Chapter 32C

Laparoscopic Hysterectomy

Ted L. Anderson

DEFINITIONS

Colpotomy ring—A device placed into the vagina prior to total laparoscopic hysterectomy to lateralize the ureters, delineate the vaginal fornices, and aid in the colpotomy incision. It may be a hollow or solid cup, or a rotating molded form, made of plastic or metal.

Laparoscopic supracervical hysterectomy (LSH)—Hysterectomy that is performed completely by laparoscopy. The uterine corpus is amputated from the cervix at the level of the isthmus. The cervical stump will remain in situ.

Laparoscopically assisted vaginal hysterectomy (LAVH)—Variant of vaginal hysterectomy in which laparoscopy is employed for adnexectomy (if indicated) and the superior portions of the hysterectomy, but not ligation of the uterine vessels.

Morcellation—The process of dividing a large uterus into small strips or pieces in order to remove it through the vagina, through a minilaparotomy or extended umbilical incision, or using an electromechanical (power) morcellator placed through a laparoscopic incision.

Pneumoperitoneum (vaginal) occluder—A device inserted into the vagina prior to total laparoscopic hysterectomy designed to maintain the pneumoperitoneum after the colpotomy incision is made until the vaginal cuff is closed.

Total laparoscopic hysterectomy (TLH)—Total hysterectomy that is performed completely by laparoscopy with no vaginal component. The vaginal cuff is closed via the laparoscopic approach.

INTRODUCTION

Hysterectomy is the most common gynecologic procedure performed in the United States with approximately 500,000 being performed annually, although the numbers seem to be trending downward slightly for the past few years. The vast majority of benign hysterectomies (over 65%) are still performed through a laparotomy incision despite the urging of professional societies like the American College (Congress) of Obstetricians and Gynecologists (ACOG) and the American Association of Gynecologic Laparoscopists (AAGL) to employ minimally invasive approaches to hysterectomy, including vaginal and laparoscopic techniques. Laparoscopic hysterectomy was first described by Harry Reich in 1989 and has slowly gained popularity from less than 0.5% of hysterectomies in 1990 to a current rate of approximately 15%. Failure of laparoscopic hysterectomy to ascend to the primary approach for hysterectomy may be due, in part, to the technical challenges associated with the large uterus or concomitant intra-abdominal pathology. Additionally, the yielding of advanced surgical training time in residencies to other necessary components of the general obstetrics and gynecology curriculum (e.g., high-risk pregnancies and primary care) creates what Reich has called “a formidable obstacle to promotion of this technique.” Indeed, most gynecologic surgeons who gain proficiency in laparoscopic hysterectomy have done so, and will likely continue to do so, during fellowship programs or other postresidency training.

P.736

The term laparoscopic hysterectomy includes a family of procedures that vary in degree to which the procedure is performed laparoscopically. This ranges from simple treatment of endometriosis or adhesiolysis and division of ovarian vasculature to completion of the entire procedure laparoscopically, including cuff closure. In 2000, the AAGL published a detailed classification system for total ([Table 32C.1](#)) and supracervical ([Table 32C.2](#)) laparoscopic

hysterectomy in order to standardize terminology and reporting of outcomes. In this chapter, the techniques of total laparoscopic hysterectomy (TLH) and laparoscopic supracervical hysterectomy (LSH) are addressed. A logical and systematic surgical approach is described, based on “honoring the anatomy” and highlighting similarities to comparable steps of the abdominal hysterectomy approach, further supporting the mantra that laparoscopy is an access, not a procedure. Laparoscopically assisted vaginal hysterectomy (LAVH) is not described here, as it is basically a variant of vaginal hysterectomy that employs the laparoscopic approach simply to mobilize adnexal structures and treat relevant abdominal pathology such as adhesions. Nor is robotic-assisted laparoscopic hysterectomy discussed. Robotic technology applied to laparoscopic surgery has stimulated the adoption of TLH by many gynecologists previously hesitant to perform that procedure. By adding three-dimensional vision and instruments with articulating tips, clearer identification of tissue planes and easier laparoscopic suturing are facilitated. However, robotic-assisted laparoscopy is neither a technique nor an access, but rather a tool for performing laparoscopic hysterectomy.

TABLE 32C.1 The American Association of Gynecologic Laparoscopists Classification System for Laparoscopic Hysterectomy

TYPE	DESCRIPTION
0	Laparoscopic preparation for vaginal hysterectomy, including diagnostic only, treatment of intraperitoneal disease, and/or adhesiolysis
I	Laparoscopic occlusion and division of ovarian pedicle, unilateral or bilateral, and dissection up to but not including the uterine artery
II	Type I + occlusion and division of the uterine artery, unilateral or bilateral
III	Type II + dissection of a portion but not all of the cardinal-uterosacral ligament complex, unilateral or bilateral
IV	Type III + complete transection of the cardinal-uterosacral ligament complex, unilateral or bilateral, with or without entry into the vagina

Types I through IV are further divided into subgroups (A) dissection or division of pedicles or vessels as described; (B) dissection of bladder including anterior colpotomy; (C) posterior colpotomy; and (D) both anterior dissection and posterior colpotomy. Type IV also includes subgroup (C) with anterior dissection and colpotomy, posterior colpotomy, amputation of the uterus from the vagina, and laparoscopic-directed extirpation of the uterus (total laparoscopic hysterectomy). Adapted from Olive DL, Parker WH, Cooper JM, et al. The AAG classification system for laparoscopic hysterectomy. *J Am Assoc Gynecol Laparosc* 2000;7:9-15, with permission. Copyright © 2000, Elsevier.

TABLE 32C.2 The American Association of Gynecologic Laparoscopists Classification System for Laparoscopic Supracervical Hysterectomy

TYPE	DESCRIPTION
LSH I	Laparoscopic occlusion and division of ovarian pedicle, unilateral or bilateral; occlusion and

division of the superior branches of the uterine vessels above the level of the internal os; with or without dissection but not occlusion of the main uterine artery, unilateral or bilateral

LSH II	Type LSH I + occlusion but not division of the main uterine artery, unilateral or bilateral
LSH III	Type LSH II + division of the main uterine artery, unilateral or bilateral

Types LSH I through LSH III are further divided into subgroups, based on treatment of the cervical stump, including (A) without excision or ablation of the cervical canal; (B) with ablation of the cervical canal; and (C) with excision of the cervical canal. Adapted from Olive DL, Parker WH, Cooper JM, et al. The AAG classification system for laparoscopic hysterectomy. *J Am Assoc Gynecol Laparosc* 2000;7:9-15, with permission. Historical Perspective

Laparoscopy was incorporated into gynecologic practice in the 1950s by Raoul Palmer in France, followed by Kurt Semm in Germany. After gaining popularity in Europe, it was spread to the United States by Melvin Cohen in the 1960s. Although there was increased utilization over the ensuing decades, early descriptions of laparoscopic appendectomy, ovarian cystectomy, and treatment of ectopic pregnancy were often refused publication in American journals as they were considered “unethical” surgical adventures. It was not until the development of microchip video cameras enabled projection of images onto television monitors in the mid-1980s, ushering in the so-called era of videolaparoscopy, that the techniques of laparoscopy became more integrated into gynecologic surgery.

Harry Reich and John DeCaprio published their landmark description of the first TLH in 1989. They used bipolar current to coagulate blood vessels, monopolar current to amputate the uterus from the vagina, and running Vicryl to close the vaginal cuff after delivering the specimen through the vagina. Viewing it as a substitute for abdominal hysterectomy and not for vaginal hysterectomy, they noted that this approach “may avoid the increased morbidity associated with abdominal surgery while retaining the surgical advantages of the abdominal approach, that is, thorough visualization and easy access to the vascular pedicles.” Shortly thereafter, Kurt Semm described the classic intrafascial supracervical hysterectomy (CISH) procedure that involved coring out the endocervical canal including the squamocolumnar junction. About this same time, Thomas Lyons described a technique for LSH that was more similar to its laparotomy counterpart. This, in part, stimulated a renewed interest in supracervical hysterectomy. Although LSH was touted initially as preserving pelvic support and improving posthysterectomy sexual satisfaction, subsequent studies have shown no difference in either sexual function or pelvic support between supracervical and total hysterectomy. However, the technique of LSH did gain increased popularity among many

P.737

gynecologic surgeons as it was easier and quicker to perform, was associated with less blood loss, allowed the surgeon to stay farther away from the ureter while securing vascular pedicles, decreased infectious complications by avoiding vaginal entry, and did not require suturing the vaginal cuff.

Today's high definition and even 3D video cameras, advanced electrosurgical instruments with interactive generators, innovative devices for safe colpotomy while protecting the ureters, and enabling tools for laparoscopic suturing should continue to enhance the acceptance of laparoscopic hysterectomy as part of our surgical armamentarium.

Advantages and Disadvantages of Laparoscopic Hysterectomy

The decision for appropriateness of hysterectomy as a therapeutic intervention is the same regardless of the approach being considered, although the access for hysterectomy is generally a function of patient pathology and surgeon skill and preference. A 2006 Cochrane database systematic review including over 3,600 patients in 27

randomized studies pointed to significant advantages of laparoscopic hysterectomy (LH) over abdominal hysterectomy (AH), including less blood loss, fewer wound infections or fevers, smaller incisions with less pain, shorter hospital stay, and speedier recovery. However, LH was associated with longer operating time and greater likelihood of urinary tract injuries. The eVALuate trial is one of the largest randomized trials comparing different approaches to hysterectomy. Conclusions pointed to LH as being associated with less pain, quicker recovery, and better quality of life compared with AH but as taking longer to perform. The report also concluded that total vaginal hysterectomy (TVH) was the preferred approach, when possible, as it offered similar benefits as LH with less cost and shorter operating times.

While TVH may be the preferred hysterectomy route for a variety of reasons, there are definitely patients in whom this approach is less than ideal. Specifically, a laparoscopic approach may be favored in patients who are morbidly obese, who have a constricted pelvic anatomy, who have no uterine descensus, or who have known or suspected concomitant pelvic disease (e.g., adhesions, endometriosis, etc). Indeed, there are few contraindications to laparoscopic hysterectomy, and most are relative contraindications related to the patient's comorbidities, including deficiencies in main physiologic functions and elevated body mass index. These would include the following:

- Medical conditions that would limit pneumoperitoneum, adequate ventilation, or Trendelenburg positioning (e.g., morbid obesity, increased intracranial pressure, ventriculoperitoneal shunt, portal or pulmonary hypertension, hemorrhagic shock)
- Severe abdominal or pelvic adhesive disease or other conditions that preclude safe entry or adequate operating space (e.g., advanced pregnancy, bulky uterine or fibroid size that precludes access to uterine vessels)
- Malignancy or other tumors in which a large specimen needs to be removed intact (e.g., ovarian cancer, dermoid, leiomyoma with necrotic degeneration or other findings suspicious for leiomyosarcoma)

On the other hand, there are recognizable challenges to performing laparoscopic hysterectomy, including the following:

- Reduced range of motion through laparoscopic ports and with conventional (straight) laparoscopic instruments resulting in reduced dexterity
- Reduced field of view in which only the tissues actively being manipulated are generally seen by the surgeon
- Reduced depth perception in converting a 3D surgical field to a 2D video image
- Reduced haptics and difficulty in assessing degree of force needed or being applied to tissues
- Reduced intuitive movements due to the fulcrum effect in which the tool tips move in the opposite direction as the surgeon's hands

In all cases, a decision regarding route of hysterectomies is largely dependent on the surgeon's capabilities. Insufficient knowledge, skill, and experience of the surgeon remain the most common reasons for assigning or converting any hysterectomy to the abdominal route.

Supracervical Versus Total Hysterectomy

Supracervical hysterectomy was first performed by Wilhelm Alexander Freund in 1878 and remained the leading technique of hysterectomy for over 80 years. At that time, there was a recognized association between cervicectomy and complications such as peritonitis, fistula, hemorrhage, ureteral injury, cystotomy, and enterotomy. In fact, the mortality rate associated with total hysterectomy through the 1930s was up to 50% higher compared with the supracervical approach. By the late 1940s, supracervical hysterectomy was largely abandoned in favor of total hysterectomy. This trend reflected the considerable refinement of surgical instruments and techniques, introduction of safer and more effective antibiotics, progression of blood banking technology with transfusions becoming more routine, and subsequent occurrence of cervical cancer in almost 2% of patients following supracervical hysterectomy.

In the early 1990s, after descriptions of successful laparoscopic techniques for supracervical hysterectomy by Kurt

Semm and Thomas Lyons, there was a resurgence of interest in supracervical hysterectomy. Some have suggested this was driven equally by surgeon interest in a laparoscopic hysterectomy that was easier, quicker, and safer to perform than TLH as well as industry supply of instruments and devices to facilitate advanced laparoscopic procedures and tissue extraction. Conventional wisdom would assume that preservation of the cervix during LSH reduces the potential for intraoperative injury to the ureter, bladder, and rectum that would more likely occur during the transection of the cardinal ligament complex required to isolate and remove the cervix. Furthermore, hemorrhage most often occurs below the level of the uterine isthmus. Despite a plethora of studies comparing laparoscopic, vaginal, and abdominal approaches to hysterectomy, comparatively, few studies have focused on the role of the cervix. A meta-analysis of 47 studies published in 2006 reported the rate of urinary tract injury in all gynecologic surgery to be approximately 0.33%. In this report, the incidence in TLH was noted to be approximately 1.3% but fell to under 0.1% with LSH. More recent studies have demonstrated that, when performing concomitant laparoscopic sacrocolpopexy, LSH has been shown to offer an almost fivefold decrease in mesh erosion compared with TVH. Accordingly, there is objective evidence that leaving the cervix does indeed offer protection from complications in selected patients.

Another driver of LSH has been patient perception that pelvic support and sexual satisfaction would be preserved or enhanced over TLH. However, a systematic review of randomized trials comparing LSH with TLH documented no differences in rates of incontinence, prolapse, dyspareunia, sexual satisfaction, transfusion rate, recovery times, and readmission rates. Interestingly,

P.738

a 2-year prospective study demonstrated significant overall improvement in sexual functioning, including increased libido, coital activity, and orgasm with decreased dyspareunia after TLH. Although several other studies have suggested increased orgasmic frequency after LSH, subsequent studies have failed to confirm these findings. Nonetheless, perception is a powerful motivating force. Many women contemplating elective hysterectomy consider preservation of the cervix a pivotal factor in the decision whether to undergo this procedure.

During the past decade, many gynecologists have reassessed the value of supracervical hysterectomy. The rationale for routine cervicectomy to prevent cervical cancer has been largely eliminated by the effectiveness of present-day cytologic and molecular screening for cervical disease, the natural history of human papillomavirus (HPV) infections in immunocompetent patients, and changes in treatment algorithms for preinvasive disease. Further, development of cervical dysplasia is rare in appropriately selected low-risk patients, and there is no evidence that supracervical hysterectomy increases the risk of cervical cancer. The incidence of cancer of the cervical stump appears to be equal to that of an intact uterus, as is the prognosis.

Finally, removal of the uterine corpus alone is often adequate treatment for women suffering from abnormal uterine bleeding or benign uterine fibroids. Nonetheless, many surgeons remain reluctant to offer this approach to women requiring hysterectomy for benign disease, citing the risk for persistent pain and cyclic vaginal bleeding necessitating subsequent trachelectomy. The incidence of persistent cyclic bleeding or spotting remains low (between 2% and 12%) and may be associated more with younger patients and those having preexisting endometriosis. In fact, some have considered the presence of extensive endometriosis to be a relative contraindication as these women may have persistence of dyspareunia if the cervix is retained.

The only absolute contraindication to supracervical hysterectomy is the presence of a malignant or premalignant condition of the uterine corpus or cervix. Supracervical hysterectomy is indicated for select patients who choose this procedure after appropriate counseling, and occasionally in surgical emergencies. Supracervical hysterectomy should not be performed simply because of the surgeon's lack of comfort with removing the cervix. Instead, assistance from more skilled surgeons should be sought.

PREPARING FOR HYSTERECTOMY

Preoperative Preparation

Prior to any elective surgical intervention, patients should be optimized with respect to comorbidities such as diabetes, hypertension, pulmonary compromise, and underlying disease processes that may affect performance of the procedure and postoperative healing; this is no different with laparoscopic hysterectomy. Special attention should be made to coordinate care with the anesthesia team in light of physiologic stresses that abdominal insufflation and prolonged Trendelenburg positioning can have on critical cardiopulmonary physiology, including peak inspiratory pressures and cardiac preload. Few objective criteria guide this assessment; it is the product of the surgeon's experience in consultation with the anesthesiologist.

In consideration of the Surgical Care Improvement Project (SCIP) protocol of the Joint Commission, plans for prophylactic antibiotics and deep vein thrombosis prophylaxis should be addressed, the latter of which may extend into the postoperative interval. Although there is no compelling objective evidence that a cathartic bowel preparation is indicated for benign gynecologic surgery, many surgeons find that decompression of the bowel through clear liquid diet or a mild laxative on the day prior to surgery is beneficial in keeping the bowel out of the surgical field.

Any discussion of patient preparation would be incomplete without mentioning the importance of informed consent. Notably, this is a process of patient counseling that is usually documented by a consent form. The process of informed consent should include a discussion of those risks that will be incurred by the patient related to any surgical procedure in general (e.g., complications of anesthesia, infection, bleeding, pain, scarring), related to the specific surgical procedure being performed (e.g., damage to the bowel, bladder, or ureters), and related to the instrumentation that will be used (e.g., thermal injury from electrosurgical devices or intraperitoneal dissemination of benign or previously undetected malignant tissue from the use of a morcellator). Further, the downstream consequences of those risks should be discussed (e.g., possible need for transfusion in cases of excessive blood loss or need for additional surgical procedures to address a ureteral injury). Finally, the potential need for conversion to a laparotomy should always be a part of the consent process for any laparoscopic procedure. In summary, the informed consent process is an educational process that should inform the patient, in terms she can understand, of all the relevant information a reasonable patient would want to know in order to make decisions related to the planned procedure.

Positioning and Port Placement

There are no specific variants from the basic principles of patient positioning for laparoscopic surgery that must be adapted for laparoscopic hysterectomy. However, a few key elements merit special attention. First, the patient should be situated sufficiently far down on the table. I find this critical concept to be underestimated often, only to encounter challenges with maneuvering the uterus when the table interferes with range of motion of the uterine manipulator after the procedure is well underway. One useful trick that can help address this is to rock the patient's hips forward to reduce lordosis, which can stabilize the patient's pelvis. Secondly, it is imperative that arm and leg position and padding relieve pressure points that could lead to nerve injury. A draw sheet placed across the operating table wrapped under well-padded arms and tucked back under the patient's back can provide excellent arm stability, maintain good function of iv's and blood pressure cuff, and allow for maximum mobility of the surgeon throughout the procedure. Third, extra measures should be taken to prevent patients from sliding cranially on the operating table with steep Trendelenburg positioning. A gel or egg crate foam pad, or a surgical beanbag, can stabilize even larger patients. Although shoulder braces are discouraged due to the increased potential for brachial plexus injury, placing them laterally over the acromioclavicular joint rather than medially on the shoulder may minimize that risk. Finally, prior to the surgical scrub, the patient should be placed in maximum Trendelenburg position to confirm adequate positioning and stability prior to starting the surgical procedure (tilt test).

Objective guidelines for optimal laparoscopic port placement are limited; the decision is usually influenced more by habit than logic. Importantly, although a surgeon may be comfortable with a particular port distribution, there needs to be flexibility in number and location of ports to accommodate procedure, pathology, and preference. Adding 1 to 2 more strategically positioned ports does not contribute significant morbidity, but may dramatically improve the ergonomics of the procedure while reducing surgical time.

The camera port is typically placed through the umbilicus in uncomplicated patients with a smaller uterus. This can be placed using a traditional closed technique before or after abdominal insufflation, with or without an optical trocar to visualize passing through abdominal wall layers. Alternatively, an open (Hasson) technique or a left upper quadrant (Palmer point) entry might be chosen. While these alternative modes of initial entry are often recommended in patients with prior surgery where periumbilical adhesions are suspected, there is no evidence that any specific entry technique always prevents injury to underlying viscera. However, the Hasson method has been associated with decreased incidence of vascular injury. A 1999 study of 814 patients undergoing left upper quadrant entry for laparoscopy described the incidence of infraumbilical adhesions depending on prior surgical history, including no prior incision (0.68%), prior laparoscopic procedure (1.6%), prior Pfannenstiel incision (19.8%), and prior vertical midline incision (51.7%). They also described the rates of “severe adhesions with potential risk for bowel injury” during trocar insertion in these same four groups as 0.42%, 0.80%, 6.87%, and 31.46%, respectively. However, they did not report the incidence of upper abdominal adhesions, nor did they include patients with prior splenectomy or bariatric surgery in whom the incidence of left upper quadrants adhesions may be increased. There is strong evidence to support using the surgeon's most common initial entry method regardless of the underlying pathology.

All subsequent accessory ports should be placed under laparoscopic guidance. Typical port placement is illustrated in [Figure 32C.1](#). It is usually helpful for at least one port to be a 10-to 12-mm size (often the midline port) to facilitate use of a 10-mm laparoscope, passing suture, introducing adhesion barriers, or passing specimen bags for tissue removal as needed. In most cases, all other ports can be 5 mm to minimize postoperative pain and reduce the chance of trocar site hernia. With a small uterus less than 10 weeks in size, a three-port technique is often adequate with umbilical placement of a camera port and a primary accessory port in the left and right lower abdominal quadrant. If the uterus is slightly larger, up to about 14 weeks in size, umbilical placement of a port for the camera still usually permits adequate visualization. However, additional (secondary) accessory ports placed higher and slightly more medial than the lower (primary) accessory ports may aid significantly with uterine manipulation and access to intended operative sites ([Fig. 32C.1A](#)). In addition to using 10-mm angled telescopes, using a 5-mm straight, angled, or flexible telescope through well-positioned accessory ports at different times during the procedure can be very useful for optimal visualization of the operative field. The primary lower lateral ports should be positioned to provide a good angle for access to ipsilateral pelvic structures and to provide retraction for access to the contralateral pelvic structures. Caution should be taken not to place these ports too low on the abdominal wall close to the pelvic bones. Such a choice of port placement, which is often driven by concern for cosmesis rather than functionality, usually results in an insufficient angle to access to the ipsilateral deep pelvic structures and increases the chance of injury to the ilioinguinal, iliohypogastric, and superficial circumflex vessels. A point at least 2-cm cephalad to the anterior superior iliac spine and at least 2 cm lateral to the rectus sheath is generally a safe starting point for placement choice. Secondary accessory ports become more important contributors to the surgical procedure as uterine size increases. When used, they should be placed cephalad and medial enough to assist with both ipsilateral and contralateral surgical maneuvers and/or retraction and to provide adequate triangulation for suturing. With a larger uterus approximating 20 weeks' size or more, port placement, including the midline camera port, will typically need to be displaced more cephalad but not necessarily more lateral as illustrated in [Figure 32C.1B](#).

FIGURE 32C.1 Trocar placement. With a uterus less than 14 weeks' size, umbilical placement of a port for the camera usually permits adequate visualization (**A**). Positions of the primary lower lateral ports and secondary accessory ports (when needed) should be chosen to optimize access for surgical maneuvers, retraction, and triangulation for suturing. With a larger uterus approximating 20 weeks' size or more, port placement typically needs to be displaced superiorly but not necessarily laterally (**B**).

