patients had pelvic lymph nodes sampled from fewer than 4 sites (limited-site lymph node sampling), and 208 patients had no pelvic lymph nodes sampled. Patients undergoing multiple-site lymph node sampling had a survival of approximately 85%, whereas patients in whom pelvic lymph nodes were not sampled had a survival of approximately 65%, a statistically significant difference ($P = 0.0027$). This survival advantage for patients with multiple-site lymph node sampling persisted even in a subgroup analysis of patients treated with postoperative whole pelvic radiotherapy.

FIGURE 52.2 Lymphatic pathways of tumor spread of endometrial carcinoma to pelvic and extrapelvic nodes.

There have been two prospective randomized trials assessing the therapeutic value of pelvic lymphadenectomy in patients with apparent stage I endometrial cancer. The ASTEC trial enrolled 1,408 patients at 85 centers in 4 countries. Median follow-up was 37 months. Patients were randomized to “standard surgery” with hysterectomy, BSO, washings, and palpation of the paraaortic lymph nodes versus standard surgery with pelvic lymphadenectomy. Postoperatively, patients were enrolled in a second randomized trial of postoperative radiotherapy versus no radiotherapy based on uterine findings. The overall morbidity was low, but patients in the lymphadenectomy group were more likely to develop lower extremity lymphedema. The authors reported that there was no difference in overall or recurrence-free survival in patients who did not undergo pelvic lymphadenectomy versus those who did.

This trial has been extensively criticized. Although the patients were randomized, there was an excess of patients

with adverse prognostic features in the lymphadenectomy arm, including 10% more patients in the lymphadenectomy arm having deep myometrial invasion. The lymph node sampling itself was inadequate, with a median of only nine nodes being recovered. The Gynecologic Oncology Group Surgical Procedures Manual, revised January 2010, requires a minimum of four nodes from each side for an adequate pelvic lymph node dissection. The performance of paraaortic lymph node dissection was left to the discretion of the surgeon. Since the randomization to postoperative external beam radiotherapy was based on uterine factors and not the presence of metastases to the pelvic lymph nodes, approximately half of those who might have benefited the most from pelvic radiotherapy, those with lymph node metastases, did not receive it.

CONSORT was a phase III randomized trial of routine lymphadenectomy versus no lymphadenectomy in women

P.1264

with apparent stage I endometrial cancer who were undergoing standard surgery with hysterectomy and BSO. Paraaortic lymph node sampling was left to the discretion of the surgeon. Postoperative therapy was at the discretion of the treating physician, but was similar between the two groups. In this trial, the pelvic lymph node dissection was adequate by GOG standards with a median of 30 lymph nodes removed in the lymphadenectomy group. Intraoperative complications were similar. Patients in the lymphadenectomy group were more likely to experience postoperative complications, which was largely due to an excess of lymphedema and lymphoceles in the lymphadenectomy group. These authors also found no difference in overall or disease-free survival in the lymphadenectomy group. However, they did conclude that systematic lymphadenectomy significantly improved the accuracy of surgical staging.

In assessing the preceding studies, it is important to understand the purpose of staging. According to the SEER Web site, among the purposes of cancer staging is to “adequately assess the extent of cancer in order to treat the disease in the most appropriate manner.” The findings of a staging evaluation are used to direct therapy in order to maximize the chance of cure while minimizing the risk of toxicity. Using this paradigm, it may be appropriate to omit lymphadenectomy in patients with grade 1 endometrial cancer confined to the endometrium who have essentially no risk of lymph node metastases. In patients with high-intermediate risk disease, surgical staging may be useful to identify those patients with lymph node metastases who may benefit from radiotherapy, while avoiding short- and long-term radiotherapy toxicity in women who can be confirmed to have negative lymph nodes.

Ben-Shachar and coworkers evaluated the impact of routine surgical staging on the treatment of 181 women with a preoperative diagnosis of grade 1 endometrioid adenocarcinoma of the endometrium. Surgical staging was performed in 82% of cases and was omitted only when the disease was apparently confined to the endometrium and the surgical risk was high. High-risk uterine features, including greater than one-half myometrial invasion, grade 3 tumors, high-risk histologic variants, and/or cervical extension were identified in 26% of patients. Lymph node metastases were identified in 3.9% of patients. Overall, the findings of the surgical staging procedure significantly impacted postoperative treatment decisions in 29% of patients, including 12% of patients who were determined to need adjuvant therapy and 17% of patients who were able to forego external beam whole pelvic radiotherapy or chemotherapy. The incidence of severe surgical complications in the surgically staged group was 3.2%.

Preoperative Assessment and Preparation

As noted above, many patients with endometrial cancer may be older and have multiple medical comorbidities. Thus, preoperative preparation is important. All patients should have a thorough history and physical examination. The history should assess the length and severity of the patient’s bleeding or other presenting complaint. It should also assess for symptoms of metastatic disease, such as abdominal or pelvic pain, changes in bowel or bladder function, lower extremity pain or swelling, abdominal bloating, early satiety, shortness of

breath, or cough. Previous medical history and symptoms suggestive of occult cardiopulmonary disease or other medical illnesses should be ascertained. Careful attention should be paid to the family history, as endometrial cancer may develop before colon cancer in up to half of women with Lynch syndrome.

The physical examination should focus on assessment for supraclavicular and inguinal lymphadenopathy, abdominal distension or fluid wave suggestive of ascites, abdominal masses, and lower extremity edema. On pelvic examination, close attention should be paid to possible vaginal, cervical, or parametrial extension of disease. Uterine size and mobility, the presence of adnexal masses, and cul-de-sac nodularity should be assessed.

Basic laboratory evaluation should include a hematocrit and type and screen. Ca-125 testing is not indicated, except in patients with uterine papillary serous carcinoma. A chest x-ray should be performed both to rule out lung metastases and to evaluate for concurrent pulmonary disease. An electrocardiogram will be needed in most patients for preoperative assessment for potential cardiac disease. Extensive preoperative radiographic assessment for metastatic disease with CT, MRI, or positron emission tomography is not indicated, unless the history or physical examination or uterine histology is suggestive of distant disease. This would be most likely to occur in patients with uterine papillary serous or clear cell carcinomas. Other preoperative testing should be performed as dictated by the patient's history and physical findings and may include complete blood count, electrolytes, and assessment of hepatic and renal function. For patients with multiple medical comorbidities, preoperative cardiac, pulmonary, or other medical consultations may be necessary. In such patients, preoperative consultation with the anesthesiologist may also be of benefit.

Once a patient has completed her preoperative evaluation and has been cleared for surgery, she should be counseled regarding her options for therapy, including surgical therapy; primary pelvic radiotherapy, which is usually reserved for patients who are not good candidates for surgery; and no therapy. Patients should be thoroughly counseled on the indications, risks, and benefits of surgery, that there is no guarantee as to outcome, and that further therapy in the form of additional surgery, chemotherapy, or radiotherapy may be necessary. The patient and her family should be given the opportunity to have all of their questions answered. Patient understanding should be confirmed by having her perform teach-back. Written informed consent should be obtained.

Standard preoperative antibiotic prophylaxis for hysterectomy should be employed, typically with cefazolin 1 to 2 g intravenously administered within 60 minutes prior to incision. For patients with penicillin allergy, clindamycin plus gentamicin or a quinolone or aztreonam or metronidazole plus gentamicin or a quinolone are acceptable alternatives.

Deep vein thrombosis occurs in 15% to 40% of patient undergoing major gynecologic surgery who do not receive thromboprophylaxis. High-risk features for thromboembolism in patients undergoing gynecologic surgery include patients older than 40 years with any of the following: history of prior deep venous thrombosis or pulmonary embolism, varicose veins, infection, malignancy, estrogen therapy, obesity, or prolonged surgery. All patients undergoing surgery for endometrial cancer should receive thromboembolism prophylaxis with low-dose heparin 5,000 units every 8 hours subcutaneously, low molecular weight heparin with enoxaparin 40 mg daily subcutaneously, or dalteparin 5,000 units daily subcutaneously or pneumatic compression devices. Double prophylaxis with pneumatic compression devices and either low-dose heparin or low molecular weight heparin should be considered for patients at highest risk. This would include patients older than 60 years with a history of prior venous thromboembolism, cancer, or hypercoagulable state. In these patients, consideration should also be given to continuing pharmacologic prophylaxis for 2 to 4 weeks after discharge.

Prior to taking the patient to the operating room, the patient should confirm the surgical site (abdomen), and this should be marked according to hospital protocol. Once in the operating room, a time-out is performed as per hospital protocol to ensure the correct patient and procedure. After the induction of anesthesia, the patient should be positioned for surgery. Some surgeons prefer the supine position for hysterectomy. It does avoid the risk of neurologic injury that can rarely occur with lithotomy position in Allen stirrups. Many gynecologic oncologists will place the patient in the lithotomy position due to the ready access to the paraaortic lymph nodes that can be achieved with the surgeon between the patient's legs.

The abdomen is usually opened through a vertical midline lower abdominal incision. This is preferable to a low transverse incision, such as a Pfannenstiel incision, because it allows for better access to the paraaortic lymph nodes. In morbidly obese patients, a paramedian or high transverse incision is sometimes used to keep the incision out of the pannus and reduce the risk of infection. Occasionally, panniculectomy in conjunction with hysterectomy may be performed.

On entering the abdominal cavity, *peritoneal washings are obtained*. The operator washes the pelvic organs with 50 to 100 mL of saline. The fluid is gently agitated, then aspirated from the posterior cul-de-sac, mixed with heparin, and submitted for cytologic evaluation.

Next, the *peritoneal cavity is carefully explored*. The approach to abdominal exploration should be systematic. Explore the pelvis last, so as not to be distracted by findings there. Facilitate the exploration of the upper abdomen by having the assistant elevate the anterior abdominal wall at the apex of the incision using a large Richardson retractor. The omentum is brought into the field and carefully examined for metastatic implants. The upper abdominal contents, including the anterior surface of the stomach, the surface of the liver, and the gallbladder, can be visualized. Starting on the right, the operator's hand is used to palpate the peritoneum of the anterior abdominal wall and the paracolic gutter. As the hand moves posteriorly, the kidney can be palpated. Then, palpate the gallbladder, right lobe of the liver, and right hemidiaphragm. The operator then explores the left upper abdomen, including the left diaphragm, left lobe of the liver, spleen, and stomach, including the pylorus. Finally, follow the left anterior abdominal wall and paracolic gutter inferiorly back to the pelvis, palpating the left kidney in the process. At this point, the cecum is identified and the appendix can be examined. The small bowel is run from the ileocecal valve to the ligament of Treitz. With the bowel on the surface of the abdomen, palpation of the retroperitoneum is facilitated. Start superiorly with the pancreas and continue inferiorly to palpate the paraaortic lymph nodes. Continue the nodal palpation to the pelvic lymph nodes bilaterally. The small bowel is returned to the abdomen. The large bowel is run in situ. Finally, while retracting the small bowel into the upper abdomen, the pelvis is carefully explored. Assess the pelvic peritoneum, with careful attention to the cul-de-sac peritoneum, for implants. Note the size and mobility of the uterus. Assess the ovaries and fallopian tubes for any masses or implants.

Once the peritoneal exploration is completed, a self-retaining retractor can be placed and the bowel can be packed into the upper abdomen with the assistance of moist laparotomy sponges. This is assisted with the use of gentle Trendelenburg positioning. Care must be taken with the use of a self-retaining retractor to keep the blades off of the psoas muscles in order to avoid injury to the femoral nerves.

Hysterectomy with BSO is begun by grasping the uterine cornua bilaterally with long Kelley or similar clamps, occluding the fallopian tubes. This allows for manipulation of the uterus during the hysterectomy, while preventing efflux of malignant cells via the tubes during the course of the procedure. A tenaculum, Leahy, or other perforating clamps should not be placed on the uterine fundus in order to avoid contamination of the field by malignant cells from the interior of the uterus.

On either side, the round ligament is ligated and transected. The pelvic sidewall peritoneum is then incised approximately 1 cm lateral and parallel to the infundibulopelvic ligament. The retroperitoneal space can be

bluntly dissected to reveal the course of the ureter through the pelvis. The ureter lies on the medial peritoneal leaf. Its identification is facilitated by the use of the suction tip in one hand and the back of a DeBakey pickup in the other. These instruments can be used to gently separate the loose areolar tissue in the retroperitoneum by dissecting in the plane medial and parallel to the iliac vessels. The ureter is at its most superficial, and therefore easiest to identify, as it crosses the bifurcation of the common iliac artery at the pelvic brim. A common mistake is to look for the ureter deep in the pelvis, where it can be confused with the superior vesicle artery. A helpful anatomic point is that the superior vesicle artery will be seen to rise out of the retroperitoneum as it is followed distally, while the ureter will tend to course more deeply in the retroperitoneum as it is followed distally. Positive identification of the ureter is achieved by visualizing its distinct peristalsis. When palpated between the operator's fingers, it gives a "popping" sensation, like a rubber band.

Once the ureter has been clearly identified, the infundibulopelvic ligament can be identified coursing anterior and parallel. It should be isolated by making a window in the posterior leaf of the broad ligament between the infundibulopelvic ligament and the ureter. Ideally, this should be performed under direct visualization so as to avoid injury to the vessels within or to the ureter. The infundibulopelvic ligament is doubly clamped using Haney clamps, transected and doubly ligated with a free tie and transfixion suture. The application of the free tie first compresses the vessels within the infundibulopelvic ligament, preventing the formation of a hematoma when the transfixion suture is placed. Thus, the transfixion suture must be placed through the infundibulopelvic ligament distal to the free tie. The utero-ovarian ligament is skeletonized back to the uterus. The adnexa should not be amputated unless there is an adnexal mass preventing access to the pelvis. This is to prevent spillage of tumor cells into the peritoneal cavity. The adnexa can be suspended off of the Kelley clamp on either uterine cornua in order to keep them out of the way during the hysterectomy.

The anterior leaves of the broad ligament and the vesicouterine peritoneum are incised, and the bladder can be dissected sharply off of the lower uterine segment and cervix. Identify the correct incision line by elevating the vesicouterine peritoneum at either end. A line of loose areolar tissue will become apparent as the air enters the vesicouterine space. If the initial incision is made inferior to this, then the bladder may be injured. If the initial incision is made superior to this, along the line where the vesicouterine peritoneum actually invests into the uterine serosa, then the plane of dissection will tend to be intrafascial instead of in the vesicouterine/vesicocervical space. Blunt dissection of the bladder should be avoided due to the risk of injury to the bladder. The operator should attempt to keep the dissection in the fine areolar tissue between the bladder and the cervix. If there is difficulty with the bladder dissection, the bladder can be dissected down just far enough

P.1266

to allow the uterine artery pedicles to be taken. After the initial pedicles are taken, the bladder dissection often becomes easier. The bladder flap is advanced through the course of the hysterectomy, as necessary. Be sure that the bladder has been taken down onto the vagina sufficiently to allow the placement of clamps below the cervix and to allow for the placement of suture to close the vaginal cuff.

The uterine arteries are now skeletonized to isolate the vessels. If possible, the pedicles on both sides are clamped before either pedicle is cut simultaneously, obviating the need to place a back clamp. The uterine artery pedicle is clamped with a Haney clamp, placing the tip perpendicular to the cervix. The pedicle is transected on the clamp with curved scissors and then ligated. Straight Ballentine clamps are then used to clamp serially down the cardinal ligaments bilaterally. Each pedicle should be approximately 1 to 1.5 cm in length. Smaller pedicles allow for the ureter to effectively fall away with each bite and allow for better hemostasis. In taking the uterine artery and cardinal ligament pedicles, the clamp should be placed just against the cervix and not "rolled off" of the cervix. The practice of "rolling" the clamp off of the cervix may cause the lateral cervix to be caught in the clamp, with risk of leaving residual cervix. Be sure that each clamp is placed medial to the last pedicle, so as to not clamp the ureter. The uterosacral ligaments can be clamped, cut, and ligated separately. Often, this is best

done with a curved Haney clamp.

When the cervicovaginal junction is reached, either a rightangled Zeppelin clamp or a curved Haney clamp, depending upon the size of the cervix and vagina, is used to clamp across the upper vagina from either side, approximately 1 cm below the cervix. The specimen, consisting of uterus, cervix, bilateral fallopian tubes, and bilateral ovaries, is now amputated with curved scissors. A figure-of-eight suture is placed through the vaginal apex between the two clamps and held, in order to decrease contamination of the peritoneal cavity with the contents of the vagina and to decrease bleeding. The lateral pedicles are sutured with Haney sutures, and the suture in the middle of the vagina is tied. Any remaining open vagina is closed with figure-of-eight sutures. The pelvis is copiously irrigated and hemostasis is assured. The pelvis should be carefully examined to be sure that there has been no injury to the surrounding pelvic organs, particularly the bladder, rectum, and ureters.

As an alternative to the traditional clamp, cut, tie technique of hysterectomy, surgical energy sources, such as bipolar cautery or harmonic scalpel, can be used to take the surgical pedicles. These modalities are more commonly employed for laparoscopic than for open hysterectomy. A popular instrument in gynecologic surgery uses a high-power current, low-voltage system that melts collagen and elastin, leading to fusion of vessels and obliteration of the vessel lumen and can fuse vessels measuring 2 to 7 mm. This system measures tissue impedance to determine when the tissue has been adequately cauterized.

Bipolar vessel sealing using the system described above for the performance of abdominal hysterectomy has been evaluated in two randomized trials. In a study of 88 patients, Aydin et al. observed that for abdominal hysterectomies performed for uterine fibroids more than 14 weeks in size, the use of bipolar cautery was associated with a significantly reduced operative time as compared to conventional suture technique, 109.9 minutes versus 124.8 minutes. There was no difference in postoperative hemoglobin reduction, hospital stay, postoperative pain, or complication rate. Hagen and colleagues found no difference in operative time, blood loss, or complications with the use of a bipolar vessel-sealing device as compared to conventional suture technique in a randomized trial of 30 women undergoing total abdominal or supracervical hysterectomy. There have been no randomized trials assessing the use of the harmonic scalpel for the performance of abdominal hysterectomy.

The choice of conventional suture technique versus the use of surgical energy should importantly include the surgeon's understanding and level of comfort with the use of the particular surgical energy source to be used. There is a risk of collateral thermal damage with the use of surgical energy. Finally, the cost of the instrument to be used as compared to any cost savings related to decreased operating time should be considered. There are no published data that assess cost issues associated with the use of surgical energy for open hysterectomy.

Once the hysterectomy has been completed, attention can now be turned to the *pelvic and paraaortic lymphadenectomy*. The bowel will need to be packed to the opposite side of the dissection. The peritoneum should be incised superiorly along the white line of Toldt. The colon can then be mobilized bluntly anteriorly and medially. The paravesical space can be opened by bluntly dissecting the bladder off of the pubic ramis, staying lateral to the superior vesicle artery. The pararectal space is opened by bluntly dissecting between the ureter and hypogastric artery.

The colon and ureter can be retracted with a large Deaver retractor, which should be oriented toward the contralateral shoulder. Sharp dissection with Metzenbaum scissors with hemoclips for hemostasis, electrocautery, or harmonic scalpel can be used to excise the fatty, lymph node-bearing tissues in the pelvis. This should include the tissues anterior and medial to the common iliac artery, anterior and medial to the external iliac artery, medial to the external iliac vein, and anterior to the hypogastric artery, extending distally along the superior vesicle artery. The external iliac vein is retracted anteriorly with a vein retractor. Blunt dissection is performed within the obturator space in order to reveal the course of the obturator nerve, often using the suction tip. The lymph nodes anterior to the obturator nerve are removed. The superior margin of the resection is the

mid-common iliac artery. The inferior margin of the dissection is the point at which the circumflex iliac vein crosses over the external iliac artery. The lateral margin of the resection is the psoas muscle. The medial margin of the resection is the ureter.

The left paraaortic lymph node dissection is extended from the level of the mid-common iliac artery superiorly along the lateral aspect of the aorta. Care must be taken not to extend the dissection too far posteriorly, where the lumbar arteries arise from the aorta. On the right, the paraaortic lymph node dissection is performed superiorly, along the anterior surface of the inferior vena cava. Small, perforating vessels are numerous on both sides, so careful hemostasis as the dissection proceeds is important.

The incidence of isolated paraaortic lymph node metastases in the absence of pelvic lymph node metastases has traditionally been estimated at 1% to 1.5%. Thus, many authors define the superior margin of the paraaortic lymph node dissection as the level of the takeoff of the inferior mesenteric artery from the aorta. However, investigators at the Mayo Clinic reported that among 63 patients undergoing pelvic and paraaortic lymphadenectomy, 16% had isolated paraaortic lymph node metastases. Among all patients with metastases to the paraaortic lymph nodes, 77% were found to have disease superior to the inferior mesenteric artery. Additionally, studies of sentinel lymph node assessment after the injection of dye into the midline of the uterine fundus demonstrate a sentinel lymph node in the paraaortic region in over half of patients. Thus, other surgeons perform paraaortic lymphadenectomy to the level of the renal vessels.

The role of sentinel lymph node mapping in the treatment of endometrial cancer is currently being evaluated. It is based

P.1267

on the concept that the lymphatic drainage from a tumor occurs in a specific pattern. If the first draining node, or sentinel lymph node, is negative for tumor, then there should be no spread of disease to lymph nodes distal to that node. By limiting the extent of the lymph node dissection, side effects, such as lymphedema, should be minimized.

The optimal technique for sentinel lymph node biopsy in uterine cancer has yet to be defined. Strategies include cervical injection, subserosal uterine injection in the area of the tumor, hysteroscopic injection directly into the tumor, and transvaginal ultrasound-guided injection into the tumor. Injection is performed using technetium 99 and/or a colored dye, such as methylene blue or isosulfan blue. The procedure can also be performed using indocyanine green, which is visualized during laparoscopy using a near-infrared camera. To maximize the detection of micrometastatic disease, the pathologic evaluation of negative lymph nodes may include immunohistochemistry for cytokeratin. The prognostic significance of micrometastases detected by immunohistochemistry is unclear. When performing a sentinel lymph node dissection, all identified sentinel lymph nodes and any suspicious lymph nodes are removed. If no sentinel lymph nodes are identified, then a full pelvic lymph node dissection should be performed on that side. In this algorithm, paraaortic lymph node dissection is left to the discretion of the surgeon.

STEPS IN THE PROCEDURE

Endometrial Cancer

- Open the abdomen through an incision sufficient to perform pelvic and paraaortic lymph node dissection, if necessary.
- Obtain pelvic washings.
- Perform systematic exploration of the peritoneal cavity and retroperitoneum.
- Grasp the bilateral uterine cornua with clamps, occluding the fallopian tubes and maintaining upward

traction on the uterus throughout the hysterectomy.

- Ligate and transect the round ligament on one side, and then extend the peritoneal incision superiorly, 1 cm lateral and parallel to the infundibulopelvic ligament.
- Bluntly open the retroperitoneal space to identify the course of the ureter through the pelvis.
- Isolate, doubly clamp, and transect the infundibulopelvic ligament, being sure to exclude the ureter from the clamps. Doubly secure the infundibulopelvic ligament with a free tie and transfixion suture.
- Repeat steps 5 through 7 on the opposite side.
- Incise the anterior leaves of the broad ligament and vesicouterine peritoneum, and then dissect the bladder off of the lower uterine segment, cervix, and upper vagina.
- Skeletonize, clamp, transect, and ligate the uterine vessels on either side at the level of the isthmus.
- Serially clamp, transect, and ligate the cardinal and uterosacral ligaments.
- After being sure that the bladder is well down, place clamps from either side across the upper vagina about 1 cm distal to the cervix, and then amputate the specimen.
- Frozen section is performed to assess grade and depth of invasion to determine the need for lymph node dissection.
- Incise the peritoneum on one side superiorly along the white line of Toldt, and then bluntly mobilize the colon anteriorly and medially.
- Bluntly open the paravesical and pararectal spaces.
- Retract the colon and ureter toward the contralateral shoulder to expose the bifurcation of the common iliac artery.
- Excise the fatty, lymph node-bearing tissues from the mid-common iliac artery proximally to the deep circumflex iliac vein distally and from the medial aspect of the psoas muscle laterally to the ureter medially. Extend the dissection into the obturator space, anterior to the obturator nerve. This will remove the tissues anterior and medial to the distal common iliac artery, anterior and medial to the external iliac artery, medial to the external iliac vein, and anterior to the internal iliac artery and extending distally along the superior vesical artery.
- Repeat steps 14 through 17 on the opposite side.
- On the left, extend the dissection laterally along the proximally common iliac artery and distal aorta to the level of the inferior mesenteric artery to complete the left paraaortic lymph node dissection.
- On the right, extend the dissection over the anterior surface of the inferior vena cava to the level of the inferior mesenteric artery to complete the right paraaortic lymph node dissection.
- Obtain hemostasis and carefully assess for any previously unrecognized operative injuries.
- Perform abdominal closure.

The use of cervical injection has been questioned, as studies have demonstrated that with dye injection into the midline uterine fundus, sentinel lymph nodes can be identified in the paraaortic lymph nodes between the inferior mesenteric artery and renal artery in over 50% of patients. With cervical injection of dye, only 5% of sentinel lymph nodes were identified along the aorta. Cervical injection for sentinel lymph node sampling is currently undergoing validation trials to confirm its accuracy.

Special Situations

Uterine papillary serous carcinomas behave in a manner similar to ovarian cancers, demonstrating spread within the peritoneal cavity even when the primary tumor is confined to the endometrium. Goff et al. evaluated the patterns of spread in patients with noninvasive uterine papillary serous carcinomas and found that with complete surgical staging, 36% of patients were found to have lymph node metastases and

P.1268

43% of patients were found to have intraperitoneal metastases. Chan et al. found that 25% of patients with noninvasive uterine papillary serous carcinomas had occult omental disease. Thus, *staging of patients with*

uterine papillary serous carcinoma should include hysterectomy with BSO, peritoneal washings and biopsies, bilateral pelvic and paraaortic lymph node dissection, and omentectomy, as is typically performed for ovarian cancer.

For patients with *stage IIB endometrial cancers with a bulky cervix*, there is a risk of parametrial extension, as for primary cervical carcinomas. Further, it can sometimes be difficult to distinguish between a primary endometrial adenocarcinoma with extension to the cervix versus a primary cervical adenocarcinoma that may extend into the lower uterine segment or above. Pelvic MRI can be helpful in making this distinction (He).

The literature regarding *treatment of patients with stage II endometrial cancers* must be evaluated carefully. Patients with endometrial cancer extending into the cervical stroma may be treated similarly to cervical cancer patients with a radical hysterectomy and pelvic and paraaortic lymphadenectomy if they are good surgical candidates. Five-year survival rates of 90% to 93% have been reported for this treatment strategy. The alternative is to treat these patients with preoperative external beam whole pelvic radiotherapy and intracavitary brachytherapy followed by completion hysterectomy with BSO. Completion hysterectomy is necessary, as radiotherapy is not as effective in treating disease in the uterine corpus as in the uterine cervix. Reisinger and colleagues reported a 5-year actuarial survival of 82% in patients with endometrioid histology treated with this strategy. Patients with high-risk histologic subtypes had only a 38% 5-year actuarial survival, with a high incidence of recurrence in the upper abdomen.

In *patients with stage III or IV endometrial cancers*, tumor debulking may be of benefit. Goff et al. reported on 47 patients with stage IV endometrial cancer. Overall median survival for these patients was 12 months. Among those patients who underwent successful cytoreduction, overall median survival was 18 months as compared to 8 months among patients who did not undergo surgery. Similarly, Chi et al. showed that among 55 patients with stage IV endometrial cancer, overall median survival was 31 months for those whose disease could be optimally cytoreduced to less than or equal to 2-cm residual disease, 12 months for those whose disease was suboptimally cytoreduced, and 3 months for those whose disease was unresectable.

Lambrou et al. also evaluated the efficacy and safety of cytoreductive surgery in patients with stage III and IV endometrial cancer. They excluded patients with uterine papillary serous carcinomas and clear cell carcinomas. They found that optimal cytoreduction to less than or equal to 2-cm maximal residual disease was possible in 72% of their patients. Overall median survival was 17.8 months for patients undergoing optimal cytoreduction and only 6.7 months for patients who could not be optimally cytoreduced. Further, they observed that the proportion of patients having major postoperative complications was actually higher among patients who were suboptimally cytoreduced as compared to those who were not, 37.5% versus 7.25%, respectively.

Bristow and coworkers evaluated the survival benefit of lymph node debulking among patients with stage IIIC endometrial cancer. All patients had macroscopic spread to pelvic lymph nodes, and approximately 50% had macroscopic involvement of the paraaortic lymph nodes. Disease-specific survival was 37.5 months among patients whose involved lymph nodes could be completely resected as compared to 8.8 months among patients whose involved lymph nodes could not be completely resected.

A retrospective analysis of 248 patients presenting with surgical stage IV endometrial cancer by Eto et al. assessed the effect of resection of intra-abdominal disease on survival in patients with and without extra-abdominal disease. Among the 93 patients with extra-abdominal disease, the most common site was lung. The extra-abdominal disease was completely resected in only 13. Complete resection of intra-abdominal disease was associated with a median overall survival of 48 months as compared with 23 months in women with ≤ 1 -cm residual disease and 14 months in women with greater than 1-cm residual disease. Even among women with residual extra-abdominal disease, there was a survival advantage associated with complete resection of the intra-abdominal disease. Other factors associated with an improved survival were better performance status,

endometrioid pathology, low grade, and receiving postoperative therapy. In this study, there was no difference in survival between women treated with chemotherapy alone, radiotherapy alone, or combined chemoradiation therapy.

In a meta-analysis of 14 retrospective cohort studies that included 672 women with metastatic or recurrent endometrial cancer, Barlin et al. observed that optimal cytoreduction to no gross residual disease was associated with a statistically significant 9.3-month improvement in overall survival for every 10% increase in the rate of optimal cytoreduction. Receipt of postoperative radiotherapy was associated with a statistically significant improvement in survival, while being treated with chemotherapy postoperatively actually had a statistically significant adverse effect on survival. The authors suggest that this may be due to suboptimally debulked patients having been more likely treated with chemotherapy rather than radiotherapy.

Role of Laparoscopy

The use of laparoscopy and particularly robotic-assisted laparoscopy has been increasing over time. Wright et al. reviewed the SEER-Medicare Database from 1997 to 2005. They identified 8,545 patients 65 years of age or older who had undergone surgery for stage I endometrial cancer. Overall, 8,018 (93.8%) underwent laparotomy while only 527 (6.2%) underwent laparoscopy. There was a clear increase in the use of laparoscopy over time, with only 3.9% of surgeries being performed via laparoscopy in 1997 as compared to 8.5% in 2005. Patient-specific factors that were associated with a greater likelihood of laparoscopic surgery included more recent year of diagnosis, younger age, white race, fewer comorbidities, higher socioeconomic status, lower tumor grade and stage, and residence in a metropolitan area. Physician-specific factors that were associated with greater likelihood of performing laparoscopy included being trained in the United States, specializing in gynecologic oncology, being at an academic institution, and later year of graduation. In a recent study evaluating hospital discharge data from the Florida Agency for Healthcare Administration, Yu reviewed data on 2,247 patients treated for endometrial cancer from October 2008 to December 2009. In this cohort, 61% of the surgeries were performed by laparotomy, 10% by conventional laparoscopy, and 29% by robotic-assisted laparoscopy.

The GOG conducted a prospective randomized trial of laparoscopy ($n = 1,696$) versus laparotomy ($n = 920$) for the treatment of stage I to IIA endometrial cancer (Lap2). Patients in both groups underwent hysterectomy, BSO, pelvic peritoneal cytology, and pelvic and paraaortic lymph node lymphadenectomy. In this study, Walker et al. reported that 434 (25.8%)

P.1269

patients had their surgery converted from laparoscopy to laparotomy. Laparoscopy was associated with a longer operative time (median 204 minutes vs. 130 minutes, $P < 0.001$), but a similar rate of intraoperative complications. Laparoscopy was associated with fewer moderate-to-severe postoperative complications (14% vs. 21%, $P < 0.0001$). Patients undergoing laparoscopy were significantly less likely to be hospitalized for more than 2 days (52% vs. 94%, $P < 0.0001$). Importantly, in a follow-up study reported in 2012, Walker and colleagues reported that although the estimated 3-year recurrence rate was 1.14% higher in the laparoscopy group as compared to the laparotomy group, the estimated 5-year survival was identical in both arms at 89.8%.

Patients undergoing laparoscopy demonstrated improved quality of life over several parameters during the first 6 weeks post-op as compared to patients undergoing laparotomy. These differences had largely disappeared by 6 months, except for better body image in the laparoscopy group. There was a modest improvement in time to return to work among patients undergoing laparoscopy. In an Australian trial comparing total laparoscopic hysterectomy to total abdominal hysterectomy (TAH) for the treatment of stage I endometrial cancer, there was overall a significantly greater improvement in quality of life at 6 weeks and 6 months as compared to baseline among women undergoing laparoscopic surgery.

Galaal et al. performed a meta-analysis of 8 randomized controlled trials, including 3,644 women, comparing

conventional laparoscopic surgery to laparotomy for the treatment of early-stage endometrial cancer. Not all trials could be assessed for all parameters. Women undergoing laparoscopy were found to have a significantly decreased blood loss and significantly fewer severe postoperative complications than women undergoing laparotomy. There was no difference in the rates of perioperative death, need for blood transfusion, or injury to the urinary tract, bowel, or vascular structures. Importantly, there was no difference in the risk of death from disease or recurrence among women undergoing laparoscopic surgery and compared to laparotomy.

Gynecologic oncologists have rapidly adopted robotically assisted laparoscopy for the performance of endometrial cancer surgery. Potential benefits over conventional laparoscopy include greater dexterity, three-dimensional vision, elimination of the counterintuitive movement of conventional laparoscopy, and improved ergonomics. The lack of tactile sensation for the surgeon may be a potential disadvantage as compared to open or conventional laparoscopic surgery. Both robotically assisted and conventional laparoscopy have a long learning curve.

A number of studies have compared outcomes of robotically assisted with conventional laparoscopy for the treatment of early-stage endometrial cancer. They consistently demonstrate that the two approaches have comparable complication rates with patients undergoing robotic surgery having a decreased blood loss, shorter hospital stay, and decreased risk of conversion to laparotomy as compared to patients undergoing conventional laparoscopy. These studies are small, nonrandomized retrospective reviews written by high-volume, experienced laparoscopic surgeons. Although the data are premature, with median follow-up of 20.7 to 31 months, recurrence risk and survival appear comparable to historical data for women treated for endometrial cancer by laparotomy or conventional laparoscopy.

The robotic surgical platform is highly complex and requires the use of specialized, disposable instruments. A significant issue with the rapid adoption of this technology without evidence of significant superiority over existing technologies is cost. Studies evaluating the cost of robotic surgery in US dollars have consistently demonstrated that it is a more expensive approach than is laparoscopy or in some studies even laparotomy, despite the longer hospital stay. Bell and colleagues compared the cost of endometrial cancer staging performed by laparotomy with a cost of \$12,943.60 versus conventional laparoscopy at a cost of \$7,569.80 versus robotically assisted laparoscopy at a cost of \$8,212.0. They concluded that there was no significant difference in cost of conventional and robotic laparoscopy. However, a difference of over \$1,000 per case adds significantly to the overall health care budget when considering that approximately 50,000 new cases of endometrial cancer are diagnosed in the United States each year.

Wright et al. used the perspective database to perform a comparative effectiveness analysis of robotic versus laparoscopic hysterectomy for endometrial cancer, analyzing data from 2,463 women. There was no difference in complication rates between the two groups. The mean cost of robotic hysterectomy was \$10,618 versus \$8,996 for conventional laparoscopic hysterectomy. They observed that patients were more likely to be treated with robotically assisted laparoscopic hysterectomy if they were treated in a larger, nonteaching hospital located outside the northeastern United States. African Americans, patients with no insurance, and women living in rural areas were more likely to undergo surgery via conventional laparoscopy.

Although some authors have suggested that conventional or robotic laparoscopy, rather than laparotomy, should be considered the standard surgical approach for endometrial cancer, it is important to keep in mind that laparotomy and laparoscopy are only methods of abdominal entry. The surgical management of early-stage endometrial cancer should include hysterectomy, BSO, pelvic and paraaortic lymph node dissection in intermediate risk and above patients, and pelvic washings. The surgeon must choose the approach that allows him or her to best care for the patient with the least risk of complications. Although for certain surgeons this may be either conventional or robotic laparoscopy, there are many surgeons for whom laparotomy remains the best and safest approach. On the other hand, *it is incumbent on all surgeons to continue to advance our skills*

throughout our surgical careers, so that we may provide the most effective, safest, and financially responsible surgical management for our patients. The best approach to the surgical treatment of endometrial cancer is likely only to continue to evolve with the introduction of new surgical technologies.

RADIATION THERAPY

At the present time, radiation therapy is rarely used as the primary or sole treatment modality for women with endometrial cancer. The goal of postoperative radiotherapy in patients with endometrial cancer is to treat the pelvic lymph node beds with external beam whole pelvic radiotherapy and upper vagina with vaginal vault brachytherapy. This has been demonstrated to decrease the risk of local recurrence, but not to improve survival. With the increasing use of surgical staging with pelvic and paraaortic lymph node dissection in the United States, the use of adjuvant pelvic radiotherapy has decreased.

The PORTEC-1 trial was a randomized trial of postoperative radiotherapy versus observation in 714 patients with stage IB, grade 2 or 3 and IC, grade 1 or 2 endometrial cancer who had undergone hysterectomy with BSO. These patients had not undergone lymph node dissection. At 10 years, Creutzberg et al. reported that the pelvic failure rate was 5% in the patients who received pelvic radiotherapy and 14% among controls, which was statistically significantly different. However, there

P.1270

was no statistically significant difference in survival, with an overall survival of 66% among patients who received pelvic radiotherapy and 73% among controls. There is general agreement that patients with low-risk endometrial cancers, stage IA or IB, grade 1 or 2, require no additional treatment postoperatively.

The role of pelvic radiotherapy in patients with high-intermediate risk endometrial cancer, as previously defined above, is less clear. In the PORTEC-2 trial, 427 patients with high-intermediate risk stage I or IIA endometrial carcinoma were randomized to postoperative treatment with external beam whole pelvic radiotherapy versus vaginal cuff brachytherapy. The primary outcome was vaginal cuff recurrence. Median follow-up was 45 months. Nout and colleagues found there was no difference in the rates of vaginal cuff recurrence or in overall or disease-free survival. There was significantly less acute grade 1 to 2 gastrointestinal toxicity in the vaginal brachytherapy group. The authors concluded that vaginal cuff brachytherapy should be the treatment of choice in patients with high-intermediate risk endometrial cancer.

Both the PORTEC trials have been criticized because comprehensive surgical staging with pelvic and paraaortic lymphadenectomy was not performed. Treatment was based on uterine findings only. Straughn and colleagues performed a retrospective review of 613 patients with stage I endometrial cancer who had undergone comprehensive surgical staging. Among 325 patients with stage IB disease, 321 did not receive pelvic radiotherapy. Fifteen (5%) of these patients recurred. All nine local recurrences were salvaged. There were 77 patients with stage IC disease, of whom 53 (69%) did not receive pelvic radiotherapy. Four (8%) patients recurred, and three of them were salvaged. For all stage I patients, the 5-year disease-free survival was 93% and overall survival was 98%. These authors concluded that pelvic radiotherapy is not needed in patients who have undergone comprehensive surgical staging because of the low risk of recurrence and high salvage rate with subsequent therapy.

In a follow-up to this study in 2003, Straughn et al. subsequently evaluated an expanded cohort of 220 patients with stage IC endometrial cancer. Ninety-nine (45%) patients were treated with radiotherapy, with external beam whole pelvic, vaginal cuff brachytherapy, or both, and 121 (55%) patients were observed. There was no statistically significant difference in the recurrence rate between the two groups. The overall 5-year survival was 92% for the patients who received radiotherapy and 90% for those who were observed. There was noted to be an improved 5-year disease-free survival of 93% among the radiated patients as compared to 75% among those who were observed. The overall salvage rate for patients who recurred was 64%.

In a separate report from the PORTEC-1 trial, there were 99 evaluable patients with stage IC, grade 3 endometrial cancers. All of these patients were treated with pelvic radiotherapy. The 5-year overall survival for this group was 58%, which is significantly lower than that found by Straughn et al. among patients with stage IC disease. It is important to remember that patients in the PORTEC-1 trial did not undergo pelvic and paraaortic lymph node dissection. The difference in survival noted is likely largely due to upstaging of patients with microscopic lymph node metastases in the Straughn series. However, it is important to note that the use of pelvic radiotherapy in the PORTEC-1 trial did not salvage these unstaged patients. Because of the higher risk of recurrence among patients with stage IC disease, particularly those with grade 3 disease, these patients are often considered for adjuvant postoperative radiotherapy, even after complete surgical staging.

Pelvic radiotherapy does carry a significant risk of complications. Among the patients randomized to whole pelvic radiotherapy in the PORTEC-1 trial, Creutzberg et al. reported 3% of patients had serious (grade 3 or 4) acute toxicity and over 20% had mild symptoms during treatment. In longterm follow-up, at a median of 13.3 years, patients treated with pelvic radiotherapy as compared to those who were not had increased incidence of urinary incontinence, diarrhea, and fecal leakage with resultant increased limitation in daily activities. Patients treated with pelvic radiotherapy also had an increased incidence of second malignancy with an observed versus expected ratio of 1.6 for patients receiving external beam radiotherapy and 1.2 for patients receiving no additional therapy as compared to a matched control population.

Patients with pelvic and/or paraaortic lymph node metastases are usually treated with postoperative radiotherapy directed to the involved nodal basins. Nelson et al. reported a 5-year disease-free survival rate of 72% for patients with pelvic lymph node metastases treated with pelvic or whole abdominal radiotherapy. Rose et al. demonstrated improved survival for patients with paraaortic lymph node metastases who were treated with paraaortic radiotherapy as compared to those who were not treated with paraaortic radiation.

Patients with stage I or II endometrial cancers who are not surgical candidates due to medical comorbidities are sometimes treated with primary pelvic radiotherapy. Fishman et al. reviewed experience at Yale from 1975 to 1992, 3.5% of all patients with stage I or II endometrial cancer were deemed medically inoperable and treated with pelvic radiotherapy alone. The 5-year disease-specific survival rate for inoperable patients with stage I disease was 80%, which was significantly less than that for operable patients at 98%. Notably, the overall 5-year survival of medically inoperable patients was only 30%, as compared to 88% for operable patients, demonstrating that many of these patients succumb to their intercurrent medical illnesses. Another treatment option for selected medically ill patients is vaginal hysterectomy.

Radiotherapy can be used successfully for *the treatment of vaginal cuff recurrence*. Huh et al. evaluated the outcomes of 69 women with stage I endometrial cancer who had been treated with hysterectomy, BSO, and pelvic (\pm paraaortic) lymph node dissection who had an isolated vaginal cuff recurrence. Treatment was whole pelvic radiotherapy with vaginal cuff brachytherapy in 62 (90%) and brachytherapy alone in 2 (3%). Treatment information was unavailable for five patients. Among these women, 81% achieved remission and the overall 5-year survival rate was 75%. Given the excellent outcomes for these patients, the authors questioned the use of adjuvant radiotherapy, either external beam whole pelvic or cuff brachytherapy, in women with surgical stage I endometrioid adenocarcinomas of the endometrium, citing benefits of decreased cost, decreased complication rates, and potential impact on quality of life.

SYSTEMIC THERAPY

Patients with advanced or recurrent endometrial cancer are often treated with *cytotoxic chemotherapy*. A recent GOG trial has demonstrated that for patients with stage III or IV endometrial cancer, chemotherapy with doxorubicin and cisplatin is superior to whole abdominal radiotherapy. Based on the findings of this trial, some authorities have advocated for the use of systemic chemotherapy rather than pelvic and paraaortic radiotherapy

in patients with node-positive disease. However, a retrospective review of 71 patients treated for stage IIIC endometrial adenocarcinoma demonstrated a higher rate of

P.1271

local-regional recurrence in patients treated without regional radiotherapy. Some authors advocate for “sandwich” therapy in node-positive and other high-risk patients, with chemotherapy followed for regional radiotherapy followed by additional chemotherapy.

RTOG 9708 was a phase 2 study to assess the feasibility, safety, toxicity, and patterns of recurrence of external beam radiotherapy with concurrent cisplatin chemotherapy followed by four cycles of cisplatin and paclitaxel chemotherapy for patients with high-risk endometrial cancer. The trial included patients with grade 2 or 3 endometrial adenocarcinoma with greater than 50% myometrial invasion, cervical stromal invasion, or pelvic-confined extrauterine disease. Overall survival and disease-free survival at 4 years were 85% and 81%, respectively. For patients with stage III disease, 4-year overall survival was 77% and disease-free survival was 72%. The regimen was well tolerated. This approach is currently being further evaluated in an RTOG trial comparing volume-directed radiation therapy with concurrent cisplatin chemotherapy followed by four cycles of paclitaxel and carboplatin chemotherapy with six cycles of carboplatin and paclitaxel chemotherapy in patients with stage III or IVA endometrial carcinoma or patients with stage I or II serous or clear cell endometrial carcinoma and positive cytology. Endometrial cancer patients with recurrent disease or distant metastases outside of the pelvis are usually treated with paclitaxel and carboplatin chemotherapy.

Hormonal therapy is also an option for patients with advanced stage disease. Both progestins and tamoxifen have been used. A recent study by Fiorica et al. demonstrated a median overall survival of 14 months in patients with advanced endometrial cancer treated with an alternating regimen of megestrol acetate and tamoxifen. Hormonal therapy tends to work best in patients with grade 1 endometrioid adenocarcinomas, which express estrogen and progesterone receptors. The major side effect of hormonal therapy is thromboembolic disease.

INCIDENTAL DIAGNOSIS OF ENDOMETRIAL CANCER AT HYSTERECTOMY

For patients who undergo hysterectomy and have the unexpected diagnosis of endometrial cancer, there are three options: observation, reoperation for staging, or pelvic radiotherapy. Treatment decisions need to be individualized and will depend on the risk of nodal or extrauterine spread, which may be estimated from the tumor grade, depth of invasion, and evidence of lymphadenopathy on CT of the abdomen and pelvis. The patient’s medical status and her willingness to undergo further surgery or radiotherapy should also be taken into account. Consultation with a gynecologic oncologist is strongly considered.

POSTTREATMENT SURVEILLANCE

The appropriate follow-up for any malignancy is dependent upon the pattern of recurrence. This will differ somewhat for type I and type II endometrial cancers. Aalders et al. evaluated 379 patients with recurrent endometrial cancer seen at the Norwegian Radium Hospital between 1960 and 1976. Local recurrence was observed in 50%, distant recurrence was observed in 29%, and both local and distant recurrence was observed in 21%. Patients who had received postoperative pelvic radiotherapy were much less likely to recur in the pelvis. One third of patients were diagnosed with recurrence within 1 year after the completion of therapy, and two thirds of patients were diagnosed with recurrence within 3 years.

There is no single, accepted follow-up strategy for patients with endometrial cancer. Physicians have often recommended routine follow-up visits at 3- to 6-month intervals with vaginal cytology at each visit and an annual chest radiograph. However, recent studies by multiple groups have demonstrated that this surveillance protocol is neither clinically nor cost-effective. These studies demonstrate that 60% to 75% of patients are symptomatic at the time of recurrence. Most patients with curable recurrences had vaginal bleeding from a vaginal lesion. Curable asymptomatic recurrences were uncommonly detected by routine screening.

Cooper et al. reported that among women with endometrial cancer, 430 Pap tests were required to detect one asymptomatic vaginal recurrence at an additional cost of \$15,142 per asymptomatic recurrence detected. Berchuck and colleagues found that the salvage rate for patients with vaginal recurrences diagnosed by vaginal cytology alone was no different than that for women with a visible lesion. They also observed that no patient with an isolated pulmonary recurrence diagnosed by chest radiograph was salvaged. In a similar study from Canada by Shumsky et al., no isolated vaginal recurrence was diagnosed by Pap test alone. Similar to the Duke study, no patient with pulmonary metastases diagnosed by chest x-ray was cured.

Despite the limited ability of routine follow-up to improve the outcomes of women with recurrent endometrial cancer, both patients and their physicians continue to favor some form of posttreatment surveillance. As emphasized by Berchuck, continued regular follow-up for some period of time with normal periodic exams is likely to provide some psychological reassurance to the patient. The focus should be on evaluation for complications of treatment and detection of vaginal recurrences, since most of these patients can be salvaged. Effective therapy is typically not available for patients who recur at distant sites.

Given these observations, routine surveillance for patients with endometrial cancer should include education of patients regarding the symptoms of recurrence, particularly vaginal bleeding, abdominopelvic or back pain, leg swelling, abdominal bloating, cough, or shortness of breath. Symptomatic patients should be instructed to report promptly for evaluation. The recent ACOG Practice Bulletin on the Management of Endometrial Cancer suggests that women with endometrial cancer could be seen in follow-up every 3 to 4 months for 2 to 3 years, then every 6 months. Berchuck recommends biannual follow-up visits. Most authors agree that patients can return to routine annual well-woman care after 5 years. Each visit should include a thorough review of systems to evaluate for symptoms of recurrence and a focused physical exam, including lymph node survey, abdominal examination, and pelvic examination with speculum exam, bimanual exam, and rectovaginal exam. Routine surveillance with Pap testing and chest radiographs cannot currently be recommended. Other studies should be obtained as dictated by the findings of the patient's history and physical examination.

Certain groups may require modifications of this follow-up scheme. For example, patients with uterine papillary serous carcinoma are often followed with serial Ca-125 determinations, similarly to patients with ovarian cancer. They are much more likely than patients with type I endometrial cancers to recur with peritoneal carcinomatosis. Patients who have been treated with radiation and/or chemotherapy may need more intensive follow-up to monitor for long-term complications of therapy. Again, there are no data to suggest that more intensive follow-up results in improved salvage rates.

P.1272

UTERINE SARCOMAS

Uterine sarcomas are rare tumors that account for only about 3% of all uterine malignancies. The most common are leiomyosarcomas, which are cancers arising from the smooth muscle of the myometrium. In a large study using populationbased databases in the Nordic countries, the incidence of leiomyosarcoma was estimated at 0.3 per 100,000 (incidence of endometrial stromal sarcomas [ESSs] 0.4 per 100,000).

Pathologically, leiomyosarcomas are differentiated from various forms of benign leiomyomas and from smooth muscle tumors of uncertain malignant potential by high mitotic rate with 10 or more mitoses per 10 high-power fields, nuclear atypia, and the presence of tumor cell necrosis. These are very aggressive tumors that commonly metastasize hematogenously. In a review of data from the Norwegian Cancer Registry from 1970 to 2000, the 5-year survival for stage I disease (by the 1988 FIGO classification) was 51% and for stage II disease was 25%. All patients with metastatic disease outside of the pelvis died within 5 years. Prognostic features for patients with stage I disease included tumor size and mitotic index.

Uterine leiomyosarcomas are typically treated with hysterectomy with resection of intraabdominal disease, if present. Removal of the ovaries has not been shown to affect survival. Thus, ovarian preservation can be considered in premenopausal women. Lymph node dissection is commonly not performed due to the low risk of lymph node metastasis. Postoperative adjuvant pelvic radiotherapy has been shown to improve local control, but not disease-free or overall survival in patients with stage I or II disease. The role of adjuvant chemotherapy is unclear. There is currently no proof that it improves survival. However, it is often offered to patients because of the high risk of distant recurrence. Treatment is usually with gemcitabine and docetaxel. There is an ongoing phase III trial, GOG 277, which compares postoperative adjuvant chemotherapy to observation for patients with early-stage leiomyosarcoma. Advanced or recurrent disease may be treated with surgical resection or radiotherapy for localized disease or with chemotherapy.

Uterine leiomyosarcoma diagnosed after uterine morcellation for presumed benign disease represents a special case that has received considerable attention recently in both the professional literature and the lay press. The incidence of leiomyosarcoma in hysterectomy or myomectomy specimens of presumed leiomyomata is unclear. The FDA Safety Communication regarding the use of laparoscopic uterine power morcellation estimates this risk as 1 in 350 women. Other studies have estimated the risk to be between 1 in 500 and 1 in 1,000. In a study of 58 patients with an incidental pathologic diagnosis of leiomyosarcoma, those undergoing uterine morcellation ($n = 19$) had an increased risk of abdominal/pelvic recurrence ($P = 0.001$) and a significantly shorter median recurrence-free survival (10.8 months vs. 39.6 months, $P = 0.002$) as compared to those undergoing TAH ($n = 39$). It is not possible to reliably differentiate between leiomyomata and leiomyosarcoma preoperatively. However, every reasonable effort should be made to rule out cervical or endometrial cancer prior to performing a uterine morcellation. Patients considering any surgical procedure should be fully counseled on the risks, benefits, and alternatives to the procedure being proposed.

ESSs are low-grade tumors that rarely metastasize distantly, but may be locally invasive. Late recurrences after 5 years may occur. Treatment is typically hysterectomy. These are hormonally sensitive tumors, and there are conflicting data regarding the effect of BSO on survival. Metastatic or recurrent disease is often treated with progestins or aromatase inhibitors. Tamoxifen should not be used, as it may stimulate the growth of these tumors.

Undifferentiated endometrial sarcomas (previously highgrade ESSs) are rare and aggressive tumors. Treatment is hysterectomy with BSO. The role of adjuvant therapy is unclear. Pelvic radiotherapy may improve local control, but not survival. Most patients die within 2 years of diagnosis.

Adenosarcomas are another rare form of uterine sarcoma. These are low-grade tumors with benign epithelial component and malignant stromal component. The prognosis is generally good, unless there is myometrial invasion or sarcomatous overgrowth. The treatment is hysterectomy with BSO.

FUTURE DIRECTIONS

As with all malignancies, the future will see increasing use of molecular staging to identify patients at risk for recurrence. This should allow for greater individualization of therapy. The GOG is currently conducting a molecular staging study in endometrial cancer. Laparoscopic and robotic surgical techniques will continue to evolve. Complete lymphadenectomy may decrease in importance, if sentinel lymph node techniques can be developed, as in melanoma and breast cancer. Chemotherapy is likely to play an increasing role in the therapy of advanced stage and recurrent disease.

Chapter 53

Ovarian Cancer

Pedro T. Ramirez

David M. Gershenson

DEFINITIONS

Intraperitoneal chemotherapy—Cytotoxic chemotherapy given intraperitoneally rather than intravenously. This is usually given via an intraperitoneal catheter in patients who have undergone optimal cytoreductive surgery.

Neoadjuvant chemotherapy—Chemotherapy given before definitive surgery to chemically debulk cancer with the intention of making future surgical efforts more successful and less complicated. Usually, several cycles of chemotherapy are given to women with advanced ovarian cancer who are poor surgical candidates because of their medical condition or perhaps the extent of disease. At the start of therapy, surgical debulking is planned if there is a response to chemotherapy, although surgery may not occur if the patient does not respond to chemotherapy or her medical condition fails to improve.

Optimal cytoreduction—Survival is related to the volume of residual cancer after initial surgery. It is preferable to remove as much tumor as possible. The definition of *optimal cytoreduction* has continued to change over the years and currently means surgical debulking so that the largest residual tumor mass is less than 1 cm in diameter.

Ovarian cancer is the leading cause of death from gynecologic malignancies in the United States. For 2014, the American Cancer Society estimates that approximately 21,980 new cases of ovarian cancer will be detected and nearly 14,270 women will die from the disease. The lifetime risk for ovarian cancer in

P.1277

American women without a family history of the disease is 1 in 70 (1.4%). Because early ovarian cancer produces few specific symptoms, most women present with advanced-stage disease for which the cost of treatment is high and the prognosis poor. Approximately 90% of malignant ovarian tumors in adults are of epithelial origin followed by sex cord-stromal tumors (6%) and germ-cell tumors (3%). Good surgery is a blend of good judgment and sound surgical technique. Much of this chapter is devoted to the natural history and results of various surgical and other treatment approaches for ovarian cancer. This background information provides the surgeon with the basis for clinical decision making concerning patient selection, choice of the right operation, and postoperative treatment recommendations. The operative techniques involved in surgery for ovarian cancer are illustrated in many of the other chapters in this text.

INCIDENCE AND RISK FACTORS

The incidence of ovarian cancer is highest in Sweden (19.6/100,000) and the United States (15.4/100,000) and lowest in Japan (10.1/100,000). In the United States, ovarian cancer incidence rates are highest in Caucasian women, intermediate in African American women, and lowest in Native American women.

Factors associated with an increase in ovarian cancer risk are age, nulliparity, and a family history of the disease. Ovarian cancer is rare before the age of 40, increases steadily thereafter, and peaks at ages 65 to 75. Parity is the most important nongenetic factor affecting risk for ovarian cancer ([Table 53.1](#)). Whittimore and colleagues analyzed 12 case-control studies in the United States and reported a significant risk reduction for

ovarian cancer with each term pregnancy (odds ratio [OR] = 0.47). The risk of ovarian cancer decreased progressively with increasing numbers of pregnancies. Similarly, the use of oral contraceptives has been shown to reduce the risk of ovarian cancer. Ovarian cancer risk decreases approximately 11% per year of oral contraceptive use to a maximum of 46% after 5 years of use. These observations have led to the theory of “incessant ovulation” in the etiology of ovarian cancer. According to this theory, risk for epithelial ovarian cancer is related directly to the number of uninterrupted ovulatory cycles. With ovulation, the surface epithelium is ruptured and then undergoes rapid proliferation and repair. At the time of ovulation, there is invagination of the surface epithelium into the underlying stroma forming inclusion cysts. The epithelium lining these inclusion cysts then undergoes neoplastic transformation under the influence of oncogenic factors. The observation that early age of menarche and late menopause are associated with an increase in ovarian cancer risk is consistent with this theory, because both increase the number of ovulatory cycles.

A second theory of ovarian carcinogenesis is the retrograde menstruation hypothesis. According to this hypothesis, retrograde transportation of carcinogens from the uterus and lower genital tract through the fallopian tube to the ovary occurs at the time of menstruation. The protective effect of oral contraceptives is consistent with this hypothesis because their use has been associated with a reduction in menstrual blood loss, thus with decreased retrograde menstruation. Conversely, the observed increase in ovarian cancer risk associated with hormone replacement therapy ([Table 53.1](#)) may be mediated through the periods of abnormal uterine bleeding that occur with many hormonal regimens. This hypothesis is also supported by the known decrease in ovarian cancer risk in women who have undergone tubal ligation or hysterectomy, because these procedures prevent the ascent of potential oncogenic factors from the lower genital tract to the ovary.

A final hypothesis concerning the genesis of ovarian cancer is that exposure of ovarian epithelium to persistently high levels of pituitary gonadotropins results in neoplastic transformation. Follicle-stimulating hormone (FSH) has been shown to promote the growth of epithelial ovarian cancer cells in vitro,

P.1278

and this effect can be blocked by luteinizing hormone (LH). A corollary to this hypothesis is that elevated circulating gonadotropin levels promote estrogen biosynthesis in the ovarian stroma, which, in turn, causes abnormal proliferation of the adjacent epithelium. Breast-feeding, which has been reported to lower the risk of ovarian cancer, is associated with reduced serum concentrations of LH and estradiol. Pregnancy and the use of oral contraceptives presumably lower the risk of ovarian cancer by inhibiting pituitary secretion of gonadotropins. This theory also receives support from the observed increased risk of ovarian cancer in women taking fertility drugs because these drugs stimulate ovulation by increasing levels of FSH, particularly in the follicular phase of the cycle.

Perhaps the most important risk factor for epithelial ovarian cancer is a family history of the disease. The estimated odds ratio for the development of ovarian cancer in a woman with one first-degree relative who has ovarian cancer is 3.1 (95% CI = 2.1 to 4.5). This risk increases even further (OR 4.6 CI = 1.1 to 18.4) in a woman with two or more primary or secondary relatives who have ovarian cancer. These odds ratios translate to a lifetime risk for ovarian cancer of approximately 5% in a woman with one first-degree relative who has the disease and 7% in a woman with two or more relatives with the disease. It should be mentioned, however, that familial ovarian cancers make up a relatively small proportion of total ovarian cancer cases. Only 5% to 10% of ovarian cancer patients report having a positive family history of the disease.

Three familial ovarian cancer syndromes have been described: Hereditary breast-ovarian cancer syndrome (HBOC), hereditary site-specific ovarian cancer syndrome (HSSOC), and hereditary nonpolyposis colon cancer syndrome (HNPCC). HBOC, the most common of the familial syndromes, is characterized by multiple cases of early-onset (<50 years of age) breast and ovarian cancers. This syndrome accounts for 75% to 90% of all hereditary ovarian cancer cases. HSSOC is manifested only by an increase in cases of early-onset ovarian cancer and makes up about 5% of hereditary ovarian cancers. Women with HSSOC are often younger and more commonly have tumors with serous histology than do women with sporadic ovarian cancer. HNPCC, or Lynch syndrome type II, is characterized by a predominance of early-onset proximal colon cancer in association with cancers of the endometrium and ovary. HNPCC is often confirmed by a mutation in one of several mismatch repair genes, in particular MLH1, MSH2, and MSH6. The estimated lifetime risk of ovarian cancer in women with HNPCC is 10% to 12%. These three familial ovarian cancer syndromes are inherited by autosomal dominant transmission through either maternal or paternal lineage. Therefore, the children of an affected parent have a 50% risk of inheriting the genetic abnormality.

Germline mutations in the BRCA1 or BRCA2 gene appear to account for most hereditary ovarian cancers. BRCA1 was identified in 1994 and is located on the long (q) arm of chromosome 17. BRCA1 is thought to be a

tumor suppressor because the normal copy of BRCA1 is always deleted in ovarian cancers that arise in women who inherit a mutant BRCA1 gene. It is estimated that germline mutations in BRCA1 are responsible for 80% to 90% of hereditary ovarian cancers. BRCA2 was identified in 1995 and is located on the long (q) arm of chromosome 13. In a recent report from the Breast Cancer Linkage Consortium, BRCA1 mutations were identified in 81% of ovarian cancer families, whereas BRCA2 mutations were detected in 14% of those families. Penetrance is variable (range 10% to 50%) from one individual to another, and it is estimated that the lifetime risk of ovarian cancer is approximately 39% in BRCA1 carriers and 11% in BRCA2 carriers.

SIGNS AND SYMPTOMS

Although most reports indicate that patients with early-stage ovarian cancer have few symptoms, a recent national survey of 1,725 ovarian cancer patients provides evidence that many of these patients actually had symptoms that they or their primary health providers ignored. The most common symptoms of patients with stage I or II ovarian cancer were abdominal bloating or pain, indigestion, urinary frequency, and constipation. Because many of these symptoms are nonspecific, patients were unaware that they could be associated with ovarian cancer. As a result, 22% of patients ignored their symptoms entirely, and 30% reported that the wrong diagnosis was made. A pelvic examination was performed in only two thirds of patients, and 45% had a delay in diagnosis of more than 3 months. Patients with advanced disease commonly reported abdominal swelling, fatigue, and weight loss. In a subsequent study, four target symptoms were significantly more common in ovarian cancer patients before diagnosis than in age-matched control patients. These symptoms included abdominal pain (frequency 30%, OR 6), abdominal swelling (frequency 16.5%, OR 30), gastrointestinal (GI) symptoms (frequency 8.5%, OR 2.3), and pelvic pain (frequency 5.4%, OR 4.3). These observations emphasize the need for patient and physician education concerning the possible relationship of rather nonspecific abdominal symptoms to ovarian cancer. A high index of suspicion, coupled with pelvic ultrasound and CA-125 testing, may lead to the earlier diagnosis of ovarian cancer in selected patients with these symptoms. Routine yearly pelvic examination has not been shown to increase the diagnosis of early-stage ovarian cancer.

Although vaginal bleeding is not commonly associated with ovarian cancer, it may be present in patients with metastatic involvement of the uterus. Likewise, endometrial hyperplasia and abnormal uterine bleeding can be caused by excess estrogen production from an ovarian stromal tumor. Ovarian cancer must be considered in a patient who presents with a pelvic mass and shortness of breath. A malignant pleural effusion from metastatic ovarian cancer is more common on the right side and is usually associated with dullness to percussion and decreased breath sounds. Finally, any patient with a clinically detected pelvic tumor on pelvic examination should undergo careful palpation of both groins to rule out inguinal lymphadenopathy secondary to metastatic disease.

PREOPERATIVE EVALUATION

Before operative intervention, each patient should undergo a thorough evaluation designed to determine the anatomic location, size, and morphology of the ovarian tumor, as well as possible sites of metastases. In addition, her general medical condition and ability to undergo a major surgical procedure should be established. All patients should undergo routine hematologic and biochemical testing. A computed tomography (CT) scan provides valuable information concerning cardiac size, as well as the presence of pulmonary metastases or a pleural effusion. Positron emission tomography (PET) scans may be more sensitive, but their value in the preoperative assessment of primary ovarian cancer has not been proven.

CT scanning with contrast may identify ureteral obstruction, retroperitoneal lymphadenopathy, omental disease, and peritoneal metastases. In a patient with ascites but no ovarian tumor, liver function studies should be performed to exclude cirrhosis or liver disease. Rarely, the presence of right heart failure and hepatic congestion will cause ascites. Paracentesis may be useful in a patient who presents with ascites and

no evidence of an ovarian abnormality. The characteristics of malignant cells present in ascitic fluid may help identify the primary site of intra-abdominal malignancy. An electrocardiogram is indicated in all women older than age 40 or in a patient with specific signs or symptoms of cardiac disease.

TABLE 53.2 Serum Markers in Ovarian Cancer

TUMOR HISTOLOGY	SERUM MARKER
Epithelial ovarian cancer	CA-125
Mucinous cystadenocarcinoma	CEA
Endodermal sinus tumor	AFP
Embryonal cell carcinoma	hCG, AFP
Choriocarcinoma	hCG
Dysgerminoma	LDH-1, LDH-2
Granulosa cell tumor	Inhibin

AFP, alpha-fetoprotein; CEA, carcinoembryonic antigen; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

Common sites of nongynecologic cancer that spreads to the ovary include gastric malignancy, colonic carcinoma, and breast carcinoma. A careful history and physical examinations should arouse suspicion of other possible primary malignancies. Any such possibilities should be evaluated with appropriate ongoing studies and diagnostic evaluation, possibly including colonoscopy, upper GI endoscopy, and/or mammography. A biopsy of a suspicious finding or easily accessible lymph node may clarify the diagnosis.

Finally, serum markers should be obtained according to the age and clinical findings of each patient. Serum CA-125 and CEA often are elevated in patients with epithelial ovarian cancer, whereas serum alpha-fetoprotein, human chorionic gonadotropin, or lactate dehydrogenase is more commonly increased in younger women with germ-cell ovarian malignancies. Serum inhibin is the most reliable marker in patients with ovarian granulosa cell tumors. The specific marker associated with each type of ovarian cancer is illustrated in Table 53.2. It is important to obtain a baseline serum marker value before surgery so that it can be used to monitor response to therapy.

PATTERNS OF SPREAD

Ovarian cancer spreads by (a) direct extension and exfoliation of tumor cells into the peritoneal cavity, (b) lymphatic metastases to regional and paraaortic lymph nodes, and (c) hematogenous dissemination (Fig. 53.1). The specific pattern of spread depends on the stage, cell type, and histologic differentiation of the tumor.

The earliest method of spread in epithelial ovarian cancer is by exfoliation of tumor cells from the ovarian surface. These cells migrate with the circulation of peritoneal fluid along the surfaces of the pelvic and

mesenteric peritoneum. They also are carried cephalad in the paracolic spaces to the omentum and undersurface of the diaphragm. Spread to the right lung occurs through the transdiaphragmatic lymphatics in the right hemidiaphragm, often producing a right pleural effusion. Surface spread to the peritoneal surfaces of the bowel and bladder is a common finding in advanced-stage ovarian cancer, but involvement of the bowel lumen or bladder mucosa is rare.

FIGURE 53.1 Patterns of spread of ovarian cancer.

Lymphatic drainage from the ovary follows two pathways. The first involves lateral spread through the broad ligament to the pelvic lymph nodes. In patients with advanced-stage disease, there may be retrograde dissemination via the lymphatics of this pathway to the round ligament to the inguinal lymph nodes. The second pathway of efferent lymphatic drainage follows the ovarian vein to the paracaval and paraaortic lymph nodes. Metastatic spread of ovarian cancer to lymph nodes is well documented even in early-stage disease ([Table 53.3](#)) and confirms that there may be separate pathways of dissemination to the pelvic and paraaortic lymph nodes. Cass and coworkers, for example, reported that 14 of 96 patients (15%) with disease visibly confined to one ovary had microscopic lymph node metastases. All 14 patients with nodal spread had poorly differentiated tumors. Isolated ipsilateral lymph node metastases occurred in five patients, and isolated contralateral lymph node metastases occurred in three patients. Pelvic lymph nodes were involved in six patients, paraaortic lymph nodes in five patients, and both in three patients. As expected, the frequency of lymph node metastases is related to stage of disease, cell type, and histologic differentiation of the tumor. Chen and Lee, for example, reported that the frequency of pelvic lymph node metastases increased from 9% in patients with clinically

apparent stage I ovarian cancer to 33% in patients with stage IV disease. Similarly, the frequency of paraaortic lymph node involvement increased from 18% in patients with clinically apparent stage I disease to 67% in patients with stage IV disease. These findings are similar to those of Burghardt and colleagues, who noted lymph node metastases in 74% of patients

P.1280

with stage III or IV ovarian cancer. The incidence of lymph node metastases increased from 20% in well-differentiated ovarian cancers to 65% in poorly differentiated tumors and was higher in serous ovarian malignancies than in mucinous or endometrioid cancers.

TABLE 53.3 Lymph Nodal Metastases in Patients with Clinically Apparent Stage I Epithelial Ovarian Cancer

AUTHOR	PATIENTS	PELVIC LYMPH NODE METASTASES	PARAAORTIC LYMPH NODE METASTASES
Onda et al. (1996)	30	6 (18%)	5 (15%)
Carnino et al. (1997)	47	1 (4%)	0 (0%)
Burghardt et al. (1991)	20	3 (15%)	1 (5%)
Sakai et al. (1997)	46	1 (2%)	1 (2%)
Chen and Lee (1983)	11	1 (9%)	2 (18%)
Li et al. (2000)	91	9 (10%)	8 (9%)
Total	245	21 (9%)	17 (7%)

Hematogenous spread of ovarian cancer to the parenchyma of the liver or lung is fortunately quite rare (<5%) at the time of initial diagnosis, but may occur, particularly in poorly differentiated tumors that become refractory to combination chemotherapy.

EXAMINATION OF OVARIAN TUMOR SPECIMENS AND HISTOLOGIC CLASSIFICATION

Ovarian tumor specimens should be described, fixed, and sectioned according to the guidelines established by the College of American Pathologists (CAP). Tumors should be classified histologically according to the World Health Organization classification and nomenclature of ovarian tumors ([Table 53.4](#)).

P.1281

Although there are numerous grading systems for ovarian cancers that use both architectural and nuclear

features, it is recommended that four grades be used, with grade 4 (undifferentiated) applied to tumors with minimal or no differentiation. Recommendations concerning the use of special staining techniques or flow cytometry in establishing the correct histologic diagnosis of ovarian tumors are made in the CAP report. Immunohistochemical staining of ovarian tumors for cytokeratin 7 (CK7) and cytokeratin 20 (CK20) is helpful in differentiating primary mucinous ovarian carcinoma from colorectal adenocarcinoma that has metastasized to the ovary. Colorectal adenocarcinomas usually stain positively for CK20 and negatively for CK7. In contrast, ovarian carcinomas usually stain negatively for CK20 and positively for CK7.