Uterine Manipulation

Selection of the ideal device for uterine manipulation depends on the nature of the hysterectomy being performed (LSH or TLH), the uterine size, and occasionally the patient size. The larger the uterus, the less effective any uterine manipulator will be in true manipulation of the uterine corpus and greater reliance will be placed on instruments placed through primary and especially secondary accessory ports. For LSH, delineation of the vaginal fornices and maintaining pneumoperitoneum after a colpotomy

P.740

incision are not primary concerns; a Hulka tenaculum or Valchev manipulator is usually adequate. However, both of these features are critical in performing TLH, where the colpotomy ring lateralizes and protects the ureters and identifies the vaginal fornices as a guide for colpotomy. A pneumo-occluder, which may be incorporated into the design of the manipulator or may be added as a separate component, maintains the pneumoperitoneum after colpotomy and amputation of the specimen from the vagina until the cuff is closed. Choice of manipulator can contribute significantly to ease of operation and shorten operating time. A wide variety of choices are available; some commonly used manipulators are depicted in [Figure 32C.2](#). Although selection of specific combinations of devices may vary with surgeon preference and experience, choosing the appropriate straight or curved manipulator and the right size and shape colpotomy ring for manipulation of the cervix and fornix when securing the blood supply and amputating the uterus from the vagina is critical to success and safety. It has been my experience that the combination of ZUMI manipulator with a Koh colpotomy ring and a balloon pneumo-occluder ([Fig. 32C.2A](#)) works well in most situations. However, when operating on patients with a greater body mass index, or with a very large uterus, I find the more rigid Advincula Arch (RUMI) manipulator with a molded colpotomy ring and occluder unit ([Fig. 32C.2B](#)) to be more useful to achieve necessary uterine elevation and manipulation.

OPERATIVE TECHNIQUE

It is often useful to think of TLH as having five components: (1) separation of the adnexal structures from the uterine corpus for subsequent preservation or removal; (2) dissecting, occluding, and dividing the blood supply prior to extirpation of the uterine corpus; (3) transection of the cardinal ligament complex with colpotomy and amputation of the cervix from the vaginal apex; (4) removing the specimen; and (5) closing the vaginal cuff. For LSH, the first two components are essentially identical. However, step 3 involves amputation of the uterine corpus from the cervix above the cardinal ligament, step 4 incorporates fewer options, and step 5 is not needed. In the case of TLH for a

very large fibroid uterus, or in the case of significantly distorted anatomy, I frequently find it quite helpful to perform an LSH first (in the absence of endometrial neoplasm) and then address the colpotomy and cervical amputation with the uterine corpus out of the operative field. All of the steps of TLH mimic or correlate with a comparable step in abdominal hysterectomy. There are some options for modification owing to the increased magnification and proximity of visual field to the surgical target appreciated with laparoscopy.

FIGURE 32C.2 Uterine manipulator examples. **A:** ZUMI curved uterine manipulator (*top*) with different sizes of Koh colpotomy rings and RUMI straight uterine manipulator (*bottom*) with attachable uterine probe. **B:** Advincula arch uterine manipulator with KohEfficient colpotomy ring including attached pneumo-occluder. **C:** ColpoProbe. All available from CooperSurgical (Trumbull, CT).

The Adnexa

Regardless of whether the ultimate goal is to remove or preserve the adnexal structures, I uniformly find it expedient to begin the laparoscopic hysterectomy by separating ovaries and fallopian tubes from the uterine fundus. This serves two distinct purposes. First, and most obvious, the adnexa are not dangling from the corpus for the remainder of the procedure potentially obscuring visual and operative access while securing the uterine vessels, amputating the uterine corpus (LSH), or performing a colpotomy (TLH). Second, and less appreciated, any subsequent procedure involving the adnexa can be deferred until the uterus can first be removed from the operative field. This provides unencumbered views of, and access to, the pelvic sidewall from both ipsilateral and contralateral approaches, thus facilitating even the most challenging of adnexal procedures involving distorted anatomy, adhesions, or endometriosis.

As with abdominal hysterectomy, separation of the adnexa can be accomplished by coagulating and dividing the round ligament first, dissecting the retroperitoneal space beneath the broad ligament to identify and isolate the ureter, then sealing and dividing the proximal fallopian tube and utero-ovarian ligament. It is important to recognize that, with laparoscopic approach, the ureter can usually be identified through the intact peritoneum crossing the pelvic brim at the bifurcation of the external and internal iliac vessels and coursing across the pelvic sidewall inferior to the infundibulopelvic ligament but superior to the uterosacral ligament ([Fig. 32C.3](#)). If this is the case, a retroperitoneal dissection at this point in the procedure does not add any benefit to the laparoscopic hysterectomy and might even result in unnecessary bleeding. Accordingly, while keeping the location of the ureter in view, the proximal fallopian tube and the utero-ovarian ligament can be coagulated and transected, preferably from the contralateral approach ([Fig. 32C.4A](#)). Tissue transection is continued parallel to the round ligament until the adnexa are completely isolated from the uterine corpus ([Fig. 32C.4B](#)).

Next, the round ligament is coagulated and transected, thus entering the broad ligament for subsequent dissection of

the uterine vessels. If the uterus is small enough, or if secondary accessory ports have been placed high enough, the round ligament should be grasped from the contralateral side to retract the uterus medially and stabilize the round ligament. Coagulation of the round ligament to open the leaves of the broad ligament and enter the retroperitoneal space, and subsequent dissection within the broad ligament, can then be accomplished from an ipsilateral approach (**Fig. 32C.4C**). Conversely, in cases where the uterus is larger, distorted by fibroids, or otherwise conformed in a manner where retraction using instruments through the contralateral ports is suboptimal, then “retraction” can be attained by pushing the uterus medially using an instrument through one ipsilateral port and coagulating, cutting, and dissecting through the other ipsilateral port, as illustrated in **Figure 32C.4D**. Note that the blades of the grasper are opened to add stability to the “retraction,” which can be aided by using existing features of the uterus (in this case a fibroid). Although it cannot be fully appreciated in this image, the “retracting” instrument has been placed through the left primary (lower) accessory port for optimal manipulation of the uterus both cephalad and medial. Then the instrument used for manipulation, coagulation, and cutting has been placed through left secondary (upper) accessory port in order to achieve the best angle for dissection of the broad ligament toward the uterine isthmus.

FIGURE 32C.3 Identification of the ureter. The ureter can usually be identified crossing the pelvic brim and coursing across the pelvic sidewall inferior to the infundibulopelvic ligament and superior to the uterosacral ligament. Understanding and identifying this anatomic relationship can prevent the need for retroperitoneal dissection for ureter identification prior to adnexectomy.

FIGURE 32C.4 Isolate adnexal structures. The proximal fallopian tube (A) and utero-ovarian ligament (B) are usually best transected from the contralateral approach. The round ligament is best transected from the ipsilateral approach (C). Retraction for transection of the round ligament and subsequent dissection of the broad ligament space can be accomplished from either a contralateral approach (C) or an ipsilateral approach (D), depending on the size of the uterus and port placement.

P.742

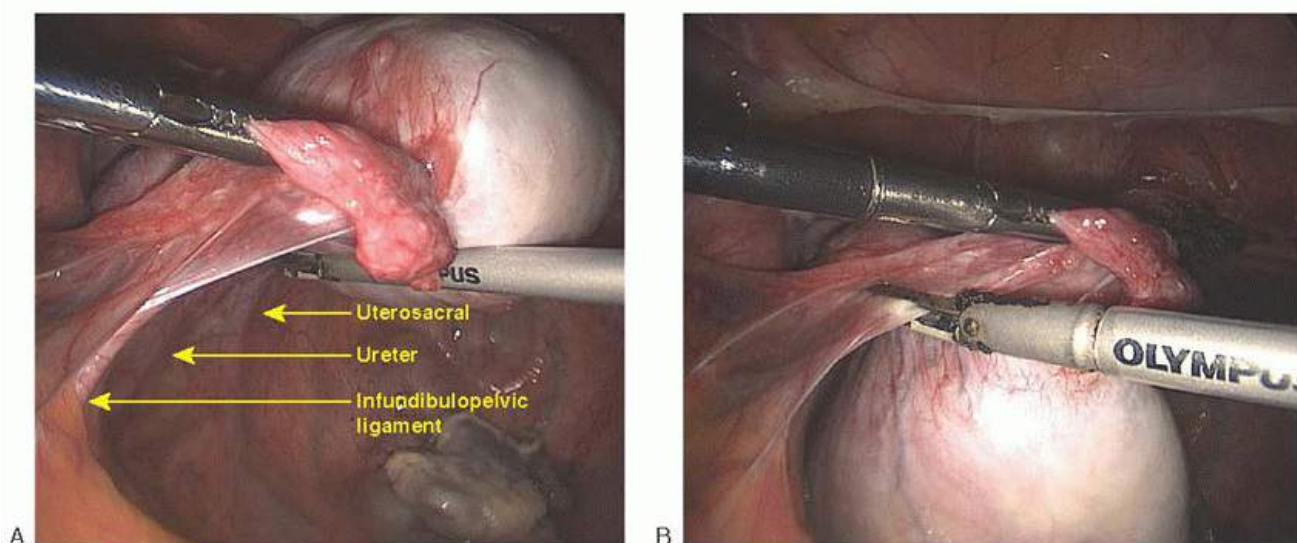

FIGURE 32C.5 Salpingo-oophorectomy. After removal of the uterine corpus, there is unobstructed access to the adnexal structures. The infundibulopelvic ligament is easily distinguished from the ureter (A) for safe coagulation and transection (B).

In cases of distorted anatomy, the more traditional approach of entering the retroperitoneal space through the round ligament, identifying the ureter, and dissecting its course toward the uterine artery prior to isolating the adnexal structures is often preferred.

If the ultimate goal is ovarian preservation, then adnexa can be ignored at this point. Alternatively, when the intent is to remove the fallopian tubes and/or ovaries, to treat ovarian pathology (e.g., remove a dermoid cyst or endometrioma), and/or to address pelvic sidewall issues (e.g., adhesions or endometriosis), this action can usually be deferred until after the uterine corpus is out of the way. At that time, the mesosalpinx or the infundibulopelvic ligament can be isolated, coagulated, and transected. Ergonomically, it is preferable to retract the adnexal structures medially from the ipsilateral side while securing and transecting the pedicles from the contralateral side ([Fig. 32C.5](#)). This approach permits an application of your energy source that is perpendicular to the pedicle, which maximizes efficient performance of the instrument and minimizes collateral thermal tissue damage.

FIGURE 32C.6 Creation of bladder flap and amputation of the uterus. The anterior and posterior leaves of the broad ligament are separated to create a bladder flap (**A**), which allows the surgeon to expose and skeletonize the ascending uterine vessels (**B**).

The Uterine Corpus and Cervix

Once the round ligament has been transected and the leaves of the broad ligament have been separated, dissection can continue to the level of the uterine vessels at the junction of the lower uterine segment with the cervix. Subsequently, a bladder flap can be created ([Fig. 32C.6A](#)) and the uterine vessels skeletonized ([Fig. 32C.6B](#)). These steps are identical to their abdominal hysterectomy counterparts and require minimal application of energy. In fact, cold sharp dissection (or only very brief pulses of bipolar current to maintain hemostasis of superficial peritoneal vessels) is preferred during this step until the anatomic limits of the bladder are defined.

P.743

When skeletonizing, coagulating, and transecting the uterine vessels, retraction of the uterus from the contralateral side is preferred as this allows the more efficient use of two operative instruments by the surgeon. However, in situations where contralateral retraction is not possible, the ipsilateral retraction technique described above can be employed. Either way, care should be taken not to twist the uterus, which can cause distortion of the anatomy and disorientation of the surgeon. It is still possible to accomplish these maneuvers effectively even if only one operative instrument can be employed. Most advanced electrosurgical instruments used in laparoscopic procedures today are designed to permit tissue dissection, sealing, and transection. A skilled experienced surgeon can use a single instrument to develop the bladder flap and skeletonize, coagulate, and transect the uterine vessels. Understanding the specific properties of your electrosurgical instrument of choice is critical.

LAPAROSCOPIC SUPRACERVICAL HYSTERECTOMY

When performing LSH, the ascending branches of the uterine vessels should be coagulated and transected at the junction of the lower uterine segment with the cervix ([Fig. 32C.7A](#)). This is also the level at which the uterus is amputated from the cervical stump. This is perhaps the most critical step in performing LSH. The optimal level of vessel transection and fundal amputation can be identified in most uteri where the curvature of the fundus “flattens out” into the cervix. This is the isthmus. You should be certain that you have coagulated the uterine vessels just inferior (toward the cervix) to where you plan to amputate the fundus. Additionally, if you continue to coagulate the uterine vessels in an ascending manner up the lateral edge of the uterus, this will not only decrease back bleeding from the uterus, but it will also accentuate the angle of the junction between the uterine fundus and cervix as a guide for amputation plane.

It has been my experience that many surgeons attempt to amputate the uterine fundus too low on the cervix. Whether it is related to difficulty in ascertaining the optimal plane for amputation, or whether it stems from a belief that excising more cervix will decrease the likelihood of subsequent cyclic bleeding, this seems to be especially characteristic of surgeons that are learning and perfecting the technique of LSH. The incidence of post-LSH cyclic bleeding does not appear to be related to length of cervix left. However, what definitely will happen if the surgeon is too aggressive in estimating the amount of tissue to amputate is that increased bleeding will be encountered associated with the rich plexus of vascular supply to the cervix and upper vagina, necessitating further efforts to achieve hemostasis. If electrosurgical energy application is employed to this end, there is an increased risk of thermal injury to the ureter or compromise of the vascular supply to the remaining cervical stump, both of which are likely not to be recognized until several days after the procedure with fistula formation or necrosis of the cervical stump, respectively. To mitigate this risk, the cervical stump should be elevated out of the pelvis using a sponge stick or other transvaginal manipulator and energy applied sparingly. Alternatively, other mechanisms for hemostasis could be considered, including vascular clips or suturing.

FIGURE 32C.7 Colpotomy and cervical amputation. When performing LSH, the vessels are coagulated and transected at the junction of the lower uterine segment with the cervix (**A**) and the uterine corpus is amputated by transecting the cervix at this location (*dotted line*). When performing TLH, the ascending branch of the uterine vessels can be coagulated and transected as they are crossing the colpotomy ring (**B**), which also serves as a guide for subsequent amputation (*dotted line*).

Subsequent to fundal amputation, the endocervical canal can be fulgurated, preferably using bipolar current, or it can be left untreated. Although it seems intuitive that fulguration of the endocervical canal would decrease the incidence of post-LSH cyclic bleeding, there is no evidence to support that belief. Rather, the probability of bleeding may be more related to patient age and/or the presence of preexisting endometriosis.

TOTAL LAPAROSCOPIC HYSTERECTOMY

When performing TLH, once the bladder flap is created, the skeletonized ascending branches of the uterine vessels can be identified crossing the colpotomy ring (**Fig. 32C.7B**). The vessels should be coagulated and transected at this level. As with LSH described above, this step and subsequent colpotomy and amputation of the uterus from the vagina are the most critical steps when performing TLH. Also, similar to the technique described for LSH, continued coagulation of the uterine vessels in an ascending manner up the lateral edge of the uterus will decrease back bleeding from the uterus at the time of vessel transection. However, in contrast with the LSH, the presence of a previously placed colpotomy ring usually delineates the vaginal fornix, providing an excellent guide for exactly where to transect the vessels and exactly where to amputate the uterus from the vagina.

P.744

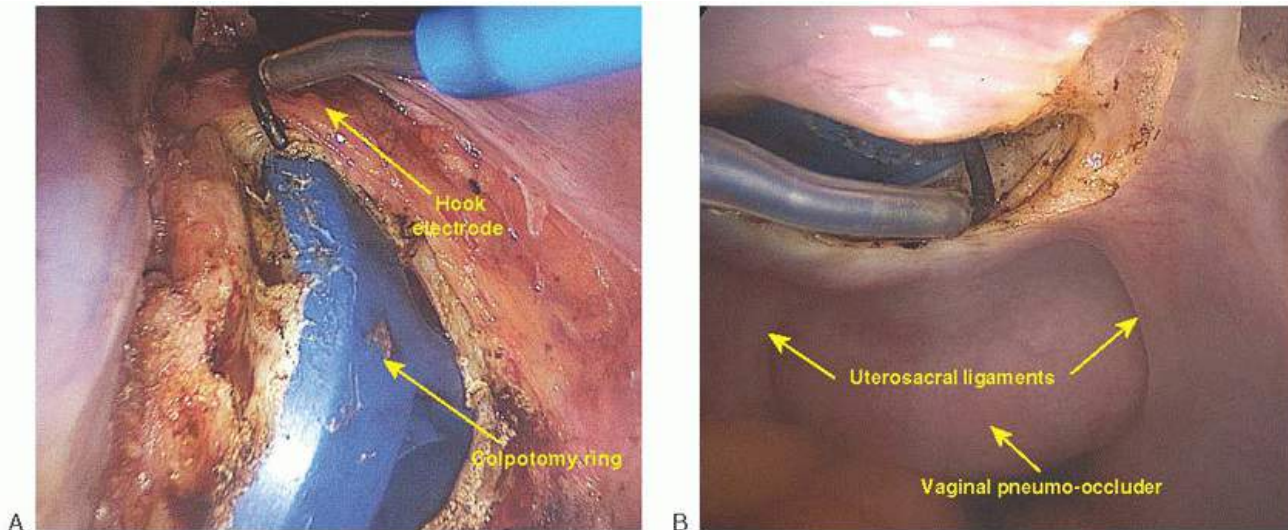

FIGURE 32C.8 Amputation of the uterus. A thin monopolar electrode (e.g., hook) is recommended for amputation of the uterus using the colpotomy ring as a guide (**A**). This applies the lowest voltage energy and minimizes the risk of thermal injury to the ureter or bladder. Amputation of the uterus and cervix at the level of the colpotomy ring transects the cardinal ligament complex, leaving the uterosacral ligaments attached to the fascia of the vaginal apex (**B**).

The colpotomy incision and amputation of the uterus are the most important steps in performing TLH with respect to potential urinary tract injury. There is no single electro-surgical instrument that has been shown to be superior in mitigating this risk. However, each instrument does have distinctive electrical and mechanical properties related to spread of thermal energy, tissue sealing, and cutting. Regardless of which instrument is chosen, a comprehensive understanding of its unique properties is critical. While bipolar current is typically used to coagulate the uterine vessels, a variety of instruments can be used to perform the colpotomy incision. Attention should be paid to minimize electro-surgical energy at this step. A monopolar hook electrode attached to a “Bovie pencil” using continuous (cutting) current is particularly useful. Using the colpotomy ring as a backstop, it has the ability to deliver very focused electro-surgical energy with low voltage (**Fig. 32C.8A**). Any oozing that is encountered can usually be handled with short bursts of monopolar discontinuous (coagulation) current. This minimizes thermal spread that results in devitalization of tissue at the cuff over time and minimizes the risk of inadvertent electro-surgical injury to the bladder or ureter.

It does not matter whether the anterior or posterior colpotomy incision is made first. It is more important to choose whichever is most identifiable and accessible so that the edge of the colpotomy ring can be identified when the tissue is divided. Once this is achieved, the amputation is simply a matter of “following the ring” circumferentially using the tip of the hook electrode for precise focal energy delivery (**Fig. 32C.8A**). Importantly, when the colpotomy ring is placed and identified appropriately, the level of cervical amputation is at the cardinal ligament. Accordingly, when the posterior colpotomy incision is made, the uterosacral ligaments remain attached to the fascia of the vaginal apex (**Fig. 32C.8B**). This facilitates incorporation of the uterosacral ligaments into the subsequent cuff closure for pelvic

support.

In cases where the uterus is particularly bulky, or there is distortion of the pelvic anatomy due to adhesions, endometriosis, or other concomitant pathology, amputation of the fundus from the cervix can be accomplished prior to attempting colpotomy and amputation of the cervix. In fact, it is often preferable to do so. In this case, the same steps described above with LSH are followed, usually amputating even higher on the cervix or even lower uterine segment. Subsequently, the plane delineated by the colpotomy ring is easier to identify and to access for cervical amputation.

STEPS IN THE PROCEDURE

Laparoscopic Hysterectomy

- Place the patient in lithotomy position, and perform tilt test to ensure stability on table.
- Drape into sterile field, uterine manipulator, colpotomy ring, pneumoperitoneum occluder (depending on procedure), and Foley catheter.
- Peritoneal insufflation and port placement depending on size of uterus.
- Identification of anatomic landmarks including ureters, uterosacral ligaments, bladder edge, and colpotomy ring.
- Coagulate and transect proximal fallopian tube(s) and utero-ovarian ligament(s) to separate adnexal structures from uterine corpus.
- Coagulate and transect round ligament and dissect broad ligament to the level of the uterine isthmus.
- Create bladder flap and skeletonize uterine vessels.
- For supracervical hysterectomy:
 - Coagulate uterine vessels at the level of the uterine isthmus.
 - Amputate the uterus from the cervix at the level of the isthmus.
- For total laparoscopic hysterectomy:
 - Coagulate uterine vessels at the level of the colpotomy ring.
 - Transect cardinal ligament and amputate the uterus and cervix from the vaginal apex, using colpotomy ring as a guide, with monopolar continuous (cutting) current
 - Isolate, coagulate, and transect infundibulopelvic ligaments (if salpingo-oophorectomy is desired).
 - Coagulate and transect mesosalpinx (if only salpingectomy is desired).
 - Remove adnexal tissue intact and uterus (with morcellation, if indicated).
 - Close the vaginal cuff incorporating the uterosacral ligaments.
 - Secure hemostasis and close trocar sites in usual fashion.

P.745

Tissue removal

When performing TLH, the uterus, cervix, and adnexal structures can usually be removed through the vagina prior to closing the cuff. This becomes more challenging with increasing uterine size, but vaginal morcellation offers an excellent technique for removal of larger specimens. Each surgeon will have to determine his or her own skill level with respect to vaginal morcellation and the size at which alternative tissue removal techniques will need to be employed. When performing LSH, tissue removal options are more limited.

Aside from extraction of tissue through the vagina, removal options include making a small laparotomy incision to remove the tissue intact or with manual morcellation, extending the umbilical incision enough to accomplish the same, or using electromechanical morcellation. Recent controversy has arisen regarding the safety of tissue morcellation. Use of electromechanical morcellation has been shown in some cases to disseminate benign tissue, or neoplastic tissue in the rare case of an undiagnosed malignancy, with potential adverse downstream consequences. Importantly, manual morcellation has not been proven to avoid this possibility; it simply has not been studied. Clearly,

morcellation should not be employed when a malignant or premalignant diagnosis is known or if preoperative assessment of the patient is suspicious for the same. In these cases, tissue needs to be removed intact, even if it means converting to a laparotomy. Critical reviews of relevant literature by different professional organizations, including AAGL and ACOG, support that tissue morcellation can be performed safely and effectively by properly trained and experienced surgeons in appropriately screened and selected patients.

FIGURE 32C.9 Closure of the vaginal cuff. After amputation of the uterus, a pneumo-occluder balloon in the vagina can maintain peritoneal insufflation (**A**) until the vaginal cuff is closed. Cuff closure should incorporate the uterosacral ligaments (**B**).

After the uterus has been removed through the vagina or an alternative mechanism, a pneumo-occluder in the vagina can maintain pneumoperitoneum until the vaginal cuff is closed (**Fig. 32C.9A**). When necessary, a ring forcep can be introduced transvaginally around the pneumo-occluder to grasp and retrieve the ovaries and/or tubes prior to closing the vaginal cuff.

Cuff Closure

With laparoscopic hysterectomy, the vaginal cuff can be closed laparoscopically or vaginally, depending on the skill of the surgeon, but the former defines a true TLH. The basic tenets of cuff closure that are considered with abdominal and vaginal hysterectomy apply to TLH, only the visual perspective and magnification changes. Both intracorporeal and extracorporeal knot-tying techniques have been described using absorbable suture. Notably, the advent of barbed suture has facilitated laparoscopic suturing because it does not require knot tying, which is the most technically challenging and skill limiting component.

There is a statistically increased incidence of cuff dehiscence with TLH. A 2007 study of over 7,200 hysterectomies reported the rates of cuff dehiscence to be 0.12% with abdominal hysterectomy, 0.29% with vaginal hysterectomy, and 4.93% with laparoscopic hysterectomy. Barbed suture was not included in this study. There is no evidence that use of barbed suture increases the incidence of cuff dehiscence. In fact, there is evidence that cuff closure in two layers using barbed sutures decreases the incidence of cuff dehiscence in TLH. Two factors that are thought to contribute to the increased cuff dehiscence rate after TLH include (1) increased magnification of the surgical field with the laparoscope, leading the surgeon to think the tissue included in the suture is more than it really is, and (2) progressive devitalization of tissue with time due to thermal effect during colpotomy, possibly extending to or beyond the suture line. Accordingly, the

greatest steps that can be taken during cuff closure to mitigate dehiscence, in addition to basic surgical principles of hemostasis and “approximation, not strangulation” of tissue, are minimizing application of thermal energy during colpotomy and incorporating adequate healthy tissue in the suture line.