PRIMARY SURGERY

Patterns of Care in Ovarian Cancer Surgery

All patients with suspected ovarian cancer should be referred to a gynecologic oncologist for evaluation and possible surgery. Unfortunately, in both Europe and the United States (where most of the outcomes studies have been conducted), too high a proportion of women with ovarian cancer are receiving substandard care. The role of comprehensive staging, particularly pelvic and paraaortic lymphadenectomy, in patients with early-stage ovarian cancer has been a topic of wide discussion, primarily because many women with early-stage disease are inadequately staged and because surgeons with the expertise to perform a lymphadenectomy are not always involved with the initial surgery. A study by Goff et al. (2006) that evaluated patterns of surgical care across the United States revealed that among women with early-stage disease, 21.4% underwent an oophorectomy with or without a hysterectomy but without any additional staging or debulking procedure and 47% did not have nodal sampling. Carney and associates found that less than 50% of ovarian cancer patients in Utah were cared for by a gynecologic oncologist. In addition, they also noted that care by a gynecologic oncologist was associated with a survival advantage. In the Maryland study, Bristow and coworkers found that the majority of ovarian cancer patients in Maryland were undergoing primary surgery in low-volume settings.

In patients with early-stage disease, lymphadenectomy, in addition to providing prognostic information, may have therapeutic value. Chan et al. evaluated 6,686 women diagnosed with clinical stage I ovarian cancer to estimate the survival impact of lymphadenectomy. The authors found that lymphadenectomy was associated with improved 5-year disease-specific survival. In addition, the extent of lymphadenectomy was significantly associated with the 5-year disease-specific survival rate (0 nodes sampled, 87%; fewer than 10 nodes sampled, 92%; and 10 or more nodes sampled, 94%; $P < 0.001$). In a study of the SEER program database from 1991 and 1996, Harlan and colleagues found that comparing the two treatment periods, the majority of women with early-stage ovarian cancer did not receive guideline therapy in both periods, although the rate was improved in the 1996 cohort. For women with advanced-stage ovarian cancer, there was a higher rate of guideline therapy use but no improvement between 1991 and 1996—62.6% versus 62.3%. The totality of this information clearly underscores the need for improvement in patterns of referral.

Early-Stage Ovarian Cancer

Comprehensive Surgical Staging

STEPS IN THE PROCEDURE

Comprehensive Staging of Early Disease (Laparoscopy)

- Entry into abdominal cavity and inspection of pelvic and peritoneal cavity
- Cytology obtained
- Affected ovary isolated by identification of infundibulopelvic ligament
- Ureter identified and isolated
- Infundibulopelvic ligament cauterized and transected
- Utero-ovarian ligament cauterized and transected
- Ovary placed in endoscopic bag intact and removed through largest trocar site assuring no spilling of ovarian tissue
- Frozen section obtained and if consistent with cancer, then formal staging performed
- Omental biopsy performed by coagulation and transection of dessicated tissue
- Pelvic and paraaortic lymph node dissection is performed bilaterally.

- Multiple peritoneal biopsies performed including both paracolic gutters, pelvic peritoneal surfaces bilaterally, and diaphragm peritoneum

Ovarian cancer is staged according to the International Federation of Gynecology and Obstetrics (FIGO) staging system ([Table 53.5](#)). The official FIGO staging for ovarian cancer was extensively changed in 2012 and has been recently published. Staging is based on a thorough surgical evaluation of the possible metastatic spread of the cancer and histologic evaluation of the primary ovarian lesion. It is too early to know if substaging of stage IC or IIIA will be reliable prognostic characteristics in general, nonresearch settings. Should preoperative evaluation suggest an area of extra-abdominal or intrahepatic metastasis, fine needle aspiration or needle biopsy of this lesion should be performed. Because ovarian cancer frequently spreads to upper abdominal structures, a vertical midline abdominal incision is recommended. This incision should be extended high enough to remove the primary ovarian tumor and to evaluate the stomach, omentum, liver, and undersurface of the diaphragm. Rupture of a cystic ovarian malignancy is associated with a poorer prognosis, so the incision should be sufficient to allow excision of the primary tumor with its capsule intact. Once the abdomen has been opened, the following steps should be performed for adequate surgical staging ([Table 53.6](#)):

1. The volume of ascitic fluid should be recorded, and a minimum of 25 mL should be sent for cytologic evaluation.
2. In the absence of ascites, separate saline washings should be obtained from the (a) pelvic cul-de-sac, (b) right paracolic space, (c) left paracolic space, and (d) undersurface of each hemidiaphragm. Approximately 100 mL of saline should be instilled in each of these areas, recovered, and sent for cytologic evaluation.

P.1283

TABLE 53.5 FIGO Ovarian Cancer Staging (January 01, 2014)

STAGE I: Tumor confined to ovaries

OLD		NEW	
IA	Tumor limited to 1 ovary, capsule intact, no tumor on surface, negative washings/ascites	IA	Tumor limited to 1 ovary, capsule intact, no tumor on surface, negative washings
IB	Tumor involves both ovaries	IB	Tumor involves both ovaries otherwise like IA
IC	Tumor involves 1 or both ovaries with any of the following: capsule rupture, tumor on surface, positive washings/ascites	<i>IC Tumor limited to 1 or both ovaries</i>	
		IC1	<i>Surgical spill</i>
		IC2	<i>Capsule rupture before surgery or tumor on ovarian surface</i>
		IC3	<i>Malignant cells in the ascites or peritoneal washings</i>

STAGE II: Tumor involves 1 or both ovaries with pelvic extension (below the pelvic brim) or primary peritoneal cancer

OLD		NEW	
IIA	Extension and/or implant on uterus and/or fallopian tubes	IIA	Extension and/or implant on uterus and/or fallopian tubes
IIB	Extension to other pelvic intraperitoneal tissues	IIB	Extension to other pelvic intraperitoneal tissues
IIC ^a	IIA or IIB with positive washings/ascites		

STAGE III: Tumor involves 1 or both ovaries with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes

OLD		NEW	
IIIA	Microscopic metastasis beyond the pelvis	<i>IIIA (Positive retroperitoneal lymph nodes and /or microscopic metastasis beyond the pelvis)</i>	
		IIIA1	<i>Positive retroperitoneal lymph nodes only IIIA1(i) Metastasis ≤ 10 mm IIIA1(ii) Metastasis > 10 mm</i>
		IIIA2	<i>Microscopic, extrapelvic (above the brim) peritoneal involvement ± positive retroperitoneal lymph nodes</i>
IIIB	Macroscopic, extrapelvic, peritoneal metastasis ≤2 cm in greatest dimension	IIIB	<i>Macroscopic, extrapelvic, peritoneal metastasis ≤2 cm ± positive retroperitoneal lymph nodes. Includes extension to capsule of liver/spleen</i>
IIIC	Macroscopic, extrapelvic, peritoneal metastasis >2 cm in greatest dimension and/or regional lymph node metastasis	IIIC	<i>Macroscopic, extrapelvic, peritoneal metastasis >2 cm ± positive retroperitoneal lymph nodes. Includes extension to capsule of liver/spleen</i>

STAGE IV: Distant metastasis excluding peritoneal metastasis

OLD		NEW	
IV	Distant metastasis excluding	IVA	<i>Pleural effusion with positive cytology</i>

peritoneal metastasis. Includes
hepatic parenchymal metastasis.

IVB Hepatic and/or *splenic parenchymal*
metastasis, metastasis to extra-abdominal
organs (including inguinal lymph nodes and
lymph nodes outside of the abdominal
cavity)

^a*Old stage IIC has been eliminated.*

Other major recommendations are as follows:

- Histologic type including grading should be designated at staging.
- Primary site (ovary, fallopian tube, or peritoneum) should be designated where possible.
- Tumors that may otherwise qualify for stage I but involved with dense adhesions justify upgrading to stage II if tumor cells are histologically proven to be present in the adhesions.

Complete abdominal inspection and palpation
Resection of ovaries, fallopian tubes, and uterus ^a
Omentectomy
Random peritoneal biopsies
Retroperitoneal lymph node sampling

^aExceptions may be made in selected patients who wish to preserve fertility.

3. The ovarian tumor should be inspected, with particular attention to the presence of papillary excrescences on the surface or rupture of the capsule. The contralateral ovary and uterus should be examined for the presence of metastatic tumor. The pathways of ovarian tumor should be removed and sent for frozen section examination. Removal of the opposite ovary and/or uterus is dependent on several factors and is discussed on

the following pages.

4. Careful inspection and palpation of the peritoneal surfaces and intra-abdominal viscera should be performed. This evaluation should be approached in a systematic fashion, beginning with the peritoneum of the cul-de-sac and small bowel mesentery. Inspection should continue with the ascending colon, liver, omentum, undersurface of the right and left hemidiaphragms, and stomach. Finally, the transverse colon, spleen, descending colon, and bladder peritoneum should be evaluated.
5. All areas suspicious for malignancy should be biopsied. In the absence of visible disease, biopsies should be taken of the cul-de-sac peritoneum, bladder peritoneum, both lateral pelvic walls, paracolic peritoneum bilaterally, and undersurface of the right hemidiaphragm. An infracolic omentectomy should be performed in patients with epithelial ovarian cancer and an omental wedge biopsy taken in patients with germ-cell or stromal tumors. Appendectomy should be performed in all patients with mucinous epithelial cancers involving the ovary. Primary appendiceal cancers, although rare, commonly spread to the ovaries and usually require right hemicolectomy as part of initial surgical staging.
6. As has been mentioned, ovarian cancer commonly spreads to both pelvic and paraaortic lymph nodes. Some patients with early-stage ovarian cancer have paraaortic lymph node metastases in the absence of pelvic lymph node spread. Therefore, these lymph node groups should be sampled separately in all patients. It is important that sampling include lymph nodes on the opposite side of the primary ovarian tumor, because isolated contralateral spread has been reported. In the setting of advanced-stage disease, prospective randomized trials reviewed by Panici et al. have shown that routine lymphadenectomy is not associated with a higher survival rate; however, it is associated with an improvement in the disease-free interval.
7. Finally, it should be emphasized that operative findings present at the time of staging must be carefully documented. Prognosis is related to the site and volume of metastatic tumor, as well as the amount of residual disease remaining after surgical debulking. Important data concerning the location and size of tumor metastases are often lost if the details concerning operative staging are not recorded.

TABLE 53.7 Criteria for Potential Fertility-Sparing Surgery in Ovarian Cancer Patients

Patient desirous of preserving fertility
Patient and family consent and agree to close follow-up
No evidence of dysgenetic gonads
Specific situations
Any unilateral malignant germ-cell tumor
Any unilateral sex cord-stromal tumor
Any unilateral borderline tumor
Stage IA invasive epithelial tumor

Fertility-Sparing Surgery

Although the majority of ovarian malignancies occur in older women for whom bilateral salpingo-oophorectomy and hysterectomy are standard treatment, a significant subset of patients is young and can be managed more conservatively ([Table 53.7](#)). Conservative management is used here to denote surgery that preserves reproductive potential without compromising curability. With some exceptions, such a strategy may be applicable for women younger than 40 years who wish to bear children.

When contemplating surgery on a young patient with a suspected ovarian malignancy, it is important to discuss with her all possible operative findings and procedures and the longterm implications of the various options. If the patient is a child, the parents need to clearly understand this information. In most instances, young patients have their initial surgery done outside major university hospitals or cancer centers. Common errors in surgical management include incomplete surgical staging and unnecessary bilateral salpingo-oophorectomy. In addition, some patients are mismanaged because of an error in the pathologic diagnosis of a rare ovarian neoplasm.

The optimal candidate for conservative surgical management is a young patient who has stage IA disease. If, on initial inspection, the suspected cancer is confined to one ovary, then unilateral salpingo-oophorectomy is appropriate. If the mass is thought to be benign, then ovarian cystectomy may be preferable. The specimen should be sent for frozen section examination. If malignancy is diagnosed, then appropriate staging biopsies should be performed, as discussed. If the contralateral ovary appears normal, it is recommended that it not be biopsied to avoid potential infertility caused by peritoneal adhesions or ovarian failure.

One should not rely too heavily on frozen section examination in making the decision to perform a hysterectomy and bilateral salpingo-oophorectomy. If the histologic diagnosis is in question, it is always preferable to wait for permanent section results for a young patient, even if this requires a repeat surgery.

The advent of in vitro fertilization technology has been a significant impact on intraoperative management. Previously, convention dictated that if a bilateral salpingo-oophorectomy is necessary, a hysterectomy should also be performed. However, current technology for donor oocyte transfer and hormonal support allows a woman without ovaries to sustain an intrauterine pregnancy. Similarly, if the uterus and one ovary are resected because of tumor involvement, current techniques allow retrieval of oocytes from the patient's remaining ovary, in vitro fertilization with sperm from her male partner, and implantation of the embryo into a surrogate's uterus. Therefore, traditional guidelines concerning surgical management of ovarian cancer may no longer be applicable in selected young patients.

P.1285

Approximately 50% to 70% of *malignant germ-cell tumors* are stage I. Except for dysgerminoma, in which the incidence of bilaterality is 10% to 15%, bilateral ovarian tumors are exceedingly rare. Such a finding almost always signifies advanced disease with metastatic spread from one ovary to the other or a mixed germ-cell tumor with a dysgerminoma component. Benign cystic teratoma is associated with malignant germ-cell tumors in 5% to 10% of cases and may occur in one or both ovaries. Therefore, *unilateral salpingo-oophorectomy—preserving the contralateral ovary and uterus—combined with surgical staging can be performed in most patients with malignant germ-cell tumors, even many with advancedstage disease*. If the contralateral ovary is enlarged, most likely it represents a benign cystic teratoma that can be managed with an ovarian cystectomy only. With the exception of stage IA pure dysgerminoma or stage IA, grade 1 immature teratoma, patients with germ-cell tumors require postoperative chemotherapy consisting of the combination of bleomycin, etoposide, and cisplatin (BEP). Several series have documented normal reproductive function in at least 80% of patients as well as pregnancies following fertility-sparing surgery and chemotherapy.

In the past few years, some investigators have advocated the practice of surgery alone for other categories of malignant germ-cell tumors, including stage IA, grade 2 and 3 immature teratomas, and stage IA yolk sac tumors.

Such an approach, however, should be taken with caution; many experts would still consider it experimental. Nevertheless, there is a trend toward careful observation following surgery alone for most patients with stage I malignant ovarian germ-cell tumors. The Children's Oncology Group is currently conducting a clinical trial that includes postoperative surveillance for patients with stage I disease. Chemotherapy is initiated only for serum tumor marker elevation.

Most *sex cord-stromal tumors* are confined to the ovary. Stage I accounts for greater than 50% (in some series as high as 100%) of granulosa cell tumors. More than 90% of Sertoli-Leydig cell tumors are stage IA. Bilaterality occurs in less than 5% of cases with either tumor type. *Therefore, optimal surgical management of most patients with stromal tumors consists of unilateral adnexectomy.* There does not appear to be a role for lymphadenectomy in patients with sex cord-stromal tumors. A study by Brown et al. evaluated 262 patients with sex cord-stromal tumors. Of these, 111 patients underwent a complete or partial staging procedure. None of the patients had evidence of positive nodes. The authors also noted that of the 117 patients whose disease eventually recurred, 6 patients (5.1%) had nodal metastases at the time of recurrence. Endometrial biopsy or curettage also should be performed in any young patient whose uterus is preserved because 5% to 15% of patients with granulosa cell tumors develop endometrial cancer or hyperplasia. Postoperative therapy may be indicated for patients with metastatic disease or for selected patients with stage I disease (e.g., poorly differentiated Sertoli-Leydig cell tumor or granulosa cell tumor with rupture). The most commonly used regimens in this setting include either BEP or the combination of paclitaxel and carboplatin.

Approximately 10% to 15% of all ovarian neoplasms are of the *borderline or low malignant potential* classification. Although they were first described more than 70 years ago, only in the last few years have we begun to fully appreciate their biologic behavior. Approximately 33% to 60% of serous borderline tumors are limited to one ovary. Extraovarian spread is noted in approximately 20% to 30% of cases. Approximately 80% to 90% of mucinous borderline tumors are confined to one ovary. Both endometrioid and clear cell borderline tumors are almost always stage I, and the vast majority is unilateral. *For patients with borderline tumors seemingly confined to one ovary, appropriate surgical management includes unilateral salpingo-oophorectomy with surgical staging.* The use of ovarian cystectomy instead of unilateral adnexectomy also has been reported, although some patients treated in this manner require repeat surgery for a recurrence of tumor in the same or opposite ovary. If bilateral borderline tumors are present, portions of one or both ovaries may be preserved with ovarian cystectomy, if feasible. Whatever the surgical approach, reported 5-year survival rates for patients with stage I borderline tumors treated with surgery alone are 95% or better.

For patients with borderline tumors and peritoneal implants, the optimal management remains controversial. However, surgical excision is the mainstay of treatment. After frozen section confirmation of borderline tumor, an effort should be made to resect all gross disease. In addition, staging biopsies of peritoneal surfaces and lymph nodes are indicated, as are cytologic washings. However, there is no consensus regarding the extent of surgical staging required, particularly with regard to the need for lymphadenectomy. A recent study was conducted to evaluate the prognostic value of lymph node involvement for borderline tumors. This was a retrospective study on 49 patients at a single institution, and a broader analysis was also performed on 1,503 patients obtained from the Surveillance, Epidemiology and End Results (SEER) database. The authors concluded that lymph node involvement does not appear as a prognosis factor in patients with advanced-stage borderline tumors. Even in the face of metastatic disease, a normal contralateral ovary may be preserved in young patients. In patients with advanced-stage serous disease, the incidence of bilateral tumors is approximately 75%. There are several reports detailing successful pregnancies following treatment in patients with borderline ovarian tumors.

The relapse risk for patients with peritoneal implants is related to the type: noninvasive versus invasive. For patients with noninvasive peritoneal implants, the lifetime risk is estimated to be at least 20%. For those with invasive peritoneal implants, the lifetime risk of relapse is estimated to be at least 50%. Consequently,

postoperative platinum-based chemotherapy is recommended for the latter diagnosis by many groups. However, no study has demonstrated a survival benefit related to postoperative chemotherapy.

Invasive epithelial tumors account for approximately 70% of all ovarian malignancies. Despite the low overall survival rate associated with these tumors, selected young patients with stage I disease can be treated conservatively. The major factors that influence the selection process are histologic grade and bilaterality, in addition to stage. Serous tumors are bilateral in about 50% of cases. The incidence of bilaterality for mucinous tumors varies widely in reported series from as low as 5% to as high as 50%, but probably is no greater than 10% to 20%. Approximately 30% to 50% of endometrioid and clear cell cancers are bilateral.

Several reports have detailed the reproductive outcomes of women with early-stage invasive epithelial ovarian cancer following treatment with fertility-sparing surgery with or without chemotherapy. A multiinstitutional study in the United States evaluated the recurrence rate, survival, and pregnancy outcome in patients with stage IA and IC invasive epithelial ovarian cancer treated with unilateral adnexectomy. Fiftytwo patients with stage I epithelial ovarian cancer treated from 1965 to 2000 at eight participating institutions were identified. Cell type was distributed as follows: mucinous, 25; serous, 10; endometrioid, 10; clear cell, 5; and mixed, 2.

P.1286

A total of 20 patients received adjuvant chemotherapy. The median duration of follow-up was 68 months. Five patients developed tumor recurrence 8 to 78 months after initial surgery. Sites of recurrence were as follows: contralateral ovary, 3; peritoneum, 1; and lung, 1. At the time of publication, 50 patients were alive without evidence of disease and 2 had died of disease 13 and 97 months after initial treatment. Twentyfour patients attempted pregnancy and 17 (71%) conceived. Of these, 17 patients had 26 term deliveries (no congenital anomalies noted) and 5 spontaneous abortions. The authors concluded that the long-term survival of patients with stage IA and IC epithelial ovarian cancer treated with unilateral adnexectomy is excellent.

Adjuvant Therapy

To begin making decisions about which patients might benefit from postoperative or adjuvant therapy, one must categorize them based on risk of relapse. The risk of relapse is approximately 1% for patients with stage I borderline ovarian tumors; thus, adjuvant therapy is not recommended.

For women with stage IA or IB *sex cord-stromal tumors*, no adjuvant therapy is recommended because of the low risk of relapse. For those with stage IC disease, however, the level of risk remains uncertain; some studies suggest that tumor rupture or the presence of ascites is prognostic, whereas others do not. For patients with high-risk *early-stage sex cord-stromal tumors* (stage IC or II), there is no standard postoperative treatment. The most commonly used regimens include the combination of bleomycin, etoposide, and cisplatin (BEP) or the combination of paclitaxel and carboplatin.

For several years, the dogma has dictated that all patients with early-stage malignant ovarian *germ-cell tumors*, except those with stage IA dysgerminoma or stage IA, grade 1 immature teratoma, require postoperative chemotherapy. Standard therapy since the 1980s has been the BEP combination. However, over the past few years, a number of groups have reported provocative results with the strategy of surveillance following primary surgery for patients with stage IA of all subtypes. In considering this strategy, the critical issue is ultimate outcome. Of course, if surveillance is successful, one can avoid the myriad acute effects of chemotherapy as well as the risk of significant late effects, such as secondary leukemia or premature ovarian failure. Even if there is a moderate relapse risk necessitating chemotherapy, if one can avoid chemotherapy in a significant proportion of patients and in addition salvage those who relapse, such management will be deemed successful. On the other hand, if very many of those who relapse ultimately succumb to their disease, it will most certainly not become part of standard practice. Where the threshold lies on the latter remains unresolved.

Bonazzi et al. conducted a prospective study of 22 patients with stage I or II, grade 1 or 2, immature teratoma of

the ovary who were treated with surgery alone. Two patients relapsed—one with stage IA, grade 2 and the other with stage IC, grade 2. Both were salvaged with surgery that revealed only grade 0 immature teratoma. Dark et al. reported on 24 patients who underwent surveillance after surgery for stage IA malignant ovarian germ-cell tumors. Nine had dysgerminoma (which most already would observe), nine had immature teratoma, and six had yolk sac tumors, with or without immature teratoma. Eight patients—three with grade 2 immature teratoma, three with dysgerminoma, and two with contralateral dysgerminoma (presumably second primary tumor)—required subsequent chemotherapy. After a median follow-up of 6.8 years, all but one patient are alive and in remission. In a follow-up report from the Charing Cross/Mt. Vernon group in the United Kingdom, which apparently included those reported earlier, 37 patients with stage I malignant ovarian germ-cell tumors underwent surveillance. However, one patient had a squamous carcinoma arising in a mature cystic teratoma, which, in our opinion, is a completely different entity. The other 36 patients included 3 with grade 0 immature teratoma (which would never require chemotherapy unless thought to represent a growing teratoma syndrome), 9 dysgerminomas, 1 embryonal carcinoma, 15 immature teratomas, 6 yolk sac tumors, and 2 with mixed germ-cell tumors. Of these 36 patients, 11 (31%) relapsed—1 with mature teratoma (which may represent growing teratoma syndrome), 2 with dysgerminoma (although 1 was a second primary in the contralateral ovary), 4 with immature teratoma, 2 with mixed germ-cell tumors, and 1 each with yolk sac tumor and embryonal carcinoma. Two of the 11 patients died. One had grade 2 immature teratoma and became pregnant. She was diagnosed 13 months after diagnosis and died of a pulmonary embolus during chemotherapy. The second patient had grade 3 immature teratoma. She relapsed 3 months after diagnosis and subsequently died after secondary surgery and multiple lines of chemotherapy.

Mitchell et al. reported nine patients with stage I malignant ovarian germ-cell tumors—six with immature teratoma and three with mixed germ-cell tumors, all of whom had yolk sac tumor elements. At the time of the report, only one patient had relapsed. She had immature teratoma of unknown grade and relapsed 8 months after a unilateral salpingo-oophorectomy, but her parents refused further therapy. Cushing et al. described 44 patients with completely resected immature teratoma (31 pure and 13 with yolk sac tumor) treated with surgery alone. With a median follow-up of 4.2 years, one patient with a mixed germ-cell tumor relapsed at 18 weeks, as indicated by a rising alpha-fetoprotein, and was salvaged with four cycles of BEP. At the time of the report, she was disease free at 57 months after completing chemotherapy.

Most recently, Mangili et al. reported 28 patients with stage I pure immature teratoma of whom 19 were treated with surgery alone. Of these 19 patients, 9 had grade 1 disease, 8 had grade 2, and 2 had grade 3 disease. Four patients (21%) relapsed—two with mature teratoma and two with immature teratoma. The two with mature teratoma recurrence were treated with secondary cytoreductive surgery, and the two with immature teratoma were treated with secondary surgery followed by BEP chemotherapy. All were salvaged.

The Children's Oncology Group (COG) is currently studying the treatment strategy of surgery plus surveillance in children with stage I malignant ovarian germ-cell tumors. If the findings appear to be promising, further study will be required in adult patients.

For patients with early-stage *epithelial ovarian cancer*, most experts currently accept a classification system of low and high risk ([Table 53.8](#)). Within the stage I category, histologic grade is the most powerful predictor of outcome. Patients with welldifferentiated or grade 1 tumors have an excellent prognosis, with a 5-year survival rate of more than 90%. On the other hand, the 5-year survival rates for patients with grade 2 or 3 tumors are approximately 75% to 80% and 50% to 60%, respectively. Other factors that have been found to have prognostic significance include large-volume ascites, dense adherence, and clear cell histology. Although older studies suggested that capsular rupture or excrescences may be associated with a worsened prognosis, more recent studies have found no independent influence of these features on prognosis. However, the issue of the influence of tumor rupture on prognosis remains controversial.

Therefore, *low-risk early-stage epithelial ovarian cancer includes patients with the following factors: (a) stage IA or IB (intact capsule, no tumor excrescences, and no malignant ascites or negative peritoneal cytology) and (b) grade 1 or 2 disease. The standard treatment for this group of patients is surgery alone, and the 5-year survival is at least 95%. A controversy about whether grade 2 belongs in the low- or high-risk category remains unresolved; it is compounded by the lack of uniformity of grading systems.*

TABLE 53.8 Early-Stage Epithelial Ovarian Cancer Risk Groups

LOW RISK	HIGH RISK
Stage IA or IB, grade 1 and 2	Stage IA or IB, grade 3
	Stage IC
	Tumor on external surface
	Ruptured capsule
	Ascites or positive peritoneal washing
	All stage II

High-risk early-stage epithelial ovarian cancer includes those patients with the following factors: (a) stages IC (ruptured capsule, tumor excrescences, positive peritoneal cytology, or malignant ascites) to II, (b) grade 3 disease, or (c) clear cell histology. In some classification systems, dense adherence is also included in the high-risk category; however, in the view of many experts, this designation is simply a surrogate for stage II disease. This high-risk subset is thought to have a relapse risk in the range of 40% to 50% and is the focus of adjuvant therapy trials.

Persistent problems with incomplete surgical staging and interobserver variability in assigning histologic grade lead one to the realization that more objective and reliable methods would be desirable for assessment of risk in early-stage ovarian cancer. Currently, there is no universally accepted prognostic molecular biomarker. There are, however, reports of several potential biomarkers. Among these are DNA ploidy, computerized morphometry, Ki-67, p53, and HER2/neu. Although none of the markers studied yet qualifies as prognostic, as technology advances, future studies will most certainly identify reliable biomarkers. Because there is no universal histologic grading system for epithelial ovarian cancer, investigators at M.D. Anderson Cancer Center recently reported a two-tier grading system for invasive serous carcinomas that emphasizes nuclear atypia rather than architecture, with mitotic count as a secondary feature. There is mounting evidence, both from genomic/molecular studies and clinical reports, supporting this low-grade/high-grade model.

Platinum-based chemotherapy has emerged as the standard treatment for patients with *early-stage epithelial ovarian cancer*. Bolis et al. reported the results of two multicenter trials conducted by the Gruppo Italiano Collaborativo in Oncologia Ginecologica. A total of 271 patients were included in these 2 trials. Trial 1 compared single-agent cisplatin with observation in patients with stage IA and IB, grade 2 or 3. Trial 2 compared single-agent cisplatin with intraperitoneal chromic phosphate in patients with stages IA, grade 2; IB, grade 2; and IC

disease. In both trials, although the cisplatin groups had a better disease-free survival, overall survival was not significantly different compared with the other arm. One possible explanation for these finding is that patients in the nonchemotherapy arm crossed over to cisplatin at time of relapse.

The Gynecologic Oncology Group (GOG) reported a randomized trial of cisplatin plus cyclophosphamide for three cycles versus intraperitoneal chronic phosphate in patients with high-risk early-stage ovarian cancer. With 204 evaluable patients randomized, relapse-free rates were 77% for the chemotherapy arm and 66% for the P³² arm. After adjusting for stage and histologic grade, the group receiving chemotherapy had a 29% decrement in estimated relapse. Chemotherapy was recommended as standard adjuvant therapy for this subset of patients because of the superior progression-free survival (PFS) and the late bowel toxicity associated with P³².

In a subsequent GOG trial, Bell and colleagues compared three versus six cycles of paclitaxel/carboplatin for patients with high-risk early-stage epithelial ovarian cancer. Although the recurrence rate associated with six cycles was 24% lower, the study was powered for a 50% or greater reduction in recurrence rate for six cycles. In addition, there was no difference in overall survival between the arms. In a recently completed GOG trial for early-stage disease, all patients initially received three cycles of paclitaxel/carboplatin and then were randomized between observation and 26 weekly doses of paclitaxel. Results of this trial are not yet available.

Two large European cooperative group trials in early-stage ovarian cancer were combined for analysis. Both the International Collaborative Ovarian Neoplasm 1 (ICON1) trial and the European Organisation for Research and Treatment of Cancer Collaborators—Adjuvant ChemoTherapy in Ovarian Neoplasm (EORTC-ACTION) trial randomized patients with early-stage epithelial ovarian cancer following surgery to observation versus platinum-based chemotherapy. Both overall survival and recurrence-free survival at 5 years were superior in the chemotherapy arm (82% vs. 74% and 76% vs. 65%, respectively).

A follow-up GOG study (GOG 0175) addressed the role of maintenance therapy in early-stage epithelial ovarian cancer. In this trial, women were randomized to three cycles of paclitaxel and carboplatin followed by either surveillance or low-dose weekly paclitaxel for 24 doses. The authors concluded that maintenance paclitaxel following standard paclitaxel/carboplatin provided no significant increase in relapse-free interval.

Advanced-Stage Ovarian Cancer

Primary Cytoreductive Surgery—Rationale

P.1288

STEPS IN THE PROCEDURE

Primary Cytoreductive Surgery—Advanced Disease

- Midline abdominal incision is performed from pubic symphysis to xiphoid.
- Ascites is drained from all quadrants of the abdomen and pelvis.
- Supracolic omentectomy is performed extending from hepatic flexure to splenic flexure of transverse colon.
- Resection of pelvic tumor including total hysterectomy and bilateral salpingo-oophorectomy and any grossly visible tumor.
- When pelvic tumor involves the distal large bowel, a rectosigmoid resection with anastomosis is performed.
- When disease is present in the small bowel, a resection of the involved segment of the small bowel is performed.
- Splenectomy performed when there is evidence of capsular or parenchymal disease.

- Diaphragmatic stripping or resection is performed when the diaphragm is either superficially involved with tumor or when there is penetration of tumor through the diaphragm.
- Partial hepatectomy or distal pancreatectomy is performed when segments of the liver or distal pancreas are involved with tumor.

Cytoreductive or debulking surgery refers to a surgical procedure for which the goal is to reduce the amount of tumor to a residual of less than 1 cm maximum diameter in a patient with metastatic ovarian cancer. Early studies suggested a relationship between the completeness of the surgery or the amount of residual tumor and survival. In a landmark paper, Griffiths demonstrated an inverse relationship between residual tumor diameter and survival; patients having residual disease less than 1.5 cm in diameter had a significantly improved survival compared with patients with bulky residual disease. Subsequent reports have confirmed these findings. As our philosophy about cytoreductive surgery has evolved, *optimal debulking* has come to denote minimal residual disease ≤ 1 cm in greatest diameter; *suboptimal debulking* denotes bulky residual disease greater than 1 cm in diameter. Chi et al. analyzed survival by diameter of residual disease to determine the optimal goal of primary tumor reduction for patients with stage IIIC epithelial ovarian cancer. The median overall survival durations by diameter of residual disease in each of the five categories were as follows: no gross residual disease, 106 months; 0.5 cm or less, 66 months; 0.6 to 1 cm, 48 months; 1 to 2 cm, 33 months; and greater than 2 cm, 34 months. Defining the extent of residual disease when dealing with tumor plaques on the peritoneal surfaces remains problematic. Furthermore, there is most certainly a lack of precision in measuring residual disease. The same group of investigators also published a study seeking to determine the survival impact of adding extensive upper abdominal surgical tumor reduction to standard surgical techniques in patients with advanced ovarian cancer. Extensive upper abdominal surgery was defined as diaphragm peritonectomy/resection, resection of parenchymal liver or porta hepatis disease, and/or splenectomy with or without distal pancreatectomy. They concluded that the addition of extensive upper abdominal tumor reduction was associated with improved survival in patients with stages IIIC to IV epithelial ovarian cancer. Interestingly, the rate of major surgical complications and the length of hospitalization were not significantly different between these patients and patients who did not undergo extensive upper abdominal tumor reduction. However, operative time and estimated blood loss were greater in the group of patients who underwent extensive upper abdominal surgery (264 minutes vs. 174 minutes, 880 mL vs. 460 mL, respectively; $P < 0.001$ for both).

Cytoreductive surgery, of course, must be considered not in a vacuum but rather in the context of responsiveness of residual tumor to postoperative therapies. Both radiotherapy and chemotherapy trials have shown a higher response rate in patients with minimal residual disease. These observations are supported by basic studies that suggest that larger tumor masses have poorly perfused anoxic areas that are not accessible to cytotoxic agents. Furthermore, larger tumors may have a greater proportion of cells in the resting phase. These nonproliferating cells may be less sensitive to cytotoxic agents. Skipper espoused the fractional cell kill hypothesis, stating that the ability of chemotherapeutic agents to eradicate cancer cells depends on both the dose of drug and the number of cells present. A given dose of drug kills a constant fraction of cells with each exposure. However, certain factors—such as cell repair mechanisms, tumor heterogeneity, the fraction of cells in G0 phase, and the development of drug resistance—serve to counteract this process. Goldie and Coldman have shown that tumor cells have an intrinsic spontaneous mutation rate; larger tumors that go untreated for an extended period theoretically have a greater probability of containing cell populations resistant to anticancer agents. Therefore, even though patients with advanced ovarian cancer may undergo optimal debulking, the small residual tumor masses may still contain drug-resistant cells that preclude ultimate cure.

Several reports have described the accomplishment of optimal cytoreductive surgery in a high percentage of patients. The morbidity and mortality associated with cytoreductive surgery also have been analyzed. These

studies generally reflect an operative mortality rate of less than 2%, a mean operating time of 3 to 5 hours, and a mean blood loss of approximately 500 to 1,500 mL. There is a wide range of postoperative complications, the most common of which are infection, hemorrhage (at times requiring reexploration), prolonged ileus, and cardiopulmonary problems. The primary question concerning the efficacy of primary cytoreductive surgery is whether improved survival is related more to the biology of the tumor or the skill and aggressiveness of the surgeon. In other words, are those tumors that can be debulked optimally also tumors that are less invasive, less infiltrative, and more indolent? Earlier studies did not suggest that this was the case. They demonstrated that patients who required extensive surgery to achieve minimal residual disease and those who had minimal disease at the outset had similar survival rates. More recent studies, however, suggest that patients with de novo minimal disease have a superior prognosis to those who are debulked to minimal disease with aggressive debulking surgery. These findings support the concept of the prognostic influence of substage categories within the FIGO stage III classification. Unfortunately, there are no randomized studies to resolve important issues in this area. Studies indicate that optimal cytoreductive surgery may confer a survival advantage, even for patients with stage IV ovarian cancer. Four large retrospective reports noted that patients with stage IV disease who were optimally cytoreduced had a statistically superior survival to patients who were suboptimally cytoreduced ([Table 53.9](#)).

Technique

Exploration

The patient is placed in either the supine or semilithotomy, depending on the likelihood of a rectosigmoid resection. A vertical midline incision is employed and extended cephalad to the level of the xiphoid. On entering the abdomen, the initial steps outlined under surgical staging are followed. After evacuation of ascites, if present, and inspection and palpation, the size of the primary tumors(s) and size and extent of metastatic deposits should be noted.

During this initial phase of the operation, the surgeon must make an assessment of the feasibility of cytoreductive surgery. In a typical patient with advanced disease, the omentum may be totally replaced by tumor, and the pelvis may be filled with tumor, making it difficult or impossible for the surgeon to distinguish normal pelvic structures. Findings that may initially dissuade the surgeon from proceeding with aggressive tumor resection include extensive parenchymal hepatic involvement, diaphragmatic involvement with extension to the pleural cavity, extensive

P.1289

infiltration of the small intestinal mesentery, or bulky nodal disease above the renal vessels. On the other hand, even if minimal residual disease cannot be achieved, debulking of omental and pelvic masses may relieve production of ascites, reduce pressure on adjacent organs, and allow the patient increased comfort, at least temporarily. Moreover, intestinal resection still may be indicated for relief of impending or true obstruction.

TABLE 53.9 Effect of Debulking on Survival in Stage IV Ovarian Cancer

FIRST AUTHOR	YEAR	SURGICAL RESULT	PATIENTS	OPTIMAL	MEDIAN SURVIVAL	P
Curtin	1997	Optimal (<2 cm)	41	45%	40	0.01
		Suboptimal	51		18	
Liu	1997	Optimal (<2 cm)	14	30%	37	0.02

		Suboptimal	33		17	
Munkarah	1997	Optimal (<2 cm)	31	34%	25	0.02
		Suboptimal	61		15	
Bristow	1999	Optimal (≤ 1 cm)	25	30%	38	0.0004
		Suboptimal	59		10	

Omentectomy

It is our preference to perform an omentectomy before focusing on the pelvis if the omentum is largely or completely replaced by tumor. If the omental tumor is adherent to the parietal peritoneum of the anterior abdominal wall, the pelvic structures, or loops of small intestine, it should be dissected from these structures. Once the omentum is mobilized and lifted cephalad, a dissection plane is developed between it and the serosa of the transverse colon, extending the dissection laterally in both directions (**Fig. 53.2A**). If the supracolic omentum is heavily involved with tumor and densely adherent to the transverse colon, it also may be necessary to establish a plane between the greater curvature of the stomach and the omentum by ligating the right and left gastroepiploic arteries and the individual gastric branches (**Fig. 53.2B**). Entrance into the lesser sac allows traction on the greater curvature of the stomach and facilitates exposure and transection of the gastric branches of the gastroepiploic arch. Occasionally, omental tumor may also involve the spleen or splenic hilum, necessitating splenectomy (see “[Splenectomy](#)”).

transverse colon. B: Omentectomy. Dissection of omentum with tumor from stomach with ligation of gastric branches.

P.1290

FIGURE 53.3 Retroperitoneal approach with lateral peritoneum incised, demonstrating the proximity of the left ovarian tumor to major pelvic vessels, the ureter, and the rectum.

Resection of Pelvic Tumor

Any adhesions of small intestine or cecum to the pelvic structures should be lysed. A self-retaining retractor then may be inserted and the bowel packed for adequate exposure. We consider that one of the most effective retractors for adequate exposure during a tumor reductive surgery is the Thompson retractor (Thompson Surgical Instruments, Traverse City, MI). If normal pelvic spaces and planes are obliterated by tumor, then the retroperitoneal approach is preferred (**Fig. 53.3**). The lateral pelvic peritoneum is incised, and the incision is carried cephalad and caudad. As part of this maneuver, the round ligament is identified and ligated as well. The retroperitoneal space is thus entered and the structures—ureter, iliac vessels, and ovarian vessels—identified by using both sharp and blunt dissection. A suction tip is ideal for dissecting areolar tissue planes if used properly. Next, the ovarian vessels are ligated. The identical procedure is performed on the opposite side of the pelvis, and the tumor mass(es) is (are) mobilized medially.

If the ureters are densely adherent to the pelvic tumor, the surgeon may need to dissect them free, in some instances along the entire length of the pelvic portion of the ureter to the ureterovesical junction. In addition, the surgeon must establish a dissection plane between the sigmoid colon and the uterus and ovaries. This portion of the procedure may take considerable effort if this plane is obliterated by tumor. On the other hand, if the surgeon determines that such dissection is not feasible or that the wall of the colon is heavily infiltrated with tumor, resection of the rectosigmoid colon may be indicated (**Fig. 53.4**). Resection of the pelvic portion of the colon allows the surgeon access to the avascular retrorectal space. The uterus is dissected from the bladder as well. It is extremely rare for ovarian cancer to involve the bladder mucosa at the time of primary surgery, but the vesicouterine peritoneum may be heavily infiltrated. In such cases, resection of this area may be necessary, occasionally in conjunction with a partial cystectomy (see “[Resection of the Urinary Tract](#)”). Hysterectomy is then

performed, the vagina is entered, and the mass is removed en bloc. In some instances, it may be necessary to ligate the uterine vessels at their origin rather than near the uterus if tumor is extensive in this area. Also, supracervical hysterectomy may be advisable if there is extensive unresectable tumor in the cul-de-sac.

FIGURE 53.4 In the retroperitoneal approach, the proximity of the left ovarian tumor to the rectum is visualized before it is decided whether the tumor can be safely dissected from the rectum or resection of the rectosigmoid colon is required.

Resection of Rectosigmoid Colon

A rectosigmoid resection may be performed in approximately 10% of patients during primary debulking ([Fig. 53.5](#)). The decision to perform this procedure depends on several factors, including the presence or absence of rectosigmoid obstruction, the amount of tumor infiltration of the lower colon and its contiguity with the ovarian tumor(s), and the probability that such a procedure will render the patient “optimally debulked.” Occasionally, a patient will limit the surgeon’s intraoperative decision-making ability by refusing to consent to possible colostomy. In our experience, resection of the rectosigmoid colon almost always can be accomplished with consequent minimal residual disease in the pelvis; the limiting factor in achieving optimal cytoreduction, however, may be unresectable bulky residual tumor in the upper abdomen or retroperitoneum. In such cases, palliative resection in the absence of obstruction is not recommended. If a rectosigmoid colon resection is performed, in most cases the colon can be reanastomosed using either a suture technique or the end-to-end anastomosis (EEA) stapler ([Chapter 47](#)). For patients who undergo a reanastomosis, a protective hepatic flexure transverse loop colostomy or loop ileostomy protects the anastomosis for those who have received pelvic radiotherapy, those with unprepared colon, or those whose anastomosis is judged to be suboptimal. Occasionally, a colostomy with a Hartmann pouch is necessary.

A recent study by Peiretti et al. evaluated 238 patients who underwent rectosigmoid resection at the time of primary cytoreductive surgery to determine morbidity and overall survival. The investigators found that complete cytoreduction was achieved in 41% of the cases. The complications associated with rectosigmoid resection were anastomotic leakage in 3% of patients and pelvic abscess in 3.7%. The median overall survival among patients with complete cytoreduction was 72 months compared with 42 months among the rest of patients ($P = 0.002$).

FIGURE 53.5 Resection of rectosigmoid colon involved with ovarian cancer. The uterus and bilateral ovarian tumors have already been removed. After mobilization of the specimen and ligation of mesenteric vessels, transection is performed using gastrointestinal anastomotic stapling devices (or reticulating stapler for distal transection), and remainder of mesentery is ligated. Usually, reanastomosis using EEA stapler can be accomplished.

Small Intestinal Resection

Although the small intestine is a common site of metastasis, both to the serosa and the mesentery, extensive tumor involvement is an uncommon finding at primary surgery. If the small intestine is extensively involved with tumor, it is usually in the terminal ileum. Occasionally, small intestinal obstruction, either partial or complete, is present at diagnosis. As noted, complete surgical staging includes careful examination of the entire length of the small intestine from the ligament of Treitz to the cecum. If, on exploration, loops of small intestine are adherent to the pelvic tumor, omental tumor, or other loops of intestine, then these adhesions should be lysed. Indications for small intestinal resection include obstruction or impending obstruction by tumor infiltrating the serosa and muscularis of a segment or a nonobstructing extensive lesion of the small intestine for which resection would result in minimal residual disease.

If the lesion involves the very terminal portion of the ileum, an ileocelectomy with resection of the cecum and portion of ascending colon adjacent to the small intestine may be necessary. Care should be taken to avoid the

presence of tumor at the points of reanastomosis. The reanastomosis may be performed using either the suture or the stapling technique. In our experience and in the literature, small intestinal resection is indicated in approximately 5% to 10% of primary operations for ovarian cancer.

Resection of the Urinary Tract

Indications for ureteral resection or partial cystectomy are uncommon during cytoreductive surgery for ovarian cancer. If ureteral obstruction is noted preoperatively, it is almost always a result of ureteral compression rather than tumor infiltration. Although adherence of the ureter(s) to masses of ovarian cancer is not an unusual finding, the surgeon can almost always separate the ureter from the tumor using sharp dissection. If the distal ureter is resected as part of cytoreductive surgery, it usually can be reimplanted into the bladder. More commonly, the ureter may be injured during the course of debulking surgery. Depending on the site of injury, a primary reanastomosis, transureteroureterostomy, or ureteroneocystostomy may be indicated. In a report by Berek and associates, 16 of 848 patients (2%) underwent partial ureteral resection. Five patients had transureteroureterostomy, two had reanastomosis, and four had urinary diversion. Twelve of the operations were part of primary cytoreductive surgery, and four were part of secondary surgery. Nine of these 16 patients had evidence of ureteral obstruction on preoperative intravenous pyelograms. A recent study by Ang et al. reported on 442 patients who underwent laparotomy for advanced ovarian cancer. Of these, a total of 14 patients underwent prophylactic stent placement. The investigators found that there were no ureteric complications during the postoperative period. Optimal cytoreduction rate in this study was 88%.

On the other hand, tumor involvement of the peritoneum overlying the urinary bladder is not an uncommon finding during primary cytoreductive surgery. Occasionally, a partial cystectomy may be necessary to achieve optimal cytoreduction. In the series of Berek and associates, eight patients had a partial cystectomy for advanced ovarian cancer. Reconstruction necessitated ureteral reimplantation in two patients and an ileal conduit in one patient. If a partial cystotomy is indicated, we prefer a simple closure with two layers of chromic catgut suture, the inner layer as a continuous running suture and the outer layer as interrupted sutures.

P.1292

In our experience, it is exceedingly rare to find involvement of the bladder mucosa with ovarian cancer at initial diagnosis. Such patients usually report hematuria in association with obvious massive disease. The definitive diagnosis can be made easily by preoperative cystoscopy.

Splenectomy

Splenectomy is indicated occasionally during primary cytoreductive surgery. Various series report the incidence of splenectomy during primary cytoreductive surgery in 5% to 11% of cases of advanced ovarian cancer. Most commonly, the hilum of the spleen is involved with ovarian cancer in association with extensive omental involvement. Rarely, isolated splenic capsular involvement or even splenic parenchymal involvement may be found. In addition to tumor debulking, splenectomy also may be indicated during cytoreductive surgery because of a traction injury with avulsion of the splenic capsule during omentectomy or mobilization of the splenic flexure of the colon in association with descending colostomy or reanastomosis after rectosigmoid colon resection.

In a report from M.D. Anderson Cancer Center, Morris and colleagues reported on 23 patients for whom the procedure was performed as part of cytoreductive surgery for advanced ovarian cancer. Splenectomy was planned preoperatively in only three of these patients. Seven patients had parenchymal involvement by tumor, 11 had capsular disease, and 5 had no pathologic involvement by tumor. Magtibay et al. evaluated 112 patients who underwent splenectomy as part of primary or secondary cytoreductive surgery. They found that the most common indications for splenectomy were direct metastatic involvement (46%), facilitation of an en bloc resection of perisplenic disease (41%), and intraoperative trauma (13%). In that same study, the authors found that 65% of patients had hilar involvement, 52% capsular involvement, and 16% parenchymal metastases. Interestingly,

patients with disease directly involving the splenic parenchyma did not have a worse prognosis than patients with disease involving the splenic hilum or capsule. In another study by Tanner et al., the investigators evaluated the significance of parenchymal splenic metastasis in patients with advanced ovarian cancer, fallopian tube cancer, and primary peritoneal cancer. A total of 576 patients were identified, and of these, 97 patients underwent splenectomy. Optimal cytoreduction was performed in 74.7% of these patients. Parenchymal disease was identified in 20.6% of patients. In the subset of patients undergoing splenectomy, overall survival was lower for patients with parenchymal splenic metastases versus those without parenchymal disease (28.5 months vs. 51.2 months, $P = 0.004$).

The methods of performing splenectomy during cytoreductive surgery may vary depending on the circumstances. Under controlled conditions (no uncontrolled hemorrhage), the surgeon may prefer to incise the gastrosplenic ligament, gain access to the lesser sac, and identify and ligate the splenic vessels as they run along the superior border of the pancreas (Fig. 53.6). The spleen then can be mobilized by transecting its attachments to the colon, the left kidney, and the diaphragm. If hemorrhage is occurring or access to the lesser sac is limited by the distribution of tumor, the surgeon may prefer to first mobilize the spleen by dividing its peritoneal attachments while compressing the splenic vessels and then ligate the splenic vessels using a posterior approach. The spleen is rotated anteriorly and medially in this technique.

FIGURE 53.6 Splenectomy. Transection of splenic artery and vein along the superior border of the pancreas after access is gained to lesser sac with transection of gastrosplenic ligament.

FIGURE 53.7 Ablation of subdiaphragmatic tumor implants with cautery after mobilization of liver. Sharp dissection, argon beam coagulator, or Cavitron ultrasonic surgical aspirator also may be used for the same purpose.

Complications associated with splenectomy include hemorrhage, infection, thromboembolic phenomena, left-sided

P.1293

atelectasis or pneumonia, injury to the tail of the pancreas (with resultant pancreatic pseudocyst), or injury to the stomach (with resultant gastric fistula). Because of the risk of severe infection following splenectomy, the patient should receive perioperative antibiotic coverage and should be vaccinated with polyvalent pneumococcal, quadrivalent meningococcal, and *Haemophilus influenzae* vaccines.

Resection of Diaphragmatic Tumor

Several reports have described experience with resection of diaphragmatic metastatic deposits in patients with advanced ovarian cancer. To gain access to the diaphragmatic surfaces, the abdominal incision is extended to just below the xiphoid process, and the liver is mobilized by transecting the entire falciform ligament and the coronary and triangular ligaments. After it is adequately exposed, the diaphragmatic tumor may be resected by stripping the peritoneum from the diaphragmatic muscle using sharp dissection with either Metzenbaum scissors or electrocautery (**Fig. 53.7**). The anesthesiologist should be notified if the pleural cavity is entered. Defects in the diaphragm may be closed with interrupted sutures. If a large defect cannot be closed primarily or can be closed only under tension, then the defect may be closed using synthetic mesh. If the pleural cavity is entered, then a thoracostomy tube should be placed.

Possible complications associated with resection of diaphragmatic tumor include pneumothorax, hemorrhage from the phrenic arteries, infection, injury to the pericardial sac, and injury to such structures as the lung, the vena cava, or the phrenic nerves.

In a review of the Mayo Clinic experience, Aletti and associates found that for the subgroup of 181 patients with ovarian cancer metastatic to the diaphragm, those who underwent diaphragm surgery had improved 5-year

overall survival compared with those who did not (53% vs. 15%). In another recent study of 262 patients with stages IIIC to IV epithelial ovarian cancer, Eisenhauer and colleagues found that patients requiring extensive upper abdominal procedures to achieve optimal debulking demonstrated a similar initial response, PFS, and overall survival to patients optimally debulked by standard surgical techniques. A recent study by Zapardiel et al. examined the value of peritoneal stripping versus full-thickness diaphragmatic resection. A total of 112 cases were identified; among them, 79 underwent diaphragmatic stripping and 33 underwent full-thickness resection. Larger residual tumors (mean, 5.1 mm vs. 1.6 mm; respectively; $P < 0.01$) were observed in the stripping group. Higher postoperative pleural effusion rates (63.6% vs. 37.9%, $P = 0.01$), but no differences in the remaining complications, were observed in the full-thickness resection group. After a mean of 31 months of follow-up, disease-free survival rates were 28% in the stripping group and 39.4% in the resection group ($P = 0.04$). No significant differences were observed for overall survival.

Resection of Retroperitoneal Lymph Nodes

The initial retroperitoneal approach for cytoreductive surgery exposes the node-bearing areas. Lymph nodes are sampled as part of the staging technique, and every effort is extended to remove suspicious retroperitoneal nodes when the peritoneal cavity has been cleared of disease (Fig. 53.8). Whether systematic removal of retroperitoneal lymph nodes should be part of optimal cytoreductive surgery had been a topic of debate for many years. Recently, the issue of systematic aortic and pelvic lymphadenectomy has come more to the forefront. Eisenkop and Spirtos reported on 100 patients with stage IIC to IV epithelial ovarian cancer who underwent a retroperitoneal lymph node dissection at the time of primary cytoreductive surgery. Sixty-six percent had positive lymph nodes. Five were microscopically positive, and 61 were macroscopically positive, of which 19 (31%) were positive by palpation, 16 (26%) were positive by inspection, and 26 (43%) were positive by dissection. On the other hand, there were 39 patients with negative or only microscopically positive nodes, and 15 of these patients (39%) were thought to have clinically positive nodes by the operating surgeon. The authors concluded that a significant proportion of patients had macroscopically positive lymph nodes that were detectable only after a dissection was in progress, and clinical impression of lymph node status was unreliable.

Morice and colleagues reported on 276 women with epithelial ovarian cancer who underwent systematic bilateral pelvic and paraaortic lymphadenectomy. The overall frequency

P.1294

of lymph node involvement was 44%. Pelvic and paraaortic lymph nodes were involved 30% and 40% of the time, respectively. In patients with apparent stage IA, IB, and IC disease, the rates of nodal involvement were 13%, 33%, and 38%, respectively.

A recent prospective randomized trial by Benedetti-Panici et al. showed that systematic lymphadenectomy improves PFS but not overall survival in women with optimally debulked advanced ovarian cancer. In addition, the median operating time was longer (300 minutes vs. 210 minutes, $P < 0.001$), and the percentage of patients requiring blood transfusions was higher (72% vs. 59%, $P = 0.006$) in the systematic lymphadenectomy arm.

For patients with malignant germ-cell tumors, especially dysgerminoma, the advantages of debulking metastatic retroperitoneal nodes are even less apparent, because these tumors are generally much more sensitive to chemotherapy than are other ovarian tumors.

Until further information becomes available, it is probably reasonable to consider debulking enlarged retroperitoneal nodes if peritoneal metastases can be cytoreduced optimally, if there is no fixation to blood vessels, and if the surgeon believes that the procedure can be successfully accomplished without undue risk.

Role of Minimally Invasive Surgery in Ovarian Cancer

At present, the role of laparoscopy in the management of ovarian cancer is evolving. There are several clinical

settings in which the potential for this surgical modality has been investigated: (a) primary surgery for early-stage ovarian cancer, (b) restaging of unstaged ovarian cancer, (c) primary cytoreductive surgery for advanced-stage ovarian cancer, (d) assessment of resectability, (e) intraperitoneal catheter placement, (f) second-look surgery, and (g) secondary cytoreductive surgery.

FIGURE 53.8 Retroperitoneal dissection of paraaortic lymph nodes involved with metastatic ovarian cancer.

Chi and colleagues compared 20 patients who underwent surgical staging via a laparoscopic approach with 30 patients who underwent surgical staging via laparotomy for ovarian or fallopian tube cancer. They found no differences in body mass index, omental specimen size, and number of resected lymph nodes. The estimated blood loss and hospital stay were lower for laparoscopy patients, but operating time was longer. LeBlanc and associates performed laparoscopic restaging in 53 patients—42 early after initial surgery for ovarian or fallopian tube cancer and 11 for second-look surgery after primary chemotherapy. Of the 42 early restaging procedures, 41 were completed successfully. An average of 20 paraaortic lymph nodes and 14 pelvic lymph nodes were removed in these procedures. Complications included a hematoma from an inferior epigastric artery injury and two lymphocysts. Eight patients were upstaged: two patients to stage IIA, two patients to stage IIIA, and four patients to stage IIIC. In addition, Lecuru and coworkers found no difference in survival between patients who underwent surgical staging for stage I epithelial ovarian cancer by either laparoscopy, laparotomy, or laparoscopy converted to laparotomy.

For patients with apparent advanced-stage ovarian cancer, laparoscopic evaluation has been investigated in the context of assessment of resectability. Two recent studies have described this approach. Fagotti and colleagues employed laparoscopy in 64 patients with suspected advanced ovarian cancer before laparotomy for primary cytoreduction. The overall accuracy rate of laparoscopy in predicting optimal cytoreduction was 90%. In a study by Angioli and associates, 87 patients with suspected advanced ovarian cancer underwent diagnostic laparoscopy. Of the 53 (61%) patients who were judged to be operable, 96% were optimally debulked. The

question of whether laparoscopy is a useful tool in determining which patients are ideal for attempt at cytoreduction has never been addressed in a well-conducted and powered study. Currently, a prospective randomized trial is being conducted in Europe where patients with advanced ovarian cancer (stage IIIC)

P.1295

will undergo laparoscopic assessment of tumor volume and then proceed with an attempt at cytoreduction versus neoadjuvant chemotherapy. This trial is known as the SCORPION trial (Surgical Complications Related to Primary or Interval Debulking in Ovarian Neoplasm).

One of the primary concerns regarding the use of laparoscopic surgery in the management of ovarian cancer has been spread of the cancer, particularly port site metastasis. Ramirez and coworkers estimated the rate of port site metastasis in patients undergoing laparoscopy for gynecologic malignancies as 1% to 2%. Vergote and colleagues reported 173 patients with advanced ovarian cancer who underwent diagnostic laparoscopy. Seventy-one patients underwent complete excision of port sites at the time of primary cytoreductive surgery. Thirty (17%) patients subsequently developed port site metastases. However, only 8 (5%) of these were clinically diagnosed, whereas 22 (31%) were diagnosed on pathologic examination of resected port sites. All of the port site metastases resolved during primary chemotherapy, and prognosis was not worsened by this finding.

Therefore, the role of laparoscopy is evolving. At present, the most useful settings for this approach appear to be primary surgery for apparent early-stage disease, restaging of apparent early-stage disease that is unstaged before referral, and assessment of resectability in patients with advanced-stage disease to determine whether primary cytoreductive surgery or neoadjuvant chemotherapy and interval debulking is preferable.

More recently, there is increasing enthusiasm for the use of robotic surgery in the management of patients with gynecologic malignancies. The use of such technology in patients with ovarian cancer has been limited. Magrina et al. performed a retrospective case-control analysis of 25 patients undergoing primary surgical debulking with the robotic approach, compared to 27 patients treated by laparoscopy and 119 patients treated by laparotomy. Sixty to seventy-five percent of patients had stage III to IV disease in the robotic and laparoscopy groups, respectively. Patients were subdivided according to extent of surgery and number of procedures required to achieve adequate cytoreduction. There was a significant increase in mean operative time among the robotics cohort (315 minutes), compared to laparoscopy (254 minutes) or laparotomy (261 minutes; $P = 0.009$). However, the robotics group had less blood loss and shortest mean hospital stay compared to laparoscopy or laparotomy. Complete debulking was achieved in 84% of patients in the robotic group, 93% in the laparoscopy group, and 56% in the laparotomy group ($P < 0.001$). There was no difference in overall survival among the three groups. These data, however, must be analyzed carefully due to the retrospective nature of the study and patient selection bias.

Primary Chemotherapy for Advanced Ovarian Cancer

For patients with advanced-stage *malignant ovarian germ-cell tumors*, the standard regimen for patients who require chemotherapy is the BEP (bleomycin, etoposide, and platinum) regimen. The optimal number of cycles remains unknown, but for these patients with a potentially greater tumor burden than those with early-stage disease, four to six cycles may be required in some instances. Generally, administering two cycles following normalization of serum tumor markers may be a reasonable guide, although there are no definitive studies to support this practice. Currently, the GOG and COG (Canadian Oncology Group) are in the process of developing an international trial for pediatric and adult patients with intermediate-risk and high-risk malignant germ-cell tumors.

For patients with advanced-stage *sex cord-stromal tumors*, platinum-based combination chemotherapy is generally recommended. As noted, the BEP combination regimen and the combination of paclitaxel/carboplatin are the most popular regimens in the United States. The GOG is currently conducting a randomized phase II

study of BEP versus paclitaxel/carboplatin in women with newly diagnosed advanced-stage and recurrent chemo-naïve ovarian sex cord-stromal tumors.

For advanced-stage *epithelial ovarian cancer*, the combination of cisplatin and cyclophosphamide was the standard postoperative regimen throughout most of the 1980s and until the mid-1990s. Subsequently, GOG initiated a randomized trial comparing the standard regimen of cyclophosphamide/cisplatin with the combination of paclitaxel/cisplatin in patients with suboptimally debulked advanced epithelial ovarian cancer. The findings of this study revealed a significant outcome advantage for the paclitaxel/cisplatin regimen in terms of PFS and overall survival. A subsequent similar study conducted by a European consortium confirmed the results of the GOG study.

Based on the results of several randomized clinical trials demonstrating equivalence of carboplatin to cisplatin in ovarian cancer, paclitaxel/carboplatin became the standard and remains so to the present.

Vasey and colleagues conducted a phase III trial of docetaxel/carboplatin versus paclitaxel/carboplatin as first-line chemotherapy for stage IC to IV epithelial ovarian cancer and peritoneal cancer. A total of 1,077 patients were enrolled in the study. Although there were no differences in PFS or overall survival between the two groups, the docetaxel/carboplatin regimen was associated with significantly less neurotoxicity but more myelotoxicity.

Variations on the Paclitaxel/Carboplatin Backbone

Several different strategies have been studied to improve the efficacy of taxane/platinum-based chemotherapy. The overarching concept is that agents with nonoverlapping cross-resistance mechanisms or alternative mechanisms of action may be complementary and may result in an enhanced therapeutic index.

The Addition of a Third Agent

The Gynecologic Cancer InterGroup reported the results of a phase III trial in advanced ovarian cancer (GOG 0182). This was a five-arm study that introduced three new drugs into first-line therapy as either three-drug combinations or sequential doublets, including liposomal doxorubicin, topotecan, and gemcitabine. The results indicated that no regimen demonstrated superiority to the control arm of paclitaxel/carboplatin.

The Addition of Antiangiogenic Agents

Two clinical trials—GOG 218 and ICON7—studied the role of bevacizumab added to the taxane/platinum backbone for women with advanced epithelial ovarian cancer. GOG 218 included two experimental arms with bevacizumab; one arm also administered bevacizumab as a maintenance agent for 16 cycles following primary chemotherapy, and the other experimental arm administered only placebo in maintenance. There was a PFS benefit in women who received bevacizumab with chemotherapy and as maintenance compared with the other two arms. However, neither bevacizumab arm demonstrated a survival advantage over chemotherapy alone. ICON7 was a 2-arm trial in which bevacizumab was administered with chemotherapy and then as maintenance versus chemotherapy alone. Similar to GOG 218, PFS was improved in the bevacizumab arm but with no survival advantage. Two subsequent phase III GOG trials—GOG 252 and GOG 262—involve the

P.1296

addition of bevacizumab to chemotherapy. GOG 252 is also testing intraperitoneal versus intravenous chemotherapy, and GOG 262 is testing the question of dose-dense paclitaxel as well. Both of these trials have completed accrual, but no results are yet available. Several other antiangiogenic agents are under study in either the primary or recurrent settings, including aflibercept, AMG 386, BIBF 1120, cediranib, pazopanib, sunitinib, and sorafenib.

Dose-Dense Paclitaxel

Dose-dense paclitaxel has also gained considerable attention recently based on the positive results of a trial conducted by the Japanese Gynecologic Oncology Group. In this trial, 631 patients with stage II to IV epithelial ovarian cancer were randomized to 6 cycles of standard paclitaxel (180 mg/m² over 3 hours) plus carboplatin (AUC = 6) every 21 days or dose-dense paclitaxel (80 mg/m² over 1 hour) given on days 1, 8, and 15 plus carboplatin (AUC = 6) given on day 1 every 21 days. PFS was significantly better in the dose-dense group (28 months vs. 17.2 months), and overall survival at 3 years was higher in the dose-dense group (72% vs. 65%). GOG protocol 0262 (described above) is also testing the dose-dense strategy.

Intraperitoneal Chemotherapy

Intraperitoneal chemotherapy also has been studied as primary treatment for patients with optimally cytoreduced advanced epithelial ovarian cancer. With the recent publication of GOG 172, three GOG studies have now demonstrated the benefits of intraperitoneal chemotherapy over intravenous chemotherapy in the treatment of this subgroup. In an intergroup study, the first such trial, 654 patients with less than 2-cm residual disease were randomized to receive intravenous cisplatin/cyclophosphamide versus intraperitoneal cisplatin plus intravenous cyclophosphamide. The median survival was significantly longer in the group receiving intraperitoneal cisplatin (49 months) than in the group receiving intravenous cisplatin (41 months). In addition, toxicity was worse in the intravenous group. The second GOG intraperitoneal study used intravenous versus intraperitoneal cisplatin as part of initial therapy. Patients on the intraperitoneal arm received an initial two cycles of moderate-dose systemic carboplatin. The results of that study showed a significant improvement in PFS for the intraperitoneal arm but only a borderline effect on overall survival. Because of significant design flaws associated with each of these GOG studies, the role of intraperitoneal chemotherapy in the management of advanced ovarian cancer remained unclear.

In the most definitive trial to date, Armstrong and associates conducted a phase III trial comparing intravenous paclitaxel plus cisplatin versus intravenous paclitaxel and intraperitoneal cisplatin, with intraperitoneal paclitaxel on day 8. The median overall survival was significantly better for the intraperitoneal chemotherapy arm: 66 versus 50 months ($P = 0.03$). However, short-term quality of life and toxicity—principally fatigue, hematologic, GI, metabolic, and neurologic—were significantly worse in the intraperitoneal arm. Furthermore, only 42% of patients in the intraperitoneal chemotherapy arm were able to complete all six cycles of planned treatment. Nevertheless, this study has generated much renewed enthusiasm for the intraperitoneal chemotherapy approach, as well as controversy. GOG 0252 tested intraperitoneal chemotherapy versus intravenous chemotherapy using a modified GOG 172 regimen as well as a second intraperitoneal regimen including paclitaxel and carboplatin. All arms also included bevacizumab. The results of this trial should be available within the next several months.

Neoadjuvant Chemotherapy and Interval Cytoreductive Surgery

Over the past 2 decades, the concept of neoadjuvant chemotherapy followed by interval debulking (as a primary cytoreductive procedure after a few cycles of chemotherapy) has emerged. This approach began to be reported in the late 1970s for certain subsets of patients, patients who were referred to an oncologist after a surgical or nonsurgical biopsy or patients who initially were poor surgical candidates because of a debilitated state related to massive effusions or comorbid conditions. However, this approach has been proposed as a potential alternative for all patients with advanced epithelial ovarian cancer or for certain subsets, such as those predicted to be suboptimally resected. The potential advantage of such an approach is to operate on a patient with an improved nutritional status, a smaller tumor burden, and superior perioperative risk.

Although several studies have explored the concept of a surrogate marker of unresectability of advanced ovarian cancer, as evidenced by the outcome of bulky residual disease, this issue remains unresolved. If accurate, such a strategy could potentially avoid a suboptimal debulking surgical procedure with the associated morbidity. The

principal focus has been on preoperative serum CA-125 or CT appearance of disease. Unfortunately, to date, neither has been accurate enough to be incorporated into standard care. Diagnostic laparoscopy has also been investigated as a tool for assessing respectability; this approach may ultimately prove to be the most practical and accurate method, but further study is indicated.

A number of retrospective series have reported the feasibility of neoadjuvant chemotherapy and interval debulking. Clinical observations from these reports indicate the following: (a) a high proportion (70% to 80%) of patients treated with neoadjuvant chemotherapy have partial or complete responses before interval surgery; (b) a high proportion of patients so treated, possibly higher than with primary cytoreductive surgery, are optimally debulked with minimal residual disease; and (c) the surgical morbidity may be reduced compared with that associated with primary cytoreductive surgery.

A recent multi-institutional trial was conducted in Europe evaluating upfront debulking surgery versus neoadjuvant chemotherapy in patients with stage IIIC or IV epithelial ovarian cancer (EORTC 55971). In this trial by Vergote and associates, 670 patients with stage IIIC or IV epithelial ovarian carcinoma, fallopian tube carcinoma, or primary peritoneal carcinoma were randomly assigned to primary debulking surgery followed by platinum-based chemotherapy or to neoadjuvant platinum-based chemotherapy followed by debulking surgery (so-called interval debulking surgery). The largest residual tumor was 1 cm or less in diameter in 41.6% of patients after primary debulking and in 80.6% of patients after interval debulking. Postoperative rates of adverse effects and mortality tended to be higher after primary debulking than after interval debulking. The hazard ratio for death (intention-to-treat analysis) in the group assigned to neoadjuvant chemotherapy followed by interval debulking, as compared with the group assigned to primary debulking surgery followed by chemotherapy, was 0.98 (90% confidence interval [CI], 0.84 to 1.13; $P = 0.01$ for noninferiority), and the hazard ratio for progressive disease was 1.01 (90% CI, 0.89 to 1.15). Complete resection of all macroscopic disease (at primary or interval surgery) was the strongest independent variable in predicting overall survival. The authors of that study concluded that neoadjuvant chemotherapy followed by interval debulking surgery was not inferior to primary debulking surgery followed by chemotherapy as a treatment option for patients with bulky stage IIIC or IV ovarian carcinoma in this study.

P.1297

MAINTENANCE THERAPY

Since 70% or more patients with advanced epithelial ovarian cancer ultimately develop disease recurrence, the strategy of maintenance or consolidation therapy after completion of primary chemotherapy has been studied. Several approaches to maintenance therapy have been tested, including hormonal therapy, vitamins, radiation therapy, chemotherapy, radioimmunoconjugates, immunotherapy, vaccines, gene therapy, biologic therapy, and complementary medicines. Unfortunately, all of these strategies have not improved overall survival. However, one trial demonstrated an improvement in PFS. Markman and colleagues studied whether 3 or 12 additional months of paclitaxel could affect time to progression in patients who had achieved a complete clinical response following primary treatment. This trial demonstrated a 7-month improvement in median PFS (28 months vs. 21 months; $P = 0.0035$). No effect on overall survival was observed. As noted above, a subsequent trial (GOG 218) reported an improved PFS in patients who continued maintenance bevacizumab versus placebo following primary chemotherapy plus bevacizumab but failed to demonstrate improved overall survival. Additional strategies are currently ongoing or planned. However, toxicity, cost, and potential adverse effects on tumor biology remain a challenge.

SECONDARY SURGERY

Secondary Cytoreductive Surgery

The term *secondary cytoreductive surgery* has no universal definition. It has been previously in multiple different settings; however, the term is currently most commonly used to refer to surgery done in patients who have developed recurrent disease after receiving primary therapy and experience a recurrence. Generally, most patients have had a prolonged disease-free interval off therapy.

Optimal candidates for such a procedure appear to be those who are platinum sensitive (>6-month disease-free interval from completion of upfront chemotherapy). To detect recurrences, the NCCN guidelines for epithelial ovarian cancer, fallopian tube cancer, and primary peritoneal cancer recommend follow-up visits every 2 to 4 months for the first 2 years, followed by 6-month intervals for the next 3 years. At each visit, physical examination and identification of the CA-125 level are recommended. Serial monitoring of serum CA-125 levels can be used as an indicator of ovarian cancer relapse. As shown by Rustin et al., such studies have a sensitivity of 79% to 95% and a positive predictive value of nearly 100%. CT is the most commonly used study to detect recurrent ovarian cancer. The sensitivity of this test is 40% to 93%.