Incorporation of the uterosacral ligaments into cuff closure has become relatively standard with abdominal or vaginal hysterectomy and has been demonstrated to decrease the incidence of posthysterectomy vaginal vault prolapse from 25% to 5%, with or without culdoplasty. Although there have been no long-term trials to show comparable results after TLH, there is every expectation for similar outcomes and incorporation of the uterosacral ligaments into the cuff closure is recommended (Fig. 32C.9B); laparoscopy is a different access, not a different procedure.

COMPLICATIONS

The nature of complications occurring with TLH is similar to that of those reported for abdominal and vaginal hysterectomy. Complications related to medical comorbidities, anesthesia, or the hysterectomy procedure may occur, as well as those related specifically to laparoscopy. Regardless of access, hysterectomy remains a relatively safe procedure with a mortality rate estimated between 0.12 and 0.34 per 1,000 procedures. Postoperative wound complications such as infection after laparoscopic hysterectomy appear to be less frequent than with abdominal hysterectomy, largely owing to the smaller size. However, complications do occur specifically related to the use of trocars. These are related to trocar insertion (specifically, abdominal wall vasculature or nerve injury and intra-abdominal vascular or intestinal injury) or to trocar site hernia (which is <1%). Trocars should be removed under visualization at the conclusion of the hysterectomy to watch for bleeding. The fascia should be closed separately from the skin at trocar sites 10 mm or greater. This can be accomplished using traditional suturing technique or by using a variety of commercially available products available for this purpose (Carter-Thomason device, Endoclose device, etc.).

TABLE 32C.3 Reported Complications in Both Arms of the eVALuate Trial

	ABDOMINAL TRIAL		VAGINAL TRIAL	
	ABDOMINAL HYSTERECTOMY	LAPAROSCOPIC HYSTERECTOMY	VAGINAL HYSTERECTOMY	LAPAROSCOPIC HYSTERECTOMY
At least one complication ^a	6.2%	7.2%	5.4%	6.7%
Conversion to laparotomy	—	3.9%	4.2%	2.7%
Bowel injury	1%	0.2%	0%	0%
Ureter injury	0%	0.9%	0%	0.3%
Bladder injury	1%	2.1%	1.2%	0.9%
Deep vein thrombosis	0%	0.3%	0%	0%
Pulmonary embolus	0.7%	0.2%	0%	0.6%

Wound dehiscence	0.3%	0.2%	0%	0.3%
Hematoma	0.7%	0.7%	1.2%	2.1%
Major hemorrhage	2.4%	4.6%	2.9%	5.1%
Anesthesia problem	0%	0.9%	0%	0.6%
Return to operating room	0.3%	0.5%	0%	0.3%

^aExcludes “conversion to laparotomy” as a complication.

A patient may have had more than one complication.

Adapted from Garry R, Fountain J, Mason S, et al. The eVALuate study: two parallel randomised trials, one comparing laparoscopic with abdominal hysterectomy, the other comparing laparoscopic with vaginal hysterectomy. *BMJ* 2004;328(7432):129, with permission. Copyright © 2004, British Medical Journal Publishing Group.

Two large studies have compared complications rates with different routes of hysterectomy. Both were published in 2004. The Vaginal Abdominal Laparoscopic Uterine Excision (VALUE) study was a prospective cohort examination of severe complications related to hysterectomy in over 37,000 women. “Severe complications” (e.g., visceral injury, hemorrhage, thromboembolic disease, myocardial infarction, stroke, end-organ failure) were noted to be low (4.4%) overall, but the risk was doubled in younger patients undergoing a laparoscopic procedure for fibroids and those with significant comorbidities, compared with similar patients undergoing abdominal or vaginal hysterectomies. Unfortunately, hysterectomies involving laparoscopy comprised only 3% of the study population and were limited to LAVH (no TLH or LSH).

The eVALuate study was actually two parallel prospective randomized trials including over 1,300 patients that compared complications of laparoscopic hysterectomy with either abdominal hysterectomy or vaginal hysterectomy. Significant findings are listed in [Table 32C.3](#). In this study, laparoscopic

P.747

hysterectomy encompassed LAVH, LSH, and TLH. In the abdominal hysterectomy arm, advantages of a laparoscopic approach were noted to include fewer infections, smaller drop in hemoglobin, less pain, shorter hospital stay, quicker recovery, and improved short-term quality of life when compared with an abdominal approach. There was an increased incidence of bladder and ureter injuries with the laparoscopic approach. The study reported an overall complication rate in laparoscopic hysterectomy increased over abdominal hysterectomy (11.1% vs. 6.2%, respectively). However, they included “conversion to laparotomy” (which is not possible in abdominal hysterectomy) as a complication of laparoscopy. When this is more appropriately considered an exercise of good surgical judgment rather than a complication, the overall rate complication rate between the laparoscopic and abdominal groups becomes nonsignificant (7.2% vs. 6.2%, respectively). Similarly, there was no significant difference in overall complication rates between laparoscopic and vaginal hysterectomy, although vaginal hysterectomies were performed in half the time. Of note, this arm of the study contained cases of “low technical challenge” and was underpowered.

Gynecologic surgery, specifically hysterectomy, is the most common cause of iatrogenic urinary tract injury.

Several studies have reported an increased rate of urinary tract injuries in laparoscopic hysterectomy compared with abdominal or vaginal hysterectomy. Most of those studies included only LAVH (not TLH or LSH) and even then represented a small percentage of the study population.

A common risk factor for bladder injury is the presence of prior cesarean section, pelvic adhesive disease, or endometriosis involving the bladder. On the other hand, greater than 90% of ureteral injuries during laparoscopic hysterectomy can be attributed to thermal injury related to division of the cardinal ligament. A case controlled study of over 5,000 hysterectomies demonstrated that the risk of urinary tract injury is increased in vaginal (1.3%) or laparoscopic (1.8%) hysterectomy when compared with abdominal hysterectomy (0.76%). Further, a 2009 study involving over 800 patients described bladder injury during hysterectomy in 2.9% of patients and ureteral injury in 1.8% of patients, 75% of which were unsuspected. Interestingly, evidence from a 2006 meta-analysis demonstrated that when cystoscopy is performed immediately after hysterectomy, 89% of ureteral and 95% of bladder injuries are detected intraoperatively. Conversely, in the absence of cystoscopy, intraoperative detection drops to 43% of bladder and only 7% of ureteral injuries.

Although overall urinary tract injury rates are low, overall postoperative morbidity is not increased when bladder injuries are recognized and repaired at the time of surgery. Indeed, intraoperative identification may help to avoid additional surgery and loss of renal function. The role of routine cystoscopy after hysterectomy continues to be debated, but fiscal analysis suggests intraoperative cystoscopy becomes cost-effective when the injury rate exceeds 2%.

Finally, the role of surgeon experience in reducing complications of laparoscopic hysterectomy cannot be overemphasized. Multiple studies have demonstrated decreased complications rates that plateau after about 100 cases and with high volume laparoscopic surgeons.

CONCLUSIONS

After performing the first total laparoscopic hysterectomy, Harry Reich envisioned its role as decreasing the need for abdominal hysterectomy by “avoiding the increased morbidity associated with abdominal surgery while retaining the surgical advantages of the abdominal approach.” Not only did his words ring true, his efforts launched an era of advanced laparoscopic gynecologic surgery enjoyed today. Indeed, laparoscopy simultaneously provides superior exposure to the adnexa and upper abdomen, which is not available to the vaginal surgeon, but simultaneously avoids a large abdominal wall incision, thus reducing the associated risk of infection, postoperative pain, and hernia. Thus, with appropriate training, skill, and experience, the surgeon performing laparoscopic hysterectomy enjoys vision and access advantages that are superior to abdominal hysterectomy while retaining the decreased morbidity of the vaginal approach.

BEST SURGICAL PRACTICES

- The choice of access for and type of hysterectomy should be based on the patient's anatomy and pathology. Supracervical hysterectomy should not be performed simply because of the surgeon's lack of comfort with removing the cervix. Instead, assistance from more skilled surgeons should be sought.
- The patient should be counseled thoroughly regarding anticipated outcomes, potential complications, preoperative preparation, and postoperative care. Risks and benefits of using energy-based instruments and morcellators should be included in the informed consent process. Discuss alternatives for tissue removal, including vaginal morcellation or laparotomy.
- Preprocedure optimization of comorbidities, especially cardiovascular, should be coordinated with the anesthesia team to minimize medical complications.
- An appropriate uterine manipulator and vaginal fornix delineator should be used for total laparoscopic

hysterectomy to improve procedural ergonomics and decrease complications.

- Anatomy should be respected. Clearly identify ureters, bladder, and other anatomic landmarks. Isolate or skeletonize vessels to be coagulated.
- Understand the electrosurgical and mechanical characteristics of energy-based instruments you are using, and apply those principles to minimize undesired thermal tissue effects.
- Prevent or minimize bleeding as much as possible during laparoscopic hysterectomy. Blood absorbs light and hinders full visualization by decreasing light intensity in the surgical field.

Chapter 33

Management of Abortion

Eva Lathrop

Carrie Cwiak

DEFINITIONS

Anembryonic pregnancy—A pregnancy in which trophoblast develops without development of embryonic tissue.

Dilation and evacuation—A surgical technique for pregnancies beyond 12 to 14 weeks gestation, utilizing advanced cervical dilation and evacuation of fetus and placenta via suction and forceps.

Early pregnancy loss—Loss of a pregnancy before 24 weeks gestation.

Electric vacuum aspiration—A surgical technique for pregnancies less than 12 to 14 weeks gestation, utilizing cervical dilation and aspiration of the fetus and placenta via suction.

Embryonic death—The finding of no cardiac activity in an embryo at least 5 mm and up to 15 mm (8 weeks) in length.

Fetal death—The finding of no cardiac activity in a fetus over 8 weeks (15 mm) gestation.

Incomplete abortion—Clinical and ultrasonic evidence of retained tissue in the uterus after an early pregnancy loss or induced abortion.

Induced abortion—Medical or surgical termination of an ongoing pregnancy.

Inevitable abortion—Dilation of the cervix without passage of pregnancy-related tissue.

Manual vacuum aspiration—Aspiration of the fetus and placenta via suction generated by a handheld syringe.

Missed abortion—Clinical or ultrasonic evidence of a nonviable pregnancy without cervical dilation or passage of pregnancy-related tissue.

The management of abortion remains a principal focus of gynecology. In the United States, each year, more than 1 million pregnancy losses occur and more than 1 million induced abortions are performed. With minimal modification, the surgical management of early pregnancy loss (EPL) is the same as for induced abortion, making uterine aspiration one of the most frequently performed operations in gynecology and one of the most thoroughly studied. In addition, the medical techniques effective for induced abortion are typically as effective for EPL. This chapter focuses on the surgical management of abortion but also summarizes other treatment options. It reviews the incidence, risk factors, preoperative assessment, and evidence-based treatment for spontaneous, illegal, and legal abortion. Readers should keep in mind that abortion technology is rapidly evolving, and new protocols may supplant those described here.

EARLY PREGNANCY LOSS

Incidence

Pregnancy loss is a common reproductive outcome. National Vital Statistics estimated that 1,118,000 total pregnancy losses occurred in 2008 in the United States (17% of all pregnancies). The incidence of EPL is dependent on the definitions utilized for EPL and for recognized pregnancy but is typically quoted as between 10% and 15% of all pregnancies. The contemporary definition for EPL is the loss of a pregnancy before 24

weeks estimated gestational age (EGA), recognizing the typical limits of fetal viability when resources are available. The greatest percentage—over 85%—of EPL occurs before 13 weeks gestation.

Fetal death is defined as no cardiac activity in a fetus over 8 weeks gestation and is uncommon after the first trimester. The U.S. National Vital Statistics System utilizes the World Health Organization (WHO) categories for fetal death: early (<20 weeks EGA), intermediate (20 to 28 weeks), and late (28 weeks or more), the latter corresponding to the international definition for stillbirth. The 2006 data from the U.S. National Center for Health Statistics report a fetal death rate of 6.05 per 1,000 live births. The incidence of fetal death decreases with increasing gestational age. Of the fetal deaths over 20 weeks in 2006, greater than 50% occurred between 20 and 27 weeks, with over one third occurring between 20 and 23 weeks. These categories overlap with the definition commonly used for EPL. In addition, individual states vary in the gestational ages at which they begin collecting data on pregnancy loss or fetal death. However, determining the upper limit by which to define EPL may be more an argument of necessity for statistical records than for clinical practice.

The true incidence of EPL is also uncertain because of the difficulty in recognizing early conceptions and losses. When Wilcox and associates monitored daily urinary β -human chorionic gonadotropin (β -hCG) in the 1980s, they found that 31% of pregnancies resulted in spontaneous abortion after implantation, but approximately 70% of these—22% of all losses—were not yet clinically identified. Wang and colleagues published data in 2003 in which 8% of all conceptions in their study were recognized pregnancies followed by spontaneous loss. Twenty-six percent of all conceptions in that study were losses before knowledge of the pregnancy. The ability to confirm pregnancy at an earlier EGA has significantly improved with the clinical use of highly sensitive urine pregnancy tests that can detect levels as low as 15 mIU/mL or 10 days after the last menstrual period. However, home pregnancy tests remain highly variable and can require levels as high as 100 mIU/mL before testing positive. Therefore, a significant amount of EPL may still be unreported.

Terminology

EPL has been previously referred to as *early pregnancy failure* and *spontaneous abortion*. In addition to sensitive urine pregnancy tests, the availability of transvaginal ultrasound has enabled the diagnosis of EPL at very early EGAs. Terminology

P.750

has thus evolved to reflect the pathophysiology of the loss. Anembryonic pregnancy occurs when the trophoblast develops in the uterus without subsequent development of embryonic tissue. The diagnosis is confirmed by the ultrasonic finding of no yolk sac or embryonic pole and intrauterine gestational sac with mean sac diameter (MSD) of 16 mm or more, though utilizing an MSD cutoff of 20 mm in clinical practice can increase the specificity of diagnosis. Embryonic death is diagnosed by the ultrasound finding of no cardiac activity in an embryo at least 5 mm and up to 15 mm (8 weeks) in length. Fetal death is diagnosed by the ultrasound finding of no cardiac activity in a fetus over 8 weeks (15 mm) gestation. The first trimester of pregnancy is generally defined as either the first 12 or 14 weeks of pregnancy.

Once the diagnosis of a nonviable pregnancy has been made by abnormal trend in β -hCG or ultrasound, then terminology is also used to describe the clinical presentation of EPL. Missed abortion refers to a nonviable pregnancy in which dilation of the cervix and passage of pregnancy-related tissue have not yet occurred. Although missed abortion was associated in the past with complications from delayed diagnosis and retained products of conception, currently, it is often made when a patient is asymptomatic. Inevitable abortion can be considered the next stage in a continual process, in which a woman has a dilated cervix but passage of tissue has not yet occurred. Incomplete abortion refers to EPL in which some, but not all, of the tissue has passed. As a clinical definition, incomplete abortion refers to a woman who is symptomatic with abnormal bleeding, pain, or signs of infection due to retained tissue in the uterus. However, after passage of the gestational sac, it can be

difficult to determine if the remaining tissue in the uterus is clinically significant in the woman with mild to no symptoms.

Risk Factors

EPL has several important risk factors. Over two thirds of EPL prior to 12 weeks EGA are associated with chromosomal anomalies, the most frequent of which are autosomal trisomies, followed by polyploidies, and then monosomy X. The earlier the gestational age at loss, the higher the frequency of chromosomal anomaly. Almost all anomalies, including some that would not appear to handicap survival (such as cleft lip), increase the likelihood of EPL. These anomalies are typically the result of random mutations, though a predisposition due to a balanced translocation or family history of a genetic defect can increase maternal or paternal risk.

Demographic details point to some other nonmodifiable risk factors. In a large study published by Nybo Anderson and colleagues, the rates of EPL increased with maternal age. Women aged 20 to 30 years, 35 years, 40 years, and 45 years saw a 9% to 17%, 20%, 40%, and 80% EPL rate, respectively. Previous studies reported an increase from 12% at ages less than 20 to 26% at age 40. Likewise, the risk increases with advancing paternal age. Race also plays a role. At each stage of pregnancy, black and Hispanic women in the United States have higher rates of pregnancy loss overall and of fetal death than do white women.

Independent of the effect of age, the risk of EPL changes with previous pregnancy history. Increasing rates are seen with increasing gravidity or parity. Personal history of one or more spontaneous losses increases the risk of recurrence. This effect is seen at all gestational ages. The risk of EPL was reported to increase with each documented loss in one study, increasing from 20% after one loss to 43% after three or more. Alternatively, the risk of EPL is lower for a woman who has not had a previous pregnancy or whose last pregnancy was successful. The length of the interval between pregnancies appears to have little impact.

Modifiable risk factors for EPL have also been identified. Overall, poor diet and obesity have each been associated with increased risk of EPL. Smoking may increase the risk of EPL. Because smoking is not teratogenic, its effect on spontaneous abortion rates may be via abortion of normal conceptuses. In one study, the risk of loss doubled; in other studies, the increase in risk was slight. Recent studies have not confirmed this increased risk. Alcohol consumption is associated with EPL as well as teratogenicity. The effects of alcohol on EPL risk appear to be greatest for those whose alcohol consumption is greater. Additionally, the risk appears to be greater with increased intake in the earlier gestational ages. Alcohol consumption as a teratogen has a dose-dependent effect and can result in mental retardation, microcephaly, midface hypoplasia, and renal and cardiac defects. Caffeine intake has been evaluated in many studies regarding EPL. Several studies had suggested an increased risk for spontaneous abortion in women who drank greater than 500 mg—or the equivalence of 5 cups—of coffee per day. However, a systematic review by Signorello and McLaughlin indicates that there is insufficient evidence supporting a causal relationship.

Certain maternal comorbidities are associated with an increased risk of EPL. Women with poorly controlled diabetes have higher levels of pregnancy loss as well as congenital anomalies. Increased rates of EPL are seen in women with other endocrine imbalances such as thyroid disease and polycystic ovarian syndrome, autoimmune disease, hypercoagulable states such as antiphospholipid antibody syndrome and thrombophilias, and chronic infections.

Cervical incompetence can lead to EPL. Cervical incompetence is more accurately defined as premature cervical dilation in midtrimester of pregnancy without uterine contractions, but the diagnosis is often made retrospectively in the women with unexplained repetitive midtrimester EPL without labor. Incidence rates range from 0.05 to 1 per 100 pregnancies. Though cervical loop electrocautery excision procedure is associated with EPL, data are otherwise lacking to confirm or refute other potential causes, such as previous cervical laceration or excessive mechanical dilation; the occurrence of this condition in primigravidas suggests alternative causes. These may

include associated uterine anomalies, prenatal exposure to diethylstilbestrol, or abnormal histology of the cervix. In addition, premature cervical dilation without labor may be inheritable.

The presence of uterine anomalies can lead to EPL as well. Uterine synechiae, or Asherman syndrome, may permit insufficient surface area to support a pregnancy and lead to spontaneous loss. Uterine septa and abnormalities of müllerian fusion can also result in pregnancy loss if the pregnancy implants on the septum and outgrows its blood supply. Although no effect is seen in the first trimester, the incidence of EPL due to uterine anomalies after 13 weeks gestation may be 20% to 25%. Leiomyomata, specifically submucosal or large myomata, can interfere with implantation and make sustained pregnancy difficult.

Prevention

It is largely unknown how to prevent EPL. A meta-analysis of four studies suggests that oral or vaginal progesterone can prevent fetal loss when given to women with threatened abortion (bleeding, but with a viable fetus). Because the studies were small and of poor quality, further study is warranted before this can be accepted as proven therapy. One study by Mills and colleagues indicated that women with diabetes with excellent glycemic control early in pregnancy had the same rate of spontaneous abortion as did controls. Optimization of maternal health and avoidance of substances may be advisable for all women to prevent EPL as well as encourage maternal

P.751

well-being. However, Cochrane reviews of randomized trials have found insufficient evidence for EPL prevention from vitamin supplementation, Chinese herbal medicine, bed rest, HCG, or beta-agonists.

Surgery may benefit some women with cervical incompetence or uterine abnormalities. For cervical incompetence, vaginal or abdominal cerclage can be performed, and those techniques are described elsewhere in this text. A Cochrane review of randomized trials concluded that cerclage reduces preterm delivery, though not perinatal mortality, in women at high risk for recurrent preterm delivery. Benefits for low-risk women are unproven. If uterine synechiae are diagnosed, hysteroscopic lysis of adhesions is recommended. Women with müllerian anomalies who experience EPL at 13 weeks gestation or later may be candidates for reconstructive operations, described elsewhere in this text. Removal of uterine fibroids, if performed only because of infertility, may help little; the effect of myomectomy on pregnancy loss rates is unknown.

Evaluation

A majority of the time, viability concerns in early pregnancy are preceded by vaginal bleeding. Bleeding in early pregnancy is common, reported in up to 25% of early pregnancies, and ensuring appropriate evaluation and management is essential for women's health. In addition to the history and physical exam, ultrasonography and serial measurement of β -hCG are important diagnostic tools to differentiate threatened, incomplete, and complete abortion. These are also important in the diagnosis of ectopic pregnancy, as an intrauterine pregnancy identified on ultrasound virtually excludes the diagnosis of ectopic pregnancy.

The average rise of β -hCG is 100% over 48 hours, but the lower limit of β -hCG rise in normal pregnancies has been shown to be as low as 53% in 48 hours. Conversely, once trophoblastic development has stopped, β -hCG clears the serum at about the same rate of 100% in 2 days. β -hCG serum levels clear faster after EPL than after induced abortion, though levels can similarly be seen to plateau toward the end of clearance. Therefore, depending on the level of β -hCG at the time of EPL, β -hCG may remain positive for up to 8 weeks thereafter.

Although persistent β -hCG levels might alert the provider to abnormal trophoblastic tissue and an increasing trend to a continuing or new pregnancy, a single β -hCG level cannot assist in diagnosis of retained products of

conception because if trophoblastic development has been interrupted, whether by EPL or induced abortion, then a positive β -hCG may be present, trending down, without retention of a clinically significant amount of tissue. Conversely, clinically significant but nonviable, retained tissue can be present with a negative β -hCG value since trophoblastic development is no longer occurring.

Increasing use of vaginal ultrasound has improved diagnostic validity, especially at early gestational ages. When an embryo is visible, management is straightforward. However, most abnormal pregnancies stop developing before an embryo is visible by sonography. The discriminatory zone is the β -hCG serum level at which an intrauterine gestational sac can be seen via ultrasound for a viable pregnancy. The discriminatory zone for vaginal ultrasound can range from 1,500 to 2,000 mIU/mL depending on laboratory and sonographic resources and has a specificity of 95% to 100%. Two additional sonographic findings have high specificity: a gestation sac at least 25 mm in mean diameter without an embryo and distorted sac shape. On the other hand, the sensitivity of these criteria appears to be low. Presence of fetal heart activity is more accurate in predicting EPL than are morphologic criteria. Several reports concur that once fetal cardiac activity is documented by ultrasonography in the first 12 weeks of pregnancy, the likelihood of subsequent fetal loss is low: about 2% to 4.5%. This does not hold true, however, for women older than age 35 or those with a history of recurrent pregnancy loss. Furthermore, studies have noted that fetal heart rates less than 100 beats per minute in the embryonic stage are associated with a significantly lower survival rate than those with normal fetal heart rates.

Given the lack of medical need for intervention in the majority of cases of EPL, clinicians need not act on a single abnormal clinical finding in a desired pregnancy, such as a falling β -hCG level or failure to observe fetal cardiac activity. Following the β -hCG trend can establish the diagnosis of normal versus abnormal (EPL or ectopic) pregnancy. Alternatively, repeating the ultrasound at an appropriate interval improves the diagnostic accuracy of this procedure.