Bristow et al. evaluated the utility of PET/CT imaging in identifying macroscopic (>1 cm) disease among ovarian cancer patients with clinically occult recurrent disease by conventional CT imaging. All patients in that study had to have a rising serum CA-125 level. The authors found that the overall accuracy of PET/CT in detecting recurrent ovarian cancer greater than 1 cm was 82%, with a sensitivity of 83% and a positive predictive value of 94%. In that study, no lesion smaller than 0.8 cm was identified by imaging.

The longer the interval between completion of primary chemotherapy and the time of recurrence, the better the outcome. Results of published studies on secondary cytoreduction for recurrent ovarian cancer are summarized in [Table 53.10](#).

Chi and colleagues analyzed their experience with 153 evaluable patients who underwent secondary cytoreductive surgery for platinum-sensitive recurrent epithelial ovarian cancer. They confirmed previous observations that the longer the disease-free interval, the longer the survival time after secondary cytoreduction (30 months for disease-free interval of 6 to 12 months, 39 months for disease-free interval of 13 to 30 months, and 51 months for disease-free interval >30 months). For patients who had residual disease ≤0.5 cm, the median

P.1298

survival was 56 months compared with a median survival of 27 months for those patients with residual disease greater than 0.5 cm. The authors further devised a set of recommendations for selection of candidates for secondary cytoreductive surgery based on the disease-free interval, the number of recurrence sites, and evidence of carcinomatosis.

Bristow and colleagues conducted a meta-analysis to determine the effect of prognostic variables on overall postrecurrence survival time among patients with recurrent ovarian cancer undergoing cytoreductive surgery. In that study of 2,019 patients, the authors found that the only statistically significant variable independently associated with postrecurrence survival time was the proportion of patients undergoing complete (no gross residual disease) cytoreductive surgery ($P = 0.019$). After controlling for other factors, each 10% increase in the proportion of patients undergoing complete cytoreductive surgery was associated with a 3-month increase in median cohort survival time.

Currently, there is an ongoing trial conducted by the GOG (Protocol 213) that is evaluating the role of secondary cytoreduction in patients with recurrent platinum-sensitive epithelial ovarian cancer, fallopian tube cancer, and primary peritoneal cancer. In this trial, patients who are considered appropriate surgical candidates are randomized to either surgery or no surgery. A second randomization is then performed where patients undergo treatment with either combination of intravenous carboplatin and paclitaxel or intravenous carboplatin, paclitaxel, and bevacizumab followed by maintenance bevacizumab. It is estimated that 660 women will be needed to address the primary objectives of this study. Another similar prospective randomized trial in Europe is also underway evaluating the role of surgery in the recurrent setting in patients with platinum-sensitive recurrent ovarian cancer, fallopian tube cancer, or primary peritoneal cancer. The trial, known as the DESKTOP III trial,

randomizes patients to surgery or no surgery followed by platinum-based chemotherapy.

Tertiary Cytoreductive Surgery

Several studies have examined the impact of a tertiary cytoreductive surgery on patient outcomes. Leitaio et al. reviewed the outcomes of patients diagnosed with ovarian cancer who underwent a tertiary cytoreduction. They found that treatment-free interval before tertiary cytoreduction, the extent of residual disease after the procedure, and the time to first recurrence were significant prognostic factors. The median disease-specific survival was 15 months for patients with a treatment-free interval up to 12 months compared to 60.4 months for patients with a treatment-free interval of greater than 12 months ($P = 0.002$). The median disease-specific survival for patients with residual disease 0.5 cm or less was 36.3 months, compared to 10.6 months for patients with residual disease greater than 0.5 cm ($P < 0.0001$). In another study, Karam et al. sought to find predictors of optimal tertiary cytoreductive surgery. They found that 64% of patients underwent an optimal cytoreductive surgery and that tumor implants of less than 5 cm on preoperative imaging were the only predictor of achieving optimal cytoreductive surgery. It should be noted that 26% of patients experienced severe postoperative complications. It is important to recognize that the only available data on tertiary cytoreduction are from retrospective studies with a small cohort of patients.

The largest series published to date on this topic was recently reported by Fotopoulou et al. In that study, the investigators evaluated 406 patients who underwent tertiary cytoreductive surgery. Median time from first to second recurrence was 18 months (2 to 204 months). Median follow-up was 14 months (0 to 182 months), and median overall survival was 26 months (95% CI, 19.62 to 32.38 months). Median overall survival for patients without residual tumor versus any visible tumor remaining was 49 months (95% CI, 42.5 to 56.4 months) versus 12 months (95% CI 9.3 to 14.7 months) ($P < 0.001$). A total of 224 patients (54.1%) underwent complete tumor resection. The most frequent tumor dissemination site was the pelvis (73%). Rates of major operative morbidity and 30-day mortality were 25.9% and 3.2%, respectively. Multivariate analysis identified platinum resistance, tumor residuals at secondary surgery, and peritoneal carcinomatosis to be of predictive significance for complete tumor resection, while tumor residuals at secondary and tertiary surgery, decreasing interval to second relapse, ascites, upper abdominal tumor involvement, and nonplatinum third-line chemotherapy significantly affected overall survival.

MANAGEMENT OF RECURRENT OVARIAN CANCER

As noted, approximately 70% of women with advanced epithelial ovarian cancer will recur after primary treatment. Although many of these women may have prolonged survival with contemporary management, few are cured. Because the therapy is largely palliative, efficacy must be balanced with toxicity. Choice of therapy is empirical, and patients with recurrent cancer typically receive multiple agents or regimens in sequence. Surgery, as discussed above, chemotherapy, hormonal therapy, radiotherapy, immunotherapy, and target agents are options.

When recurrence is initially diagnosed, patients are generally categorized as being platinum sensitive, platinum resistant, or platinum refractory. This classification is based on the duration from the completion of primary therapy until diagnosis of recurrence. Patients exhibiting a treatment-free interval of 6 months or longer are considered to be platinum sensitive. Those who recur in less than 6 months are classified as platinum resistant. And the worst prognosis group, platinum refractory, are those whose disease progresses during primary therapy.

Platinum-sensitive disease. Patients who are considered to be platinum sensitive have a relatively high probability of responding again to platinum-based chemotherapy. Based on the literature, options include paclitaxel/carboplatin, docetaxel/carboplatin, pegylated liposomal doxorubicin/carboplatin, or gemcitabine carboplatin. The choice of regimen is based on several factors, including any residual toxicity from primary

therapy and potential side effects of each regimen. In general, all of these regimens appear to be roughly equivalent in terms of efficacy. In addition, bevacizumab may be added to any of these regimens.

In 2012, Aghajanian reported the results of the OCEANS trial, in which 484 women with platinum-sensitive ovarian cancer were randomized to either gemcitabine/carboplatin plus bevacizumab for 6 to 10 cycles followed by bevacizumab until progression versus gemcitabine/carboplatin plus placebo for 6 to 10 cycles followed by placebo until progression. Both the response rate (78.5% vs. 58.4%) and the median PFS (12.4 months vs. 8.4 months) were significantly improved for women receiving bevacizumab.

Platinum-resistant disease. For women with platinum-resistant disease, a nonplatinum agent is generally recommended. Options include pegylated liposomal doxorubicin, gemcitabine (with or without cisplatin), topotecan, docetaxel,

P.1299

weekly paclitaxel, or hormonal therapy (tamoxifen or aromatase inhibitors). In addition, bevacizumab with or without chemotherapy is an option. Patients who achieve stable disease or response are usually treated until disease progression or untoward toxicity occurs. While clinical trials are always recommended as an option in every disease setting, this group is particularly encouraged to consider trials, if available.

Platinum-refractory disease. This disease status is fortunately uncommon. However, the probability of response to any agent is low. These patients are also excellent candidates for clinical trials.

Novel therapeutics. Several promising novel drugs or targeted agents are currently under investigation in women with recurrent ovarian cancer. Several trials involving PARP (poly[ADP-ribose] polymerase) inhibitors have been reported, are ongoing, or are planned in the near future. Apparently, deficiency in BRCA1 or BRCA2 causes extreme sensitivity to the inhibition of PARP. PARP inhibition blocks repair of single-strand breaks. Although normal cells can bypass these lesions by using homologous recombination, this is not possible for BRCA-mutated cancer cells. Several different PARP inhibitors are currently under development.

Targeted therapies are also currently under investigation. However, none has yet been approved for ovarian cancer treatment. Genes within the PI3K/AKT and MAP kinase pathways have commanded the most attention based on early molecular investigations. For example, potential druggable targets for clear cell carcinoma of the ovary include *mTOR*, *PI3K*, *c-MET*, and *VEGF*. Based on the observations that low-grade serous carcinomas have a 5% frequency of *BRAF* mutations and a 20% to 40% frequency of *KRAS* mutations, the MAP kinase pathway is a major focus for therapeutics. In the initial phase II trial of the MEK inhibitor, selumetinib, for recurrent low-grade serous carcinoma, a promising response rate of 15% was observed. A number of subsequent MEK inhibitor trials for this subtype are planned in the near future.

Other novel agents under investigation include antifolate receptor antibodies, vaccines, various immunologic therapies, and drugs that may affect p53-mutated cancer cells, among others.

MANAGEMENT OF INTESTINAL OBSTRUCTION

Approximately 25% of ovarian cancer patients develop intestinal obstruction in the terminal phase of their illness. One of the major dilemmas facing the gynecologic oncologist is whether to operate on a patient with refractory ovarian cancer and an intestinal obstruction. Signs and symptoms of intestinal obstruction resulting from ovarian cancer include nausea and vomiting, abdominal cramping, abdominal distention, and progressive constipation. In patients who have only partial obstruction, these symptoms and findings may be episodic and more subtle. Routine abdominal x-ray may support the diagnosis. Dilatation of the small intestine and air fluid levels suggest involvement of the small bowel. Dilatation of the colon may characterize large-bowel obstruction. In patients with early, partial obstruction, the radiographic findings may be nonspecific. CT scan of the abdomen and pelvis is often useful given the fact that it may provide information regarding sites of obstruction and degree of

carcinomatosis at the time of patient presentation.

Although intestinal obstruction in patients with ovarian cancer may be caused by adhesions, progressive tumor usually is the inciting factor. Of course, if the patient has received abdominopelvic radiotherapy, obstruction that is due to adhesions should be considered. In our experience, and that of others, however, most cases of intestinal obstruction in ovarian cancer patients who have received prior radiotherapy are related primarily to tumor progression. Surgical options may be offered to the patient depending on a number of factors that dictate the success of surgical management. These include the site of obstruction, the number of obstructions along the small or large bowel, the number of prior chemotherapies regimens, prior episodes of bowel obstruction, the nutritional status of the patient, and the overall functional status of the patient.

The site(s) of the obstruction may be solitary or multiple. In 5% to 10% of patients, there is simultaneous obstruction of the small and large bowel. Colon obstruction usually occurs in the area of the sigmoid colon because of growth of pelvic tumor and resultant extrinsic compression; occasionally, there may be obstruction of more proximal segments. Small-bowel obstruction is usually the result of adherence of loops of bowel by mesenteric or serosal tumor implants.

Once the appropriate evaluation is completed and the diagnosis of intestinal obstruction is made, the gynecologist should outline a plan of management. The decision of whether to operate or manage the patient nonoperatively is colored by the fact that surgery for patients with refractory ovarian cancer is associated with significant morbidity and mortality, the obstruction cannot be relieved in almost 20% of those undergoing surgery, and postoperative survival is disappointingly brief. In reported series, the serious complication rate has ranged from 28% to 49%, and the operative mortality rate is in the range of 12% to 16%. The median survival rate for patients who have undergone surgery is in the range of 3 to 5 months.

Although some investigators have used projected survival (usually >2 months) as a parameter to decide on type of management, such an indicator is too unpredictable. Pothuri et al. reviewed a series of patients undergoing surgery for intestinal obstruction due to recurrent ovarian cancer and found that the mean time from original diagnosis of ovarian cancer to obstruction was 2.8 years. Surgical correction (intestinal surgery performed for relief of obstruction) was attained in 84% of cases. Successful palliation (the ability to tolerate a regular or low-residue diet by 60 days after surgery) was achieved in 71% of cases. Major surgical morbidity was documented in 22% of patients. Interestingly, postoperative chemotherapy was administered in 79% of patients in whom surgical correction was possible. In addition, the median survival was 11.6 months in patients with successful palliation versus 3.9 months for all other patients. The authors noted that with respect to quality of life, it is important to consider that 56% of patients undergoing surgery for bowel obstruction had either a colostomy or permanent gastrostomy tube. Finally, the authors recommended that patients not be considered ideal surgical candidates if they have bulky carcinomatosis, rapidly progressive disease, multiple sites of obstruction, poor performance status, or heavy pretreatment with chemotherapy and radiation.

For initial management of a patient with small-bowel obstruction, we prefer the insertion of a nasogastric tube. In patients for whom no surgery is planned, a percutaneous gastrostomy is recommended. This procedure has resulted in excellent palliation for terminal-stage ovarian cancer patients, avoiding the discomfort of the nasogastric tube and allowing the patient to be easily cared for at home in most cases. With such a device, the patient may even continue to eat, although the nutritional benefit is essentially nil.

A recent study by Chi et al. evaluated outcomes data on patients undergoing palliative operative or endoscopic

P.1300

procedures for malignant bowel obstruction due to recurrent ovarian cancer. This report focused on patients with malignant bowel obstruction due to recurrent ovarian cancer. Procedures performed with an upper or lower GI endoscope were considered "endoscopic." All other cases were classified as "operative." Following the

procedure, the presence or absence of symptoms was determined and followed over time. Palliative interventions were performed on 74 gynecologic oncology patients during the study period, of which 26 (35%) were for malignant GI obstruction due to recurrent ovarian cancer. The site of obstruction was small bowel in 14 (54%) cases and large bowel in 12 (46%) cases. Palliative procedures were operative in 14 (54%) patients and endoscopic in the other 12 (46%). Overall, symptomatic improvement or resolution within 30 days was achieved in 23 (88%) of 26 patients, with 1 (4%) postprocedure mortality. At 60 days, 10 (71%) of 14 patients who underwent operative procedures and 6 (50%) of 12 patients who had endoscopic procedures had symptom control. Median survival from the time of the palliative procedure was 191 days (range, 33 to 902) for those undergoing an operative procedure and 78 days (range, 18 to 284) for those undergoing an endoscopic procedure. The authors concluded that patients with malignant bowel obstructions due to recurrent ovarian cancer have a high likelihood of experiencing relief of symptoms with palliative procedures.

Optimal preoperative preparation is desirable if a patient is judged to be a suitable candidate for surgical intervention. For patients with complete colonic obstruction or perforation of the small or large intestine, a surgical emergency exists unless the patient is in such poor condition that such an intervention is not feasible. In emergency cases, the patient should be stabilized with intravenous fluids and antibiotics before surgery. Emergency surgery is rarely indicated for patients with a small intestinal obstruction. It is preferable to optimize the patient's condition with nasogastric tube decompression and rehydration. In addition, a barium enema is usually indicated to rule out a coexisting colonic obstruction. If the patient is malnourished, then intravenous hyperalimentation may be indicated preoperatively.

Colonic obstruction usually is treated by performing a colostomy. The selection of the site of colostomy depends on the area of obstruction and the ability to find an adequate bowel segment free of cancer. Most commonly, a transverse loop colostomy is indicated in the presence of a descending colon or sigmoid colon obstruction. There is increasing experience with the use of colonic stents as a substitute for colostomy. A study by Caceres et al. aimed to review the experience with colonic stent placement for patients presenting with a large-bowel obstruction due to recurrent gynecologic malignancy. Thirty-five patients were identified—25 patients had recurrent ovarian cancer, 7 patients had recurrent endometrial cancer, 2 patients had primary peritoneal carcinoma, and 1 patient had recurrent cervical cancer. The median age at the time of stent placement was 54 years (range, 21 to 79). The median length of the large-bowel obstruction was 6.5 cm (range, 1 to 20 cm). Six patients had a lumen of 1 to 2 mm before stent placement, while 29 patients had complete obstruction and needed balloon dilatation before deployment of the stent. Twenty-seven patients (77%) underwent successful stent placement and immediate decompression at the time of colorectal stent placement. Of the patients who had successful stent placement, 9 (33%) underwent additional surgery to relieve obstruction. Of the 27 patients who underwent successful stent placement, the median survival after placement was 7.7 months (95% CI, 3.19 to 11.9 months). The authors concluded that in the management of patients with large-bowel obstructions due to recurrent gynecologic cancer, colonic stents appear to be a reasonable option that may enable patients to avoid major surgery.

A number of options are available for small-bowel obstruction, depending on the operative findings. Most commonly, there are multiple sites of obstruction in the terminal ileum, in which case an ileo-ascending colon bypass or ileo-transverse colon bypass is preferable. In such situations, it is usually both unwise and inappropriate to attempt resection and reanastomosis. If, on the other hand, there is an isolated area of obstruction, then a resection and reanastomosis may be indicated. The anastomosis may be either hand sewn using a two-layer technique or approximated with surgical staplers ([Chapter 47](#)). We generally prefer the latter because of the time-saving aspect. Frequently, there may be extensive tumor with multiple areas of obstruction, making both bypass and resection impossible. A tube gastrostomy, if possible, is indicated in such a situation. Procedures such as these are among the most demanding because of the meticulous, often tedious dissection

required. Enterotomies are not uncommon and should be repaired as soon as they are identified. Complications of small intestinal procedures include wound infection, intraperitoneal abscess, sepsis, pneumonia, “blind loop syndrome,” and enterocutaneous fistula.

BEST SURGICAL PRACTICES

- In the United States, more than 22,000 new cases of ovarian cancer are detected annually, and more than 16,000 women will die of the disease. The lifetime risk of ovarian cancer for a woman in the United States is 1/70. This risk increases to 5% in a woman with one first-degree relative who has ovarian cancer and to 7% if she has two or more relatives with the disease.
 - Pelvic examination is inaccurate in assessing ovarian size and morphology, particularly in postmenopausal women and in women who are overweight. No ovarian cancer screening technique has been shown to be cost-effective to reduce the incidence or improve survival of ovarian cancer.
 - Numerous studies have shown improved survival in both early- and advanced-stage ovarian cancer when the initial surgery has been done by a gynecologic oncologist. A careful evaluation of an adnexal mass using transvaginal ultrasound, serum CA-125, and, occasionally, supplemented by other imaging studies will usually identify the patient with a high risk of malignancy who should be referred for surgery by a gynecologic oncologist.
 - Surgery for ovarian cancer includes both careful staging to document the extent of the disease and resection or debulking of the tumor. Careful attention to accurate and comprehensive staging is most important in early-stage disease, for which postoperative therapy decisions may depend on the findings and histopathologic diagnosis. In patients with advanced disease, maximum surgical debulking to less than 1-cm diameter of residual disease should be the goal.
 - In some young women with ovarian cancer, fertility-sparing surgery is possible. In a woman with a lesion apparently confirmed to a single ovary (or rarely both ovaries) who desires future pregnancy, ovarian and uterine conservation should be discussed preoperatively. At surgery, a unilateral oophorectomy and careful staging should be done, but the opposite ovary should not be biopsied if it appears normal. If the diagnosis or staging findings are uncertain, it is best to close and await a final review of the permanent sections on the staging studies. Reoperation is preferable to unnecessary radicality in a young woman in whom fertility is a concern.
-
- P.1301
- In women with advanced ovarian cancer, optimal cytoreduction to less than 1-cm residual disease—ideally to microscopic residual—has clearly been shown to confer a survival advantage. This is true even in patients with stage IV disease. The techniques required to perform radical cytoreduction in ovarian cancer patients and the judgment to know when it is appropriate are a combination of skill and experience, and it is usually done by gynecologic oncologists operating in hospitals with good teams of anesthesiologists, consultants, and critical care experts.
 - Laparoscopic and robotic surgery for ovarian cancer is currently limited to patients with apparent early-stage disease. Its role in the setting of advanced disease remains investigation.
 - Postoperative chemotherapy is usually required for patients with ovarian cancer; in some cases, chemotherapy may be given before any definitive surgery. This is an important part of the management of ovarian cancer, but it is not addressed in this surgical textbook.
 - Patients with recurrent ovarian cancer may benefit from secondary cytoreductive surgery if there is a disease-free interval greater than 6 months, there is isolated recurrent disease, and location and number of recurrences are predictive of complete cytoreduction.

Chapter 54

Pelvic Exenteration

Mario M. Leitao Jr
Richard R. Barakat

DEFINITIONS

Total pelvic exenteration—Removal of all pelvic organs, often en bloc, including removal of the uterus (if present), cervix (if present), bilateral adnexa (if present), bladder, possibly urethra, rectum, and possibly anus. This can be done in either a supralelevator or infralevator fashion (see later definitions).

Anterior pelvic exenteration—Similar to total pelvic exenteration except that the rectum and anus are not removed. Additionally, the posterior aspect of the vagina may also be left in place.

Posterior pelvic exenteration—Similar to total pelvic exenteration except that the bladder and urethra are not removed. Additionally, the anterior aspect of the vagina may also be left in place.

Supralelevator exenteration—Any of the above (total, anterior, or posterior) but the dissection and resection are limited to the pelvic contents above the levator muscles of the pelvis.

Translevator exenteration—Any of the above (total, anterior, or posterior) and the dissection and resection involve resection of a portion of the levator muscles with the contents traversing these muscles and including portions of the labia minora, and occasionally the labia majora, as well as surrounding tissues.

Wet colostomy—An end colostomy with the ureters placed into the colostomy resulting in drainage of both stool and urine. This is an old practice that was abandoned, but it has resurfaced with a recent modification.

P.1308

Noncontinent urinary conduit—A constant drainage system for the urinary stream most often involving insertion of the ureters into a portion of isolated small intestine that is then brought out to the abdomen.

Continent urinary conduit—A urinary drainage system in which the patient ultimately will self-catheterize and avoid a bag for constant drainage. Various types of these conduits exist.

INTRODUCTION

Dr. Alexander Brunschwig was the first to report on the complete excision of pelvic viscera for advanced cancer (i.e., pelvic exenteration) in 1948. He described this procedure as “the most radical surgical attack so far described for pelvic cancer and also [what] would appear to be the most radical of abdominal operations that have been carried out with some measure of consistency.” The first operation was performed on December 12, 1946, at Memorial Hospital, which eventually became Memorial Sloan Kettering Cancer Center, in New York. **Figures 54.1** and **54.2** are diagrams from Brunschwig's manuscript. This manuscript included 22 cases, 15 of which were recurrent cervical cancers, and follow-up was very short (maximum follow-up was 8 months). There were 5 (23%) perioperative mortalities and a total of 9 (41%) deaths within 8 months. Subsequent reports from the same institution of the same procedure in patients with ovarian and endometrial cancers described 5-year overall survival (OS) of 7% and 14%, respectively, with morbidities of over 60% and perioperative mortalities of 23%. In 1989, Lawhead and colleagues reported an updated series on mostly cervical cancer patients; the 5-year OS was 23%. These early reports suggested that the procedure had a perioperative mortality that was similar to the 5-year OS, at the cost of severe short-term and long-term morbidity as well as absence of vagina. Therefore, it fell out of favor and was infrequently performed for many years.

FIGURE 54.1 Levels of transection for a translevator total pelvic exenteration, as described by Dr. Alexander Brunschwig. “c” is the transection at the rectosigmoid junction. “u” and “u” are the levels of transection of the ureters. “PW” is the perineal phase with transection of the vulva, perineum, and anus. This has remained the basic level of transection to date. However, portions of the labia and the entire clitoris can often be spared. (Reprinted from Brunschwig A. Complete excision of pelvic viscera for advanced carcinoma. *Cancer* 1948;1:177-183, with permission. Copyright © 1948 American Cancer Society.)

FIGURE 54.2 The end result of an exenteration as described in Dr. Alexander Brunschwig's original manuscript. The perineum is primarily closed without vaginal reconstruction, and a wet colostomy is noted. (Reprinted from Brunschwig A. Complete excision of pelvic viscera for advanced carcinoma. *Cancer* 1948;1:177-183, with permission. Copyright © 1948 American Cancer Society.)

As surgical techniques and perioperative management improved over subsequent years, investigators began to report improving outcomes with decreasing perioperative mortalities. Additionally, publications after the year 2000 report continued decreases in perioperative mortality. These reports are described in greater detail later in the chapter. Pelvic exenteration is now felt to be a reasonable option in select cases, if performed by experienced surgeons. It can provide a chance at long-term cancer control and survival, but it remains a highly morbid procedure.

Pelvic exenterations can be modified based on the tumor size and location. There are multiple options for vaginal reconstruction as well as for different types of urinary system diversions separate from the fecal system. Permanent end colostomies are still required in the vast majority of cases, but in highly select situations, it may be possible to reconnect the large bowel and avoid a permanent colostomy. The indications for these pelvic exenterative procedures have also been expanded at certain institutions. More attention is also paid to sexual issues in these women as well as to overall quality of life after such extensive procedures. The most commonly performed exenteration is a total pelvic exenteration, followed by anterior, and then posterior ([Table 54.1](#)).

INDICATIONS AND PREOPERATIVE EVALUATIONS

The selection of patients suitable for a pelvic exenteration is highly complex and individualized. The most common indication is recurrent cervical carcinoma limited to the central pelvis in a patient who has received prior full-dose pelvic radiotherapy ([Table 54.2](#)). Exenteration is also considered in select cases of patients with recurrent endometrial, vulvar, or vaginal carcinomas. Uterine sarcomas are extremely rare. The majority of patients with these tumors will have extrapelvic sites of disease at the time of recurrence, in which case

P.1309

exenterative procedures are contraindicated. However, in cases of pelvic-only recurrences in patients with uterine sarcomas, exenteration may be possible. Exenteration is most often only considered if radiation therapy has been already utilized in the past and no further radiation therapy is possible. Primary exenteration at the time of initial diagnosis, as well as in patients who have not undergone prior radiation, has been reported, but should be reserved for few select cases.

Exenteration was largely abandoned for patients with recurrent ovarian cancers after Barber and colleagues reported a dismal 5-year survival of 7%. However, this report was published in a time prior to effective systemic therapies. Total and/or anterior pelvic exenteration is still not a consideration in the vast majority of patients with newly diagnosed or recurrent ovarian cancers except in exceptional situations (e.g., palliation for a hemorrhaging pelvic tumor not amenable to other palliative measures). In general, palliation is rarely accepted as an indication for exenterative procedures. However, some form of supralelevator posterior exenteration (i.e., “modified posterior exenteration”), as well as other bowel resections, are now routinely considered and performed in patients with newly diagnosed and recurrent ovarian cancers. These modified posterior exenterations are not as extensive, and ovarian cancer outcomes are generally quite different from those of the other sites. We will not include these modified posterior exenteration procedures for ovarian cancer in the remainder of the chapter.

P.1312

The first important step in the preoperative assessment is a thorough medical evaluation. Exenterations are highly morbid procedures, and patients must be deemed fit to undergo such an extensive surgery. Patient age is also an important consideration. Patients must be able to manage the multiple drains that are placed at the time of surgery and, ultimately, the permanent abdominal stomas that are created. An exenteration may not be a good option for a patient who has significant limitations in self-care. These procedures are also significantly body altering. Patients often are not quite prepared for, nor truly understand, the impact that this surgery will have on their bodies. It is our routine practice to have all patients who are being considered for an exenterative procedure undergo a formal psychological assessment to identify any potential underlying psychological pathology, assess their understanding of the proposed surgical procedure, prepare them for the sexual implications of the procedure, and provide guidance on coping methods. This consultation will also help the patient make more informed decisions regarding continent or noncontinent urinary diversions as well as vaginal reconstruction.

The ideal candidate for a pelvic exenteration is a patient with primary cervix or vaginal apex cancer who develops a small (<2 cm) central pelvic recurrence at the vaginal apex (or cervix if present) after definitive whole pelvic radiation. Patients with pelvic recurrence after radical hysterectomy are usually best treated with pelvic radiation. Patients should be evaluated by a radiation oncologist to determine whether all radiation options have been exhausted and also to discuss the possible use of intraoperative radiation therapy.

A “terrible triad” of symptoms has been described to be clinical contraindications to exenterative procedures. These include hydronephrosis, sciatic pain, and leg edema. These symptoms are felt to reflect lateral pelvic extension and/or involvement of the pelvic sidewall structures. Lateral extension of tumor is considered a contraindication to exenterative procedures by many. However, experienced centers have reported reasonable outcomes after exenterative and nonexenterative procedures in patients with laterally extended or pelvic sidewall-based recurrences. Laterally extended resections present unique challenges that require special procedures. It is beyond the scope of this chapter to describe the details of the surgical steps of such laterally extended resections, which often involve major vascular resections, major nerve resections, bony resections including sacrectomy, and/or sidewall musculature resection in addition to the other typical exenterative resection of pelvic viscera.

An absolute contraindication to exenteration is the presence of confirmed extrapelvic disease. It is imperative to rule out the presence of such distant disease as best as possible. Computed tomography (CT) or positron emission tomography (PET) scanning of the chest, abdomen, and pelvis must be routinely performed. Any suspicious findings must be thoroughly evaluated. Any easily accessible lesion, such as palpable adenopathy in the inguinal or supraclavicular regions, can be biopsied in the office. Assessment of most other lesions can be accomplished utilizing image-guided biopsies by interventional radiologists. Occasionally, a surgical procedure, such as diagnostic laparoscopy or mediastinoscopy, is needed to evaluate a suspicious lesion seen on CT or PET scanning. A pelvic magnetic resonance imaging (MRI) should also be considered as it will provide a more detailed anatomic view of the pelvic recurrence in relation to surrounding structures. This could help in determining the extent of the exenteration.

Pelvic MRI is a valuable imaging modality in the preoperative assessment of resectability and surgical planning in patients considering exenteration. It is standard at our institution to obtain a preoperative pelvic MRI as we feel it most accurately details the extent of lateral, anterior, and posterior tumor involvement. However, few data exist specific to the value of pelvic MRI in these rare recurrent gynecologic malignancies eligible for exenteration. MRI has been reported to be a valuable tool in surgical planning for patients with locally advanced and recurrent colorectal cancers. Forner and colleagues reported less enthusiastic results in a series of 43 patients undergoing pelvic exenteration for gynecologic malignancies. The sensitivity, specificity, positive and negative predictive values for MRI, and complete resection were 85%, 52%, 60%, and 80%, respectively. This is a small single institution experience and may not reflect that at other institutions. Preoperative MRI should be considered, but surgeons must recognize the potential limitations of the correlation of MRI findings with intraoperative and final pathologic results. Pelvic MRI may not be entirely accurate for determining complete resection, but it will help in deciding whether a less than translevator total pelvic exenteration may be an option. It will also help in assessing cases that may require laterally extended resections.

The value of preoperative PET scanning is controversial. Many surgeons who perform exenteration will obtain a PET scan to assess for the presence of metastatic disease. It is unclear if routine PET imaging adds more value as compared to good-quality multidetector thin-slice CT scan. Husain and colleagues reported the results of a prospective trial assessing PET scan prior to pelvic exenteration. In four cases, CT or MRI failed to detect metastatic disease that was identified on PET scan and confirmed with pathologic sampling. The negative predictive value of PET scanning was 100%, meaning no metastatic disease was found at surgery in the setting of a normal PET scan. PET scanning did have some false-positive cases. Increased FDG uptake was noted in nine cases on PET scanning. Biopsies were performed in all nine cases, and only five (56%) were confirmed to have metastatic disease.

Combined PET/CT scanning has become more commonplace and is often ordered nowadays instead of separate CT and PET scans. A small retrospective series of 33 cases by Burger et al. reported some promising accuracy data on preoperative PET/CT scanning. However, none of the 33 cases had distant metastasis. False-positive nodal findings were noted in two cases. PET/CT imaging is useful and accurate in ruling out metastatic disease in these patients and should be considered (PET scanning if CT was already done). However, it is important to recognize the significant false-positive rate associated with this type of imaging. Before abandoning an attempt at exenteration, all suspicious metastatic lesions should be biopsied in order to confirm the presence of disease.

An exploratory minimally invasive surgical (MIS) procedure (i.e., laparoscopy) may also be useful in patients under evaluation for exenteration. Laparoscopic exploration can be done prior to the planned exenteration, or it could be performed the same day. Findings may aid with the decision of whether or not to proceed with the exenteration. The value of this is most likely greatest in centers in which MRI and PET/CT imaging are not easily available. Plante and Roy and Kohler et al. have reported that an exploratory laparoscopy can avoid an unnecessary laparotomy in nearly 50% of patients planned for exenteration due to findings of metastatic or unresectable disease. Both of these series did not utilize routine, nor current,

P.1313

imaging modalities such as PET scanning or the more modern stronger magnet MRI scanners.

SURGICAL TECHNIQUES

Preoperative Preparation

The obvious first step is an extensive, detailed discussion with the patient and the family regarding the planned procedure, what will be removed, the significant risk of morbidity, the body changes that will occur, the effects on sexuality, and the longterm outcomes. As mentioned previously, we would suggest that these patients be referred to a psychologist who has knowledge of exenterative procedures. This psychologist should perform a formal evaluation and any needed counseling and will provide the patient with resources for issues that may develop after surgery. A discussion is needed regarding patient desires for vaginal reconstruction and type of urinary diversion as well as regarding the potential for rectal reanastomosis versus end colostomy. Patients should be referred to stoma specialist for marking of the abdomen to assist in optimal positioning of the stoma.

Although routinely done in the past, admission to the hospital the day before surgery usually is unwarranted unless there is a significant medical concern that arises during standard preoperative outpatient medical and surgical evaluation and clearance processes. Any underlying medical comorbidities should be optimized. The role of preoperative bowel preparation is unclear. Multiple randomized trials in patients undergoing colorectal resections failed to demonstrate any advantage to mechanical bowel preparations, and some

actually suggested a potential disadvantage to such preparations. Mechanical bowel preparation is likely unnecessary in patients who will not have a large bowel-based continent urinary diversion. Elimination of stool from the large intestine may ease the creation of a continent pouch, but this is highly surgeon dependent. Strong recommendations regarding routine bowel preparation prior to exenteration cannot be made. While there is no evidence-based reason for routine bowel preparation, some surgeons find that gross fecal contamination during the construction of a large bowel conduit is unappealing.

Patient positioning is standard low lithotomy using some form of Allen stirrups. Hair removal should be avoided. However, if absolutely necessary, then clippers, not razors, should be used prior to scrubbing of the skin. Large-bore peripheral intravenous access should be placed, as well as some form of central venous access. This will be tremendously helpful in managing these patients during and after surgery. Standard antibiotic prophylaxis should be administered prior to skin incision. Combined thromboprophylaxis should be used as these patients are at the highest risk of venous thromboembolism. Sequential compression devices are placed prior to induction of anesthesia. Low molecular weight heparin (LMWH) is also administered prior to the start of the surgical procedure. Many would recommend that LMWH be continued for 4 weeks postoperatively.

FIGURE 54.3 Developed paravesical and pararectal spaces of the right hemipelvis. These spaces are relatively avascular and often can be developed bluntly with some sharp dissection using cautery if needed. These spaces should be developed distally to the levator muscles of the pelvic diaphragm.

Some gynecologic oncologists will be able to perform not only the exenteration but also most of the reconstructive procedures. However, these are long procedures and many centers take a team approach in which gynecologic oncologists work with colleagues from their group and possibly colleagues from other specialties as well to complete these cases. It is becoming more common for a gynecologic oncologist, plastic surgeon, urologist, and radiation oncologist all to be involved for various parts of the procedure. Teamwork and communication prior to, during, and after surgery are most important.

Initial Steps and Exploration

As described previously, surgeons first may choose to perform a laparoscopic evaluation to potentially avoid an unnecessary laparotomy. However, this is not routinely done in the setting of normal preoperative MRI and PET/CT scanning.

The abdomen is opened using a standard large vertical midline incision extending above the umbilicus. These procedures are not amenable to lower transverse abdominal incisions. The entire peritoneal cavity is closely inspected, and any suspicious lesions are sent for frozen section. A standard paraaortic nodal assessment is performed and frozen section also obtained. It is controversial as to whether to limit the paraaortic nodal assessment to the lower area below the inferior mesenteric artery or to carry this assessment up to the level of the renal veins. An exenteration should not be performed if there is confirmed disease outside the pelvis, including the paraaortic lymph nodes.

The retroperitoneal pelvic spaces can all be developed while awaiting frozen section results. The pararectal and paravesical spaces are developed first ([Fig. 54.3](#)). The pararectal

P.1314

space is delineated by the iliac vessels laterally, by the ureter medially, and by the uterine vessels anteriorly. The paravesical space is delineated by the iliac vessels and obturator muscle laterally, obliterated umbilical artery and bladder medially, and the pubic rami anteriorly. These two spaces are developed and lateral tumor extension can be assessed. The round ligament, if present, is ligated, and the paravesical space is carried forward and medially into the space of Retzius ([Fig. 54.4](#)). Dissection of these spaces is important in assessing resectability. **No major organs are transected until the result of all frozen section analyses are available and do not reveal disease, and dissection of the planes suggests a negative resection margin.** The above dissection and development of spaces should be performed regardless of whether a total, anterior, or posterior exenteration is planned. The decision to perform a total, anterior, or posterior exenteration is based on the tumor location and size and whether a negative margin resection is possible. These decisions can be made based on preoperative imaging and pelvic examination. However, the final determination is made intraoperatively. All patients who are planned to undergo a less than total exenteration should be counseled and consented for a possible total exenteration if deemed necessary intraoperatively to achieve a negative margin resection.

FIGURE 54.4 Space of Retzius. This is also an avascular space if developed correctly with blunt and sharp dissection using cautery. Care should be taken to not injure the venous plexus overlying the inferior aspect of the bladder and surrounding urethra (plexus of Santorini) in order to avoid excessive bleeding from this area. This dissection is carried distally to the level of the urogenital diaphragm.

FIGURE 54.5 Rectosigmoid transection. A stapling device can be used to transect the rectum/rectosigmoid/sigmoid at the desired point (A). Branches of the superior rectal artery must be controlled either with standard suture techniques or using any of the available vessel-sealing devices (B).

Total Pelvic Exenteration

The rectum is then transected at the upper portion of the rectum or at the level of the rectosigmoid junction, depending on the location and size of the tumor. A mesenteric window is created just beneath the colonic wall. A stapler (GIA) is then used to transect the rectum, rectosigmoid, or sigmoid (Fig. 54.5). The mesentery is then divided straight back to the origin of the mesentery. This can be done in several ways. Most commonly, the peritoneum of the mesentery is scored with monopolar cautery. The mesenteric fat and vessels are then ligated and transected, most often with a vessel-sealing device. The proximal end of the transected colon is then retracted upward and out of the surgical field. The ureters are clipped with metal clips and transected with a scalpel or scissor above the level of prior pelvic radiation therapy field, which is often just at the pelvic inlet where they encounter the common iliac arteries (Fig. 54.6).

The lateral pelvic vessels are then sequentially secured and transected at the pelvic sidewalls all the way down to the levator muscles of the pelvis (Fig. 54.7). Again, this is facilitated with the use of any of the commercially available vessel-sealing devices. Stapling devices can also be considered but are now less commonly used. The internal iliac artery and vein can be ligated beyond their posterior divisions if needed to facilitate specimen resection and/or control pelvic bleeding. The rectal mesentery and vessels are secured at the level of the presacral fascia down to the planned level of rectal transection. Extreme caution is needed to not enter behind the presacral fascia. This will risk injury to the sacral veins, which are very difficult to control because they retract into the bony spaces of the sacrum. Various techniques can be used to control sacral bleeding if encountered. These include (a) use of a sterile thumbtack into the sacral foramina; (b) use of bone wax, which can be difficult to handle; and (c) use of commercially available hemostatic agents. A unique method to possibly control sacral hemorrhage is to place a small piece of abdominal wall muscle into the sacral foramina where the bleeding is coming from. Monopolar coagulation current

P.1315

can then be applied to this piece of muscle to form a seal. Finally, in the rare situations in which all else fails to control pelvic/sacral hemorrhage, a pelvic pack (using multiple lap pads individually or a larger bag) can be compressed into the entire pelvis. The procedure is then terminated and the patient taken to the recovery room with a plan to remove the pelvic packing the following day. Anteriorly, the space of Retzius is further developed down to the level of the levator muscles.

FIGURE 54.6 The ureters are clipped with metal clips and transected at or above the pelvic brim. The resulting hydronephrosis during the remainder of the procedure will facilitate the ureteral anastomosis to the conduit.

FIGURE 54.7 The lateral and posterior pelvic vessels and other pedicles are transected sequentially and circumferentially down to the level of the levator muscles. Here we see a stapling device being used, but any of the available vessel-sealing devices can be used to facilitate this dissection.

If a supralelevator approach is planned, the urethra and vagina can be transected at the level of the levator muscles. This can be done with simple monopolar cautery. The distal rectal wall is isolated and transected with a stapling device. The en bloc specimen can then be delivered vaginally. If a translevator approach is planned, the levator muscles must be incised and the urethra, vagina, and rectum are not transected. A perineal approach is initiated just prior to or at the time that the levator muscles are approached abdominally. A line of transection is identified and encompasses the entire urethral meatus, labia minora, vaginal opening, and anus (**Fig. 54.8**). The labia majora and clitoris are generally spared unless involved by tumor. This line of transection can be made with a scalpel, but most often, it is done using monopolar cautery. The paravaginal and para-anal and pararectal fatty tissue is then transected. Monopolar cautery may be used, but even so, this transection is often bloody. Currently available vessel-sealing devices can again be used for this portion of the procedure and will greatly facilitate this dissection and lessen bleeding. The perineal approach aims toward the coccyx, the levator muscles are transected at this level and circumferentially to encompass the entire specimen (**Fig. 54.9**), and the specimen is delivered through the large defect (**Fig. 54.10**).

FIGURE 54.8 Planned line of perineal transection. The perineum is incised using monopolar cautery and encompasses the urethra, vaginal opening, and the anal opening. The labia majora and clitoris can often be spared.

FIGURE 54.9 Completing the exenteration. The tissue lateral to the specimen is transected and secured using a vessel device circumferentially. The levator muscles are transected and, as seen here, approached jointly from the pelvic and perineal sides.

Anterior Pelvic Exenteration

Many of the steps for an anterior exenteration are the same as above except that the rectum is not resected. The posterior aspect of the vagina can sometimes be preserved as well and may help prevent development of rectal fistulae.

Posterior Pelvic Exenteration

As above, many of the steps are similar except that the bladder is preserved and the ureters are not cut. The anterior wall of the vagina also may be preserved and may help prevent development of urinary fistulae.

URINARY DIVERSION

The decision to perform a noncontinent or continent urinary diversion must be individualized. Noncontinent diversions are created from a portion of terminal ileum, and continent diversions are made with portions of the ileum and ascending/transverse colon. Noncontinent diversions will necessitate a permanent stoma bag on the abdomen as the urine freely empties from the stoma. A continent diversion will eventually allow for patient self-catheterization and eliminate a stomal bag. However, continent diversions are more complex and take much longer to create than a simpler noncontinent diversion. There are no best guidelines to help select between the two; often, it is left to the surgeon's experience and discretion.

P.1317

Generally speaking, noncontinent diversions may be a better option for patients in whom the ability to self-catheterize may be problematic, such as the elderly or those with physical limitations.

FIGURE 54.10 Removal of the en bloc specimen (A) with resultant defect seen from the perineal aspect (B and C).

FIGURE 54.11 Types of long-term ileal conduit-related complications. (Reprinted from Madersbacher S, Schnidt J, Eberle JM, et al. Long-term outcome of ileal conduit diversion. *J Urol* 2003;169:985-990, with permission. Copyright © 2003, Elsevier.)

The noncontinent ileal conduit is easier to create than are the continent conduits, but it does result in a permanent bag on the abdomen for urinary drainage. The possibility of not needing an additional bag on the abdomen with a continent pouch is attractive to many patients. However, there are little data assessing complication rates or patient satisfaction between the two types of urinary conduits. Madersbacher and colleague reported on 131 patients who had an ileal conduit created at the time of cystectomy and had been followed for at least 5 years. They noted a total of 192 conduit-related complications among 87 (66%) patients, with a mean of 2.2 complications per patient. **Figure 54.11** depicts the types of complications that developed. The most common stomal complications were parastomal herniae, stomal stenosis, and bleeding/irritation. Surgical intervention to correct a stomal complication was necessary in 15 patients. Bowel-related complications included bowel obstruction, diarrhea, and fistulae. Infectious complications were mostly urinary tract infections and pyelonephritis. Conduit complications were mostly anastomotic stricturing. A fair number of patients required surgical interventions to manage some of the complications that developed. The rate of complications continued to increase with longer survival. **Figure 54.12** illustrates the number of complications and the rate of patients experiencing complications based on the number of years since conduit creation. Complications developed in 45% of patients surviving 5 years and 94% of those surviving more than 15 years.

FIGURE 54.12 Rate of complications based on time from creation of ileal conduit. (Reprinted from Madersbacher S, Schnidt J, Eberle JM, et al. Long-term outcome of ileal conduit diversion. *J Urol* 2003;169: 985-990, with permission. Copyright © 2003, Elsevier.)

In a series of 100 patients undergoing exenteration for gynecologic malignancies, Forner and Lampe reported that continent pouch creation resulted in an increased median operating time of 97 minutes compared to cases in which an ileal conduit was done. The mean age of patients receiving a noncontinent diversion was 63 years, compared to 52 years for those in which a continent diversion was created. The overall complication rate was slightly higher with continent pouches (48% vs. 31%). Long-term, continent pouches were associated with more instances of urinary stone formation and more urinary tract infections. Similarly, Urh et al. noted a significantly higher rate of stone formation with continent pouches compared to ileal conduits (35% vs. 2%). However, they did not note an increased infectious risk with continent compared to noncontinent diversions. Continent diversions were also associated with greater rates of urostomy stricturing. In this series, noncontinent ileal diversions were preferentially performed in older patients and in those with multiple medical comorbidities. There was no difference between the two types of diversion with regard to anastomotic leaks or strictures, renal insufficiency, fistulae

P.1318

formation, or reoperation to correct a conduit problem. It is important to note that planned continent diversions may not actually be continent. Up to a quarter of these continent diversions may ultimately be incontinent for various reasons, and difficulty catheterizing the stoma may be an issue in some patients. Overall, quality of life is quite similar between patients who have a continent diversion and those who have a noncontinent diversion.

Noncontinent Conduit Creation

A 15- to 25-cm portion of terminal ileum is identified and isolated 15 cm from the ileocecal valve. The length of ileum used is dependent on the length needed from the ureters to the skin. This portion of ileum that will become the ileal conduit is transected at either end. Various methods can be used, but most commonly, this is accomplished using a GIA stapling device. The small bowel can then be reanastomosed in a side-to-side fashion using a standard approach. The associated mesentery is preserved to maintain adequate blood supply. If needed for mobility, the mesenteric fat can be transected toward the base of the mesentery. The proximal end of the conduit will be the end that the ureters will be inserted into (i.e., the "butt" end), and the distal end will become the stoma. The ureters are trimmed so that the distal end is free of radiation effect. If the rectosigmoid has not been transected (i.e., an anterior exenteration), then the left ureter must be tunneled underneath the rectosigmoid through an avascular window in the posterior aspect of the mesentery. A site is chosen on either side of the proximal end of the conduit to ensure a tension-free anastomosis. This site is usually 2 to 3 cm from the staple line, and a 1-cm opening is created. Stents are used by most surgeons, although some feel they are unnecessary.

The distal (i.e., stomal) end of the ileal segment is opened by transecting the staple line. A long thin clamp, such as an Addison clamp, can be passed through this open stomal end and passed to the small ureteral opening at the proximal end. The stent is passed through this opening and out the stomal end and also passed retrograde into the renal pelvis. The ureter is spatulated for about 5 to 6 mm prior to inserting the stent. The ureteral anastomosis is then created using interrupted 3-0 or 4-0 absorbable sutures, such as Vicryl, and sutured to the serosa of the ileal conduit. Care should be taken not to place too many sutures, as doing so may lead to necrosis and stricturing. Tunneling of the ureter through the ileum has been reported, but this is not necessary. These steps are then repeated for the other ureter. The butt end of the conduit can then be secured to the fascia overlying the sacral promontory to prevent excessive motion of the conduit and avoid tension on the newly created anastomoses.

The distal (stomal) end of the conduit is then brought through a preselected site on the abdomen. The stoma is then created using a typical "rosebud" technique. Interrupted 2-0 or 3-0 absorbable sutures are used. A bite is taken through the skin and then brought through a portion of the ileal serosa, then passed through the entire end of the stomal opening. The knots are placed laterally on the skin. The ileal conduit can be sutured to the peritoneum just under the stomal opening. A large-bore catheter without a balloon can be placed through the stoma to maintain patency. This catheter, as well as the ureteral stents, can be secured to the skin with suture. The catheter can be removed 2 to 4 weeks postoperatively, and the ureteral stents can be removed 6 to 8 weeks postoperatively. A peritoneal drain is often placed in the vicinity of the ureteral anastomosis to assess for any urinary leakage in the postoperative period. This drain can be removed 1 to 2 weeks later if there are no signs of urinary leakage.

Continent Conduit Creation

Multiple types of continent diversions have been described. The details of some of these are discussed elsewhere in this textbook. The majority of these continent conduits use varying portions of the ileum, cecum, ascending colon, transverse colon, and, in some, the appendix. The two main types differ based on the continence mechanism. One type relies on pressure differentials between the stomal limb and the low-pressure pouch (i.e., pressure gradient), and the other type relies on a flap-valve mechanism for continence. In the United States, the most commonly used continent diversions after pelvic exenteration for gynecologic malignancies are the Indiana or Miami pouch. These have minor differences but are quite similar. In both, the appendix is removed if still present, the colonic portions are used to create the pouch, the ureters are anastomosed directly into the colonic pouch, and the ileal limb is plicated and becomes the catheterizable stoma. These pouches rely on the higher pressure in the ileal limb, compared to the low-pressure colonic urinary reservoir, to maintain continence. The flap-valve-based pouches use the appendix as the catheterizable stoma, which is hidden in the umbilicus using an appendiceal Mitronoff approach; various modifications exist. This type of pouch allows for the ureters to be anastomosed into the ileal limb as described above for the ileal conduit instead of directly into the colonic reservoir. Surgical details of Miami pouch are described in [Chapter 55](#).

It is beyond the scope of this chapter to detail the steps of all the available types of continent urinary diversions. In general, a low-pressure urinary reservoir is created from the colonic segment that is isolated by detubularizing it and folding it upon itself. Ureteral stents are brought through the colonic reservoir and through the abdominal wall through separate stab wounds instead of through the stoma. For drainage, a large-bore catheter such as a Malecot is placed through the pouch and brought through another separate stab wound on the abdomen. This large-bore catheter allows for irrigation of the pouch, which will continue to secrete mucus for some period of time. A Foley catheter or red Robinson catheter is also placed through the catheterizable stoma to maintain patency. All of these catheters and stents are secured to the abdominal wall to help prevent them from being prematurely dislodged. A peritoneal drain is placed in the vicinity of the pouch to assess for postoperative urinary leakage. The drains, catheters, and stents are removed over time depending on postoperative healing, usually within 6 to 8 weeks.

The decision as to which type of continent urinary diversion to create will depend on surgeon preferences and experience as well as certain patient characteristics. There are advantages and disadvantages to pressure gradient and flap-valve diversions. Pressure gradient pouches are slightly less complex to create and are the only option, other than a noncontinent ileal conduit, for patients who do not have an appendix. The stoma in these diversions also tends to be easier to catheterize, but is placed on the abdomen; thus, there will be an additional stoma on the abdomen in patients who may also have an end colostomy. Flapvalve urinary diversions are slightly more technically challenging and require an intact appendix of sufficient length. However, the appendiceal stoma can be created at the base of the umbilicus, resulting in a "hidden" stoma. Another advantage of these appendiceal pouches is that the ileum is no longer the stoma and is used as a site to attach the ureters. This has the advantage of allowing the surgeon to make the ileal limb as

reach the ureters, thereby minimizing the additional ureterolysis needed when creating the other type of pouches in which the ureters have to be brought up to the urinary reservoir.

COLONIC DIVERSION

A permanent end colostomy is the most commonly performed colonic diversion and/or reconstruction. It is the only option in patients who undergo a translevator total or posterior exenteration. An end colostomy is relatively simple to create, and standard approaches are well described ([Chapter 47](#)). The transected end of the proximal colon is brought through the abdomen through a preselected site that is best located in the left lower quadrant just below the level of the umbilicus. The colostomy creation is often reserved for the end of the procedure just as the abdomen is planned to be closed. The staple line is excised. Absorbable (2-0 or 3-0) sutures are used to secure and mature the stoma. The mucosa is everted and approximated to the skin. Approximately four or five sutures are placed circumferentially and are passed through the skin, through the seromuscular layer approximately 2 to 3 cm below the level of the stoma, through the serosal edge of the stomal opening, and through approximately 1 to 2 cm of mucosa. The suture is then tied, everting the distal colonic mucosa.

Colorectal or coloanal anastomoses are generally discouraged in patients who have undergone a supralelevator exenteration and have previously had their pelvis irradiated. The greatest concern is the high rate of anastomotic leak. Husain and colleagues noted that 7 of the 13 (54%) patients in whom a low rectal anastomosis was created without a diverting colostomy or ileostomy developed a rectal anastomotic leak. All required surgical intervention with creation of a permanent colostomy. One of these patients died of sepsis postoperatively. An additional 2 patients developed a rectovaginal fistula within 6 months, leaving only 4 (30%) of the 13 patients with intact bowel continuity. Depending on how one views these data, a low rectal anastomosis may or may not be a viable consideration. Similarly, Mirhashemi and colleagues noted a 35% rate of anastomotic leaks or fistulae in previously irradiated patients irrespective of whether a protective stoma was created. The rate of anastomotic complications was only 8% in those who had not been previously irradiated. These findings have been confirmed by other investigators. In general, a permanent colostomy is preferred in patients who have been previously irradiated, whereas a colorectal anastomosis may be possible in those who have not been previously irradiated. A colorectal anastomosis may be considered in highly select, previously irradiated patients who are highly desirous of avoiding a colostomy. These patients must be well informed of the high rate of complications associated with reanastomosis and of the fact that there is a real possibility of ultimately requiring a permanent colostomy.

FIGURE 54.13 Double-barreled wet colostomy. (Reprinted from Chokshi RJ, Kuhrt MP, Schmidt C, et al. Single institution experience comparing double-barreled wet colostomy to ileal conduit for urinary and fecal diversion. *Urology* 2011;78:856-862, with permission. Copyright © 2011, Elsevier.)

Wet Colostomy

The wet colostomy was the urinary and fecal diversion first used by Brunschwig ([Fig. 54.2](#)). In his original description, the ureters were inserted into the colon just proximal to the stoma. This was associated with a significant rate of ascending urinary tract infections, metabolic abnormalities, renal disease, and large amounts of foul-smelling watery output. This wet colostomy approach was abandoned in favor of separate urinary and fecal diversions as described above. In 1989, a new technique for a wet colostomy, using a double-barrel approach, was described by Carter et al. In this procedure, the rectosigmoid is transected as indicated for the exenterative procedure. Instead of bringing out the end of the transected colon to form an end colostomy, a loop colostomy is formed approximately 10 to 15 cm from the transected end ([Fig. 54.13](#)). The selected portion is pulled through the abdomen at the preselected site.

The antimesenteric wall of the colon is incised, and then, both stomas are matured as described above in the same opening. A rod is often placed just under the loop at the level of the skin to help prevent it from retracting. This rod can be removed 7 to 10 days postoperatively. The ureters are spatulated and anastomosed into the distal limb of the wet colostomy in a similar manner as described above. The seromuscular layer can be imbricated over the ureteral anastomosis as shown in [Figure 54.14](#), but this is controversial and not done by all surgeons. Ureteral stents are brought through the stoma.

FIGURE 54.14 Ureteral anastomosis into the distal limb of the double-barreled wet colostomy. (Reprinted from Chokshi RJ, Kuhrt MP, Schmidt C, et al. Single institution experience comparing double-barreled wet colostomy to ileal conduit for urinary and fecal diversion. *Urology* 2011;78:856-862, with permission. Copyright © 2011, Elsevier.)

Backes et al. reported their outcomes after a doublebarreled wet colostomy compared to separate urinary and fecal diversions at the time of pelvic exenteration for recurrent gynecologic cancers previously irradiated. A double-barreled colostomy was performed in 12 patients, and separate diversions of various types were performed in 21 other cases. The median length of stay was significantly shorter after a doublebarreled colostomy (14.5 days vs. 20 days; $P = 0.01$). Creation of a double-barreled colostomy also resulted in shorter operative times (627 minutes vs. 724 minutes; $P = 0.01$). There were no conduit or anastomotic leaks in the patients who had a double-barreled colostomy, compared to 6 (29%) patients in the other group who developed a leak ($P = 0.06$). Although not statistically significant, percutaneous nephrostomies were needed at some point in only 2 (17%) of the double-barreled colostomy cases, while they were needed in 8 (38%) of the separate diversion cases. There were also no electrolyte abnormalities noted in the wet colostomy group. Bacteremia and/or sepsis was also less likely after a wet colostomy (8% vs. 48%; $P = 0.03$). These favorable outcomes were still seen when comparing wet colostomy to ileal conduits alone. It appears that a double-barreled wet colostomy may be a valuable technique for urinary diversion at the time of total pelvic exenteration.

PELVIC FLOOR RECONSTRUCTION

A multitude of techniques and approaches exist for reconstruction of the pelvic floor with or without neovagina creation. Some of these procedures are detailed in the following chapter. Although gynecologic oncologists introduced many of these techniques in pelvic surgery, these days, most of these reconstructive procedures are now often performed by our plastic surgery colleagues.

The optimal reconstruction in patients who do not wish to have a neovagina is unclear. The most simple method would be primary closure of the perineal defect alone. Some recommend

P.1321

placement of an omental J-flap in the pelvic defect to help ameliorate complications such as bowel obstructions, enterocutaneous fistulae, and perineal herniae seen after primary closure. However, the data are not consistent in demonstrating such a benefit. Myocutaneous flaps, mostly vertical rectus abdominis myocutaneous (VRAM) flaps, have also been suggested to be beneficial in closure of the large perineal/pelvic defects. This has not been confirmed, and Chokshi et al. found no difference in outcomes comparing VRAM flaps to primary closure.

Neovagina creation has been described using various methods including procedures that use the omentum, portions of the colon, various synthetic and allogenic grafts, or myocutaneous flaps. The gracilis myocutaneous neovagina has been the most commonly used technique for neovagina construction. VRAM-based neovagina creation has also been suggested to be a reasonable option. There are advantages and disadvantages to any type of pelvic reconstruction with or without neovagina creation. Because pelvic exenteration with neovagina construction is a relatively infrequent procedure, there are insufficient data to strongly support one method over another, and the choice of pelvic reconstruction remains individualized.

OUTCOMES AFTER PELVIC EXENTERATION

Morbidity and Mortality

Pelvic exenteration is a complex procedure with a significant risk of morbidity. These complex procedures should only be considered and offered at specialized centers that can provide the multidisciplinary and intense perioperative care that is required. [Tables 54.3](#) and [54.4](#) summarize some of the reported perioperative outcomes and complications. These tables provide a general idea of the outcomes, but it is important to note that there is extensive heterogeneity in the manner in which perioperative outcomes and complications are captured, assessed, and reported between all the referenced articles. Pelvic exenterations are lengthy procedures associated with significant blood loss and a long postoperative length of stay. Many centers report median/mean operative times in excess of 6 hours, with some in excess of 9 hours. Multiple liters of blood loss can be expected. Even today, the length of hospital stays ranges from 2 to 4 weeks.

Perioperative mortality is also significant but has dramatically decreased over time ([Table 54.3](#)). The initial series of pelvic exenterations reported a perioperative mortality of 23%, but modern series report much lower rates of mortality ranging from 0% to 9%. The average perioperative mortality is 9% combining series published before 2000, compared to 3% in those published after 2000. This is likely a reflection of vast improvements in preoperative medical optimization of patients, improved surgical techniques often with subspecialized surgical teams, routine use of prophylactic antibiotics, improved intraoperative anesthetic management, and improved postoperative care in modern intensive care units. Despite a significant reduction in perioperative mortality, both mortality and morbidity are significant following pelvic exenteration, and careful and thorough preoperative informed consent for the patient and her family is important.

Perioperative complications can be expected to occur in at least half of all pelvic exenteration cases ([Table 54.3](#)). There is also a significant risk of requiring additional surgical procedures to correct some of these complications. The spectrum of complications is vast, and virtually any type of complication can occur ([Table 54.4](#)). Surgeons and centers must be aware of this and be able to appropriately handle and manage these complications. Infectious, wound-related complications, venous thrombosis and embolic events, fistulae,

bowel obstruction/ileus, and renal/metabolic abnormalities account for the majority of complications that can occur both in the early and late (often much later) postoperative periods. Because of the variation in the surgical procedure and patient comorbidities, there are no data to provide specific guidance for optimal postoperative care. However, there are some general principles that may optimize postoperative outcomes. Continuous gastric drainage with either a nasogastric or orogastric tube is discouraged as this can lead to an increased risk of pulmonary and other complications. Early ambulation is a key to improving recovery. Total parenteral nutrition is used so that a favorable metabolic state can be maintained during the immediate postoperative period and there is no urgency to resume oral feedings. Antibiotic prophylaxis beyond 24 hours of surgery should not be done unless there are signs or symptoms of an infectious process. Intravenous patient-controlled analgesic delivery systems have been useful at our institution.

Survival

OS was dismal in the early series of pelvic exenteration, with almost no patients surviving 5 years after the exenteration. However, this has dramatically changed, and series published since then report approximately 40% to 60% of patients surviving 5 years or more (Table 54.5). In highly select cases, pelvic exenteration is the only currently available therapeutic option that can provide any chance of long-term survival. Prognostic indicators of survival following pelvic exenteration have been evaluated, but data remain inconsistent. Tumor histology, lymphovascular space invasion, age, primary site, primary versus recurrent disease, tumor size, tumor grade, and BMI have not been shown to be reliable. The only prognostic factor that has been consistently associated with a significant improvement in OS has been a negative margin resection (R0). To offer the greatest chances of prolonged survival, the surgeon should attempt to evaluate the margins intraoperatively and make every effort to obtain a negative surgical margin.

Forner and Lampe found that pelvic nodal metastasis was associated with a worse outcome. However, multiple other series have not confirmed a worse outcome in the setting of pelvic or paraaortic nodal metastasis. Schmidt and colleagues noted a 5-year OS of 51% in patients with pelvic nodal metastasis, which was not statistically worse compared to those with negative nodes (5-year OS 67%). However, cases with paraaortic nodal metastasis had a 5-year OS of only 17%. Based on this evidence, most gynecologic oncologists will not proceed with an exenterative procedure if aortic nodal metastasis is identified, but may be willing to complete the surgery in the face of a single positive pelvic node.

MINIMALLY INVASIVE SURGICAL APPROACHES

Pelvic exenteration has traditionally been performed via a large vertical midline incision, and this remains the standard approach. Recent advances in MIS techniques have led some surgeons to consider exenterative procedures using laparoscopy with or without robotic/computer assistance. The first report of a successful laparoscopic total pelvic exenteration for recurrent gynecologic malignancy was published in 2003 by Pomel and colleagues. This was a supralevator total exenteration with en bloc resection of bladder, uterus, vagina, ovaries, and rectum using endoscopic stapling devices. The specimen was delivered through the resulting vulvar opening. A coloanal anastomosis was performed perineally, and a protective, temporary loop ileostomy was matured through the left lower abdominal trocar site. An ileal conduit was performed extracorporally by extending the infraumbilical trocar site. The ileal conduit stoma was then matured through the right lower abdominal trocar site. The estimated blood loss (EBL) was 250 cc, and the operative time was 9 hours. The patient was discharged 16 days later. Ferron et al. reported their experience with five laparoscopically assisted vaginal pelvic exenterations. The umbilicus was used as the camera trocar site, and an additional four operative trocars were used. Urinary reconstructions were performed through a lateral 5-cm incision. Trocar sites were used to place stomas and bring out drains to the extent possible. No complications were noted in three (60%) of the five patients, and the other two patients developed a perineal and abdominal wall abscess only. Hospital stay ranged from 13 to 33 days.

^aShort median follow-up of 1.75 mo.
OS, overall survival.

A larger series of 16 consecutive laparoscopic anterior pelvic exenterations for recurrent gynecologic malignancies was reported by Puntambekar and colleagues in 2006. A total of five ports were used, and these were all supraleveator anterior exenterations. Urinary diversion was created by implanting both ureters into the intact sigmoid colon and using stents to exiting through the anal canal. The average operative time was 240 minutes and EBL was 200 mL. Only three (19%) patients experienced a postoperative complication: partial small bowel obstruction ($n = 2$) and ureteric leak ($n = 1$). The mean postoperative stay was only 3.5 days. No long-term follow-up is available.

Martinez and colleagues reported their outcomes comparing 14 laparoscopic pelvic exenterations to 29 pelvic exenterations performed via laparotomy. All types of exenterative procedures were performed using both approaches. The median operative time was 13 minutes longer laparoscopically, and the median length of stays was similar (26.5 days vs. 28 days). Blood loss was significantly less using a laparoscopic approach, but overall complications were similar between laparoscopy and laparotomy. A few case series have been published using the robotically assisted surgical platform, including reports by Lambaudie et al. and Davis and colleagues.

MIS approaches have uniformly been shown to offer significant advantages for many other gynecologic procedures for both benign and malignant conditions. An MIS approach to perform an exenteration is interesting. However, only small series have been published and no short- or long-term followup is yet available. Ongoing refinement of MIS techniques hopefully will lead to further improvements in perioperative outcomes for these patients, but that remains to be determined.

BEST SURGICAL PRACTICES

- Pelvic exenteration is a complex surgical procedure that should be performed by experienced surgeons in centers familiar with this procedure and capable of offering the intense and complex perioperative care that is required.
- The important first step is the identification and adequate evaluation of appropriate candidates in whom exenteration may offer a benefit. Medical comorbidities and performance status must be carefully evaluated and optimized preoperatively. All efforts must be made to exclude extrapelvic metastasis, and exenteration must be abandoned if this is discovered. PET/CT scanning has been shown to be useful in this evaluation.
- The goal of exenteration should be a negative margin (R0) resection. We have found preoperative pelvic MRI to be helpful in this regard.
- The ideal candidate for exenteration is a patient with a recurrent gynecologic malignancy in the central pelvis measuring 2 cm or less who has been previously treated with primary radiation. However, because of reduction of morbidity and mortality, the indications for exenterative procedures have been tremendously expanded and can be considered in other settings.
- Pelvic exenteration requires a multidisciplinary approach involving a gynecologic oncologist, plastic surgeon, sometimes urologist, often a radiologist, radiation oncologist, and a psychologist. Intraoperatively, a multiteam approach will help reduce individual surgeon fatigue since these are long procedures.

P.1327

- It is important to offer as much psychological evaluation, assessment, and assistance as possible since most patients cannot fully understand the consequences of the procedure they will be undergoing.
- The choice of urinary diversion is complex. Advantages and disadvantages exist for noncontinent and continent diversions. Similarly, various types of continent diversions exist, each with their own advantages and disadvantages.
- A wet colostomy had been largely abandoned, and separate urinary and fecal diversions have been thought to be superior. However, a recently described use of a novel doublebarreled colostomy technique suggests that this may be a very reasonable method for a combined urinary and fecal diversion with comparable, or even improved, outcomes compared to the various separate techniques.
- The optimal method for pelvic defect reconstruction and neovagina creation remains to be determined. Multiple techniques exist, and the decisions must be individualized.

Chapter 55

Surgical Reconstruction of the Pelvis in Gynecologic Cancer Patients

Jeffrey M. Fowler

Pankaj Tiwari

Ritu Salani

DEFINITIONS

Continent ileocolonic urinary conduit—A urinary diversion technique that utilizes a portion of the proximal large bowel and terminal ileum to construct a low-pressure urine storage pouch and a high-pressure efferent limb to create a continent system that is catheterized intermittently by the patient.

Full-thickness skin graft—A skin graft that includes the entire thickness of skin, which is cleaned of subcutaneous tissue.

Gracilis myocutaneous flap—A flap based on the gracilis muscle and overlying fat and skin. The vascular supply is primarily based on the medial circumflex artery proximally. The distal muscle belly is supplied by minor vascular pedicles from the superficial femoral artery that can be sacrificed. Innervation is from the obturator nerve branches, resulting in a sensate flap.

Noncontinent urinary conduit—A loop of intestine (small or large bowel) isolated into a free draining stoma for urinary diversion.

Omental J-flap—A technique for revascularizing the pelvis after exenteration. The omentum is detached from the greater curvature of the stomach and brought down as a flap based on the left (or occasionally right) gastroepiploic artery. It is first sutured to the sacral promontory posteriorly, the pubic symphysis anteriorly, and pelvic walls laterally to form a pelvic lid.

Pudendal thigh flap—A fasciocutaneous tissue transfer flap based on blood supply from the internal pudendal artery and/or random subcutaneous vascular supply. This flap can be designed as a peninsular rotational flap or as an island flap.

Rectus abdominis myocutaneous flap—A versatile flap based on the rectus muscle and supplied by the inferior epigastric artery. The flap is taken from the supraumbilical portion of the abdomen and can be oriented in a transverse, vertical, or oblique design.

Rhomboid flap—A tissue transfer flap of skin and subcutaneous tissue, which is mobilized to fill an adjacent defect. This flap is supplied by random vascularization and most often designed close to a 1:1 height-to-width ratio.

Split-thickness skin graft—A partial-thickness skin graft harvested of varying dermal thickness.

INTRODUCTION

The cornerstone of gynecologic oncology fellowship training is the development of proficiency in radical pelvic surgery to adequately excise and stage disease and to address treatment or disease-related complications. From a surgical standpoint,

surgical innovation has evolved with the goal of maintaining or improving survival while minimizing the extent of tissue removal and improving quality of life. As a result, gynecologic oncologists have gained expertise not only in radical pelvic surgery but also in gastrointestinal, genitourinary, and pelvic/vaginal reconstructive surgery.

Surgical procedures for preinvasive and invasive gynecologic neoplasia have become less radical over time where appropriate. Unfortunately, a small portion of patients will require an extensive and/or radical surgical procedure in order to cure primary disease. Occasionally, an ultraradical procedure such as the pelvic exenteration is required to address recurrent gynecologic malignancies. Therefore, reconstructive surgical procedures are often necessary with the outcome goals that include wound healing, decrease in acute and chronic morbidity, and restoration of anatomic form and function. Incorporating a pelvic/vaginal reconstructive procedure into radical pelvic surgery may be relatively straight forward but can often be quite complex considering that reconstruction may be enmeshed within a surgical case that includes multiple major surgical procedures that make up the entirety of the case. The gynecologic oncologist is best suited to orchestrate this multifaceted surgical process, and it is extremely important that the surgeon be well versed in the reconstruction options available in order that it is optimally planned. The objective of this chapter is to outline the most common reconstructive options and techniques available after radical and ultraradical pelvic surgery for gynecologic malignancies.