The traditional approach to threatened abortion, characterized by uterine bleeding without cervical dilation or expulsion of tissue and demonstration of a potentially viable fetus, has been watchful waiting. The chance of EPL after threatened abortion can be as high as 50%. Reliably predicting fetal outcomes in such situations is not yet possible, and serial β -hCG levels or ultrasound examinations may be necessary to determine viability of a pregnancy that is not actively being passed.

In the case of missed abortion and in the absence of gestational trophoblastic disease, little to no trophoblastic tissue proliferation occurs after the pregnancy loss, and so, the current uterine size or ultrasound findings typically indicate the EGA at the time of loss. The discrepancy between current EGA and expected EGA based on last menstrual period or previous normal ultrasound suggests how long ago the loss actually occurred and, in extreme cases, may suggest whether infection, hemorrhage, and/or disseminated intravascular coagulation (DIC) is likely. Missed abortion in which the pregnancy is retained for 8 weeks or more has been associated with hemorrhage and DIC.

Diagnosis of incomplete abortion has come full circle from a basis of clinical symptoms, to detection of retained tissue in the uterus on ultrasound, back to clinical diagnosis. Harwood et al. noted that the endometrial thickness after EPL was as high as 29 mm in asymptomatic women. Similar studies have concluded that no cutoff value could predict which patients would require surgical management after medical or expectant management of EPL. Follow-up studies after early medical and surgical abortion have found similar results, leading to the conclusion that the thickness of the endometrium after completion of a pregnancy has a wide range of normal variability. Therefore, the diagnosis of incomplete abortion is typically made on clinical grounds and then confirmed by ultrasound findings. In other words, a thickened endometrium in an asymptomatic woman need not be acted upon.

Management

After confirmation of EPL, the first, and perhaps most important, step is to counsel the women and her partner. Helping the couple to grieve appropriately can minimize psychological sequelae from what can be a devastating loss. Subsequent clinical management is largely discretionary. Historically, surgical management was recommended for EPL due to a higher incidence of infectious and bleeding complications associated with delayed diagnosis, or the misclassification of illegal abortion as incomplete abortion. However, for women with missed, inevitable, or incomplete abortion, several options are available. Patient preference should generally determine the management as long as there is hemodynamic stability and absence of infection.

P.752

Many women faced with the disappointing diagnosis of EPL prefer prompt surgical evacuation. Surgical management of EPL is dependent upon EGA determined by current uterine examination and ultrasound and upon clinical diagnosis. EPL up to 12 to 14 weeks EGA should be performed by uterine aspiration, via either manual vacuum aspiration (MVA) or electric vacuum aspiration. As with induced abortion, sharp curettage is no longer standard of care for EPL as it is associated with more blood loss, postoperative hemorrhage, anemia, pain, and operative time compared to manual or electric aspiration. The safe limits of EGA for uterine aspiration are dependent on clinician experience and available equipment, but it can be safely performed up to 14 weeks EGA if the appropriate-sized cannula is available for use with either manual syringe or electric vacuum. As with induced abortion, cannula size in mm should typically correspond to uterine size in weeks gestation, plus or minus 1 mm in cannula size. Utilizing a cannula that is too small can result in increased operative time, bleeding, and risk of retained products, especially in the case of EPL that has occurred several weeks before. Although nonviable fetal tissue frequently softens over time, placental and trophoblastic tissue can become indurated and less likely to pass through a too-small cannula. For missed abortion, the guidelines for preoperative cervical preparation for induced abortion can be followed (see [“Preoperative Cervical Preparation”](#)). For inevitable and incomplete abortion, minimal to no cervical dilation may be necessary if the cervix is already dilated enough to admit the correct-sized cannula. The technique of uterine aspiration, via manual or electric vacuum, is identical to that for induced abortion (see [“Manual Vacuum Aspiration”](#) and [“Electric Vacuum Aspiration”](#)).

Site of uterine aspiration may depend on time of day, staff and equipment resources available, local protocols for sedation, and clinical presentation. The syringe used for MVA is portable, inexpensive, and convenient for outpatient use. The technique is described in detail later in this chapter. Blumenthal and Remsburg found that for surgical management of EPL, MVA in the clinic or emergency room was more cost-effective than was uterine aspiration in an operating room. Development of a protocol for MVA in an office or emergency room can decrease patient cost and increase patient satisfaction. Many women prefer in-office MVA for surgical management of EPL. As with other in-office procedures, patients must be clinically stable, without multiple comorbidities, and otherwise appropriate candidates for in-office sedation and surgical management. Clinicians who are contemplating provision of in-office MVA may be more comfortable initially offering it to patients with incomplete abortion or at an early EGA and then increasing the range as their comfort level allows.

Dependent on the skill of the physician, EPL past 12 to 14 weeks EGA can also be managed surgically, via dilation and evacuation (D&E). For women with a closed cervix, preoperative cervical preparation is essential. The guidelines for cervical preparation for induced abortion can be followed for fetal loss in the second trimester as well. For D&E, larger cannulas are available for use with electric vacuum aspiration. But for an EGA larger than the size of the suction cannula available, Bierer forceps should be utilized for safe evacuation of fetus and placenta. Even with retained placenta after second- or third-trimester loss or delivery, use of Bierer forceps for evacuation is safer and more efficient than the traditional horseshoe curette. The technique of D&E for fetal loss or retained placenta is identical to that for induced abortion (see [“Dilation and Evacuation”](#)).

Antibiotics should be administered as soon as possible for women with infectious complications of EPL, and timely uterine evacuation is recommended. However, perioperative antibiotic prophylaxis has not been found to

decrease infection when used for incomplete abortion. It is unknown whether antibiotic prophylaxis is effective in other presentations of EPL like inevitable or missed abortion.

There are no studies that specifically address venous thromboembolism (VTE) associated with surgical management of EPL or induced abortion. The guidelines for VTE prophylaxis for gynecologic surgery may be followed in either situation (see “[Venous Thromboembolism Prophylaxis](#)”).

Analgesia should be used and can be provided via paracervical anesthesia, sedation, or combination of the two. Sedation is more likely to be associated with postoperative nausea and vomiting than paracervical block (PCB) alone. For sedation regimens, anxiolytic and narcotic medications are effective, whether via oral or intravenous administration. For the surgical management of EPL, randomized trials have concluded that adding an NSAID to a narcotic sedation regimen provides no additional benefit. And in comparison to sedation, general anesthesia provided no additional relief from postoperative pain but was associated with higher patient satisfaction. Whether this is due to the patient's emotional state or her perception of increased pain relief with general anesthesia, preoperative patient counseling may increase satisfaction with sedation. Any benefit must be balanced against the potential complications of induction of anesthesia in addition to the fact that anesthesia is associated with more need for blood transfusion. The WHO Safe Abortion Guidelines recommend that general anesthesia not be routinely used first line for management of abortion, suggesting that the risks of general anesthesia outweigh the benefits in most cases.

Another option to expedite the expulsion of the pregnancy after EPL is medical management via the prostaglandin analogue, misoprostol. For missed abortion in the first or second trimester, randomized trials have shown that medical management is a safe and effective option for women desiring to avoid surgery. When compared to immediate surgical management, Graziosi et al. noted a cost savings to offering initial misoprostol management followed by surgery if the abortion was not complete by 24 hours. Though patient satisfaction was 58% in each arm of the trial, satisfaction was significantly decreased for women who started misoprostol treatment but eventually required surgical aspiration. When randomized versus placebo, misoprostol resulted in higher rates of complete abortion for fetal loss, at shorter time intervals, without an increase in side effects. Compared to smaller doses, 800 µg of misoprostol is most effective without additional side effects. At this dose, vaginal is similar to oral administration in overall success rates (70% to 90%) but superior in time to successful completion of abortion with less vomiting. Sublingual administration is also similar in efficacy to vaginal but with higher incidence of diarrhea. A randomized, controlled multicenter study by Zhang and colleagues comparing medical management with surgical evacuation found an 84% completion rate by day 8 when vaginal dosing of 800 µg of misoprostol was repeated at 48 hours if passage had not yet occurred, without increase in side effects. In that study, 83% of the woman stated they would recommend the medical treatment to others.

For EPL, only one of two trials has found the addition of mifepristone to the misoprostol regimen increases rates of complete abortion. Laminaria, methotrexate, and the practice of moistening misoprostol prior to vaginal insertion did not increase success. In comparison to other prostaglandins, misoprostol is superior to prostaglandin E but similar to gemeprost. Pain management should be provided and may include NSAIDs or narcotics, with more pain control required at higher EGAs.

P.753

For incomplete abortion in the first trimester, medical management with vaginal misoprostol had success rates of 80% to 91% in randomized trials compared to 89% to 100% success with surgical management. As expected, vaginal misoprostol was associated with less use of surgical aspiration overall but higher incidence of unplanned surgery for completion of abortion. Vaginal misoprostol was also associated with more days of bleeding, more need for pain relief, and slightly less patient satisfaction, but no difference in gastrointestinal symptoms, need for blood transfusion, anemia, infection, death, or serious complication. As for missed abortion, vaginal misoprostol provides the same efficacy as oral but with less gastrointestinal side effects. For incomplete abortion, repeated

oral doses did not significantly increase the success of abortion completion but did increase side effects. There are no studies comparing medical management to surgical or expectant management for incomplete abortion in the second trimester.

A third option is to await spontaneous expulsion of the pregnancy. Expectant management has been found to have a wide range of success for missed abortion (56% to 98%) and incomplete abortion (52% to 85%) in the first trimester, as defined by no need for surgical intervention. When randomized to surgical management, expectant management was associated with a greater incidence of unplanned surgery for completion of abortion, bleeding, and blood transfusion. However, cost was decreased, and rates of infection, return to normal activity level, and psychological outcome were similar. Rates of success at 6 to 8 weeks were not significantly improved compared to 2 weeks, suggesting that 2 weeks is a reasonable time period to allow complete abortion to occur before intervening. When randomized to misoprostol management, expectant management has similar outcomes for incomplete abortion but inferior efficacy for missed abortion. When categorized by sonographic criteria, Luise et al. noted that 91% of incomplete abortions resolved spontaneously compared with 66% of anembryonic pregnancies. If choosing expectant management, a woman deserves counseling that several days or weeks may pass before resolution and that medical or surgical intervention may ultimately be necessary. Women with a diagnosis of anembryonic pregnancy may be counseled that their success rates may be lower with expectant management. Conversely, women at later gestational ages may not be good candidates for expectant management due to the longer time interval required for expulsion as well as the higher risk of bleeding and need for intervention.

According to a recent meta-analysis, there is insufficient evidence to prescribe one of the above management plans in any given clinical situation. Surgical management is more likely to result in completion than medical management, and medical management is more likely to result in completion than expectant management, but the inverse is true of costs incurred. Patient safety and satisfaction are equivalent with any of these management plans, with the exception that expectant management for EPL in the second trimester has not been studied in randomized trials. Certainly in the face of severe anemia, hemodynamic instability, pain, or infection, surgical evacuation should be performed. Without these, patient preference should be strongly considered. There is no evidence to support the use of antibiotic prophylaxis with medical or expectant management of EPL.

Aftercare for EPL includes surveillance for signs of abnormal grieving reactions or depression, preconception or contraceptive care depending on future fertility desires, and return to regular preventive reproductive care. In the absence of complications, contraception can be initiated immediately, following the same guidelines as for induced abortion (see “[Postoperative Care](#)”). Routine follow-up visits are not necessary after uncomplicated management of EPL.

Complications

Early diagnosis of EPL has reduced the risk of complications. In the 1970s, the maternal case fatality rate was estimated to be 4.5 deaths per 100,000 fetal deaths. The most frequent causes of maternal death from fetal death were uterine perforation and coagulopathy. As with induced abortion, advances in care have made mortality from EPL a rare event. The Centers for Disease Control and Prevention (CDC) identified 62 maternal deaths from pregnancy loss in the United States between 1981 and 1991. This represented a case fatality rate of 0.7 deaths per 100,000 pregnancy loss. In 2002, there were two maternal deaths that were due to pregnancy loss. Infection, hemorrhage, and embolism were the leading causes of death. The mortality risk increased with gestational age; women who were older and of minority races also were at increased risk of death.

EPL is a potentially sensitizing event for Rh-negative women. Rates of use of Rh immunoglobulin (RhIG) after EPL are significantly lower than after induced abortion. RhIG candidates at 12 weeks gestation or

earlier should receive a 50-µg dose; later abortions mandate a 300-µg dose.

The profound grief that frequently accompanies EPL often receives insufficient attention. Women and men experience the stages of grief. Guilt may be a difficult stage to resolve without help, and counseling plays an important role.

ILLEGAL ABORTION

Incidence

Despite the availability of legal abortions, small numbers of illegal procedures continue to occur in the United States. Estimates of the incidence of illegal abortion in the United States before 1970 or legalization ranged from 200,000 to 1.2 million per year; estimates for the late 1970s ranged from 5,000 to 23,000 per year. More recent estimates are not available; however, a national survey of US abortion patients demonstrated 1.2% of patients reported using misoprostol for self-induction of abortion and 1.4% reported self-inducing with other substances. Illegal abortions occur in large numbers in developing countries, where, according to WHO estimates, close to 50,000 women continue to die of illegal abortion complications each year, and deaths from unsafe abortion account for approximately 13% of all maternal deaths.

Risk Factors

Lack of access to safe, legal abortion is the most important risk factor for having an illegal procedure in the world today. Little is known about characteristics of women in the United States who may still obtain illegal abortions, although in a national survey assessing abortion patients' reports of previous selfinduction, women who have self-induced live in geographically diverse areas in the United States, the majority are not foreign born, but the level of use overall appears to be higher among foreign-born women.

Techniques

Although a wide variety of illegal abortion methods are used around the world, two methods dominate in the United States: oral abortifacients and intrauterine instrumentation. Orally administered substances include self-obtained misoprostol, turpentine, laundry bleach, large doses of quinine, and various herbs. Intrauterine techniques were less common, more effective, and more dangerous; these ranged from intrauterine injection of soap or phenol disinfectants to insertion of

P.754

foreign objects. Self-induction of abortion, by any technique in the United States, while difficult to estimate, appears to be very rare.

Complications

Transcervical administration of toxic substances carries a high risk of serious complications. The most frequently reported complication of illegal abortion is retained products of conception, although the incidence of such complications is unknown. In many countries in Latin America, Africa, and Asia where elective abortion is illegal or highly restricted, the black-market or private pharmacy availability of misoprostol has increased dramatically and led to important improvements in abortion safety, because misoprostol has reduced reliance on instrumentation of the cervix.

The number of illegal abortion deaths in the United States declined dramatically during the 1970s. During the 1975 to 1979 interval, women in both extremes of the reproductive age span had higher death rates from illegal abortion than did other women. The racial discrepancy in death rate was more striking: The mortality rate for black and Hispanic women was more than 10 times greater than for white women.

As with morbidity, the likelihood of mortality is strongly related to the abortion technique. Of the 17 illegal abortion deaths from 1975 to 1979, only one followed ingestion of an abortifacient (pennyroyal oil). The other deaths were related to intrauterine techniques, ranging from injection of cleaning solutions to insertion of foreign bodies (e.g., catheters, cotton swabs, thermometers, and coat hangers). Sepsis (10 cases) and air embolism (three cases) accounted for most of these deaths. The last reported death from illegal abortion in the United States was in 2004.

Management of Septic Abortion

Most women with septic abortion respond rapidly to uterine evacuation plus broad-spectrum antibiotics. Before beginning treatment, intrauterine and blood cultures should be obtained. An upright radiograph of the abdomen may identify a residual foreign body, gas bubbles in the uterus, or free air under the diaphragm; these findings direct management.

Antibiotic administration should begin immediately upon identification of septic abortion. Coverage should include gram-positive, gram-negative, and anaerobic bacteria. Ideally, in a case of septic abortion, the patient should go directly from the emergency department to the operating room. Peak serum levels of antibiotics will be present within an hour of their administration. Further delay of uterine evacuation is unwarranted and can compromise recovery. Prompt elimination of the necrotic infected tissue is critical. Tissue obtained during curettage should quickly go for microbiologic cultures. The yield of organisms, especially anaerobes, is often higher from a tissue specimen than from a swab inserted into the uterus.

Subsequent management is governed by the response of the woman and by microbiologic findings. All women with septic abortions should be closely observed after surgery, with special attention to vital signs and urine output, to detect incipient shock. Prompt aggressive therapy is essential if septic shock develops.

Postabortal sepsis from *Clostridium perfringens* has become rare. When this infection occurs, however, it can be catastrophic. In the absence of hemolysis, *C. perfringens* bacteremia can be managed by uterine aspiration and antibiotics. In the presence of hemolysis, hysterectomy and more aggressive medical therapy may be indicated.

LEGAL ABORTION

Incidence

Legal abortion is one of the most frequently performed operations in the United States. In 2009, 784,507 induced abortions were reported. The national abortion ratio was 227 abortions per 1,000 live births in that year. The abortion rate was 15.1 abortions per 1,000 women aged 15 to 44. The total number of induced abortions and the rate of induced abortion both declined by 5% from 2008 to 2009, the most recent year for which data are available.

Demographic Characteristics

The majority of women having induced abortions in the United States tend to be young, white, single, and of low parity. Non-Hispanic white women had the lowest rate of induced abortion at 8.5/1,000 women aged 15 to 44, and non-Hispanic black women had the highest rate of induced abortion at 32.5/1,000 women aged 15 to 44. In 2009, most (64%) abortions took place at 8 weeks gestation or earlier; 92% occurred at 13 weeks gestation or earlier. Only 7% of procedures were done between 14 and 20 weeks gestation and 1.3% at more than 21 weeks. Before 1990, provision of very early (<6 weeks of gestational age) abortions was rare. Between 2000 and 2009, the percentage of abortions performed at 6 weeks or less increased by 47%. Most abortions take place safely in freestanding clinics (93%) and physician's offices (2%). In-hospital procedures (5%) are necessary when women have a higher risk of medical or surgical complications.

Preoperative Counseling

In a recent large study, the reasons most often cited by US women for choosing abortion were that having a baby would interfere with her education, work, or ability to care for her other dependents. A majority (73%) could not afford a baby, and almost half were having relationship problems and did not want to be single mothers. Preoperative counseling should include a nonjudgmental discussion of all alternatives available, including continuing the pregnancy and adoption. Abortion procedures are reviewed and compared, including the risks, benefits, and expected experience with each method. Women choose surgical abortion to avoid the perceived involvement, awareness, pain, or emotional impact of medical abortion. Women choose early medical abortion in order to avoid surgery or anesthesia, to experience a simpler or more natural process, or in situations in which medical abortion was available sooner. Conversely, in comparison to surgical abortion, early medical abortion is associated with a longer duration of bleeding, and patients should be counseled accordingly. Contraceptive options, eligibility, and desires should also be reviewed during preoperative counseling.

Legal Considerations

It is important for clinicians to know the legal restrictions to abortion in their state. State regulations include, but are not limited to, waiting periods, counseling requirements, parental involvement for minors, ultrasound requirements, specific scripted consents, and insurance regulations.

Preoperative Medical Evaluation

The preoperative evaluation should include counseling, informed consent, a brief history, and a limited physical examination. The history taking should focus on relevant data, such as gynecologic problems (e.g., leiomyomata, uterine anomalies,

P.755

cervical stenosis) or medical problems (e.g., cardiac disease, asthma, morbid obesity) that might influence the course of the operation. Physical examination should include the heart and lungs (if anesthesia is to be used), abdomen, and pelvis. Although ultrasonography is not necessary on a routine basis, it is useful in several scenarios. Ultrasound is recommended if the size, shape, or position of the uterus is unclear as in the case of very early pregnancy, when uterine size is inconsistent with EGA per last menstrual period, and in preparation for most second-trimester cases. If ectopic pregnancy or a uterine anomaly is suspected, ultrasound should also be utilized. Ultrasound is a routine component of early medical abortions, which requires exclusion of ectopic pregnancy before use of most regimens. It is imperative to be aware of the legal requirements regarding ultrasound and abortion in a given state in order to be in compliance with these requirements when possible. Routine laboratory tests include the hematocrit (or hemoglobin) and Rh type. Additional laboratory tests may be indicated in patients with medical disorders that could influence surgical approach, anesthesia options, or the decision to perform a hospital-based procedure. Many clinicians perform a urine pregnancy test on all patients requesting abortion. Screening for chlamydia and gonorrhea need not be routine but should be targeted based on risk factors, symptoms, or examination. If bacterial vaginosis is detected preoperatively, it should be treated.

Preoperative Cervical Preparation

Osmotic dilators help to prepare the cervix for D&E abortions and can occasionally be used for earlier aspiration abortions in certain circumstances ([Fig. 33.1](#)). Osmotic dilators currently available in the United States include laminaria, Lamichel, and Dilapan. Laminaria are hygroscopic sticks of seaweed that dilate the cervix over several hours. The mode of action is not well understood, but the principal mechanism appears to be desiccation of the cervix. This drying can alter the ratio of collagen to ground substance, thus changing collagen crosslinkages. Alternatively, laminaria can alter the elaboration, release, or degradation of uterine prostaglandins. Laminaria cause the cervix to dilate the areas not in physical contact with the laminaria; whatever the mechanism, it is more

complex than mere passive stretching, as previously thought. Maximum dilation is achieved at 12 and 24 hours after placement. Laminaria is made of natural resources, and there have been historical concerns of potential increased infection risk. There are no studies that show an increased risk of infection with laminaria and several studies that demonstrate the safety of and lack of increased infection with laminaria use.

FIGURE 33.1 Osmotic dilators. **Top:** Laminaria of various sizes. **Bottom:** Lamicel in 5- and 3-mm sizes.

Lamicel is a cylinder of polyvinyl alcohol sponge impregnated with magnesium sulfate. It works within several hours, achieving maximum dilation by 6 hours postplacement, and has the advantage of uniform size (either 5 or 3 mm diameter), assured sterility, and easy insertion and removal. Lamicel is effective as a cervical preparation agent a few hours before procedures up to 16 weeks and can be used overnight in preparation for procedures up to 17 to 18 weeks, but Lamicel is rarely used as a sole agent for cervical preparation for later procedures given the limits of its dilation capabilities. Dilapan-S is another available synthetic osmotic dilator, made of a polyacrylate-based proprietary hydrogel, and is available in 3 and 4 mm diameters and lengths of 55 and 65 mm. Dilapan-S swells rapidly demonstrating significant dilation by 2 hours. Most of the dilation is completed by 4 to 6 hours after placement, but it continues to expand up to 24 hours. Dilapan-S does have some potential problems; it shortens as it expands, prompting the recommendation to choose the longer length to ensure continuous dilation of the internal os, and it can be difficult to remove.

Osmotic dilators are convenient in an outpatient setting. Placement of any of the available brands for 3 to 4 hours before abortion frequently dilates the cervix sufficiently for abortion. Women can be sent home with laminaria in place overnight, allowing for maximal dilation. In-facility admission for observation is not necessary. Compared with use of metal dilators, use of laminaria dramatically reduces the risk of cervical injury and uterine perforation. This protection against trauma can be especially important for young teenagers with immature cervixes who are at increased risk for cervical injury. Disadvantages include the cost, inconvenience, and occasional cramping involved. Instances of extramural delivery after placement of osmotic dilators are rare.