VAGINAL AND VULVAR RECONSTRUCTION

Radical surgery of the vagina and vulva often leaves a large defect where primary closure is not feasible. There is a wide range in the complexity of surgical situations that require reconstruction. Reconstructive goals include bringing in healthy tissue to fill the defect in order to enhance wound healing, and restoration of anatomic form and function. In these situations, reconstructive surgery is optimal when applied concurrently with the primary extirpative procedure but sometimes performed secondarily for repair of vaginal stenosis or vulvovaginal wound breakdown resulting from previous treatment complications. There are general guidelines that prioritize reconstructive options based on the size and location of the vaginal defect; however, the optimal reconstructive procedure will be dependent not only on the site and extent of the defect but also upon previous therapy applied to the pelvis and other intraoperative variables. Many reconstructive techniques are available, and most often, there is no one best option for any situation requiring reconstruction ([Table 55.1](#)). Important considerations include not only the goals at the site of reconstruction but also the patient's preoperative history and intraoperative condition, total length of the procedure, and potential donor site sequelae.

Patients with large pelvic soft tissue defects in addition to a vaginal defect are usually best managed with a large myocutaneous flap to provide biologic tissue bulk to the vacant pelvis, neovascularization, and vaginal reconstruction. Flaps should be outlined prior to the abdominal incision and potential ostomy sites taken into consideration. If possible, all pelvic reconstructive surgeries performed during an exenteration should be supplemented with an omental J-flap to form a pelvic lid in order to provide for additional neovascularization and to protect the small bowel. Considering the importance of minimizing severe postoperative morbidity, pelvic/vaginal reconstruction should be prioritized over complicated, timeconsuming, and higher-risk low rectal anastomosis and continent urinary conduits in the patients undergoing extensive total pelvic exenterations.

TABLE 55.1 Common Reconstruction Options in Gynecologic Oncology

GRAFT/FLAPS	RECONSTRUCTION INDICATION
Split-thickness skin graft	Vulvar and vaginal

Full-thickness skin graft	Vulvar and vaginal
Rhomboid flap	Vulvar
Y-V advancement flap	Vulvar
Pudendal thigh flap	Vaginal
Bulbocavernosus flap	Vaginal
Rectus abdominis flap	Groin, pelvic, vaginal, and vulva
Gracilis flap	Vulvar or neovagina
Gluteus maximus flap	Vulvar and perineal
Tensor fasciae latae flap	Groin

Patients with the largest defects are usually those undergoing infralevator total exenterations. A single large oblique rectus abdominis myocutaneous (RAM) flap is often sufficient to provide needed bulk in the pelvis, enhance closure of the perineal defect, and provide tissue for vaginal reconstruction. Supplemental flaps can be added to a single RAM that is adequate for providing bulk but not sufficient to complete the neovagina. Adding a full-thickness skin graft (FTSG) on a bed of omentum, supplementing with a pudendal thigh flap, and/or using a bulbocavernosus myocutaneous paddle to augment remaining longitudinal anterior or posterior defects are all very good supplemental options. Other alternatives to the RAM usually require bilateral procedures including the gracilis myocutaneous flap (GMF) or gluteal thigh flaps although they are not practical for addressing defects remaining after supralelevator exenterations. Bilateral thigh flaps are better suited for extensive posterior defects. Potential advantages of these alternatives to the RAM include the opportunity for two surgical teams working simultaneously and avoiding any conflict with choosing the appropriate site for bilateral stomas, although many surgeons do not consider bilateral stomas to be a contraindication to the RAM.

Managing vulvar defects in a patient with no previous surgery or radiation therapy is relatively uncomplicated. Reconstruction for deep vulvar defects and/or radical partial excision of the vagina where it is important to bring in wellvascularized tissue to fill in dead space, provide neovascularization, and restore anatomic appearance and function can be more challenging especially if there is a history of previous surgery or irradiation. Ultraradical procedures that leave the patient with various combinations of pelvic, vaginal, and/or perineal defects provide the greatest challenge. Preoperative

P.1330

planning is important, and the surgeon needs to be prepared to choose from a portfolio of reconstructive options based on the extent of the radical surgery and other intraoperative factors. Therefore, it is necessary that the gynecologic oncologist be proficient with multiple reconstructive options in order to optimally address the various vulvar/vaginal defects one may encounter.

SKIN GRAFTING

A graft is defined as any free tissue that is placed into a wound bed. Grafts differ from flaps in that they do not carry an intrinsic vascular supply. A skin graft must rely on the vascularity of the wound bed to optimize “graft

take,” which is simply defined as adherence of the skin graft to the underlying wound bed with eventual neovascularization into the graft. Factors that impact skin graft survival include the thickness of the graft, whether it is a full-thickness or split-thickness skin graft (STSG); bacterial contamination of the wound bed; and postoperative complications such as hematoma formation or shearing of the graft. FTSG and STSG are both excellent options for vaginal reconstruction. FTSGs include the entire dermal layer. The advantage to an FTSG is an improved cosmetic appearance with a reduced incidence of secondary graft contracture. Disadvantages to FTSG include a lower possibility of “graft take” in wounds where bacterial contamination may be a concern. Both STSG and FTSG must be harvested from a donor site. Secondary donor site deformity usually constrains the size of the FTSG. STSG, on the other hand, can be harvested from a large square surface area and have varying degrees of thickness of dermis. Thin STSG have the highest likelihood of “graft take”; however, they are also most prone to secondary contraction as the wound heals. Balancing donor site issues, cosmetic concerns, wound contamination, and secondary graft contracture will lead to the optimal choice for graft placement.

Split-Thickness Skin Graft Harvest

Although STSG can be harvested from a variety of locations, the authors prefer to conceal the donor site. As such, the most common sites for harvest are the upper thighs. A small graft can be harvested using a hand-driven Weck blade, which is calibrated to harvest grafts that are 0.008, 0.010, and 0.012 inch thick. More commonly, a power-driven dermatome is used (e.g., Brown and Zimmer). A guard is selected according to the size needed. The thickness of the graft to be taken is then set. Despite this setting, the distance between the blade and instrument must always be checked by putting a Bard-Parker No. 15 blade between the blade and the guard, which approximates 0.015 inch.

Before harvesting the graft, the skin should be cleaned and mineral oil applied to lubricate the skin (see Steps in the Procedure box). The dermatome is turned on and engages the skin at an angle, exerting pressure on the skin. The dermatome is slowly pushed while the assistant helps by offering countertraction. Once the graft is harvested, it is placed in a saline-soaked sponge. If one wants to limit the size of the graft, it can be meshed. Grafts can be meshed in a variety of ways. An STSG can be “pie crusted” where a No. 15 blade is used to create full-thickness 1-to 2-mm holes within the main body of the graft. This allows for serous fluid to be evacuated from underneath the graft, which enhances adherence of the graft to the wound bed. STSGs can also be meshed with skin graft mesher (Zimmer), which produces a multiplied ratio of available surface area. Grafts are typically meshed 1:1, 1:2, or 1:3. Meshing to the latter ratio must be done with caution as the greater the number of mesh interstices, the more fragile the graft.

STEPS IN THE PROCEDURE

Split Skin Graft Harvest Step-by-Step Approach

- Evaluate the recipient site for healthy wound bed.
 - Choose the donor site (the authors prefer the upper thigh).
 - Place mineral oil to the donor site.
 - Use countertraction to provide a flat surface for the dermatome to pass.
 - Harvest skin graft between 0.008- and 0.012-inch thickness: Mesh or “pie-crust” as indicated.
 - Secure the graft (dermal site down) to the wound bed.
 - Bolster the graft in place to limit shear forces at the wound.
 - Dress the donor site with semipermeable gauze or equivalent dressing.
 - Maintain bolster dressing for 5 to 7 days.
-

Grafts can be affixed with staples or with absorbable chromic gut or synthetic absorbable suture (3-0 or 4-0). The authors prefer suture placement, as staple removal in the clinic can prove quite uncomfortable for the patient. At present, there is no ideal way to treat the donor site. For a small area, Opsite is useful because it decreases pain; however, the major disadvantage is that the donor site weeps large amount of fluid in the ensuing 24 hours. An alternative is Xeroform gauze (3% bismuth tribromophenate) over the donor site, which is then allowed to dry over the wound. The authors' preferred donor site dressing is Glucan II (Molnlycke Health Care, USA), a transparent dressing that can be suture affixed over the wound. This dressing does not dry out, as does Xeroform gauze, and also provides optimal relief from the discomfort of the open donor wound.

Full-Thickness Skin Graft Harvest

Theoretically, full-thickness skin grafts can be harvested from anywhere on the body where there is sufficient skin laxity to allow for excision and primary closure of the donor defect. One of the more common regions for FTSG harvest is the groin region above the level of the inguinal ligament. This donor site provides for a 5 × 10 cm graft harvest with primary closure. Grafts can also be harvested bilaterally. If a larger graft is necessary, the hypogastrum provides a full-thickness skin that can measure 10 × 20 cm depending on the degree of abdominal subcutaneous laxity.

FTSGs are harvested freehand using a Bard-Parker No. 10 or 15 blade (see Steps in the Procedure box). The blade incises the skin and is turned in an angle and elevated, leaving a small amount of dermis at the base. Any excess fat is then excised with Iris scissors. Unlike the STSG donor site, FTSG donor sites can be primarily closed at the time of graft harvest. Both skin edges are then elevated to obtain closure. Depending on tension at the closure, 3-0 or 4-0 monofilament, absorbable suture is used.

P.1331

STEPS IN THE PROCEDURE

Full-Thickness Skin Graft Harvest Step-by-Step Approach

- Evaluate recipient site for healthy wound bed.
- Choose the donor site (authors prefer groin or lower abdomen).
- Incise the skin of the donor site at margins of graft design.
- Harvest skin graft with full-thickness dermis and into subcutaneous tissue.
- Trim the underlying subcutaneous fat leaving dermal exposure.
- “Pie-crust” graft to allow for serous exudate.
- Secure the graft to the donor site and the close recipient site in layered fashion.
- Bolster the graft in place to limit shear forces at the wound.
- Maintain bolster dressing for 5 to 7 days.

As with STSG, it is important to “pie-crust” an FTSG to allow for the exudation of serous fluid. Should fluid collect beneath the graft and wound surface, the graft will not be able to adhere to the bed. Areas of nonadherence will ultimately undergo necrosis. Meshing is usually not necessary for an FTSG. Once the FTSG has been affixed to the wound bed, a bolster must be placed. Bolsters can be fashioned in a variety of ways. The authors prefer cotton balls, mineral oil, Xeroform gauze, and a tie-over dressing with 2-0 silk sutures. Bolster dressings are typically left in place for 5 to 7 days and then removed in clinic.

FIGURE 55.1 An omental “J-flap” is developed by separating the right-sided portion of the omentum, first from the transverse colon and then from the greater curvature of the stomach leaving a left-sided vascular pedicle. This pedicle then is positioned over the pelvic defect and loosely sutured in place.

Alternatives to Graft Placement

In some patients, use of an autologous graft placement may need to be delayed prior to achieving wound closure. Typically, such patients have a contaminated or clean-contaminated wound. Under such circumstances, the success of an STSG or FTSG viability may be unpredictable due to the degree of bacterial contamination. The use of xenograft (porcine) or cadaveric graft should be considered in these circumstances. Substitutes such as these will adhere to the underlying wound bed if the conditions are favorable. This strategy can be used as a test to evaluate the wound for receipt of either an FTSG or an STSG. Even in circumstances where a xenograft or cadaveric graft “takes” to the underlying wound bed, they will typically undergo resorption over a 3-week period allowing an opportunity for definitive closure.

INTEGRA Meshed Bilayer Wound Matrix (Integra Life Sciences Corp., Plainsboro, NJ) is an additional skin substitute that allows for assessment of the quality of the wound bed. INTEGRA consists of a porous matrix of cross-linked bovine tendon collagen and glycosaminoglycan and a semipermeable polysiloxane (silicone) layer. As such, the meshed bilayer allows drainage of wound exudate and provides a flexible adherent covering for the wound surface. The collagen-glycosaminoglycan biodegradable matrix provides a scaffold for cellular invasion and capillary growth. Over a 3-week period, the scaffold undergoes neovascularization. Once adherent to the wound bed, it provides an excellent recipient site for definitive autologous graft placement. INTEGRA not only allows for confirmation that a wound bed has been optimized for graft placement but also provides an additional several millimeters of soft tissue coverage if necessary.

Omental J-Flap with Skin Graft

By modifying the omental flap that is normally used to close off the pelvic inlet after exenteration (**Fig. 55.1**) (see Steps in the Procedure box), with or without low coloproctostomy,

P.1332

the surgeon can create an omental cylinder, providing anterior, posterior, and lateral walls for the neovagina (**Fig. 55.2A**). When the cylinder is sutured to the introitus and lined with a skin graft (split or preferably full thickness) and expanded in the postoperative period by a soft rubber vaginal form, a satisfactory functional neovagina can be created (**Fig. 55.2B-D**). The FTSG works well for neovaginal reconstruction with similar graft survival as compared to STSG, but is less likely to contract postoperatively compared with the STSG. However, when options are limited due to prior intervention or when faced with a bulky pedicle, for example, in obese patients, fullthickness grafts may be at higher risk of necrosis, favoring the STSG approach.

FIGURE 55.2 A: Drawing of the sagittal view of the pelvis after total exenteration. The colon has been reanastomosed to the rectum. The omentum has been taken off the stomach and brought into the pelvis as a J-flap for closing the pelvic inlet. The distal omentum of the J-flap is available for rolling into a cylinder, thus creating the walls of the neovagina. **B:** The distal omentum is rolled into a cylinder to be lined with an STSG. **C:** A foam rubber vaginal mold is covered with a condom. The skin graft is sutured over the mold. **D:** Drawing of a sagittal view of the omental flap neovagina, lined with a skin graft fashioned over a foam rubber vaginal mold

covered with a condom.

STEPS IN THE PROCEDURE

Omental J-Flap Neovagina Step-by-Step approach

- Separate the omentum from the transverse mesocolon.
 - Confirm viable blood supply from left gastroepiploic artery, which is preserved.
 - Create and ligate gastroepiploic pedicles along the greater curvature of the stomach (usually from right to left).
 - Suture the distal aspect of the omental J-flap onto the posterior distal vagina or perineum.
 - Suture the skin graft over the vaginal mold with skin epithelium against the stent.
 - Lay the stent with skin graft on the posterior omental bed and fold the omentum over the stent to create the omental pocket.
 - Close the anterior aspect of the omental pouch.
 - Keep the stent secured within the omental tube by suturing the labia closed.
 - Carefully remove the stent in approximately 7 days.
-

P.1333

If construction of the neovagina is performed immediately following total pelvic exenteration, it is important to ensure that hemostasis in the pelvis is complete before applying the skin graft. If hemostasis is uncertain, the omental pocket for the neovagina should be packed with gauze. When hemostasis is secure and serous drainage has stopped, the packing can be removed and the graft can be taken as a secondary procedure and applied to a vaginal form and placed in the omental pocket.

In **Figure 55.2D**, a sagittal section shows a patient who has undergone a total pelvic exenteration. The rectal stump was retained, and the descending colon was mobilized and brought down into the pelvis for a coloproctostomy. The omentum has been detached from the greater curvature of the stomach and brought down as a flap based on the left gastroepiploic artery. It is first sutured to the sacral promontory posteriorly, the pubic symphysis anteriorly, and pelvic walls laterally to form a pelvic lid. In patients who have insufficient omentum to form both the pelvic flap lid and walls of the neovagina, the omentum making the pelvic lid can be supplemented by the use of a sheet of synthetic, absorbable mesh with or without a skin graft lining as described by Elaffandi et al. Once the skin is placed in the neovagina, the graft eventually becomes almost indistinguishable from normal vaginal mucosa on histologic examination. After the development of estrogen receptors, the maturation index from cells of the graft can be influenced by the administration of systemic estrogen similar to normal vaginal mucosa.

FIGURE 55.3 A: A full-thickness graft is harvested. In the photograph, the graft is almost 6 inches in diameter, which will provide a vaginal diameter of about 1 ½ inches. **B:** The graft has been folded over a soft foam mold (skin side in) and sewn into a tube to form the neovagina.

In **Figure 55.3A**, an FTSG has been harvested and rolled into a tube. It has been our practice to suture the graft over a soft foam mold (we use Model Magic (Crayola, Inc., Easton, PA)) that can be constructed to fit the individual defect giving the surgeon flexibility in choosing the length and diameter of the stent. The skin graft is folded over the vaginal form, and the edges of the graft are sutured with a running fine synthetic absorbable suture (**Fig. 55.3B**). The graft and stent are inserted into the omental tube so that the epithelial surfaces are opposed. The labia majora are sutured together for 7 days to allow for the skin graft to “take” and to prevent the stent from being extruded out of the neovagina. For a period of 6 months thereafter, a vaginal stent should be worn at all times, except during intercourse and douching, in order to prevent graft shrinkage, which leads to vaginal stenosis. After 6 months, the vaginal form is worn only at night if the patient is not sexually active. The omental J-flap with a skin graft lining has proven to be a reliable technique for vaginal reconstruction and is associated with minimal added morbidity and can result in satisfactory vaginal function.

Skin Grafting of Vulvar Defects

Most vulvar defects that are the result of a simple excision (wide local excision, partial or total vulvectomy) can be closed primarily, especially if the surgical field has not been treated with radiation and the lesion is less than 4 cm. Radical procedures for vulvar malignancies result in very deep defects where a skin graft will not be sufficient to close the defect if reconstruction is required. Skin grafting is useful when it is necessary to perform a superficial but large surface “skinning” vulvectomy that often involves resection of perineal and perianal skin in addition to the vulva. These are large surface area resections usually performed for extensive VIN or Paget disease and can be difficult or impossible to close primarily leading to wound dehiscence and/or disfigurement. The procedure and reconstruction has been described by Caglar and colleagues and also Dettenmaier et al. Reconstruction by placing a skin graft over the subcutaneous tissue is preferable to allowing such a large defect to heal by secondary intention.

Preparation of the donor site, harvesting the STSG, and care for the donor site are described above. The recipient site

is prepared by ensuring meticulous hemostasis (**Fig. 55.4A**). Meshing is recommended considering the risk for infection and serous drainage collections in these larger external and perianal wounds. Larger slits are designed to accommodate the vaginal introitus and anus. The edges of the meshed graft are sutured to the edges of the vulvar defect with fine absorbable suture in an interrupted fashion (**Fig. 55.4B**). Moist gauze is then packed and

secured over the defect as a bolster to ensure that the graft is in contact with the subcutaneous tissue. It is important that the patient is immobilized for 5 to 7 days to prevent the graft from shearing from the recipient site. Therefore, deep vein thrombosis prophylaxis should be instituted, and the patient may require a Foley catheter and/or a rectal tube while at bed rest. The secured packing is carefully removed so as to not inadvertently disrupt the adherent graft. Dainty and others have reported the use of fibrin tissue adhesives, and wound vacuum-assisted closure devices has been reported to improve graft viability during vulvovaginal reconstruction.

FIGURE 55.4 Large superficial vulvar defect. **A:** Large superficial defect of the vulva, perineum, and perianal region after skinning vulvectomy for VIN 3. **B:** Anterior aspect of defect closed primarily without tension and posterior aspect covered by STSG. A bolster will then be placed so that the graft remains in contact with the subcutaneous tissue.

Tissue Transposition Flaps

Adjacent tissue transfer flaps or skin flaps are sufficient for the majority of situations encountered that require reconstruction after radical vulvar surgery except for the most extensive resections. Tissue transposition flaps can also be used as alternatives to skin grafts and myocutaneous flaps for vaginal reconstruction. These local flaps can be supplied by random vascularization from the underlying subcutaneous vascular network or derive their blood supply from a single-vessel or defined vascular territory. Tissue transposition flaps are relatively easy to perform, and provide well-vascularized tissue with needed bulk for deeper vulvar defects that are not amenable for primary closure or superficial skin grafting. A unilateral or bilateral rhomboid flap as described by Burke et al. is usually sufficient for most vulvar defects. Other options that may be used as an alternative to a myocutaneous flap, especially for extensive vulvar defects in a radiated surgical field, include the medial thigh and gluteal V-Y advancement flap and rotational flap. Monstrey and colleagues have described the use of a very versatile pudendal thigh flap in 19 patients. Bulbocavernosus flaps have also been used for many years to repair various vulvovaginal defects, but Green and the group from the Cleveland Clinic have recently revisited this

Rhomboid Flap

Large lateral vulvar defects can be satisfactorily closed with a unilateral rhomboid flap, while perineal defects of most any size are usually best closed with bilateral flaps. The rhomboid flap is raised according to the measured vulvar or perineal defect and best designed with a 1:1 height to width ratio. Conditions that may compromise the vascular supply such as previous irradiation and/or surgery in the area of the skin flap may also compromise graft viability. In addition to adequate blood supply, successful healing of these flaps is dependent on positioning and closure without tension.

A unilateral flap is illustrated in [Figure 55.5A, B](#). Prior to making the incisions to create the flap, the defect is measured and then a design is marked to the appropriate size so that it will be able to be rotated into and fill the defect without tension

P.1335

once it is sutured into place. The incision is then made through the skin and subcutaneous tissue down to the level of the fascia. Next, the deep aspect of the subcutaneous tissue is dissected off of the fascia, starting from the apex and back toward the base of the flap. In order to take tension off of the flap, the subcutaneous edges of the flap are approximated to the subcutaneous edges and base of the defect with interrupted 3-0 polyglycolic absorbable (PGA) suture. Undermining of the deep subcutaneous tissue adjacent to the surgical defect may assist wound closure without tension (see Steps in the Procedure box). A subcutaneous drain with suction may be placed for large defects for drainage and elimination of dead space. The skin is closed with interrupted 3-0 PGA in a mattress fashion.

STEPS IN THE PROCEDURE

Rhomboid Flap Step-by-Step Approach

- Verify hemostasis within the recipient bed.
- Design flap so that the distal aspect of the flap corresponds to the transverse diameter of the defect. The height-to-width ratio of the flap is roughly 1:1.
- Incise skin and subcutaneous tissue of flap down to the fascia.
- Mobilize the subcutaneous tissue of the flap off of the fascia.
- Undermining surrounding subcutaneous tissue is necessary.

- Position the flap within the defect.
- Suture the flap into the defect in layers to eliminate dead space and tension.

P.1336

Most anterior defects can be closed primarily; however, radical vulvar surgery often leaves a significant posterior perineal defect. While primary closure is often possible, close approximation of the vagina and anus is not desirable. Due to their bulk, large rotational skin flaps and myocutaneous flaps are not practical in this situation. Bilateral rhomboid flaps are usually the ideal reconstructive option to fill these defects. The flaps are designed according to the size of the defect with the goal of meeting in the midline without tension (**Fig. 55.6A**). The mobilized flaps are stabilized by suturing the subcutaneous fat to the base of the defect and to the subcutaneous fat at the defect edges and to the “sister” flap in the midline (**Fig. 55.6B**). The skin is closed with interrupted 3-0 PGA in a mattress fashion (**Fig. 55.6C**). Usually, a drain is not needed in this situation.

FIGURE 55.6 Bilateral rhomboid flaps. **A:** Deep posterior perineal defect after radical resection of vulvar carcinoma with planned bilateral rhomboid flap design. **B:** Rhomboid flaps are mobilized and will be rotated into the defect. **C:** Finished bilateral rhomboid flaps. V-Y Advancement Flap

The V-Y flap is an excellent option for large unilateral and bilateral vulvar defects. These flaps are technically easier to perform compared to the GMF, have a reliable vascular supply, are sensate, and can still fill a relatively large defect. The flap is dependent on random perfusion for its vascular supply from the pelvis and medial leg muscles. The flap is designed in the shape of a triangle and usually harvested from the medial thigh or the gluteal fold. The flap is designed with the apex either at the gluteal fold or on the medial thigh with the base at the wound defect (Fig. 55.7A). The skin and subcutaneous tissue is incised down to the underlying fascia, and the flap is mobilized according to the size of the defect, which results in the shape of a “V” (Fig. 55.7B). The flap is advanced or “slid” over to the medial edge of the defect without tension and sutured in a similar fashion as described for the rhomboid flap. The resulting suture line now has the appearance of a “Y” (Fig. 55.7C). Immobilization and drains can be considered depending on the size of the flap and extent of subcutaneous dissection.

P.1337

Pudendal Thigh Flap

The pudendal thigh fasciocutaneous flap is based on blood supply from the internal pudendal artery and can be designed as a rotational flap with a peninsular base or as an island flap with a pedicle when there is a need for tunneling or increased flap mobility. When the integrity of the blood supply is in question, the nonisland version of this flap should be used to take advantage of random subcutaneous blood supply. The flap is reliable, is easy to harvest, leaves an inconspicuous donor site scar, and is less bulky than is a myocutaneous flap. Unilateral

flaps are quite useful for filling partial vaginal defects that are posterior or augmenting unilateral myocutaneous flaps during total vaginal reconstruction. Bilateral flaps may be sufficient for total vaginal reconstruction. The flap is sensate and does have the potential for hair growth.

The flap is outlined over the labial-crural fold and is usually 5 to 6 cm in width and up to 15 cm in length (**Fig. 55.8A**), but is usually designed on a 2:1 length-to-width ratio. The skin and subcutaneous tissue are incised down to and through the deep fascia (**Fig. 55.8B**). A posterior-based rotational flap is then mobilized and can be rotated into the vaginal defect and sutured in multiple layers to eliminate dead space and tension (**Fig. 55.8C, D**). A subcutaneous drain is recommended for the large donor site prior to closing.

Myocutaneous Flaps

The role of reconstructive surgery has continued to evolve in gynecologic surgery since the introduction of radical pelvic surgery in the mid-twentieth century.

Incorporation of myocutaneous flaps into the reconstruction scheme of patients undergoing radical pelvic surgery has been extremely important in minimizing perioperative complications and improving functional outcome and/or quality of life. Myocutaneous flaps are oriented on a single artery or specific region of blood supply and rotated into the recipient defect. These flaps provide an excellent bed for neovascularization, can fill a large void in a previously radiated devascularized pelvis, and can be used to form a neovagina and/or fill a perineal defect. Incorporation of the myocutaneous flap for reconstruction in exenterations and extensive vulvectomies was initially performed with the GMF; however, Soper et al. compared it to the newer RAM flap and found this flap more reliable and associated with a lower rate of flap necrosis. The RAM fills the pelvic defect more effectively considering the limited mobility of the GMF. Often, the GMF and the gluteus maximus flap are better suited for posterior vulvar and perineal defects secondary to its proximity to the defect.

When myocutaneous flaps are required, selecting the appropriate procedure requires awareness of anatomy, size of the potential defect, and knowledge of the impact of potential complications. A careful review of prior surgical and radiation records is necessary, as this may impact viability of the selected flap. Furthermore, as these procedures are more commonly performed at the time of radical surgery, appropriate planning includes goals of outcomes, restoration of normal anatomy, and minimizing postoperative morbidity. There are a number of general surgical principles and instruments that apply to all of the myocutaneous flap options discussed in this chapter (**Table 55.2**).

FIGURE 55.8 Pudendal thigh flap. **A:** Left flap design for secondary vaginal reconstruction in a young woman with vaginal stenosis after an abdominoperineal resection and posterior vaginectomy. **B:** Flap is mobilized and includes both the subcutaneous tissue and adductor fascia. **C:** Flap is sutured into the subcutaneous tissue of the posterior vaginal defect. **D:** Subcutaneous tissue along the donor site is undermined and this defect closed primarily. Rectus Abdominis Flap

The RAM, based on the inferior epigastric artery, is the most reliable and versatile myocutaneous flap for gynecologic oncology patients. The advantages and indications for this versatile flap have been reviewed by Lee and Dumanian. This flap has reliable blood supply and skin paddles that can be designed vertically, transversely, or obliquely with a wide 360 degree arc of tension-free rotation. The flap can be used for vaginal, vulvar, and groin reconstruction stent for vaginal reconstruction (**Fig. 55.9A, B**). When a larger flap is needed, the oblique flap is used as it also takes advantage of the lateral abdominal wall blood supply above the umbilicus. Carlson et al. found that risk factors for graft failure include significant peripheral vascular disease, previous abdominal surgery most notably transverse incisions and previous stomas, and obesity. Preoperative pelvic angiography to assess patency of the blood supply to the rectus muscle can be considered but will not

always predict graft viability. However, verification of the blood supply to the lower extremity should be performed prior to surgery if the patient has symptoms of claudication,

history of peripheral vascular disease, heavy smoking, and/or prior pelvic radiation.

TABLE 55.2 Surgical Principles for Myocutaneous Flaps

1.	Key Surgical Instrumentation
a.	Bipolar, jeweler forceps (coated)—fine-tipped forceps to allow for manipulation of the vascular adventitia without risking traumatic injury during vessel dissection
b.	Dissecting scissors (Reynolds tenotomy, littler)—fine-tipped dissecting scissors to allow for vascular dissection if increased pedicle length is desirable prior to flap transposition
c.	Microvascular clips (automatic or manual applier)—hemostatic clips during flap dissection
d.	Weitlaner retractors (medium, sharp)—self-retaining retractors during pedicle dissection
e.	Richardson retractors—wide, right-angled retractor to facilitate flap and vascular exposure
2.	Surgical Principles
a.	Predetermination of the size and shape of the flap to fit the defect is imperative.
b.	Patient positioning should be comparable to the postoperative position so that tension is not increased across the flap.
c.	Obese patients (BMI > 35) may present a challenge due to a variable blood supply to the skin and decreased mobility of the flap.
3.	Perioperative Morbidity
a.	Flaps may be associated with vaginal abscess or cellulitis, which is often amenable to antibiotics and conservative measures.
b.	Surgical intervention/revision may be required for flap necrosis and flap prolapse.
c.	Care of donor site is also key, and tension at this site should be avoided as it may lead to myonecrosis or compartment syndrome.
4.	Delayed Complications
a.	Delayed complications can include the formation of enterocutaneous fistulas, though less common when compared to no reconstruction.

- b. Scarring or atrophy of the flap may also occur, which may affect sexual and functional outcomes.
- c. Donor site complications, including leg weakness, have also been reported.

The flap is outlined above the umbilicus so that the medial aspect can be incorporated into the laparotomy incision (**Fig. 55.10**). The inferior epigastric artery is checked by Doppler prior to harvesting the flap. A transversely oriented flap is approximately 12 cm in width and 9 cm long (**Fig. 55.11**). A vertically oriented flap can range up to 12 cm in length and 8 cm in width (**Fig. 55.11**); both types of flaps include skin, subcutaneous tissue, and a 3- to 4-cm strip of anterior rectus sheath (**Fig. 55.12**). The subcutaneous tissue is incised perpendicular to the fascia. The subcutaneous tissue on the lateral aspect of the flap is dissected off of the fascia in a lateral to medial direction with care taken to preserve the attached subcutaneous tissue over the smaller strip of anterior fascia. The superior aspect of the rectus sheath and the underlying rectus muscle is incised. Next, the rectus muscle is dissected off the lateral and inferior anterior fascia, which leaves the disc of fascia under the skin island of the flap. The rectus muscle and flap are dissected away from the posterior sheath, and, in a cephalad to caudad direction, the entire muscle with its attached flap is carefully mobilized by dissecting it off of the anterior sheath and from the lateral attachments down to the level of its tendinous insertion at the pubic bone (**Fig. 55.11**). During this step, care must be taken to avoid injury to the inferior epigastric artery, which becomes identifiable below the level of the umbilicus (**Fig. 55.13**).

FIGURE 55.9 Versatility of inferior-based RAM flap. **A:** RAM sutured around a rigid stent for vaginal reconstruction. **B:** Large right-sided groin defect after irradiation and resection of bulky right-sided groin recurrence. (From Fowler JM. *Gynecol Oncol* 2009;115:158, with permission.)

The flap is then carefully mobilized into the pelvis so that there is no tension on the vascular pedicle. For a neovagina, the flap is folded into a conical shape and the edges are approximated with interrupted or running 2-0 PGA suture to maintain the shape. The neovaginal opening is sutured to the vulvar/perineal skin with 2-0 PGA suture (**Fig. 55.11**). Attention to the

P.1340

position of the flap is crucial to ensure that it has not rotated or twisted on its vascular pedicle. The donor site can usually be closed primarily by approximating the posterior sheath of the donor side to the anterior and posterior fascia on the contralateral side. If needed, this can be augmented with a biologic mesh to eliminate tension or if there is a concern for a significant abdominal wall defect.

Gracilis

The GMF is a commonly used flap for vaginal or vulvar reconstruction. It was originally described in pelvic reconstructive surgery by McCraw et al. in 1996. The gracilis muscle, which originates from the pubic symphysis and inserts on the medial tibial condyle, functions as a thigh adductor. This thin, flat muscle lies between the adductor longus and sartorius muscles anteriorly and the adductor magnus and the semimembranosus posteriorly (**Fig. 55.14**). The relationship of these muscles to the gracilis will vary along the length of the gracilis muscle. Due to the presence of the abductor longus and magnus muscles, the gracilis muscle is an expendable muscle, making it an excellent choice for reconstructive surgery. The anatomy and blood supply of this flap have been detailed by Whetzel and Lechtman. The dominant blood supply to the flap arises from the ascending

branches of the medial circumflex femoral vessels. This vascular pedicle is typically 6 cm in length and enters the muscle approximately 7 to 10 cm below the origin. Additional branches of the femoral vessels also supply the muscle and enter the distal third of the muscle belly, and the overlying skin is supplied by perforating vessels from the gracilis muscle. Thus, the flap can be 5 to 8 cm in width and up to 15 to 20 cm in length, allowing for versatility in its use. Depending on the defect size and location, flaps may be unilateral or bilateral, similarly to pudendal thigh flaps, and the flap can be oriented transversely or longitudinally.

The operation begins with the patient in the dorsal supine position. The hips are abducted 45 degrees and flexed 30°, the knees are extended, and the feet are placed in gynecologic stirrups. This extended-knee position provides maximum visualization of the gracilis muscle and the overlying cutaneous skin. The muscle is identified by drawing a line from the pubic tubercle to the medial aspect of the knee. This line will represent the anterior aspect of the flap, and then the size and shape of this flap can now be designed (**Fig. 55.15A**). The gracilis, which lies posterior to the adductor longus muscle, can be easily identified by applying traction on the tendinous insertion of the muscle. The incision is carried down to the deep fascia, and the muscle is isolated in a distal to proximal direction (**Fig. 55.15B**). The great saphenous vein is identified and should be positioned anterior to this dissection within the subcutaneous tissue. The fascia of the adductor longus is reflected and then the adductor longus, adductor brevis, and the gracilis muscle are identified, which eventually exposes the neurovascular pedicle of the gracilis muscle (**Fig. 55.15C**). The vascular pedicle, which arises approximately 7 to 10 cm below the pubic tubercle, is preserved, and the skin paddle is anchored to the muscle to prevent shearing (**Fig. 55.15D**). For gynecologic reconstruction, the distal muscle is divided and the flap can be rotated and, if applicable, brought under a skin bridge (**Fig. 55.15E**). The proximal aspect of the muscle may be left intact or divided depending on the arc of rotation that is required. Bilateral flaps are typically used for vaginal reconstruction, and the flaps are brought through the bridge with the skin surfaces facing each other. The flaps are sutured together and then secured to the vaginal opening and periosteum of the sacrum to prevent prolapse. The donor site can then be closed primarily, and closed suction drains are used at the harvest sites.

Postoperatively, flap viability should be confirmed with inspection. Patients are encouraged to ambulate after the first postoperative day, and prolonged sitting should be avoided. Soper et al., Deutinger et al., and others have reported that early complications requiring intervention may occur in up to 50% of patients, and flap loss rates may reach as high as 15%. Disadvantages of the GMF include the relatively high graft necrosis rate of 13% to 38% secondary to its tenuous blood supply and donor site complications including cosmesis, discomfort, and decreased adductor strength. Most common issues arising include skin necrosis resulting in vaginal drainage and infection resulting in skin sloughing, which may require debridement. However, longterm outcomes are significantly improved when compared to no reconstructive surgery. In 2010, Scott and his associates at the University of Washington reported a series of 27 consecutive patients managed over 17 years. Eighteen had RAM flaps for vaginal reconstruction, and 4 had gracilis flaps. Although 52% had postoperative complications, 50% reported satisfactory sexual function. In efforts to reduce the complication rates, modifications to the GMF have been described. In 1989, Soper et al. reported the use of smaller flaps for the construction of a neovagina with improved outcomes. This modification enhanced mobility of the flap and decreased the risk of wound breakdown and necrosis.