Alternatively, preoperative preparation of the cervix with misoprostol can facilitate abortion. Misoprostol, a prostaglandin E derivative, is safe, inexpensive, stable at room temperature, and effective in improving the Bishop score of the cervix. It is superior in cost efficacy and side effect profile in comparison to gemeprost. The drug can be given orally, vaginally, buccally, or sublingually. In general, misoprostol is better tolerated when given by the vaginal route versus the oral route; this probably relates to different pharmacokinetics when absorbed through the vagina versus through the gut. Both the sublingual and buccal routes demonstrate effectiveness similar to that of the vaginal route, while the side effect profile remains slightly higher than that of

the vaginal route. Buccal use generally has fewer side effects than the sublingual route. Women often prefer an oral route to vaginal self-administration, but when placed in the vagina by the clinician at the end of the pelvic examination, most patients find this manner of administration acceptable. A randomized controlled trial (RCT) by Singh and colleagues suggests that misoprostol 400 µg per vagina 3 to 4 hours before the operation may be the optimal dose. Administration 1 hour before a procedure has been found not to be effective, and short intervals without proven efficacy should be discouraged. This has been reiterated by the Society of Family Planning (SFP) in the clinical guidelines for cervical preparation for procedures 14 weeks or below. In this guideline, cervical preparation with misoprostol can be considered for women who may be at increased risk of complications from cervical dilation: women in the late first trimester, adolescents, and women in whom cervical dilation is expected to be difficult due to either patient factors or provider experience. Recent data show an inferior

P.756

effect of same-day misoprostol for preoperative cervical priming in second-trimester procedures as compared with laminaria administered the day before the procedure. In the SFP guideline addressing cervical preparation for second-trimester abortions, misoprostol can be considered as an alternative to laminaria for early second-trimester cases (13 to 16 weeks) in women considered at low risk for cervical injury but should not routinely replace laminaria. After 16 weeks, misoprostol can be used in conjunction with laminaria in select cases but provides inadequate dilation alone at later gestations. Disadvantages of cervical preparation with misoprostol include the delay required, spotting and cramping, and occasional expulsion of the pregnancy in the waiting room.

Prophylactic Antibiotics

Induced abortion patients should receive prophylactic antibiotics. A meta-analysis of the RCTs on this topic by Sawaya and colleagues showed decreased risk for postabortal endometritis for women deemed low and high risk for infection when prophylactic antibiotics were given as part of routine abortion care. The choice of antibiotic and duration of therapy are unclear. Both tetracyclines and nitroimidazoles have been shown to be effective. Doxycycline is the most commonly recommended prophylactic antibiotic in the setting of surgical abortion and has been shown to substantially reduce the risk of postabortal infection. The regimen of 100 mg of doxycycline preoperatively followed by 200 mg immediately postoperatively has been shown to decrease infection risk by 87%. Alternatives to this include azithromycin or metronidazole in prophylactic doses. However, if one administers antibiotics for more than 24 hours, prophylaxis ends and presumptive treatment of *C. trachomatis* begins. In high-risk populations, presumptive treatment of all patients for chlamydial infection (or bacterial vaginosis with metronidazole) may be a reasonable course of action.

Venous Thromboembolism Prophylaxis

As for EPL, there are no studies that specifically address VTE associated with surgical management of induced abortion. The Society of Gynecologic Surgeons' systematic review concluded that, other than early ambulation, no prophylaxis is required for minor surgeries in patients without significant risk factors for VTE, as they are considered low risk for VTE. Patients having minor surgery who have two or more risk factors for thromboembolism (previous VTE, thrombophilia, malignancy, etc.) are at moderate risk, and prophylaxis can be provided via intermittent compression devices, with the addition of heparin if the risk is particularly high. Although based on limited numbers of trials of gynecologic surgery, these recommendations are feasible for the management of high-risk abortion patients who would typically be managed in an operating room.

Preoperative Preparation

If local anesthesia is to be used alone, no preoperative fasting is necessary, but if conscious sedation is a possibility, the patient should fast for at least 6 hours before the procedure. Similarly, if conscious sedation is used, the patient should be instructed to bring someone with her to escort her home. She should empty her

bladder before being placed in the dorsal lithotomy position; catheterization is unnecessary. An antiseptic is applied to the cervix and vagina (e.g., povidone-iodine or chlorhexidine). Routine sterile precautions (e.g., drapes, caps, masks, and gowns) are unnecessary. The clinician should use a “no-touch” technique: He or she wears sterile gloves and does not touch those ends and portions of the sterile instruments inserted into the uterus. Use of local anesthesia predominates in the United States. Although local anesthesia does not completely relieve discomfort, it is less expensive and safer than general anesthesia. As with EPL, the benefits as well as the risks must be considered before using general anesthesia. It is a good general rule, when performing abortions under local anesthesia, to use slow, controlled movements. A support person who can talk to the patient also helps alleviate anxiety and discomfort.

Paracervical Anesthesia

To perform a PCB, the clinician should use the smallest volume of the lowest concentration of local anesthetic. Local anesthetics vary in their toxicity; for example, chlorprocaine is substantially less toxic than lidocaine. With lidocaine, a 0.5% concentration is safer than a 1% solution and is equally effective. The total dose of lidocaine should not exceed 5 mg/kg or 300 mg, whichever is less. Maximum is approximately 20 mL of 1% lidocaine or 0.25% bupivacaine for a 50-kg woman, with 10 mL being typically sufficient. Alternatively, use of local anesthesia with vasoconstrictor (e.g., epinephrine 1:200,000) slows systemic absorption of anesthetic and allows a larger total dose, although the epinephrine has additional risks and side effects. Some clinicians buffer the lidocaine solution with sodium bicarbonate to decrease burning. Vasovagal episodes occur rarely and can be treated with atropine.

Paracervical anesthesia is widely used prior to abortion procedures and has been shown to decrease pain from cervical dilation and uterine aspiration. Approaches include infiltration of the cervix at the 12-o'clock position (for application of the tenaculum) and then injection at four sites (at the 2-, 4-, 8-, and 10-o'clock positions) or two sites (at the 4- and 8-o'clock positions) at the junction of the cervix and vagina. Submucosal injection precludes inadvertent intravascular injection. Despite its widespread use, a systematic review of pain control for first-trimester abortions found insufficient evidence of a clear benefit to PCB and was not able to support its use without further well-designed RCTs. This systematic review did find evidence of decreased pain with first-trimester procedures in women who were given conscious sedation and general anesthesia or who listened to music during the procedure. In 2012, Renner et al. performed an RCT, single blinded with a sham arm to minimize confounders with adequate power to detect differences in perceived pain, and were able to demonstrate a clear decrease in pain in the PCB group and higher satisfaction overall with the abortion experience. Deep injection (3 cm) and a delay of a few minutes between injection and dilation may maximize the benefits of the PCB.

Hemorrhage Prophylaxis

Intraoperative blood loss is typically minimal with surgical management for induced abortion (as well as for EPL). Although many clinicians routinely provide misoprostol, methylergonovine maleate (methergine), or oxytocin with first- or second-trimester uterine evacuation, evidence for use of uterotonics to prevent significant blood loss is limited. For first-trimester procedures, one study has shown that intramuscular methergine significantly decreases uterine atony and need for reaspiration. However, oral methergine is unstable at room temperature and utilizing it for prophylaxis is not recommended. Prophylactic oxytocin does not significantly decrease blood loss in the first trimester. And there are no studies of misoprostol use in this setting.

In the second trimester, an RCT found that vasopressin administered with paracervical anesthesia significantly

decreases blood loss with D&E, most notably at later EGAs. As little as 4 U (0.2 mL) mixed in with the anesthetic lowers the blood loss significantly; overall, vasopressin lowers fourfold the risk of a hemorrhage of 500 mL or

more. It is important to remember to administer vasopressin when opting to administer regional or general anesthesia, in which case the vasopressin can be mixed with saline and injected paracervically. The SFP guideline for postabortion hemorrhage recommends its routine use with D&E to decrease blood loss. 400 μ g of misoprostol, when studied alone or with osmotic dilators for preoperative cervical preparation, was found to have little to no effect on blood loss. Larger misoprostol doses, as are typical for controlling postpartum hemorrhage, have not been studied for postabortion hemorrhage. Administration of oxytocin during D&E procedures after 20 weeks, when oxytocin receptors are present to some degree, may be helpful in preventing excess blood loss, and its use is determined by provider preference. Lack of evidence for prophylactic use does not preclude the use of uterotonics for treatment of hemorrhage (see [“Immediate Complications”](#)).

Manual Vacuum Aspiration

As with EPL, sharp curettage is an obsolete method for induced abortion, supplanted by uterine aspiration, which usually involves dilation of the cervix, followed by manual or electric vacuum (suction) aspiration at 12 to 14 weeks gestation or earlier. *Menstrual regulation*, *menstrual extraction*, and *minisuction* are euphemisms for early uterine aspiration and are used widely in many parts of the world. The most common technique used for this early “regulation,” as well as later procedures done by manual vacuum with syringe, is MVA. This technique uses a plastic cannula as small as 3 mm in diameter and as large as 12 mm, with a self-locking syringe (50 to 60 mL) as a source of suction ([Fig. 33.2](#)). A large series using MVA in early pregnancy reported a 99% success rate on nearly 2,400 abortions done at less than 6 weeks gestation. MVA has been shown to be as safe and effective as electric vacuum through 10 weeks of gestation and can be used in conjunction with forceps in later procedures. For early MVA procedures, dilation is often unnecessary. Consequently, anesthesia may not be necessary, although analgesia can ease the cramping that occurs toward the end of the aspiration. After insertion of the appropriate cannula, the clinician attaches the syringe and releases the pinch valve to create a vacuum and begin suctioning. Alternatively, some clinicians connect the cannula to the syringe before insertion. The abortion involves rotary and in-and-out cannula movement, allowing blood and tissue flow into the syringe. This should be repeated until the gritty feel of the endometrium occurs and bubbles appear in the syringe, indicating completion of the procedure. The clinician should not remove the cannula from the uterus while a vacuum exists in the syringe, because the endocervical canal should not be aspirated; likewise, the clinician should not advance the plunger of the syringe while the cannula is connected and is within the uterus. Air embolism can result. The syringe and cannula are technically disposable, although standard instructions are available for providers to disinfect the syringe and use it multiple times.

Electric Vacuum Aspiration

Electric vacuum aspiration requires few instruments. It is useful to have an ultrasound machine available in case one is not able to enter the uterus or suction adequate tissue; however, ultrasound is not necessary to perform abortions. Most clinicians prefer to use a bivalve speculum. A speculum with standardlength blades, however, prevents the cervix from being drawn toward the introitus during the procedure and makes the operation more difficult. The commercially available Moore modification of the Graves speculum, which has 1-inch shorter blades of standard width, prevents this. Some clinicians prefer an atraumatic tenaculum; however, these tend to slip off more readily than does the single-toothed variety. Alternatively, having an extra single-toothed tenaculum can sometimes be helpful. If difficulty during dilation occurs, the clinician can place the second tenaculum on the posterior cervix to stabilize it. Sounding before the procedure is unnecessary and should not be done, as it increases the risk of perforation. If the direction of the cervical canal is in question, then the clinician can gently probe with a small dilator. Pratt dilators are preferable to Hegar dilators for abortion because they require less force to dilate the cervix. A useful modification of the Pratt dilators is the Denniston dilator; this is similar to the Pratt dilator but is plastic. Hence, it is light, slightly flexible, and inexpensive, yet it is capable of being autoclaved.

Traction on the cervix is important during suction aspiration; it both stabilizes the uterus and straightens the angle between the cervix and corpus, which should reduce the risk of perforation. The tenaculum should have a firm purchase on the cervix. High vertical placement at the 12-o'clock position, with one tooth in the canal and one on the anterior cervix, almost eliminates the risk of the tenaculum tearing through during dilation. In contrast, a superficial horizontal application of the tenaculum is more likely to allow the tenaculum to pull off but will not obscure the vision and movement of instruments for the provider. If the uterus is retroverted, some clinicians prefer to place the tenaculum on the cervix at the 6-o'clock position ([Fig. 33.3](#)). If the puncture site on the cervix bleeds after tenaculum removal, direct pressure nearly always stops the bleeding. Silver nitrate or Monsel

solution can be used if pressure does not achieve hemostasis. While use of the tenaculum straightens the angle of the uterus, the operator must remain cognizant of the anatomy. For an anteverted uterus, instruments used for the procedure often need to be at an angle, with the intrauterine

P.758

tip of the instrument pointing upward. If the instrument was inserted straight back in a patient like this, there would be an increased risk for posterior perforation.

FIGURE 33.3 Traction on the cervix during dilation. **Top:** Tenaculum placed vertically on the anterior lip. **Bottom:** Tenaculum placed vertically on the posterior lip for a retroverted uterus. Note posterior direction of dilator.

Gentleness is the key to safe cervical dilation. Dilation should allow insertion and rotation of the desired cannula. Pratt dilators are measured in French units or mm of circumference. Hence, to determine the diameter, the clinician needs to divide by pi or approximately 3. For example, to insert an 8-mm cannula, dilation with Pratt dilators to 25 F allows free rotation. The clinician should hold the dilator between the thumb and index finger to limit the force applied. In addition, the other fingers can remain extended to prevent plunging forward in case of sudden loss of resistance. No-touch technique or protecting ends of dilators and cannulas that enter into the uterine cavity should be practiced meticulously throughout the procedure. Dilation need not start with the smallest dilator on the set; starting with a larger size (e.g., 15 F instead of 13 F) may reduce the risk of perforating the uterus or creating a false channel.

If more than two fingers of force is necessary during dilation, the clinician should stop and reassess the situation, rather than risk injuring the cervix. One option is to use a smaller cannula than originally planned. Alternatively, the clinician can pack the cervix with one or more osmotic dilators, interrupt the procedure, and then complete the operation several hours later, by which time adequate dilation will have been achieved. Another treatment option is to administer oral or vaginal misoprostol and complete the procedure in several hours. Performance of the procedure in two stages is far preferable to forceful dilation.

After adequate dilation, the clinician inserts the cannula. In general, the diameter of the cannula in millimeters should be equal to the weeks of gestation from last menses, plus or minus 1 week. For example, an 8-mm cannula may be adequate for evacuating a pregnancy of 9 weeks 0 days' gestation, but a 10-mm cannula may be used to evacuate a pregnancy of 9 week 6 days if cervical dilation allows. The exception is for patients with uterine fibroids, in which added uterine size is not related to intrauterine tissue. Skilled clinicians often prefer to use even smaller cannulas than this guideline suggests; the clinician must weigh the advantage of needing less dilation against the potential disadvantages of longer operating time and an increased risk of incomplete abortion.

FIGURE 33.4 Distal ends of rigid curved 8-mm cannula and flexible 8-mm cannula with twin whistle-tip ports.

The most frequently used cannulas in the United States are clear plastic, with a slight angulation ([Fig. 33.4](#)). The clinician should insert the cannula into the lower uterine segment. For electric vacuum aspiration, a hose with a swivel handle attaches to the cannula and then to the vacuum machine. The clinician then turns on the suction machine and aspirates the uterus with the cannula ([Fig. 33.5](#)). One of the principles of abortion technique is to start working in the lower uterine segment. The fundal contents of the uterus are brought down by suction and the involution of the uterus as it empties. The flexible plastic cannula ([Fig. 33.5](#)) suctions opposite sides of the cavity simultaneously and provides a distinct gritty sensation when the evacuation is complete. Bubbles will also appear in the suction tubing when the procedure is complete. Some clinicians use a sharp curette to check for completeness at the

P.759

end of the operation; however, completion of the procedure can be determined by the grittiness of the endometrium and the pink bubbles in the tubing, and routine use of the sharp curette should be avoided to maximally decrease the risk of perforation. If the gritty sensation is not appreciated with a rigid plastic cannula, a small (e.g., 8-mm-diameter) Karmantype double-port cannula provides the same gritty sensation as a metal curette and is far safer.

FIGURE 33.5 Uterine aspiration. **Top:** Cannula inserted just beyond internal os. **Bottom:** Aspiration with rotating motion.

The operation is not finished until the clinician or another trained observer has examined the aspirated tissue. This is to confirm the presence of fetal tissue, which usually excludes the possibility of an ectopic pregnancy. Since 1972, more than 20 women in the United States have died from ectopic pregnancies undetected at the time of attempted suction aspiration. This tissue inspection will not detect the rare twin ectopic pregnancy, commonly termed “heterotopic.”

Pregnancies of 9 weeks gestation and later will have recognizable fetal parts; earlier pregnancies may not. Identification of chorionic villi and membranes in these earlier pregnancies is essential. The clinician rinses the aspirated tissue in a fine mesh strainer under tap water to remove blood and clots. A glass dish is useful for examining the tissue suspended in water ([Fig 33.6](#)). For early pregnancies, white vinegar (instead of water) may facilitate the recognition of villi. Back lighting from a horizontal x-ray viewing box is especially useful ([Fig. 33.6](#)). Villi appear soft, fluffy, and feathery, with discernible fingerlike projections; in contrast, decidua appears coarse and shaggy ([Fig. 33.7](#)). Amnion and chorion are filmy and transparent; decidua is translucent. With early pregnancies, a magnifying glass, dissecting microscope, colposcope, or standard microscope (3,100) can help identify villi ([Fig. 33.8](#)). It is essential to learn the difference between the appearance of villi and decidua; this is useful in the management of EPL, as well as in distinguishing between bleeding from EPL and ectopic pregnancy.

When the clinician cannot confirm fetal tissue, he or she should reevaluate the patient, with special attention to the adnexa. Repeat aspiration (perhaps with ultrasound guidance) is often appropriate. A sensitive urine pregnancy test or a quantitative β -hCG can be helpful. Ultrasound can sometimes identify a gestational sac. Failure to identify villi in the presence of a positive pregnancy test suggests several possibilities: recent spontaneous abortion, failed attempted abortion, perforation with aspiration outside the uterus, or ectopic pregnancy. The clinician must carefully evaluate these possibilities.

FIGURE 33.6 Examination of aspirated tissue over x-ray viewing box for back lighting.

FIGURE 33.7 Left: Typical fluffy villi of placenta. **Right:** Shaggy decidua. (Reprinted from Munsick RA. Clinical test for placenta in 300 consecutive menstrual aspirations. *Obstet Gynecol* 1982;60:738, with permission. Copyright © 1982 The American College of Obstetricians and Gynecologists.)

Women with uterine anomalies, such as a bicornuate uterus, have a high risk of failed attempted abortion. Sometimes, the unique anatomy makes it difficult to enter the horn with the pregnancy. One useful approach is to perform the aspiration under ultrasound guidance. If the clinician can insert a bent sound into the cavity with the pregnancy, he or she can then place the bent sound inside a flexible 8-mm plastic cannula as a stent or guide. With ultrasound guidance, the clinician then inserts the cannula into the cavity and removes the sound, connects the cannula adapter, and then aspirates the cavity. Another alternative is to use medical abortion. Rarely, hysterotomy may be needed if aspiration and medical abortion fail in the setting of müllerian anomalies.

FIGURE 33.8 Wet-mount microscopic appearance of placental villi. (Reprinted from Munsick RA. Clinical test for placenta in 300 consecutive menstrual aspirations. *Obstet Gynecol* 1982;60:738, with permission. Copyright © 1982 The American College of Obstetricians and Gynecologists.)

Dilation and Evacuation

D&E is the surgical technique recommended for pregnancies beyond 12 to 14 weeks gestation, utilizing advanced cervical dilation, followed by evacuation of fetus and placenta via suction and forceps. During the 1970s, D&E emerged as the most frequently used method for second-trimester abortions. The proportion of abortions performed by surgical (aspiration or evacuation) techniques is inversely related to gestational age (Table 33.1). Even at gestations greater than 20 weeks, D&E remains the dominant method of abortion in the United States. In April 2007, the U.S. Supreme Court upheld a decision to ban an abortion procedure called D&X, in which there is a partial breech delivery of a fetus and decompression of the calvarium to complete the delivery. The law does not contain an exception to permit the procedure to protect the health and life of the mother. Broader repercussions of this ruling are unknown.

TABLE 33.1 Percentages of Reported Legal Abortions, by Method and Gestational Age, Selected States, United States, 2009

TYPE OF PROCEDURE	%		
Suction aspiration (≤ 13 wk)	74.4		
D + E (> 13 wk)	8.0		
Medical (≤ 8 wk)	15.3		
Medical (> 8 wk)	0.9		
Other (includes hysterotomy, hysterectomy, and others)	1.6	100.0	100.0

STEPS IN THE PROCEDURE

Surgical Abortion Care

- Understand state-specific legal requirements for abortion provision.
- Preoperative medical evaluation:
 - Options counseling
 - Informed consent
 - Brief history and limited physical exam
 - Establishment of gestational age
 - Decide upon most appropriate surgical procedure
 - Hb and Rh status
- Preoperative cervical preparation if indicated.
- Administration of prophylactic antibiotics.
- Administration of anesthesia if other than local anesthesia indicated.
- Dorsal lithotomy position.
- Empty the bladder if the patient has not already done so.
- If suction aspiration (MVA or EVA):
 - Bimanual exam if not done in preoperative evaluation or different provider.
 - Follow no-touch technique for remaining steps.
 - Insert speculum.
 - Apply antiseptic to cervix.
 - Apply tenaculum to cervix.
 - Administer paracervical block if indicated.
 - Gently perform cervical dilation appropriate for gestational age and chosen cannula size.
 - Gently insert cannula, attach syringe or suction tubing, and gently begin repetitive rotary and in-and-out motions to evacuate tissue.
 - Limit number of passes through the cervix.
 - The procedure is complete when the endometrium has a gritty feel in all quadrants, no further tissue is evacuated, and pink foamy bubbles appear in the cannula.
 - Examine the aspirate and ensure it correlates with expected findings for gestational age.
 - Remove tenaculum.
 - Assess for hemostasis.
 - Remove speculum.
 - Return to dorsal supine position.
- If dilation and extraction:

- Remove vaginal gauze and laminaria if placed, and ensure the number removed correlates with the number placed.
- Insert speculum.
- Place ring forceps on anterior lip of the cervix.
- Administer vasopressin.
- Assess cervix for adequate dilation.
- Insert 14- or 16-mm cannula, attach to suction tubing, and drain amniotic fluid.
- Insert forceps (under ultrasound guidance if preferred), and remove tissue. Evacuation should occur from the lower uterine segment whenever possible and in as few passes as possible through the cervix and uterus to minimize risk of perforation and cervical trauma.
- Confirm complete evacuation with 1 pass with the cannula.
- Examine tissue to confirm removal of all fetal parts.
- Ensure hemostasis, and remove ring forceps and speculum.
- Return to dorsal supine position.

Based on data from the 1970s, D&E is clearly safer than alternative methods through 16 weeks gestation. At later gestational ages, the distinction blurs between D&E and labor induction methods in terms of morbidity and mortality. Patients often prefer D&E because they avoid experiencing labor. However, many physicians have not been surgically trained to provide later D&E procedures. Often, the choice of

P.761

abortion method at this later stage depends on access to abortion services, the presence of skilled personnel, and whether the fetus needs to be intact for autopsy after fetal loss. When fetal cardiac activity is present, some physicians prefer to administer feticidal agents, such as digoxin or potassium chloride, under ultrasound guidance preoperatively. A randomized, controlled trial by Jackson and colleagues found that doing so had no operative benefit. The use of feticidal agents, either intra-amniotic or intrafetal digoxin or fetal intracardiac potassium chloride, has not been shown to improve the safety of second-trimester medical or surgical abortions, and its routine use is not recommended. In select instances, such as a medical induction after 20 weeks gestation, women and/or providers may prefer feticide to avoid any transient fetal survival after expulsion. For D&E procedures, accurate preoperative determination of gestational age by ultrasound is essential. Underestimation of gestational age can lead to inadequate dilation, which complicates the procedure. D&E differs from uterine aspiration in two principal ways: D&E requires wider cervical dilation, and physicians need forceps to evacuate more advanced pregnancies.

Dilating the cervix to a large diameter over several minutes manually can damage the cervix. Indeed, the first large study of this question revealed a higher incidence of low-birth-weight infants in subsequent desired pregnancies. Hence, D&E procedures beyond about 14 weeks gestation should use osmotic dilators or misoprostol or both for cervical preparation. Patients must understand that once osmotic dilators have been inserted, the abortion needs completion. Occasionally, the patient may abort just from the dilator, but out-of-facility expulsion is rare. Rarely, a patient changes her mind about abortion after placement of an osmotic dilator. Although some women have continued their pregnancies uneventfully after removal of the devices, others have developed infections and/or aborted.

To achieve adequate dilation, many clinicians insert osmotic dilators several hours to several days before D&E ([Fig. 33.9](#)). For example, five laminaria placed overnight result in 1.5- to 2-cm dilation with minimal discomfort for most women. Use of a single Lamicel for about 4 hours produces as much dilation as do several laminaria at 14 to 16 weeks gestation, and the same is true for the use of a single Dilapan-S.