Gluteus Maximus Flap

Due to its proximity and abundance of tissue, the gluteus maximus muscle has been used for reconstruction of posterior vulvar and perineal defects, although it does have a limited arc of rotation. The tissue used for this flap is typically oriented just posterior to the defect and can provide a large amount of both muscle and adipose tissue, providing “padding” over bony promontories and obliterating dead space. The superior and inferior gluteal arteries provide the blood supply for this flap and arise from the gluteal line of the ilium and sacrum and insert on the greater tuberosity of the femur. As this muscle is critical for extension of the lower extremity and

ambulation, care to preserve of muscle function is required. Therefore, it is not considered to be an “expendable” muscle as opposed to the gracilis, tensor fasciae latae (TFL), and rectus muscles. In order to retain the muscular insertion and origin, the flap is commonly advanced in the V-Y fashion, thus releasing only the superior half of the muscle, but can also be used as a standard muscle flap.

P.1342

FIGURE 55.14 Gracilis muscle. The gracilis muscle originates at the pubic tubercle and inserts on the medial tibial conduit.

The V-Y myocutaneous advancement flaps are designed with the patient in lithotomy position. The skin island is designed by outlining the flap from the base of the vulvar defect and the apex oriented toward the inferior border of the muscle. The skin island is centered above the ischial tuberosity and the skin incision advanced through the subcutaneous tissue exposing the entire muscle. Depending on the location, either the superior or inferior half of the muscle fibers can be divided, keeping the gluteal vessels intact. The skin island is then advanced to cover the defect, and the leading edge is sutured to distal margin. The donor site is closed, creating a “Y.”

For use of a gluteal muscle flap, an incision is made over the skin of the muscle at the midgluteal region. The

superficial muscle is exposed and lateral edge identified and dissected toward the muscle insertion. The muscle is then exposed and isolated. The muscle, which is attached at its origin, is rotated to cover the defect. Postoperatively, patients should be placed on bed rest in lateral decubitus position and avoid direct compression to the donor site. Physical therapy should also be initiated. Common complications, such as erythema and wound separation, can typically be managed conservatively, and long-term outcomes of flap survival outcomes are excellent.

P.1343

FIGURE 55.15 Harvesting the GMF. **A:** A line is drawn from the pubic tubercle to the medial condyle of the knee. This line represents the anterior border of the flap. In this picture, the gracilis tendon is localized and then elevated in order to more easily identify the gracilis. **B:** The initial incision is along the anterior border of the flap. The plane between the gracilis muscle and the underlying adductors is developed. **C:** The posterior border of the flap is incised and the gracilis further mobilized from the adductor muscles. **D:** The neurovascular pedicle is identified and preserved. Note the saphenous vein within the anterior portion of remaining subcutaneous tissue. **E:** The mobilized GMF has been rotated posteriorly under the skin bridge to fill the vaginal/perineal defect.

Tensor Fasciae Latae

The TFL is suited for coverage of the groin and other anterior abdominal wall defects as fascia can be included in the TFL and the flap has a wide arc of rotation. The dominant vascular pedicle is the ascending branch of the lateral circumflex artery, which also supplies the gluteus maximus and portions of the vastus lateralis muscles (**Fig. 55.16A**). The flap is designed with the patient in the supine position, and a line is created from the insertion at the anterior superior iliac spine (ASIS) to its insertion at the lateral aspect of the knee. This muscle lies between the biceps and rectus femoris, and the skin island can have a width of up to 8 cm and length of 20 cm (**Fig. 55.16B**). Once the size is determined, an incision is made and dissection begins distally and anteriorly, separating the muscle from the surrounding structures and muscles. The vascular pedicle is identified approximately 10 cm below the ASIS, which is preserved, as dissection continues in a cephalad direction. The flap can then be rotated to cover the defect (**Fig. 55.16C**). Following the procedure, a suction drain is placed in the donor site, the incision is closed primarily, and the leg is placed in a circumferential dressing. If the site cannot be closed primarily, use of skin grafting and bolster dressings may be required.

P.1344

When possible, early ambulation is encouraged. The TFL flap is associated with an excellent blood supply and heals readily, therefore making it a safe and relatively trouble-free choice for reconstruction. The scar at the donor site may be suboptimal, particularly if a skin graft is required and primary closure cannot be achieved. Complications related to the muscle function, such as lateral knee instability, can infrequently occur, and appropriate care should be taken.

FIGURE 55.16 A: TFL anatomy. **B:** Harvesting the TFL flap. **C:** Rotation of TFL into defect.

URINARY CONDUITS

The introduction of the urinary conduit by Bricker in the 1940s represented a significant improvement for gynecologic oncology patients requiring urinary diversion to address severe disease and treatment-related sequelae, or in conjunction with a pelvic exenteration. Prior to the original “Bricker pouch” or ileal conduit, patients suffered from chronic fistulas, crude wet ostomies, and early generation stoma appliances. These patients had a poor quality of life, a high risk of sepsis, and other metabolic abnormalities. Conduits from various bowel segments have been reviewed by Hautmann. These include common choices such as the ileal or transverse colon noncontinent conduits and the ileocolonic continent conduit. Less commonly applied options are the Kock continent pouch and a recently reintroduced modification of a double-barrel wet colostomy. Orthotopic neobladder to urethra reconstruction is rarely applicable to the gynecologic oncology patient.

One ideal conduit for urine does not exist, and the choice for any given patient will be individualized, based on the age of the patient, previous treatment history, prognosis, indications for diversion, extent of the exenteration, and the need for other procedures at the time the conduit is constructed. Farnham and Cookson have discussed the multitude of short and long-term complications that are possible with any type of conduit. Metabolic abnormalities, stoma, and anastomosis problems may differ according to the bowel segment chosen. Consideration must also be given to the potential effect on the function of the gastrointestinal tract due to the loss of the bowel segments required for conduit construction, in addition to the potential metabolic consequences of absorption of urine metabolites from the conduit. Most importantly, the surgeon should have the ability to perform more than one type of conduit as the optimal choice may be dictated by unexpected findings at the time of surgery.

Traditional Noncontinent Urinary Conduits

The ileal conduit is the most commonly chosen route for urinary diversion and is the standard to which other options for urinary diversion are compared. It is considered to be the least technically demanding of the options available, especially in the patient without a history of pelvic irradiation. Advantages of this choice include the relative technical ease of loop construction, ability of the ureters to reach the loop, mobility of the loop for stoma placement, and that metabolic complications are minimized. Potential disadvantages include compromised integrity of the small-bowel anastomosis site and variable viability of the stoma. Stoma stenosis of the ileal loop, leading to difficulty in ostomy care and higher pressures within the loop, is a potential problem, and the incidence is increased in previously irradiated and/or obese patients. One may consider choosing a Turnbull loop for the stoma or using a more reliable segment of bowel for the conduit in patients at a higher risk for this problem. Other serious postoperative problems that are increased in patients with a history of pelvic irradiation are complications of the small-bowel anastomosis and the ureteroileal anastomosis. Nevertheless, the use of ileum for urinary diversion still remains an option in the patient with previous pelvic irradiation due to its ease of construction, relatively acceptable complication rate, and high rate of upper tract preservation in appropriately selected patients. The options and factors included in decision making have been well addressed by Parekh and Donat and also by Chang et al.

P.1345

Alternative segments of bowel exist for noncontinent urinary diversion. Initially, the sigmoid conduit was popular with the advantages of decreased reflux and stoma stenosis, and avoidance of a small-bowel anastomosis. Disadvantages of the sigmoid loop include decreased mobility of the mesentery for stoma placement and potential complications related to irradiation. Segreti et al. have reported excellent results with the transverse colon conduit in a series from M.D. Anderson. Most of these patients had pelvic exenteration following pelvic irradiation. The blood supply to this conduit is relatively uncompromised, and anastomosis of radiated bowel segments is avoided. The transverse colon loop is also more amenable to creating the ureterocolic anastomosis with shorter ureters. Stoma complications are less likely with colon loops compared to small bowel, and there is freedom in sighting the stoma secondary to mobility provided by the transverse colon mesentery.

Double-Barrel Wet Colostomy

The original ureterosigmoidostomy proximal to the stoma site allowed for mixing of stool and urine within the colon prior to the stoma opening plus long periods of exposure of urine to the colon mucosa. This method was associated with numerous complications such as pyelonephritis, electrolyte abnormalities, diarrhea, and secondary colon cancer. Backes et al. have described a modified double-barrel wet colostomy as an alternative in the patient who requires both urinary and fecal diversion. It has the advantage of one stoma instead of two and does not require a bowel anastomosis, and there is no intracolonic mixing of urine with stool. The double-barrel approach consists of a diverting descending colon or sigmoid loop colostomy with the distal limb limited to

10 to 15 cm in length from the stoma ([Figs. 54.13](#) and [54.14](#)). A loop colostomy is sighted at a location in the left lower quadrant, ensuring that the ureters reach the distal limb without tension. The length of the distal limb is designed so that it is no longer than necessary in order to minimize stasis and urine absorption. The ureters are implanted along the antimesenteric tenia of the distal limb giving a reservoir for free urine drainage without fecal contact within the colon.

NONCONTINENT CONDUIT TECHNIQUE

Bowel Loop Construction

There are more similarities than differences in the surgical techniques for construction of the various noncontinent urinary conduits. As in any reconstructive surgical procedure, the viability of the tissues being used and suture lines without excessive tension are of the utmost importance. The bowel segment chosen for the urinary conduit loop should appear healthy, have a reliable vascular supply, be able to reach the anticipated stoma site, and ideally be out of the previously irradiated field. The length of the segment will be approximately 10 to 20 cm based on the ability of the ureters to reach the loop and mobility of the conduit to the stoma site. The segment of bowel is harvested with the use of surgical stapling instruments, and gastrointestinal continuity is reestablished with reanastomosis. Ultimately, the staples of the efferent end will be cut away for the stoma, while the staples at the butt end of the loop should be isolated from urine by a running absorbable suture placed between the body of the conduit and the staple line. Ideally, the stoma should be constructed prior to the ureteral anastomoses in order to avoid twisting of the loop mesentery or disrupting the attached ureters. The butt of the loop should be secured to the soft tissue in the pelvis or abdomen to keep tension off of the ureteral intestinal anastomosis.

Ureteral-Bowel Anastomosis

The ureters are mobilized from their avascular attachments within the retroperitoneum while preserving the adventitial blood supply. The distal ends of severely stenotic and stiff ureters should be trimmed if feasible; however, their length should be preserved until it is clear that they will reach the conduit without tension. Care is taken to not injure or devascularize the ureter any further after it is mobilized. Atraumatic forceps and sharp scissors are used to prepare the ureter and bowel. The distal ureter is spatulated to widen the ureteral orifice. After this step, a fine absorbable suture is placed at the apex of the spatulation, and this is used (rather than forceps) to manipulate and position the ureter from this point on in order to minimize the risk of crush injury. Both running and interrupted suturing techniques with 4-0 delayed PGA suture have been described in the construction of a watertight anastomosis. Prior to completing the anastomosis, Silastic stents are placed with a self-retaining pigtail in the renal pelvis and a straight end brought out through the stoma. This may be facilitated by using a metal Yankauer sucker through the conduit stoma as described by Winter et al. ([Fig. 55.17](#)). The stents are secured within the conduit by using fine gut suture placed through the bowel loop and the stent and tied as a loose loop. The integrity of the anastomosis is then tested with a blue dye saline mixture, and any defect will need to be reinforced or reconstructed.

Ileocolonic Continent Diversion (Miami Pouch)

Some gynecologic oncologists favor the continent urinary conduit as the patient's quality of life may be improved by elimination of the urinary ostomy bag with its attendant problems of awkwardness, odor, reduced self-image, and sexuality. However, there are unique pathologic and physiologic changes in pelvic organs after irradiation for gynecologic malignancies. Perioperative irradiation doses are usually less for most urologic malignancies as compared to definitive radiation for gynecologic malignancies. Thus, pathophysiologic changes of irradiation-induced endarteritis, resulting in ischemia and later fibrosis, are not as severe in patients with urologic malignancies and are absent in other patients undergoing urinary diversions required for congenital anomalies.

On the other hand, reflux of urine and intermittent infection over a prolonged period of time can lead to deterioration of the upper renal units often associated with long-term ileal or colonic loops. Due to its low-pressure storage pouch, the continent urinary conduit may prevent contaminated urine from refluxing into the kidney, reducing the risk of chronic pyelonephritis. Options for a continent conduit include the Kock pouch (constructed entirely from small bowel) and a variety of modifications of the ileocolonic reservoir.

Technique for Ileocolic Continent Urostomy (Miami Pouch)

The ureteral-intestinal anastomosis must be as free as possible from potential stricture formation that would result in hydronephrosis and eventual upper renal unit deterioration. Techniques that require the irradiated ureter to be buried in the muscular layers of irradiated colon to achieve the nonrefluxing feature of continent urostomy may be associated with an increased risk of stenosis and secondary hydronephrosis that is higher than acceptable. The integrity of the upper renal tracts remains to be evaluated in prospective, randomized trials between the incontinent urostomies and the ileoascending colonic variety of these operations. All continent

P.1346

urostomy pouches should have similar physiologic characteristics, including a low pouch pressure of less than 40 cm H₂O pressure, even at volumes greater than 500 mL. This reduces the chance of ureteral reflux and reduces the incidence of incontinence.

FIGURE 55.17 Ureteral-bowel anastomosis. After the distal end of the intestinal segment is isolated, a metal Yankauer suction cannula with tip removed is advanced to the planned anastomotic site. A transmural incision is made over the end of the cannula with the electrosurgical instrument. The ureteral anastomosis is secured with interrupted 4-0 delayed absorbable sutures. The metal cannula helps incorporate the seromuscular and mucosal layers as the needle is placed against and run along the metal cannula from inside to outside (insert). A 7-F 70-

cm single-J stent is threaded through the cannula and passed directly into the ureteral lumen. (Reprinted from Winter WE III, Krivak TC, Maxwell GL, et al. Modified technique for urinary diversion with incontinent conduits. *Gynecol Oncol* 2002;86:352, with permission. Copyright © 2002, Elsevier.)

The surgical technique for the continent conduit described in this chapter is for the Miami pouch as reported by Penalver et al. and later Salom and the group from the University of Miami (see Steps in the Procedure box). The compliance of large bowel, especially after irradiation therapy, is less than that of small bowel. A larger segment of detubularized colon—that is, the entire ascending and proximal transverse colon (Miami pouch)—may overcome this problem and allow pressures within the pouch to remain at acceptable low levels (**Fig. 55.18**). The distal ileum is transected 10 to 15 cm proximal to the ileocecal valve. The cecum and the segment of ascending colon are mobilized up to the right colic flexure, and the transverse colon is transected just distal to the middle colic artery (**Fig. 55.19**). Continuity of the bowel is restored with an ileotransverse enterocolostomy. If an appendectomy has not been performed, it should be done during the procedure (alternatively, the appendix is used by some as the efferent limb instead of the distal ileum but not likely to be feasible in the irradiated patient). The colon is opened with cautery along the tenia and folded onto itself to create a U-shaped intestinal plate (**Fig. 55.20A**). The legs of the “U” are anastomosed in a side-to-side fashion with absorbable staples, or double row of interrupted or running absorbable 3-0 sutures, to form the posterior wall of the reservoir (**Fig. 55.20B**). This effectively “detubularizes” the segment of bowel and reduces the potential for high pressure in the colon segment.

P.1347

STEPS IN THE PROCEDURE

Miami Pouch Step-by-Step Approach

- Isolate a segment of bowel that includes the distal 12 to 15 cm of ileum and the ascending and transverse colon transected distal to the middle colonic artery.
- The colonic portion of the isolated segment is incised along the tenia and thus detubularized.
- The opened ascending and transverse portions of the colon are anastomosed in a U-shaped fashion, which creates the posterior wall of the pouch.
- The distal ileum is catheterized with a 14-F silicone rubber Foley catheter and tapered to the diameter of the catheter with a gastrointestinal stapler.
- The ileocecal valve is then reinforced with three 2-0 silk sutures placed in concentric purse strings approximately 0.5 cm apart.
- The ureters are mobilized in order to bring them to the posterior wall of the pouch without tension.
- The ureters are spatulated and anastomosed to the transverse colon portion (nonirradiated) portion of the posterior wall and then stented.
- The anterior portion of the pouch is closed creating the low-pressure reservoir.
- The pouch is anchored to the anterior abdominal wall.
- The ileal portion is brought out through the anterior abdominal wall to create the stoma.
- A pelvic drain is placed posterior to the pouch.
- The Foley is left to straight drain for 14 days and irrigated with saline every 4 hours.
- Stents are removed in 14 to 21 days and removed along with the Foley after a contrast study of the urinary reservoir and the ureters is performed to assure the absence of any urinary leakage, reflux, or upper tract obstruction.

FIGURE 55.18 The ileocolonic pouch requires a larger volume of colon. The small bowel is transected about 10 to 15 cm from the ileocecal valve. Incision is carried up the avascular plane of Treves. The transverse colon is transected to provide an equal segment of transverse colon to the right colon. Care is taken to preserve the middle colic artery.

The left ureter is passed through the sigmoid mesocolon before entering the reservoir, unless the sigmoid colon has been removed. A mucosal incision is made to create a sulcus in which the ureters will be anastomosed. The distal ends of the ureters are spatulated and, with 4-0 polyglycolic acid sutures, anastomosed to the submucosal layers of the colon. The muscular wall of the colon and the low-pressure reservoir, in effect, provide the antireflux mechanism. Extraluminally, the ureteral adventitia is fixed to the bowel serosa. The ureters are stented with 7-French single-J ureteral diversion stents that are secured distal to the ureterocolic anastomosis with absorbable

P.1348

sutures (**Fig. 55.21**). The nontunneled ureteral anastomosis has worked well for the Miami 5 group as the incidence of reflux, and obstruction has been similar to that recorded with other forms of ureteral-intestinal anastomosis.

FIGURE 55.19 Pictured is the isolated segment of colon that will be used for construction of a Miami pouch. Approximately 10 to 15 cm of distal ileum are used, as are the entire ascending and half of the transverse colon. (Reprinted from Estape R, Mendez L, Angioli R, et al. Urinary diversion in gynecologic oncology. *Surg Clin North Am* 2001;81:787, with permission. Copyright © 2001 W.B. Saunders Company. Published by Elsevier Inc. All rights reserved.)

FIGURE 55.20 A: The transverse colon is brought along the side of the right colon. Interrupted sutures are placed in the adjacent segments of colon. A cautery is used to open the antimesenteric border of the transverse and right colon to the cecum. **B:** A TA-55 Polysorb stapler loaded with 0.6-mm staples is used to close the posterior wall of the opened pouch.

Tapering the segment of distal ileum and placing purse-string sutures at the level of the ileocecal valve helps create the continence mechanism. A 14-French rubber catheter is placed into the distal ileum. The ileum, with the rubber catheter in place, is clamped using a series of three or four Babcock clamps on the mesenteric side. Allis clamps are placed on the antimesenteric border of the ileum and gently pulled to provide traction. A stapling instrument is applied to the ileum longitudinally between the Babcock and the Allis clamps to reduce the lumen diameter down to the caliber of the underlying 14-French catheter ([Fig. 55.22](#)). This tapering is done to increase the pressure within the ileal segment, which provides a greater differential in pressure between the efferent limb and the colonic reservoir. Three purse-string sutures (0.5 cm apart) of 2-0 silk or polypropylene are placed in the seromuscular layer of the ileal segment at the level of the ileocecal valve to increase the final closure pressure and achieve urinary continence ([Fig. 55.23](#)). By tapering the segment of the distal ileum and placing purse-string sutures at the ileocecal valve, the pressure of this segment of bowel exceeds the reservoir pressure at all times, thereby resulting in full continence. The tapered ileal segment is exteriorized as a stoma to the right lower quadrant of the abdomen for future self-catheterization by the patient. The anterior wall of the reservoir is then closed with absorbable staples or suture. A 3-way Foley catheter can be used in place of the 14-French catheter for postoperative pouch drainage and to facilitate mucous irrigation. The reservoir is secured to the abdominal wall peritoneum with absorbable suture, and the catheter and single-J stents are secured to the skin after stoma formation low in the right lower quadrant.

FIGURE 55.21 The opened segment of colon is brought together as a “U,” and then the posterior wall is closed first. After this step, the ureters can be brought into the pouch, secured to the mucosa, and catheterized, as seen here.

Approximately 2 weeks after surgery, a contrast study of the reservoir and an intravenous urogram are performed to evaluate for leakage, reflux, or upper tract obstruction. If the radiographs show normal findings, the ureteral stents are removed, and the patient is taught to irrigate and catheterize the pouch. Initially, the patient catheterizes the stoma every 2 to 4 hours and irrigates it four times a day. The patient may gradually decrease the frequency of catheterization and irrigation if continence and/or obstruction of the catheter by mucus are not a problem. Patients describe a feeling of fullness or slight cramping in the right lower quadrant, indicating the need to empty the reservoir. The average frequency of catheterization is five to six catheterizations in 24 hours. The time needed for emptying the reservoir is about 3½ minutes. The amount of urine for each catheterization averages 365 mL (range, 250 to 500 mL). Urodynamic evaluation of the reservoir reveals that the basal pressure fluctuates between 10 and 20 cm of water, whereas in the tapered ileum it varies between 50 and 60 cm of water.

FIGURE 55.22 The second procedure to maintain continence when constructing a Miami pouch is tapering of the distal ileum. The ileal segment is tapered over a 14-French catheter. Care must be taken to taper the antimesenteric side so as not to disrupt blood supply.

FIGURE 55.23 The continent feature of the efferent system is constructed by two separate surgical techniques. This photo illustrates two purse-string sutures placed adjacent to the ileocecal junction.

series, 68 of 90 (76%) underwent pelvic exenteration for recurrent cervical cancer, and the majority (93.5%) had been previously irradiated. The most common complications were urinary tract infection/pyelonephritis (40%), ureteral stricture/obstruction (20%), difficult catheterization (18%), and pouch leakage (14%). Although complications related to the creation of the Miami pouch are not infrequent, early detection and conservative management are now recommended to manage the majority of these patients safely. In this study, ureteral strictures (all at the ureterocolonic anastomosis) were encountered in 10 patients (13%). Conservative management includes balloon dilation, stent placement, and nephrostomy placement and was successful in 8 of 10 patients. Ureteral obstruction that was caused by stone formation was treated with lithotripsy in 1 patient; the other required surgical revision because of the dimension of the stones. Another 5 patients presented with ureteral obstruction, 4 of whom were successfully managed conservatively. The total number of patients with stones was 4 (5.2%); only 1, as previously mentioned, required surgical revision. Five patients developed a fistula with the Miami pouch; 3 of these patients were also managed conservatively. In their report, based on their 15-year experience, the Miami pouch was associated with urinary tract infection rate in 40% and ureteral stricture rate in 20%; however, the rate of urinary continence in these patients was 93%. Alago et al. and Hartenbach and colleagues have emphasized conservative management of complications whenever possible, but surgical intervention should not be delayed when indicated.

In summary, the Miami pouch continues to be an excellent choice for continent urinary reconstruction after radical resection for gynecologic cancer in the properly selected patient. Absolute contraindications include baseline impaired renal and hepatic function in addition to inability to catheterize at the appropriate intervals. Continent urinary diversions require larger segments of bowel and longer operative time; are more complex with multiple suture lines, valves, and tapered efferent limbs; and require more complicated perioperative and long-term care. While there is the potential for no or less ostomies with improved body image and quality of life, these conduits can be associated with a higher complication rate including metabolic abnormalities, malabsorption, diarrhea, and need for nonsurgical and surgical intervention to manage complications.

LOWER GASTROINTESTINAL RECONSTRUCTION AFTER EXENTERATION

In many patients with gynecologic malignancies, resection of the rectosigmoid colon may be indicated to achieve optimal cure rates. In diseases ranging from primary ovarian cancer to recurrent cervical cancer, an abdominoperineal resection may need to be performed for proper surgical management. In cases in which the anus is resected, the patient has few options except end colostomy. However, efforts have been made in patients who have rectal and anus-sparing procedures to improve the technical and functional results by reanastomosis.

The first event that truly led to technically easier anastomotic operations was the widespread use of circular stapling devices in the 1980s. At first, fears existed that these stapled anastomoses would leak more frequently than the traditional hand-sewn technique. However, studies of the double-staple line by Knight and Griffen confirmed the adequacy of the circular stapling device. The ability to resect tumors deep in the pelvis (>2 cm above the dentate line) with adequate margins (at least 2 cm) and perform a technically simple anastomosis procedure has spared many patients an undesirable end colostomy. This technique is described in [Chapter 47](#).

The straight end-to-end colorectal anastomosis is not without its critics. Functional studies have revealed poor results with defecation disorders (leakage, urgency) in as many as 30% of patients, usually related to residual rectal length. Wheeler reported on incontinence and dysfunction in gynecologic patients undergoing very low straight colorectal anastomoses, with complications occurring in at least 25% of patients. Frequency disorders associated with these low, straight colorectal anastomoses are a result of loss of rectal storage function. Many patients tend to improve over time, probably from an increased reservoir function of the remaining rectal stump; however, this adaptive period may last up to 2 years. For this reason, surgical options to improve functionality in patients undergoing rectosigmoid colon resection and anastomosis have been introduced with good result.

Though colorectal anastomoses are common in gynecologic oncology, it is important to be aware of potential complications of the procedure, especially during a pelvic exenteration in a previously irradiated patient. Major complications may occur in up to 25% of patients undergoing a colorectal anastomosis as part of a pelvic exenteration. One of the most serious risks is the occurrence of anastomotic breakdown, which occurs in a range from 7% to 20% for colorectal anastomoses following radical pelvic surgery in the radiated patient. Furthermore, Husain and the Memorial Hospital group reviewed their series of patients undergoing a low rectal anastomosis at the time of a continent urinary diversion and reported an unacceptably high rate of anastomotic leak (54%) and fistula formation (15%). Goldberg et al. reported a cancer recurrence rate of 45% in patients, which occurred at the anastomosis site, even when negative margins were obtained. These results led most gynecologic oncologists to abandon the practice of low rectal anastomosis at the time of a total pelvic exenteration.

It is controversial as to whether a protective ostomy reduces the incidence of anastomosis leak. Though data in the colorectal literature suggest that diversion may be beneficial, the experience with gynecologic malignancies is less clear. In patients undergoing a pelvic exenteration, the history of pelvic radiation is likely to be a major risk factor for fistula formation and anastomotic breakdown independent of the presence of a protective diversion. Berek, Hacker, and Lagasse reported that 35% of previously irradiated patients in the UCLA series had an anastomotic breakdown (even with a proximal diversion) versus 7.5% in those with no history of radiotherapy. In general, though the presence of a protective colostomy may not decrease the risk of breakdown, it may result in a less morbid postoperative course.

Colonic J-Pouch Reservoir for Very Low Coloproctostomy

Patients in whom a very low anterior resection of the colon was performed were frequently left with an end sigmoid colostomy and low Hartmann pouch. Historical attempts to reestablish continuity of the fecal stream in patients requiring very low anastomosis (<5 cm from anus) of the colon to the rectum at or below the level of the levator sling met with discouraging results. Tenesmus and fecal frequency are common side effects of very low end-to-end coloproctostomy after very low rectosigmoid resection. This is especially true in gynecologic

P.1351

oncology patients with irradiated rectosigmoid colons whose compliance is reduced. The creation of a rectal J-pouch reservoir as reported by Wheeless et al., even in irradiated colon and rectum, appears to restore the rectal ampulla bulb reservoir and is an effective method of substantially decreasing these troublesome symptoms.

FIGURE 55.24 Rectal J-pouch coloproctostomy. **A:** A cutaway view of the completed rectal J-pouch is shown positioned over the anus and rectal stump with the EEA stapler inserted through the anus up the rectum. The anvil of the stapler has been inserted into the pouch, and two adjacent purse-string sutures are applied and tied around the central rod. The stapler is closed and activated. **B:** Completed rectal J-pouch coloproctostomy.

As shown in [Figure 55.24A, B](#), the sigmoid colon is folded on itself with 5 to 7 cm extending into the afferent and efferent segments. A defect is opened in the bottom of the J-pouch, and the 10-cm in-line stapler with 4.8-mm staples is placed in both loops of the colon and fired. The end-to-end anastomosis (EEA) stapler is inserted through the rectum after two purse-string sutures are placed in the rectal stump and the bottom of the J-pouch. The EEA stapler is fired, and the anastomosis is completed. The integrity of the anastomosis is tested by inserting a sigmoidoscope per anus, pumping air through the sigmoidoscope into the J-pouch, and observing all stapled sutured lines for air leaks under saline placed into the pelvis.

The use of this technique in patients undergoing surgery for gynecologic malignancy, particularly those whose condition has been previously treated with total pelvic irradiation and brachytherapy, has not been extensive. Some suggestion has been made that with the J-pouch there is a better blood supply, leading to a decreased incidence of anastomosis breakdown in patients with a history of pelvic radiotherapy. The colonic J-pouch is not without complications, and the principal shortcoming is incomplete emptying. Several studies have been directed at the limb length of the J-pouch. To minimize this problem, the consensus seems to be to construct a reservoir with a limb length of 5 to 7 cm. In summary, colon J-pouches may significantly improve the quality of life for patients, especially those patients who have irradiated bowel and in whom significant portions of the small bowel have been removed. Though this technique is used less commonly today, all who perform gynecologic oncology surgery should be familiar with this technique and the indications for its use as well as the associated risks and benefits.

THE ROLE OF RECONSTRUCTION

The role of reconstruction in gynecologic oncology is most important during a pelvic exenteration. Few surgical procedures match the complex combination of individual major surgical procedures, extent of tissue resection, lengthy operative time, and risk of perioperative morbidity and mortality. However, other radical surgical procedures including radical vulvectomy and occasional radical pelvic resections for ovarian or cervical cancer and even radical resections for infection or radiation necrosis may require significant reconstruction to optimize recovery and postoperative quality of life. The gynecologic surgeon who is involved with managing these major problems should be experienced with the reconstructive procedures discussed in this chapter because the surgical resection of pelvic disease is but half of the operation; reconstruction of the pelvis to improve healing and restore anatomy and function provides the best opportunity to restore the patient to a happy and functional quality of life. Brunschweig's original description of the pelvic exenteration in 1948 was a bold surgical innovation that offered patients

P.1352

the opportunity for cure where it was otherwise not possible. Since this early report, many modifications have been incorporated into this ultraradical procedure to tailor the extent of resection, provide reconstruction, and improve resectability. More recent series published on the pelvic exenteration reveal an improved perioperative mortality rate, but this ultraradical procedure is still associated with high rates of acute and chronic morbidity.

BEST SURGICAL PRACTICES

- Patients with gynecologic cancer may suffer from significant pelvic, genitourinary, and gastrointestinal deficits related to treatment and/or disease. Incorporating a pelvic/vaginal reconstructive procedure into radical pelvic surgery may be relatively straight forward but can often be quite complex considering that reconstruction may be enmeshed within a surgical case that includes multiple major surgical procedures that make up the entirety of the case. The gynecologic oncologist is best suited to orchestrate this multifaceted surgical process, and it is extremely important that the surgeon be well versed in the reconstruction options available in order that it is optimally planned.
- Reconstructive surgical procedures are often necessary with the outcome goals that include wound healing, decrease in acute and chronic morbidity, and restoration of anatomic form and function. Reconstructive surgery is optimal when applied concurrently with the primary extirpative procedure. Many techniques are available for vulvar/vaginal reconstruction, and most often, there is not one best option for any situation requiring reconstruction. Important considerations include not only the goals at the site of reconstruction but also the patient's preoperative history and intraoperative condition, total length of the procedure, and potential donor site sequelae.
- Skin grafting is optimally utilized for large superficial vulvar defects and for vaginal reconstruction in conjunction with an omental J-flap. The recipient site should be well vascularized and clean. The FTSG undergoes minimal secondary shrinkage, while the STSG can be harvested into larger grafts if needed.
- Tissue transposition flaps are relatively easy to design and excellent options for filling large vulvar defects when primary closure is not feasible or desirable. These local flaps can be supplied by random vascularization from the underlying subcutaneous vascular network or derive their blood supply from a single-vessel or defined vascular territory. Conditions that may compromise the vascular supply such as previous irradiation and/or surgery in the area of the skin flap may also compromise graft viability. In addition to adequate blood supply, successful healing of these flaps is dependent on positioning and closure without tension.
- Incorporation of myocutaneous flaps into the reconstruction scheme of patients undergoing radical pelvic surgery has been extremely important in minimizing perioperative complications and improving functional

outcome and/or quality of life. Myocutaneous flaps are oriented on a single artery or specific region of blood supply and rotated into the recipient defect. These flaps provide an excellent bed for neovascularization, can fill a large void in a previously radiated devascularized pelvis, and used to form a neovagina and/or fill a perineal defect.

- The RAM, based on the inferior epigastric artery, is the most reliable and versatile myocutaneous flap for gynecologic oncology patients. Advantages of this flap are the reliable blood supply and skin paddles that can be designed vertically, transversely, or obliquely with a wide 360 degree arc of tension-free rotation. The flap can be used for vaginal, vulvar, and groin reconstruction. When a larger flap is needed, the oblique flap is used as it also takes advantage of the lateral abdominal wall blood supply above the umbilicus.
- Urinary conduits from various bowel segments have been described, which include common choices such as the ileal or transverse colon noncontinent conduits and the ileocolonic continent conduit. One ideal conduit for urine does not exist, and the choice for any given patient will be individualized, based on the age of the patient, previous treatment history, prognosis, indications for diversion, extent of the exenteration, and the need for other procedures at the time the conduit is constructed.
- The ileal conduit is the most commonly chosen route for urinary diversion and is the standard to which other options for urinary diversion are compared. Complications of the small-bowel anastomosis, stoma, and ureteral-intestinal anastomosis are possible, especially in the previously radiated patient. The transverse colon conduit is an option when viability of the ileal loop is a concern. The doublebarrel wet colostomy is an alternative in the patient that also requires fecal diversion and has the advantage of one stoma instead of two and does not require a bowel anastomosis, and there is no intracolonic mixing of urine with stool. The Miami pouch offers the advantage of a continence mechanism and the opportunity for improved quality of life.
- *Rectal reconstruction:* When the anus and distal rectum can be preserved, several techniques to reestablish rectal continuity exist. The use of end-to-end stapling devices has allowed much more distal reanastomoses than was possible with hand-sewn anastomoses. In some patients, the loss of rectal storage function of the healthy sigmoid colon may lead to seepage, urgency, and incontinence. A rectal J-pouch may solve this problem. In all cases of low rectal anastomosis in a previously radiated pelvis, a temporary protective colostomy should be strongly considered.
- The role of reconstruction in gynecologic oncology is most important during a pelvic exenteration. Few surgical procedures match the complex combination of individual major surgical procedures, extent of tissue resection, lengthy operative time, and risk of perioperative morbidity and mortality. Each major step in the exenteration demands that the surgeon considers factors that impact surgical options further into the case, and therefore, occurrence of poor choices, surgical misadventure, and misfortune is often magnified. While vaginal reconstruction for sexual intercourse may not be a priority for some of the patients, pelvic/vaginal reconstruction plays a major role in facilitating wound healing and minimizing significant and potentially deadly short- and long-term morbidities.

ACKNOWLEDGMENTS

We would like to acknowledge Clifford R. Wheelless Jr, MD; Manuel Penalver, MD; and Luis Mendez, MD, for their contributions to the current and prior editions of this chapter. Dr. Wheelless is a pioneer in the field of reconstructive gynecologic surgery, and Dr. Penalver was instrumental in incorporating the continent ileocolonic conduit into reconstruction after ultraradical pelvic surgery in women with gynecologic malignancies. Thank you to Jay W. Carlson, D.O. for contributing the images of the full-thickness skin graft.