In the 13- to 16-week interval, vacuum aspiration alone is often adequate; thereafter, forceps evacuation predominates. A cannula 14 mm in diameter can evacuate pregnancies through about 16 menstrual weeks

gestation. For later pregnancies, the cannula primarily drains amniotic fluid at the beginning of the evacuation and draws tissue into the lower uterus for forceps evacuation. Specially designed Bierer forceps for D&E are far superior to standard sponge forceps, as they are designed to cause minimal trauma to the surrounding endometrium. As with suction aspiration, evacuation should occur from the lower uterus to minimize the risks of perforation. Some physicians use the cannula with suction at the end of the procedure to confirm complete evacuation. Some physicians routinely perform D&E procedures under ultrasound guidance, although this is not a requirement.

FIGURE 33.9 Laminaria in place after overnight preparation of the cervix. (Reprinted from Grimes DA, Hulka JF. Midtrimester dilatation and evacuation abortion. *South Med J* 1980;73:448, with permission. Copyright © 1980 Southern Medical Association.)

The physician must confirm completion by identifying all major fetal parts (four extremities, spine, and calvarium). The calvarium is the component most frequently missed during the initial evacuation. Gentle exploration of the fundal and cornual areas with the forceps usually enables location and removal of the calvarium. Intraoperative ultrasonography can be helpful. If ultrasonography is not available, the physician may be able to remove the speculum and insert one digit into the uterine cavity to locate the missing part.

If the abortion cannot be completed with ease, the physician should interrupt the procedure. If the patient is hemodynamically stable, a safe and simple remedy is to discontinue the operation and administer misoprostol or oxytocin for 2 to 3 hours in the recovery room. After the patient returns to the operating room, the physician usually finds the retained tissue at the internal os, from which it can be easily removed. No D&E abortion needs to finish in a single session; time often helps. Once membranes rupture, the uterus contracts to expel its contents.

In D&E abortions, the skill of the physician is critical. D&E abortion requires specific training that is often not routinely acquired in a US OB/GYN residency. The likelihood that a physician will offer abortion services is highly correlated with whether he or she was trained in residency. The physician should study operative technique. He or she should then observe and assist skilled physicians and then perform D&E procedures only under direct supervision. Use of ultrasound guidance for residents learning D&E was associated with a dramatic lowering of the perforation rate and a reduction in operating time. The gestational age range can advance as skill grows. In summary, D&E is a specialized surgical technique that can be learned with appropriate training.

Hysterotomy and Hysterectomy

Neither hysterotomy nor hysterectomy should be a primary method of abortion. The morbidity, mortality, expense,

and pain associated with these operations are greater than with alternative methods. Hysterotomy for abortion should be used only when usual surgical and medical approaches fail. **Figure 33.10** depicts a hysterotomy to evacuate a 14-week pregnancy in the left horn of a bicornuate uterus; both labor induction and attempts to enter to pregnant horn through the cervix with ultrasonography and laparoscopy guidance had failed in this primigravida. Hysterectomy is appropriate in rare cases in which preexisting pathology, such as large leiomyomata (**Fig. 33.11**) or carcinoma in situ of the cervix, justifies hysterectomy. Counseling regarding loss of future fertility and increased risk of complications compared to other approaches to abortion, that is, D&E or labor induction, should accompany any decision to perform a gravid hysterectomy for abortion.

Postoperative Care

Women should expect some spotting and bleeding after the procedure that improves with time and usually stops by 1 to

P.762

2 weeks. They should be instructed to notify the clinician with any signs of a complication: fever, pain, prolonged bleeding or bleeding more than a period, dizziness or weakness, passage of tissue, and ongoing symptoms of pregnancy. Pregnancy symptoms that do not dissipate within 1 week or normal menses not returning within 6 weeks are reasons to return. They should be given 24-hour emergency phone numbers. Any woman whose procedure did not definitely identify tissue should be actively managed to rule out ectopic pregnancy. Women may resume work the day following an abortion or when they feel up to it.

FIGURE 33.10 Hysterotomy incision in left uterine cavity, 14 weeks gestation, after failed labor induction abortion and failed attempted dilation and evacuation. The patient had a single cervix and two cavities. Nonpregnant cavity seen at right.

Almost all forms of contraception may be started on the day of an abortion procedure, including the placement of intrauterine devices. Commonly, a postoperative visit is scheduled 2 to 3 weeks after the procedure to ensure complete abortion and rule out any complications. However, there is no medical need for a routine follow-up after a surgical abortion. If women are thoroughly educated regarding the signs and symptoms of an ongoing pregnancy or other complications, and encouraged to follow up with any of these issues, questions, or concerns, routine postoperative visits can be avoided. Alternatively, many providers find this visit useful to assess contraceptive use and satisfaction, as well as to provide regular gynecologic care that may not be a routine part of the preoperative abortion care—for example, cervical cytology. Routine β -hCG testing should not be done at

this visit. After an uncomplicated procedure, β -hCG can be detected for a mean of 30 days and up to 60 days. Therefore, it is not useful for ruling out retained tissue and causes confusion when found to be positive.

Early Medical Abortion

Early medical abortion has also begun to play a significant role in provision of abortion, accounting for 16.5% of procedures in 2009. As an alternative to surgical abortion, early medical abortion has allowed for increased access to abortion at earlier gestations and via more nontraditional providers such as family medicine physicians. The most effective regimen for early medical abortion is the antiprogesterone mifepristone plus the prostaglandin misoprostol. Mifepristone is a derivative of norethindrone; it binds to the progesterone receptor but does not activate it. When bound, it blocks progesterone activity and acts to alter the decidua, allowing trophoblast separation. This alone can lead to bleeding and in vivo prostaglandin release that can cause an abortion in early pregnancy. Mifepristone alone, however, results in completed abortion 64% to 85% of the time. For induced abortion, success rates are significantly increased when mifepristone is combined with a prostaglandin analogue that dilates the cervix and contracts the uterine muscle to expel the pregnancy. The regimen approved by the U.S. Food and Drug Administration (FDA) calls for a single oral dose of mifepristone 600 mg, followed in 48 hours by misoprostol 400 mg orally, both doses given in the clinician's office. This has been approved for use up to 49 days' gestation. Success rates with this regimen range from 92% to 97%.

Several RCTs have investigated this regimen. Data currently support alternative dosage, route, timing, and gestational age criteria than those established by the FDA guidelines. These changes result in improved efficacy and patient convenience, decreased cost, and sustained safety.

Several studies have shown that 200 mg of mifepristone effect abortion at rates equivalent to 600 mg. El-Refaey and colleagues first reported this finding in 1995. This was confirmed by a study by WHO, reporting in 2000 that there was found no difference in the completed abortion rate between women given 200 mg of mifepristone compared with those given 600 mg. Additionally, this study included women up to 63 days' gestation. This equivalence in dosing is secondary to nonlinear pharmacokinetics. The binding site for the mifepristone is rapidly saturated. Women given 100 mg, 200 mg, and 800 mg have a peak serum concentration of 2.0 to 2.5 μ g/mL approximately 2 hours after ingestion, regardless of dosage given. Therefore, pharmacology and economics support use of 200 mg mifepristone.

Several studies have also investigated misoprostol dosing and route of administration. As with cervical preparation, vaginal dosing of misoprostol has superior efficacy with less side effects overall when compared with oral dosing. Schaff and colleagues compared oral (400 µg and 800 µg) versus vaginal (800 µg) misoprostol following 200 mg mifepristone. Compared to either dose of oral misoprostol, they found a statistically significant higher level of completed abortions in those who received vaginal misoprostol (84%, 92%, and 96%, respectively). Randomized trials have found that buccal or sublingual dosing was equivalent to vaginal dosing in efficacy, but with more side effects.

P.763

Investigators have also questioned the timing of the misoprostol dosing and where it should be administered. Acceptability of women to self-administer the misoprostol at home has been shown repeatedly. Schaff and colleagues also explored efficacy of different schedules of prostaglandin administration. Following 200 mg of mifepristone, more than 2,000 subjects were randomized to self-administration of 800 µg misoprostol vaginally 24, 48, and 72 hours later. Completed abortions were found in 98%, 98%, and 96%, respectively. Patient satisfaction decreased with increasing time interval. However, decreasing the time interval further to 6 hours post mifepristone has been associated with decreased success in two randomized trials. With patient acceptability and convenience of avoiding additional clinic visits, self-administration of misoprostol at home 24 to 48 hours after mifepristone allows for an effective but flexible regimen for patients.

Lastly, the upper limit of gestational age can be extended to 63 days. When mifepristone 200 mg is followed in 24 to 48 hours by misoprostol 800 mg vaginally, complete abortion rates 95% or greater can be achieved through 63 days' gestation; this has been supported by several trials. Some small studies have found success using the combination of mifepristone and misoprostol for gestations up to 91 days; however, most agree that the likelihood of success declines with advancing gestational age.

If the alternative, evidence-based regimen is chosen, appropriate patient consent and education about variance from the FDA regimen are required in order to dispense mifepristone. NSAIDs, antiemetics, and antidiarrheals can decrease associated side effects. Narcotic prescriptions can be provided for additional pain control as needed. Women undergoing medical abortion who do not bleed within 24 hours of receiving misoprostol should contact their provider, as they may be at higher risk of ectopic pregnancy. Follow-up can be accomplished as early as one week post mifepristone, using repeat ultrasound or serum β -hCG to rule out a continuing pregnancy. Alternative follow-up protocols utilize clinical symptoms and low sensitivity urine pregnancy tests to determine which women need further evaluation for unsuccessful abortion. An inability to follow up in the time frame specified or in the event of an emergency should preclude provision of a medical abortion. In the few percent of women who fail to abort or who have incomplete abortions, observation or repeated dosing of misoprostol can be offered. For women who continue to have vaginal bleeding, in-office completion of the process with a handheld syringe and cannula ([Fig. 33.4](#)) is an option. If aspiration is needed, no additional dilation is usually required. Patients should be counseled before starting that in the rare event of ongoing pregnancy after medical abortion, suction aspiration is recommended because of the teratogenic effects of misoprostol.

Medical abortion is safe, effective, and well tolerated. With current regimens, cramping and bleeding are common, but infection and bleeding heavy enough to require transfusion are rare. Data collected from postmarketing experience since the FDA approval of mifepristone in the United States in September 2000 have demonstrated the safety. More than 460,000 women have undergone medical abortion in the United States between 2000 and mid-2005. Serious complications have included seventeen ectopic pregnancies, hemorrhage requiring blood transfusion (in < 0.03%), and seven serious bacterial infections, including five deaths from *Clostridium sordellii* sepsis. In light of potential complications and the abortion experience occurring outside of the provider's office, thorough counseling and patient understanding are imperative.

Before the marketing of mifepristone in the United States, physicians relied on other medical abortifacient regimens. One regimen included a single intramuscular injection of methotrexate, 50 mg/m² body surface area, followed 3 to 7 days later by vaginal administration of misoprostol, 800 µg. The efficacy of the combined regimen was 90%. In a randomized, controlled trial, this regimen proved superior to the same dose of misoprostol given alone. At 49 days' gestation or less, methotrexate and misoprostol can achieve success rates similar to those with mifepristone and misoprostol, but the process is slower with methotrexate: Providing the misoprostol at 7 days postmethotrexate rather than 3 days has been shown to increase efficacy to as high as 98%. From 20% to 30% of women require 1 to 5 weeks to complete the abortion. On the other hand, methotrexate remains an option when mifepristone is not available or when ectopic pregnancy cannot be ruled out. Methotrexate works as an antimetabolite; it continues to be used in the medical management of ectopic pregnancy.

Another alternative is use of misoprostol alone. The success rates with misoprostol alone have consistently been shown to be lower than when misoprostol is used as an adjunct with mifepristone or methotrexate. Although gastrointestinal side effects increase with multiple doses, success rates with multiple doses approach 93%, and therefore, a multidose regimen is a viable option when mifepristone is not available. Similar to when misoprostol is used with mifepristone, buccal or sublingual dosing is as effective as vaginal dosing but tends to lead to more side effects.

Medical approaches may be especially useful for challenging abortions. These include patients with müllerian anomalies, large cervical leiomyomata, prior failed attempted abortion, or obesity. Should the medical regimen not effect abortion, surgical completion is made substantially easier by this preparation of the cervix.

Labor Induction

Although D&E has supplanted many labor induction abortions, the need for such abortions continues, particularly at later gestational ages. In contrast to D&E, the proportion of abortions performed by labor induction increases with gestational age ([Table 33.1](#)). However, available resources or provider training typically dictates whether both D&E and induction can be offered, as D&E is more cost-effective than is induction but requires specialized surgical training. For settings and clinical presentations in which woman can self-select the method used, grief processes are unaffected by method chosen. Medical abortifacients in the United States used for induction of labor in the second trimester include uterotonic drugs, such as prostaglandins and oxytocin, with or without mifepristone. Uterotonics act directly on the myometrium to stimulate contractions. Prostaglandins available in the United States include misoprostol, vaginal prostaglandin E₂ (PGE₂) preparations, and 15-methyl PGF_{2a} for extra-amniotic use. Extra-amniotic administration of ethacridine lactate is an induction method that is infrequently used. The practice of intrauterine instillation of hypertonic solutions (saline, urea) has significantly decreased since the 1990s. Because of the increased induction time, the potential serious side effects, and the availability of safe and effective alternatives, the use of this method is not recommended.

Misoprostol as a second-trimester induction agent has emerged as a safe and effective agent. Its ease of use, affordability, and stability at room temperature make it a first-line prostaglandin option. The first study by Jain and Mishell used 200 µg vaginally every 12 hours, which was found to be as effective as vaginal PGE₂ suppositories and was associated with fewer side effects. As with early medical abortion, efficacy is significantly increased when 200 mg of mifepristone

is combined with misoprostol. Starting misoprostol dosing 48 hours versus 24 hours after mifepristone results in shorter induction time, though the overall success rate is not affected. In RCTs, dosing intervals for misoprostol seem to affect induction times more so than the dose itself: Three-hour intervals result in shorter induction times. Misoprostol doses lower than 400 mcg are effective when preceded by mifepristone or a loading dose of 600 to 800 µg misoprostol. Oral, vaginal, and sublingual dosing appear to be equally effective when preceding by a

loading dose, with the exception of nulliparous women who may benefit more from continued vaginal dosing. Studies have not been consistent as to whether women prefer nonvaginal over vaginal administration. Neither moistening the misoprostol nor adding laminaria dilators improves efficacy. The regimen recommended by the Royal College of Obstetricians & Gynaecologists and the WHO is based on a trial by Ashok et al. Thirty-six to forty-eight hours following 200 mg of mifepristone, 800 µg misoprostol was given vaginally followed by 400 µg orally every 3 hours, with a maximum of four oral doses. If abortion did not occur, patients rested for 12 hours before the misoprostol dosing was repeated. This regimen resulted in 97% successful abortion with a mean induction to abortion time of 6.25 hours (in those that were successful). Of the 1,002 patients in the study, complications were seen in 11 (0.01%): Ten had significant bleeding, and seven of these women required transfusion. One woman had significant hemorrhage and was found to have a myometrial tear upon laparotomy. She had received one dose of prostaglandin. Both mifepristone and misoprostol are not currently labeled for second-trimester termination.

Clinical trials of induction regimens have varied in terms of gestational age range, definition of success (delivery of the fetus vs. fetus and placenta), and medication combination or dose utilized, often preventing direct comparison between regimens. The high success rates observed in several of these trials suggest that regimens may be safely adjusted to fit the clinical presentation. When mifepristone is not available or infection requires immediate induction, misoprostol alone still results in high success rates. Although feticide with digoxin or potassium chloride does not improve success rates, it may be used to prevent the possibility of a live birth. Other prostaglandin regimens can be safely and feasibly administered. If prostaglandins are not available or are contraindicated, oxytocin alone can result in completed abortion up to 90% of the time, though induction time is longer. The frequency of fever, vomiting, and diarrhea was significantly lower with oxytocin compared with PGE₂ and misoprostol, but more attention is required in order to avoid complications. One regimen includes oxytocin, 50 U in 500 mL of dextrose and normal saline administered intravenously over 3 hours; maintenance fluid (dextrose in normal saline) then follows for 1 hour. In stepwise fashion, the concentration of oxytocin increases by 50 U every 4 hours to a maximum of 300 U/500 mL. The investigators administered oxytocin in isotonic fluid and interrupted the oxytocin infusion every 4 hours for diuresis. With prolonged high-dose oxytocin infusion in hypotonic solutions, water intoxication and death can result.

The decision about labor induction in women with a previous uterine scar remains a difficult one for clinicians. There are reports of uterine rupture both with and without previous cesarean delivery and with almost all induction methods. A systematic review of uterine rupture associated with misoprostol induction in the second trimester found that the rupture rate was 0.28% in women with a previous hysterotomy compared with 0.04% in women with an unscarred uterus. Conversely, a case series of 100 women at 14 to 28 weeks with previous cesarean delivery undergoing induction with misoprostol reported no uterine ruptures. Further study is necessary. Women with a uterine scar require detailed counseling about the risk of rupture. If induction is chosen, it should be completed in a hospital setting where complications can be managed appropriately.

One of only two RCTs that compared D&E to induction included intrauterine instillation and misoprostol induction, as well as later gestational ages in the induction arm only; there were higher rates of complications and surgery related to retained placenta with induction. When limited to just misoprostol induction, complication rates were still higher than with D&E, again predominantly related to retained placenta. However, Green et al. demonstrated a low (6%) curettage rate with misoprostol induction when they allowed women *who were not bleeding* up to 4 hours to deliver the placenta, suggesting there are ways to further increase the safety of induction. Women undergoing labor induction need the same meticulous, attentive obstetric care as do women in labor with childbirth, even if the need for cervical exams may not be as frequent. NSAIDs, antiemetics, and antidiarrheals can decrease associated side effects. Pain control can be successfully achieved with patient-controlled analgesia (PCA) pumps. If the membranes rupture, then labor must conclude within a reasonable

period. In many cases, the preferred means of concluding a slow induction abortion is D&E. Twenty-four hours is a reasonable limit for labor induction abortions. Frequently, the cervix is open several centimeters, and D&E proceeds quickly. If significant bleeding is present, then active management of a retained fetus or placenta prevents morbidity. If spontaneous delivery of the placenta has not occurred within a few hours after delivery, the placenta should be removed by suction aspiration. Notably, misoprostol is associated with a significantly lower rate of retained placenta when compared with PGE₂ or oxytocin (2% vs. 15%).

Complications

Morbidity

Legal abortion in the United States is safe. Less than 1 woman in 100 develops a serious complication, and less than 1 in 100,000 dies as a result of the operation. This mortality rate is far below the rate for women who elect to continue their pregnancy, which ranges from 10 to 14 times higher for women who progress to deliver a live infant.

Gestational age is one of two important determinants of the likelihood of morbidity. In [Table 33.2](#), which lists serious complication rates for abortion by gestational age, the term *serious complication rates* is defined as fever of 38°C or higher for 3 or more days, hemorrhage requiring transfusion, or unintended surgery. These data, derived from a 1970s multicenter study including 84,000 abortions, relate to those women without concurrent sterilization or preexisting medical conditions and for whom follow-up information was available. Abortions performed at the 7 to 10 weeks gestation interval had the lowest incidence of serious complications. Thereafter, complications increased progressively with advancing gestational age. The method of abortion is the second principal determinant of the likelihood of complications. [Table 33.3](#), derived from the same study as [Table 33.2](#), demonstrates that suction aspiration is the safest available abortion method. The risk of serious complications with D&E at 13 weeks gestation or later is higher than that with suction aspiration and lower than that with labor induction abortion.

Abortion complications have three temporal categories: immediate, delayed, and late complications. Immediate complications are those that develop during or within 3 hours of the operation. Delayed complications occur more than 3 hours

P.765

and up to 28 days after the procedure. Late complications develop thereafter.

TABLE 33.2 Serious Complication Rates for Legal Abortions by Gestational Age: United States, 1975-1978^a

GESTATIONAL AGE (WK)	RATE ^b
6	0.4
7-8	0.2
9-10	0.1
11-12	0.3
13-14	0.6

15-16	1.3
17-20	1.9

^aFor women with follow-up and without concurrent sterilization or preexisting conditions. Serious complications include temperature of 38°C or higher for 3 days or more, hemorrhage requiring blood transfusion, and any complication requiring unintended surgery (excluding aspiration).^bPer 100 abortions.

Immediate Complications

Hemorrhage Reported rates of hemorrhage vary widely, reflecting both diverse definitions (100 to 1,000 mL blood loss) and imprecision in estimating volumes of blood loss. Rates of hemorrhage range from 0.05 to 4.9 per 100 abortions in large case series reports. The best index of clinically important hemorrhage is probably the rate of blood transfusion. The rate of transfusion associated with suction aspiration in a large multicenter study was 0.06 per 100 abortions. For abortions performed later in pregnancy, investigators have reported hemorrhage and transfusion rates of up to 1 and 0.26 per 100, respectively, for D&E.

TABLE 33.3 Serious Complication Rates for Legal Abortions by Method: United States, 1975-1978^a

METHOD	RATE ^b
Suction aspiration	0.2
Dilation and evacuation	0.7
Saline instillation	2.1
Prostaglandin instillation	2.5
Urea-prostaglandin instillation	1.3

^aFor women with follow-up and without concurrent sterilization or preexisting conditions. Serious complications include temperature of 38°C or higher for 3 days or more, hemorrhage requiring blood transfusion, and any complication requiring unintended surgery (excluding aspiration).^bPer 100 abortions.

When hemorrhage occurs after suction aspiration, physical exam is necessary to determine if cervical laceration, uterine perforation, or atony is the most likely etiology. For uterine atony, administration of uterotonic agents and manual compression usually resolve the problem. Vasopressin can be injected intra- or paracervically. As with labor-related atony, methylergonovine maleate may be given (0.2 mg intramuscularly) as well as prostaglandins: carboprost 250 µg intramuscularly or misoprostol 1,000 µg per rectum. Administration of oxytocin during D&E, when oxytocin receptors are present to some degree, may

be helpful in controlling hemorrhage. Should bleeding persist, reassessment of the endometrial cavity by suction aspiration, with ultrasound if available, should be done to rule out retained tissue. Occasionally, internal compression of the cavity by a large Foley catheter or a Bakri balloon can be helpful. If these measures fail, uterine artery embolization can be done in a stable patient, with the last resort being hysterectomy.

With the increasing cohort of women who have had cesarean deliveries, the risk of encountering placenta accreta during abortion is increasing as well. In a series of more than 16,000 D&E abortions, the incidence of placenta accreta leading to hysterectomy was 4 per 10,000 cases.

Cervical Injury Cervical injury encompasses a broad spectrum of trauma. The most common type is a superficial laceration caused by the tenaculum tearing off during dilation. At the other extreme are the cervicovaginal fistula and the longitudinal laceration ascending to the level of the uterine vessels. Rates of cervical injury range from 0.01 to 1.6 per 100 suction aspiration abortions and increase up to 3% for D&E. Several risk factors for cervical injury during suction aspiration have emerged. Among factors within the control of the physician, use of laminaria and performance of the abortion by an attending physician (rather than a resident) lower the risk significantly, whereas use of general anesthesia raises the risk significantly. Use of laminaria and performance of the abortion under local anesthesia by an attending physician together yield a 27-fold protective effect. Cervical preparation with misoprostol may confer similar benefits as laminaria at early gestations, although more extensive experience will be needed to confirm this. Among factors beyond the control of the physician, later gestational age, previous cesarean delivery, and age of 17 years or younger increase the risk.

Acute Hematometra Also termed the *postabortal syndrome*, acute hematometra is an important complication of suction aspiration; its cause is unknown. The incidence of this syndrome ranges from 0.1 to 1.0 per 100 suction aspiration abortions, according to the available literature.

Women with this condition develop severe cramping, usually within 2 hours of the abortion. Vaginal bleeding is less than expected. The woman may be weak and sweaty and her uterus large and markedly tender. Treatment consists of prompt repeat aspiration, usually without anesthesia or dilation. Evacuation of both liquid and clotted blood leads to rapid resolution of the symptoms. The clinician can aspirate the blood with a suction cannula, a Karman cannula and syringe, or even a catheter attached to wall suction. Administration of a uterotonic after the repeat evacuation is standard. Whether routine prophylactic use of a uterotonic would reduce the incidence of acute hematometra is unknown.

Anesthesia Complications Pain experienced during abortion relates not only to the choice of anesthesia but also to the characteristics of the patient. Young women (13 to 17 years

P.766

old) and those with depression before the abortion report more pain than do other women.

Local anesthesia is safer than general anesthesia for both first- and second-trimester abortions. In an Italian study, use of general anesthesia had a relative risk for all complications combined of 1.8 (95% confidence interval, 1.4 to 2.5). The largest effect occurred with hemorrhage. Similarly, use of general anesthesia for D&E abortion in the United States increases the risk of serious complications. Overall, the attributable risk related to general anesthesia is low, and many women are willing to assume incremental risks in order to have no discomfort during the operation.

Perforation Perforation is a potentially serious but infrequent complication of abortion. The incidence of perforation is about 0.2 per 100 suction aspiration abortions.

Several risk factors for perforation exist. Performance of an aspiration abortion by a resident rather than by an attending physician increases the risk more than fivefold; on the other hand, cervical dilation by laminaria decreases the risk about fivefold. The risk of perforation increases significantly with advancing gestational

age. Multiparous women have three times the risk of nulliparous women. The use of routine ultrasound guidance for D&E was noted to reduce the risk of perforation in one study.

The two principal dangers of perforation are hemorrhage and damage to the abdominal contents. Lateral perforations in the cervicoisthmic region are particularly hazardous because of the proximity of the uterine vessels. Perforations of the fundus are more likely to be innocuous. Indeed, most perforations are not suspected or detected. In a series of patients undergoing combined abortion and sterilization by laparoscopy, the investigators found a sixfold higher rate of uterine perforation than they had suspected clinically (20 vs. 3 per 1,000 abortions).

Not all perforations require treatment. Many suspected or documented perforations require only observation. Perforation with a dilator or sound is unlikely to damage abdominal contents. If the perforation occurs before suction, the procedure can be completed under either ultrasound or laparoscopic guidance with extra observation after the procedure. On the other hand, a recognized perforation with a suction cannula or forceps warrants further surgery to rule out organ injury. It is recommended to administer broad-spectrum prophylactic antibiotics when perforation occurs.

If the clinician suspects a perforation, the procedure should stop immediately. If unmanageable hemorrhage, expanding hematoma, or injury to abdominal contents occurs, prompt laparotomy is necessary. In a stable patient, laparoscopy can be useful in documenting perforation and assessing damage; if necessary, the physician can complete the abortion under laparoscopic visualization. Any woman with severe pain within hours after the abortion should be evaluated for possible perforation with bowel injury.

Delayed Complications

Retained Tissue Although retained tissue after abortion can pass without incident, it can also lead to hemorrhage, infection, or both. This complication occurs infrequently, however. Its incidence after suction aspiration abortion is less than 1 per 100 abortions.

This complication usually manifests itself within several days of the abortion. Women present with cramping and bleeding, with or without fever. As with management of EPL, β -hCG levels are typically not helpful for diagnosis once an ongoing pregnancy has been ruled out. Similarly, the need for reaspiration is determined based on clinical symptoms and then confirmed by ultrasound findings, since the thickness of the endometrium after successful abortion is variable. Prompt administration of antibiotics along with outpatient suction aspiration is needed. Close follow-up is necessary.

Infection Postabortal infection can result simply from the procedure or from retained tissue. The organisms responsible for postabortal infection are similar to those responsible for other gynecologic infections. Administration of broad-spectrum antibiotics and uterine reaspiration (if retained tissue is present) are the cornerstones of therapy. The likelihood of febrile morbidity after abortion depends on the method used. The incidence of fever of 38°C or higher for 1 or more days is usually less than 1 per 100 abortions by suction aspiration. Corresponding figures for D&E are 1.5 per 100 abortions and for urea-prostaglandin, 6.3.

A number of risk factors for infection exist. Women are at increased risk if they have untreated endocervical gonorrhea or chlamydial infection. Later gestational age abortions also increase the risk. Likewise, use of local rather than general anesthesia for suction aspiration increases the risk. Preoperative prophylactic antibiotics decrease the incidence of infection.

Late Complications

Rh Sensitization Legal abortion is a potentially important cause of Rh sensitization for women at risk. The likelihood of sensitization increases with advancing gestational age (and, hence, larger volumes of fetal erythrocytes). One study has quantified the risk of Rh sensitization from first-trimester suction aspiration without RhIG prophylaxis. A total of 3.1% of women whose first pregnancy terminated by suction aspiration without RhIG prophylaxis had antibodies in their second pregnancy. Subtracting 0.5% (the percentage of

women estimated to have become sensitized primarily during the second pregnancy), the investigators estimated the risk of sensitization from suction aspiration to be 2.6%. Thus, on a nationwide basis, the clinical impact of failure to administer RhIG to candidates after abortion may be substantial. Candidates should receive 50 µg of RhIG after abortions performed at 12 weeks gestation or earlier or 300 µg after abortions performed later in pregnancy.

Adverse Pregnancy Outcomes Investigators have linked induced abortion with a broad array of adverse reproductive outcomes, ranging from infertility to ectopic pregnancy. Most published reports, however, suffer from serious methodologic shortcomings that limit their usefulness. To examine the potential association between first-trimester induced abortion and subsequent reproductive performance, epidemiologists have performed an exhaustive review and analysis of the world literature. This includes more than 150 epidemiologic studies published in 11 languages. The findings of this analysis are largely reassuring. No increase in the risk of secondary infertility and ectopic pregnancy appears, even in studies with substantial power to detect differences in rates. Midtrimester pregnancy loss is no more common among women who have had one previous abortion than among women pregnant for the first time. Similarly, the risk of premature delivery does not increase for women having undergone induced abortion. On the other hand, low birth weight is more frequent in first births after abortion by sharp curettage performed under general anesthesia compared with first-pregnancy births. This does not occur after other methods of abortion, such as suction aspiration. The question of the effect of repeat induced abortion and second-trimester abortion remains unresolved, but the increased risk associated with sharp curettage provides an additional reason why this method should be avoided. Firstborn infants of women who had one induced abortion

P.767

have risks of morbidity and mortality similar to those of other firstborn children.

FIGURE 33.12 Case fatality rates from legal abortion by year, United States, 1972 to 1987. (Reprinted from Bartlett LA, Berg CJ, Shulman HB, et al. Risk factors for legal induced abortion-related mortality in the United States. *Obstet Gynecol* 2004;103:729, with permission. Copyright © 1982 The American College of Obstetricians and Gynecologists.)

Additional studies have corroborated the absence of adverse effects of induced abortion on subsequent reproduction. Outcomes studied included infertility, ectopic pregnancy, spontaneous abortion, and adverse obstetric outcomes. One unresolved issue is placenta previa. Sophisticated studies have found either no or a marginally significant increase in the risk (relative risk, 1.3; 95% confidence interval, 1.0 to 1.6), which was comparable to that with EPL.

Induced abortion does not threaten a woman's emotional health. In contrast, the most common emotional reactions to induced abortion are a sense of relief accompanied by sadness and loss. In several studies, abortion appeared to improve the emotional well-being of women by resolving an intense personal crisis. Specifically, claims of a postabortion trauma syndrome lack scientific merit. Studies to date have failed to adequately assess or control for any preexisting mental illness in women who have had an abortion.

The putative association between induced abortion and breast cancer remains controversial. Although a number of case-control studies have found an association, this appears because of recall bias among controls. Women who are well (controls) are less likely to report prior induced abortions than are women with breast cancer (cases). This type of information bias has been documented in studies from Sweden. Two large cohort studies, which are less likely to be biased than are case-control studies, have shown either no effect or a protective effect of induced abortion on later breast cancer. No firm evidence links abortion to other cancers.

Mortality

Since 1972, when the CDC first began nationwide surveillance of abortion deaths, the safety of abortion has improved dramatically. As shown in [Figure 33.12](#), the overall death rate fell from 4.1 deaths per 100,000 abortions in 1972 to 0.7 in the data published for the decade between 1988 and 1997. In an extensive review by Raymond and Grimes in 2012, estimating the mortality rate associated with live births and legal abortions in the United States from 1998 to 2005 found the pregnancy-associated mortality rate for women who delivered a live neonate to be 8.8/100,000 live births and the mortality rate related to induced abortion to be 0.6/100,000 legal induced abortions. This demonstrates the risk of death to be 14 times higher for women continuing with pregnancy to a live birth than for women undergoing legal induced abortion. The most recent abortion surveillance report from the CDC, based on US data, reports a case fatality rate of 0.64 deaths per 100,000 reported legal abortions.

The causes of death from legal abortion have changed as well. After abortion became legal in 1973, abortion-related deaths declined because of an increase in the skill and experience of providers. When the abortion surveillance system identified procedures that increased risks, practitioners changed their procedures to increase safety. For example, this led to the decline of instillation procedures identified as riskier in the 1970s and the use of general anesthesia in the 1980s. For the 1998 to 2005 time period, the main causes of death were hemorrhage, infection, and complications from anesthesia, which accounted for nearly three fourths of deaths. Embolism, noncardiovascular conditions, cardiovascular conditions, and other causes accounted for the rest.

The risk of death from legal abortion, as reported by Bartlett and colleagues, increases exponentially with increasing gestational age: The earlier the abortion, the safer the abortion ([Table 33.4](#)). The risks from 1988 to 1997 (and therefore not including mifepristone abortions) are as follows: The risk with gestational age ≤ 8 weeks is 1 per million, at 12 weeks is 0.4 per 100,000, at 16 to 20 is 3.4, and at ≥ 21 weeks is 8.9 per 100,000 procedures (76 times higher than with the earliest procedures). Given the fact that earlier abortions are safer, issues such as access to abortion are medically relevant. These include number of trained providers, cost, and gestational age limit of particular institutions.

The risk of death for women of black and other races was about twice that of white women. For women having

second-trimester procedures, mortality rates for D&E were 2.5 times lower than those for instillation and other procedures, although this was not statistically significant. No statistically significant difference in risk related to maternal age or parity was found in this last time period of record.

TABLE 33.4 Legal Abortion Case Fatality Rates and Relative Risks by Selected Categories: United States, 1988-1997

RISK CATEGORY	N ^a	RATE ^b	RELATIVE RISK AND 95% CONFIDENCE INTERVAL
Age group (y)			
≤19	0.7	20	1.2 (0.6-2.2)

CONCLUSION

Abortion is a frequent outcome of human conception; thus, management of abortion and its complications is an important responsibility for clinicians. Chromosomal anomalies are the single most important cause of EPL. For women with threatened abortion, use of ultrasonography and β -hCG monitoring can help predict the outcome of the pregnancy. For women who either require or desire prompt evacuation after EPL, either aspiration or labor induction may be appropriate.

Small numbers of illegal abortions continue to occur in the United States. Legally induced abortion, however, is one of the most frequently performed—and one of the safest—operations in contemporary practice. Less than 1 per 100 of those having an abortion suffers a major complication, and less than 1 per 100,000 dies from causes associated with the procedure. The marketing of mifepristone in the United States for early abortion has broadened the options available to women, and use of misoprostol for cervical preparation before aspiration represents an important advance in gynecology.

BEST SURGICAL PRACTICES

- Management of EPL includes surgical management, medical management with misoprostol, or expectant management. Suction aspiration at early EGAs can be accomplished with a manual syringe or an electric vacuum source. D&E is a safe technique for later EGAs. Intervention is not required in the absence of

symptoms. Patient preference can direct management plan in most cases.

- Septic abortion requires aggressive management. This includes obtaining intrauterine and blood cultures, administration of broad-spectrum antibiotics, and prompt surgical evacuation of the uterus.
- Suction aspiration is the most frequent method of legal abortion in the United States. MVA is increasing in use as an alternative to using electric vacuum. Both may safely be done in outpatient facilities.
- Preoperative medical evaluation for induced abortion should include patient's medical, surgical, and anesthetic history, confirmation of gestational age, and thorough counseling about all available options, including continuing pregnancy, adoption, and medical and surgical abortion. Abortion regulations vary by state and should be followed by providers.
- Cervical dilation necessary for first-trimester suction aspiration can be achieved with osmotic dilators, medical preparation with misoprostol, or manual dilation. If manual dilation is necessary, a variety of dilators are available. Gentle dilation is imperative in prevention of uterine perforation.
- Prophylactic measures can be adopted into routine practice in order to decrease complication rates. Prophylactic antibiotic use is indicated for all surgical management of induced abortion, including MVA, electric vacuum aspiration, and D&E. The use of vasopressin decreases the risk of hemorrhage during D&E. The incidence of retained products of conception after surgical abortion can be decreased if aspirated tissue is inspected for presence of fetal tissue or chorionic villi.
- Pain control is essential in abortion care. This is most easily achieved with paracervical anesthesia. Additional measures include relaxation techniques, sedation, and general anesthesia. Risks and benefits of all options must be considered with respect to the patient's emotional or physical status.
- Second-trimester abortion can be achieved surgically via D&E. D&E is generally safer and faster, but only in the hands of a properly trained physician. Adequate preoperative cervical preparation is essential and can be achieved with osmotic dilators or misoprostol. Intraoperative ultrasound may decrease operative time as well as complications. Special forceps are used to facilitate evacuation of later gestations.
- Medical abortion with mifepristone and misoprostol is a safe way to terminate early gestations. The most effective regimens administer misoprostol at least 24 hours after mifepristone and in high doses. Thorough patient counseling will increase patient satisfaction and decrease complications. In order to be a candidate for medical abortion, a

P.769

patient must be able to understand the regimen, have access to emergency care if needed, and be able to follow up to ensure completion of the procedure.

- Labor induction can be performed using prostaglandins (misoprostol, $\text{PGF}_{2\alpha}$, PGE_2) or oxytocin. Multiple regimens for prostaglandins exist; the most effective regimens utilize mifepristone and short dosing intervals of misoprostol. Clinicians must weigh efficacy and speed of abortion against side effects like fever, nausea, vomiting, and diarrhea. Use of prostaglandins in women with scarred uteri remains an area that requires further study.
- Complications of abortion include hemorrhage, cervical injury, uterine perforation, retained products, infection, anesthetic complications, and Rh sensitization. Morbidity and mortality from legal abortion are very rare.

Chapter 34

Ectopic Pregnancy

Mark A. Damario

DEFINITIONS

Abdominal pregnancy—A pregnancy that develops in the peritoneal cavity. Most abdominal pregnancies are secondary, the result of early tubal abortion or rupture with secondary implantation of the pregnancy into the peritoneal cavity. A primary abdominal pregnancy is one that implants directly into the peritoneal cavity.

Arias-Stella reaction—A reaction in endometrial cells associated (but not exclusively) with ectopic pregnancy, showing nuclear enlargement, irregularity, and hyperchromasia with cytoplasmic vacuolization.

β -hCG assay—A quantitative determination of the serum concentration of the human chorionic gonadotropin hormone

obtained using a highly sensitive immunoassay that is specific for the β -subunit of human chorionic gonadotropin. Useful in the early diagnosis of ectopic pregnancy.

Cervical pregnancy—A pregnancy developing in the cervical canal below the level of the internal os.

Culdocentesis—Aspiration of fluid from the cul-de-sac (pouch of Douglas) via a needle puncturing the vaginal wall between the uterosacral ligaments.

Dilatation and curettage—A surgical procedure in which the endometrial cavity contents are removed and submitted for histologic study. Useful in the early diagnosis of ectopic pregnancy when β -hCG assays and transvaginal ultrasonography are nondiagnostic and a nonviable pregnancy is suspected.

Ectopic pregnancy—A pregnancy that develops following implantation anywhere other than the endometrial cavity of the uterus.

Heterotopic pregnancy—Combined intrauterine and extrauterine pregnancy.

Interstitial pregnancy—A pregnancy developing in the interstitial portion of the oviduct.

Laparoscopy—A surgical technique that allows for both diagnosis and treatment of an ectopic pregnancy. Remains the “gold standard” method of diagnosis.

Ovarian pregnancy—A pregnancy developing in the ovary. Criteria for diagnosis include the following: (a) The ipsilateral tube is intact and clearly separate from the ovary, (b) the gestational sac definitely occupies the normal position of the ovary, (c) the sac is connected to the uterus by the utero-ovarian ligament, and (d) ovarian tissue is unquestionably demonstrated in the wall of the sac.

Persistent ectopic pregnancy—Continued presence of viable trophoblastic tissue after conservative surgical treatment of an unruptured ectopic pregnancy. The typical presentation includes persistence of β -hCG concentrations that do not fall appropriately following conservative surgery.

Salpingectomy—Operative removal of an oviduct.

Salpingotomy—Operative opening made in the oviduct that is used to remove an unruptured tubal pregnancy for the purpose of retaining the oviduct.

Serum progesterone assay—A quantitative determination of the serum concentration of progesterone hormone. Useful in the early diagnosis of ectopic pregnancy.

Transvaginal ultrasonography—Ultrasound imaging of the female pelvis using an endoscopic probe

placed in the vagina. Useful in the early diagnosis of an ectopic pregnancy.

Tubal pregnancy—The most common type of ectopic pregnancy. May involve the ampullary, fimbrial, or isthmic portion of the oviduct.

Ectopic pregnancy was first recognized in 1693 by Busiere when he was examining the body of a prisoner executed in Paris. Gifford of England made a more complete report in 1731 that described the condition of a fertilized ovum implanted outside the uterine cavity. Ectopic pregnancy has since become recognized as one of the more serious complications of pregnancy. One of the leading causes of maternal morbidity and mortality in the United States, it still accounted for 6% of all maternal deaths from 1991 to 1999, according to the Centers for Disease Control and Prevention (CDC). Despite significant advances in diagnosis and treatment, ectopic pregnancy remains the leading cause of maternal death in the first trimester.

Today, early diagnosis of ectopic pregnancy is possible with highly sensitive and rapid β -human chorionic gonadotropin (β -hCG) assays and the aid of advanced vaginal ultrasonographic equipment. The benefit of early diagnosis is that expectant medical therapy or conservative surgery becomes possible.

P.772

Conservative management in the case of a small ectopic pregnancy that is present without rupture is usually successful when preservation of the oviduct to maintain or enhance fertility is important. Physicians should maintain a high index of suspicion for ectopic pregnancy and should be cognizant of the importance of early diagnosis and early intervention. This chapter summarizes the contemporary methods for diagnosis and treatment of ectopic pregnancy.

EPIDEMIOLOGY OF ECTOPIC PREGNANCY

Although the total number of pregnancies has declined over the past four decades, the rate of ectopic pregnancy increased in most Western nations. In the United States, the incidence of ectopic pregnancy increased from 4.5 per 1,000 pregnancies in 1970 to 19.7 per 1,000 pregnancies in 1992. In Norway, an increase from 12.5 to 18.0 per 1,000 pregnancies was reported from 1976 to 1993. One contributing factor for the rising ratio of extrauterine to intrauterine pregnancies is felt to be the rising incidence of sexually transmitted diseases as well as the efficacy of modern antibiotic treatments for pelvic inflammatory disease (PID). A second factor may be the increased ability to detect the disease. Although the risk of death from ectopic pregnancy declined among all races and ages in the United States, women of black and other minority races remained at significantly increased risk of death from ectopic pregnancy compared with white women. Although the overall incidence of ectopic pregnancy in the United States during 1970 to 1989 increased approximately fivefold, the risk of death from ectopic pregnancy declined by 90%. This decline in mortality from ectopic pregnancies may have been related both to the increased awareness of the condition and improved diagnostic and therapeutic methods.

Tracking trends in the incidence and outcomes of ectopic pregnancy has been more difficult in the past two decades due to changes in diagnosis and treatment, including a larger proportion of patients treated as surgical outpatients or medically with methotrexate (MTX) (as opposed to hospital discharge surveys). Utilizing computerized data systems in a large managed care organization, Van Den Eeden et al. identified an annual rate of 20.7 per 1,000 pregnancies between 1997 and 2000. Utilizing administrative claims data, Hoover et al. identified an annual rate equivalent to 6.4 per 1,000 pregnancies between 2002 and 2007.

PATHOLOGY

A tubal gestation traditionally has been defined as one that implants and grows within the tubal lumen. Budowick and associates have suggested that tubal implantation actually occurs in the lumen but is soon followed by penetration into the lamina propria and muscularis to become extraluminal. Pauerstein and colleagues demonstrated that trophoblastic infiltration can be predominantly intraluminal or predominantly extraluminal, or,

occasionally, mixed. It is impossible to ascertain in the operating room the predominant pattern of growth of a given tubal pregnancy. In any event, fimbrial expression usually is an unacceptable method for removal of ectopic pregnancy. Not only is the method traumatic, but it frequently does not remove all of the trophoblastic tissue. The resultant persistent ectopic pregnancy may therefore require additional therapy.

ETIOLOGY OF ECTOPIC PREGNANCY

Tubal Damage Secondary to Inflammation

Both the increased incidence of sexually transmitted disease resulting in salpingitis and the efficacy of antibiotic therapy in preventing total tubal occlusion after an episode of salpingitis are related to the increasing incidence of ectopic pregnancy. Levin and associates have demonstrated that the risk of ectopic pregnancy is increased in women with a primary history of PID. Westrom compared women with PID confirmed by laparoscopy with healthy women, matched by age and parity, and found a sixfold greater incidence of ectopic pregnancy in women with PID, an alarming rate of 1 ectopic pregnancy out of every 24 gestations. Similar statistics have been reported by other authors. Many of the patients in these studies had received antibiotic treatment for salpingitis.

Before antibiotics became available for the treatment of PID, salpingitis was usually so acute that the inflamed tube became totally occluded, and permanent sterility was the result. Women who attempted to conceive after a pelvic infection were successful less than 40% of the time. Today, the rate of pregnancy exceeds 60% for patients adequately treated with antibiotics. After initial appropriate treatment of an infection with antibiotics, agglutination of the cilia can still occur, and synechial bands can form within the tubal lumen to cause partial tubal obstruction. Westrom has demonstrated by laparoscopy that bilateral tubal occlusion occurs in approximately 12.8% of patients after treatment for the first tubal infection, in 35% after two infections, and in 75% after three or more infections. In addition, Westrom found that approximately 4% of all pregnancies subsequent to salpingitis were ectopic.

Fallopian tubes containing a gestation are frequently normal on macroscopic visualization and gross histologic examination. Vasquez and colleagues, using scanning electron microscopy and light microscopy studies of tubal biopsies from five groups of women, discovered marked differences in their ciliated surfaces. The proportion of ciliated cells was significantly lower in biopsy specimens taken from 25 women with tubal pregnancies as compared with biopsy specimens from seven women with intrauterine pregnancies at the same stage of gestation. Marked deciliation was likewise seen in eight women who had undergone biopsies during tubal reconstructive surgery. In another study, Gerard and colleagues found that seven of ten fallopian tube samples from patients with ectopic pregnancy were PCR positive for *C. trachomatis* DNA. Therefore, the increased occurrence of sexually transmitted diseases contributing to subclinical tubal epithelial damage may be an important contributor to ectopic pregnancy. Comprehensive programs to prevent sexually transmitted diseases undertaken in Sweden and Wisconsin have been found to decrease not only the incidence of *C. trachomatis* infections and other sexually transmitted diseases but also the rate of ectopic pregnancies.

Contraceptive Devices

The use of intrauterine devices (IUDs) has been associated with an increased incidence of ectopic pregnancy. In a summary of published reports on ectopic pregnancy, Tatum and Schmidt observed that 4% of the pregnancies that occurred with an IUD in place were ectopic. In a recent meta-analysis, Mol and associates reported a range of odds ratios from 4.2 to 45 from heterogeneous studies of IUD use and ectopic pregnancy. Subtle tubal epithelial damage or actual PID episodes are likely responsible for the observed association between IUDs and ectopic pregnancy.

Oral Contraceptives

The overall risk of an ectopic pregnancy is lowered in women using oral contraceptives. When oral contraceptives fail, however, the risk of an ectopic pregnancy is slightly increased. This increase is presumed secondary to the inhibitory progestin

P.773

effect on tubal motility. This hypothesis is supported by several studies implicating progestin-only oral contraceptives in the etiology of ectopic pregnancies.

Prior Tubal Surgery

An operative procedure on the oviduct, whether a sterilization procedure or tubal reconstructive surgery, can cause an ectopic pregnancy. The incidence of ectopic pregnancies occurring after neosalpingostomy for distal tubal obstruction ranges from 2% to 18% (**Table 34.1**). The rate of ectopic pregnancy after a microsurgical reversal of a sterilization procedure is only about 4%, presumably because the tubes have not been damaged by prior infection.

The U.S. Collaborative Review of Sterilization Working Group followed a total of 10,685 women undergoing tubal sterilization in a multicenter, prospective cohort study. The overall cumulative probability of pregnancy in the study cohort 10 years after sterilization was 18.5 per 1,000 procedures (failure rate of 1.85%). The 10-year cumulative probability of ectopic pregnancy for all methods of tubal sterilization was 7.3 per 1,000 procedures. From these data, one can therefore estimate that in the setting of a positive pregnancy following tubal sterilization, there is an approximately 40% risk that the pregnancy will be ectopic. The type of sterilization procedure and age of the patient at the time of sterilization appear to be relevant factors. Women sterilized by bipolar tubal coagulation before the age of 30 years had a probability of ectopic pregnancy that was 27 times as high as that of women of similar age who underwent postpartum partial salpingectomy (31.9 vs. 1.2 ectopic pregnancies per 1,000 procedures). In addition, ectopic pregnancy was often seen many years after the sterilization procedure. The annual rates of ectopic pregnancy in the 4th through 10th years after sterilization were no lower than that seen in the first 3 years.

The pathophysiology of ectopic pregnancy after elective tubal sterilization is not clear. It is possible that a tuboperitoneal fistula in a previously coagulated segment of fallopian tube may allow spermatozoa to escape and reach the oocyte. Such fistulae have been demonstrated radiographically by Shah and colleagues in 11% of 150 women after laparoscopic electrocoagulation. Improper surgical technique (such as incomplete coagulation or misplacement of a mechanical device) may also influence the sterilization failure rate and incidence of ectopic pregnancy, although their likelihood is presumably low.

Assisted Reproductive Technologies

Ectopic pregnancies are known to occur after in vitro fertilization (IVF) and related techniques, although the incidence may be decreasing. The Society for Assisted Reproductive Technology (SART) reported that 2.1% of pregnancies established after IVF in the United States during 2000 were ectopic, although the CDC reported that only 0.7% of pregnancies established after IVF utilizing fresh, nondonor oocytes were ectopic in 2010. Several theories have been proposed regarding the occurrence of ectopic implantation after transcervical intrauterine embryo transfer. Potential factors include the possibility of direct injection of embryos into the fallopian tube, uterine contractions provoked by the transfer catheter that propel the embryos retrograde, position or depth of the transfer catheter in the uterine cavity, and the volume of transfer medium. Verhulst and colleagues reported that tubal damage was a major risk factor. These researchers found that the ectopic pregnancy rate after IVF was significantly greater in patients with tubal disease (3.65% of pregnancies) than in those without tubal disease (1.19% of pregnancies). Strandell and associates found that a history of a previous ectopic pregnancy and a history of a previous myomectomy also appear to be risk factors for ectopic pregnancies following IVF.

A couple of recent reports suggest that the rate of ectopic pregnancy may be significantly lower following frozen transfers rather than fresh transfers utilizing blastocyst-stage embryos. Ishihara and colleagues reported an ectopic pregnancy rate of 0.81% following frozen-thawed single blastocyst transfers as opposed to 1.8% following fresh IVF single blastocyst transfers and 1.4% following fresh intracytoplasmic sperm injection single blastocyst transfers. Shapiro and associates reported no ectopic pregnancies following frozen-thawed blastocyst transfers as compared to 1.5% in fresh cycles. Possible speculative etiologies for these findings include a potential difference in endometrial receptivity as well as uterine contractility between fresh and frozen transfer cycles.

Assisted reproductive technologies may also be associated with higher incidences of less common forms of ectopic pregnancy, including heterotopic pregnancies and tubal stump

P.774

pregnancies. Tummon and coworkers reported a 2% risk of heterotopic pregnancy in women undergoing IVF who had distorted tubal anatomy. This is about 100 to 200 times the reported incidence of combined intrauterine and extrauterine pregnancies occurring spontaneously. These authors found that the risk of heterotopic pregnancy appeared to increase proportionately with the number of embryos transferred. Ko and coauthors reported six tubal stump (postsalpingectomy) pregnancies among 1,466 ectopic pregnancies occurring in patients undergoing assisted reproductive technology ART (including ovulation induction and IVF-ET).

TABLE 34.1 Summary: Ectopic Pregnancy after Tubal Surgery

PROCEDURE	TECHNIQUE	TOTAL PREGNANCY (%)	PREGNANCY RANGE (%)	ECTOPIC (%)	ECTOPIC RANGE (%)
Salpingoscopy	Macrosurgery	42	35-65	3.4	1-20
	Microsurgery	52	31-69	1.8	0-16
Fimbrioplasty	Macrosurgery	42	36-50	14	10-18
	Microsurgery	59	26-68	6	4-11
Neosalpingostomy	Macrosurgery	27	20-38	4.2	2-10
	Microsurgery	26	17-44	7.7	0-18
Tubal anastomosis	Macrosurgery	44	25-83	9.2	0-15
	Microsurgery	62	35-78	2.3	1-6.2
Removal of ectopic pregnancy	Salpingectomy	42	38-49	12	8-17
	Salpingostomy	57	39-73	11	0-20

TABLE 34.2 Risk Factors for Ectopic Pregnancy

Chronic PID
Prior tubal surgery
Surgical sterilization
Use of an IUD
Previous ectopic pregnancy
DES exposure
Progestin-only contraceptives
Assisted reproductive technologies
Infertility
Developmental tubal anomalies
Multiple sex partners
Early age at first intercourse
Cigarette smoking
Vaginal douching

Developmental Anomalies

Intramural polyps and tubal diverticula can block or alter tubal transport of fertilized ova. Congenital absence of segments of the fallopian tube with peritoneal fistulae can also predispose to tubal pregnancy. Women exposed to diethylstilbestrol (DES) in utero are at higher risk of ectopic pregnancy. These women may have absent or minimal fimbriae and fallopian tubes that are shorter and thinner than normal.

Other Causal Factors

Several studies have demonstrated that cigarette smoking seems to be an independent, dose-related risk factor for ectopic pregnancy. Other lifestyle factors, such as multiple sex partners and early age at first intercourse, are associated with an increased risk. Vaginal douching has also been associated with a slightly increased risk of ectopic pregnancy, probably by increasing the overall risk of pelvic infections and resultant tubal damage. A summary of risk factors related to ectopic pregnancy is summarized in [Table 34.2](#).

SITES OF ECTOPIC PREGNANCY

About 95% of extrauterine implantations occur in the oviduct. About 55% of these tubal implantations occur in the ampulla, the most common site: Implantation in the isthmic portion accounts for 20% to 25%, implantation in the infundibulum and fimbria accounts for 17%, and implantation in the interstitial segment (cornua) accounts for 2% to 4%. Ectopic implantations occur less often in the ovary, the cervix, and the peritoneal cavity (**Fig. 34.1**).

FIGURE 34.1 Sites and incidence of ectopic pregnancy.

Walters and colleagues reported that 16% of tubal pregnancies result from a contralateral ovulation. Transmigration of the ovum in the peritoneal cavity can occur because the oviducts and ovaries may be situated close together in the culde-sac. Alternatively, this phenomenon could also result from transmigration of the embryo through the endometrial cavity into the opposite oviduct.

EFFECTS OF ECTOPIC PREGNANCY ON FUTURE REPRODUCTION

Tubal pregnancy is associated with a poor prognosis for subsequent reproduction. In most cases, an extrauterine pregnancy represents an impairment of the fertilized ovum's ability to migrate through the deep rugae of the oviduct as a result of altered tubal function. The morphologic abnormality is usually bilateral and irreversible and can produce repeated ectopic pregnancies or permanent sterility. In a 1975 study, Shoen and Nowak concluded that about 70% of patients who have an ectopic first pregnancy are unable to produce a living child. As many as 30% of the patients who have an ectopic first pregnancy will have a repeat ectopic pregnancy, which compares with the total repeat ectopic rate of 10% to 15% for the overall population of reproductive-age women. More than half of the subsequent extrauterine pregnancies will occur within a 2-year period, and 80% will occur within 4 years of the initial ectopic pregnancy. In reviewing the experience of the Kaiser Foundation hospitals, Hallatt reported a 9.2% overall incidence of repeat ectopic pregnancies among 1,330 women who had extrauterine pregnancies. The potential reproductive capacity for a patient who has had an ectopic pregnancy therefore depends on her reproductive history. If an ectopic pregnancy was the result of her first reproductive effort, then the prognosis for future pregnancies is much worse than if the complication occurred after one or more successful pregnancies.

In a recent publication utilizing the Danish national health registries, Karhus et al. reported on the long-term reproductive outcomes in women whose first pregnancy was ectopic. They reported that women who had a first ectopic pregnancy between 1977 and 2009 had a long-term rate of deliveries of 69% and overall 17.6% risk of further ectopic pregnancies. They mentioned that the emergence of IVF may have improved the delivery chance for latter cohorts of women in their study as compared to previous studies.

Mueller and associates have estimated that 92% of infertility in women who have had a tubal pregnancy results from tubal

damage that is due to the tubal pregnancy itself or other factors that had predisposed to its occurrence. A history of infertility itself is a risk factor for ectopic pregnancy. A twofold increase in the risk of tubal pregnancy exists among infertile women with no evident abnormality during infertility evaluation.

TUBAL ECTOPIC PREGNANCY

The morbidity and mortality associated with extrauterine pregnancy are directly related to the length of time required for diagnosis. In a CDC survey, two thirds of all patients who were later proven to have an ectopic pregnancy were previously seen by a physician, and either the diagnosis was deferred or the condition was incorrectly assessed. For a successful outcome, an ectopic pregnancy must be diagnosed early. In some clinics where the condition is treated frequently, a high proportion of cases are diagnosed and treated before tubal rupture occurs. In some cases, however, the symptoms that bring a patient to seek medical care are caused by an already-leaking or ruptured ectopic pregnancy. As many as 15% of all tubal pregnancies rupture before the first missed menstrual period, particularly if a patient's usual menstrual pattern is very irregular.

Diagnostic accuracy is often improved in repeat ectopic pregnancies. The vast majority of patients with repeat ectopic pregnancies will be diagnosed and treated before tubal rupture. A difference with a repeat ectopic pregnancy is that the patient herself often raises the question of an extrauterine pregnancy. Being suspicious, the patient may seek medical care earlier and provide a more specific medical history than does a patient experiencing her first ectopic pregnancy. The result is often an earlier diagnosis and an improved chance for a successful outcome.

Some form of vaginal bleeding occurs around the expected time of menses in more than 50% of women with an ectopic pregnancy, so that many patients and their physicians are unaware that a pregnancy has occurred. The vaginal bleeding may be followed by a period of amenorrhea. Clinical symptoms of an ectopic pregnancy usually appear 6 to 10 weeks after the last normal menstrual period.

DIAGNOSIS

Classic Symptoms: Pain, Bleeding, and Adnexal Mass

The classic presentation of pain and uterine bleeding with the finding of an adnexal mass has been the clinical hallmark of an extrauterine pregnancy, but even classic presentations can be misleading. Schwartz and DiPietro observed that of the patients who presented with the classic signs and symptoms, only 14% had an ectopic pregnancy. The severity of the symptoms and signs depends on the stage of the condition, but in the early stages of an ectopic gestation, symptoms are less predictive than in the more advanced stages of the disease. A discrete, unilateral mass separate from the adjacent ovary has been detected in less than one third of all proven ectopic pregnancies. Locating a mass depends on many factors, including the diagnostic skill of the examiner, the degree of pelvic peritonitis present, the presence or absence of tubal rupture, and the degree of stoicism and cooperation of the patient. Even when all factors are optimal, an adnexal mass can be felt in only half of the cases.

Diagnostic Studies

Three major advances have made early diagnosis of extrauterine pregnancy possible: (a) the development of highly sensitive and rapid β -hCG assays, (b) the ability to use ultrasound to evaluate the uterus and the adnexa (vaginal sonography further increases the accuracy of diagnosis), and (c) the application of laparoscopy as a diagnostic tool. Suction curettage can be useful under certain circumstances (e.g., to help establish the presence of a nonviable intrauterine pregnancy). Other diagnostic methods, such as serum progesterone assays or color Doppler flow analyses, can also provide useful information.

β -hCG Assays

The principal endocrine marker of pregnancy is hCG, which is synthesized by the trophoblast. hCG is a glycoprotein consisting of two subunits: α and β . The α -subunit has significant homology with other glycoprotein hormones, such as follicle-stimulating hormone, luteinizing hormone, and thyroid-stimulating hormone. The β -subunit, on the other hand, is specific to hCG, and antibodies against the β -subunit form the basis for current immunoassays. Current commercial automated β -hCG immunoassays use enzyme fluorometry, enzyme spectrometry, or chemiluminescence methods, as opposed to the traditional radioimmunoassay methods commonly used in the past. An immunoassay for β -hCG can detect levels of hCG as low as 5 IU/L of serum with less than a 0.2% incidence of false-negative results. β -hCG can be detected in maternal serum as early as 7 to 8 days after ovulation or approximately the day after blastocyst implantation.

The quantification of serum β -hCG levels is useful in determining the viability of pregnancy. To optimally use β -hCG data in treating a patient with a problematic pregnancy, one should first have a thorough understanding of the particular assay used. The World Health Organization has established reference standards for β -hCG assays. The Third or Fourth International Standards (Third or Fourth IS) are the most commonly used reference standards used by the available commercial kits of today. These standards are roughly equivalent to the First International Reference Preparation (First IRP) but are quite a bit different from the Second International Standard (Second IS). The Second IS contains about 20% intact hCG and was initially developed for use in hCG bioassays. One international unit of β -hCG based on the First IRP is equal to approximately 0.58 IU of β -hCG using the Second IS. Fortunately, the Second IS has been exhausted and is no longer used. The First IRP, Third IS, and Fourth IS are highly purified preparations that were developed to overcome the deficiencies seen in the use of a heterogeneous standard. This notwithstanding, due to the continuing variation of assay methodologies and β -hCG standards, there remains considerable between-method variation in β -hCG assay results.

Serum hCG concentrations increase in an exponential fashion in early pregnancy. During the period of gestation in which the hCG concentration is less than 10,000 IU/L (First IRP), or about 25 to 30 days postovulation, the time required for doubling of hCG levels remains relatively constant, with a mean of 1.9 days. Kadar and colleagues reported that 87% of women with ectopic pregnancies and 15% of women with normal intrauterine pregnancies could expect to have hCG doubling times of more than 2.7 days when the hCG concentration measured less than 6,000 IU/L. The lower limits of the increase in serum hCG for viable intrauterine pregnancies have been established by Barnhart and colleagues in a large cohort study. In this study, the serial β -hCG titers of 287 women who presented with pain and/or bleeding in the first trimester and were ultimately diagnosed with a viable intrauterine pregnancy were evaluated. For viable intrauterine gestations less than 10 weeks from last menstrual period or those with an initial β -hCG titer less than 5,000 mIU/mL, the investigators noted that the curve generated for serial hCG concentrations best fit a log-linear model. Overall, β -hCG concentrations tended to

P.776

double every 2 days. The median rise of hCG after 1 day was 50% and after 2 days was 124%. The slowest or minimal rise for a normal viable intrauterine pregnancy, however, was 24% at 1 day and 53% at 2 days. Interval β -hCG determinations interpreted within the context of several values can therefore be of prognostic significance in the differentiation between normal intrauterine and extrauterine pregnancies. A normal rise in hCG production, however, does not always differentiate an ectopic from a viable intrauterine pregnancy. Shepherd and associates reported that, in their experience, a normal rise in hCG production did not reliably differentiate an ectopic from a viable intrauterine pregnancy in the symptomatic patient. Early ectopic pregnancies can initially secrete appropriate amounts of hCG because of a well-vascularized placental bed.

Serum Progesterone Assay

Serum progesterone levels reflect the production of progesterone by the corpus luteum in early pregnancy. During the first 8 to 10 weeks of gestation, serum progesterone concentrations change little; as pregnancy fails, the levels decrease. Matthews and colleagues reported progesterone levels in 29 patients with ectopic pregnancy using a direct radioimmunoassay that offers results within 4 hours. Patients with normal intrauterine pregnancies had serum progesterone levels greater than 20 ng/mL, and all patients with ectopic pregnancies had progesterone levels less than 15 ng/mL. Yeko and associates proposed that all ectopic pregnancies could be potentially diagnosed at the first emergency visit with a single serum progesterone determination using a discriminatory value of 15 ng/mL. Other authors, however, have demonstrated significant overlap in the serum progesterone concentrations in ectopic and normal intrauterine pregnancies. One large study by Gelder and colleagues reported that 98% of patients with a normal intrauterine pregnancy had progesterone levels greater than 10 ng/mL and that 98% of patients with ectopic pregnancies not associated with ovulation induction had progesterone levels less than 20 ng/mL. Unfortunately, 31% of viable intrauterine pregnancies, 23% of abnormal intrauterine pregnancies, and 51% of ectopic pregnancies in this series had progesterone levels that fell between 10 and 20 ng/mL, which greatly limited the clinical usefulness of the test. Hahlin and colleagues reported that a serum progesterone value of less than 9.4 ng/mL combined with an abnormal hCG increase had a positive predictive value of 1.0 for pathologic pregnancy. In 1992, Stovall and colleagues reported that in a group of more than 1,000 first-trimester pregnant patients, the lowest serum progesterone level associated with a viable pregnancy was 5.1 ng/mL. Therefore, these investigators established the lower cutoff limit of serum progesterone levels of 5 ng/mL; patients below this threshold had a nonviable pregnancy with 100% certainty and therefore underwent curettage. Patients with serum progesterone levels greater than 25 ng/mL had a 97% likelihood of having a viable intrauterine pregnancy in this study.

Transvaginal Ultrasonography

Pelvic ultrasound has revolutionized the diagnostic process of ectopic pregnancy. Transvaginal ultrasonography, in particular, may identify masses in the adnexa as small as 10 mm in diameter and can provide more detail about the character of the mass than clinical exam ([Fig. 34.2](#)). At the same time, transvaginal ultrasonography can evaluate the contents of the endometrial cavity and can document the presence of a viable intrauterine pregnancy with great accuracy. In addition, transvaginal ultrasonography allows for the simultaneous assessment for the presence of free peritoneal fluid.

FIGURE 34.2 Tubal ectopic pregnancy documented by endovaginal sonography.

Transvaginal ultrasonography is usually considered superior to transabdominal ultrasonography in the diagnosis of ectopic pregnancy. Although the latter provides a broader perspective of the abdominal cavity and pelvis, transvaginal ultrasonography generally provides better resolution of the internal female genitalia. A 5-MHz transvaginal transducer allows for a deeper penetration of the pelvis than transducers of higher frequency, whereas a 7.5-MHz transvaginal transducer provides for better near-resolution at the cost of shallower penetration. On rare occasions, an ectopic pregnancy may be located beyond the reach of the transvaginal transducer's scanning field. On these particular occasions, incorporation of transabdominal ultrasonography may be an important adjunctive step.

Jain and colleagues compared endovaginal and transabdominal ultrasound results in 90 patients with a positive serum pregnancy test (**Table 34.3**). The specific diagnosis of ectopic pregnancy was impossible using only transabdominal ultrasound before 7 gestational weeks. Normal intrauterine pregnancies could be detected earlier with endovaginal ultrasound because the yolk sac, fetal pole, and fetal heart motion could be seen sooner. Fetal heart motion was detected as early as 34 days after the last menstrual period in patients with identifiable fetal poles at the time the crown-to-rump length was 0.3 cm.

Although diagnosis by transvaginal ultrasound can be quite useful, it may at times be confusing. One problem is that a pseudogestational sac that is due to a decidual cast can be mistaken for an amniotic sac. A useful differentiating feature is the “double-line” image, caused by the faint hypoechoic decidual lining of the uterus and the hyperechogenic rim of the trophoblast surrounding the gestational sac. The double-line image can be seen as early as 5 weeks after the last menstrual period. Even in the presence of the double-line image, however, it is important to further follow the course of pregnancy and subsequently confirm a viable intrauterine pregnancy with the ascertainment of ultrasonographically imaged intrauterine cardiac motion.

Although not always seen, Frates and Laing reported that the presence of a noncystic extraovarian adnexal mass, extrauterine cardiac motion, or a “tubal ring” by transvaginal ultrasonography is highly specific for ectopic pregnancy (98.9%), with a high positive predictive value (96.3%). These

P.777

authors described that the direct imaging of the ectopic pregnancy using any of these differentiating features is possible in 84% of cases.

TABLE 34.3 Pregnancy Earliest Seen with Ultrasonography

EARLY INTRAUTERINE PREGNANCY	ENDOGENITAL	TRANSABDOMINAL
Gestational sac seen		
Gestational sac size	0.5 cm	0.5 cm
Gestational sac age	4.3 wk	4.3 wk
Double decidual outline		
Gestational sac size	0.6-0.7 cm	1.0 cm
Gestational sac age	4.4 wk	5.0 wk
Yolk sac seen		
Gestational sac size	0.7 cm	1.0 cm
Gestational sac age	4.6 wk (34 d)	5.0 wk (35 d)

Fetal pole seen		
Gestational sac size	0.7 cm	1.7 cm
Gestational sac age	4.6 wk	6.0 wk
Fetal heart motion seen		
Crown-rump length	0.3 cm	0.6 cm
Gestational sac age	4.6 wk (34 d)	.5 wk (47 d)

Many authors have reported on correlations between threshold levels of hCG above which an intrauterine gestational sac is expected by ultrasonography in a normal pregnancy (discriminatory zone). Early on, Kadar and colleagues described a threshold level of hCG above which an intrauterine gestational sac was expected by abdominal sonography in a normal pregnancy (discriminatory zone). This threshold hCG level was initially characterized as a titer of 6,500 IU/L or higher using the First IRP. Presently, transvaginal ultrasonography reliably detects intrauterine gestations as early as 1 week after missed menses (β -hCG > 1,500 IU/L; 5 to 6 weeks gestation). Barnhart and associates reported that with a β -hCG concentration of 1,500 IU/L or higher, an empty uterus on transvaginal ultrasonography identified an ectopic pregnancy with 100% accuracy. Even using a discriminatory serum β -hCG concentration of 1,000 IU/L, Cacciatore and associates identified an intrauterine gestation in all intrauterine pregnancies and in none of the ectopic pregnancies. Furthermore, these investigators reported that the detection of an adnexal mass in combination with an empty uterus had a sensitivity of 97%, specificity of 99%, positive predictive value of 98%, and negative predictive value of 98%, provided that serum β -hCG concentrations exceeded 1,000 IU/L. The coupling of hCG titers with transvaginal ultrasonographic findings has therefore greatly facilitated the early diagnosis of ectopic gestation. It must be stressed, however, that considering the variations in β -hCG assays, ultrasound equipment, and sonographer experience, each institution must determine their own discriminatory thresholds for the sonographic detection of an intrauterine pregnancy.

The advent of color-flow Doppler technology may potentially further improve the accuracy of noninvasive diagnostic methods. Kurjak and colleagues reported that ectopic pregnancies are characterized by the identification of peritrophoblastic flow associated with an adnexal mass by color Doppler techniques. Kirchler and coworkers showed that color Doppler qualitative blood flow analyses of the tubal arteries can help localize the side of a tubal ectopic pregnancy. These investigators reported a between-side difference in tubal blood flow of 20% to 45%, with increased blood flow seen on the side of the ectopic pregnancy. Emerson and colleagues demonstrated that color-flow Doppler capability can help differentiate between viable intrauterine pregnancy, completed abortion, incomplete abortion, and ectopic pregnancy by analyzing uterine color Doppler appearance, intrauterine venous flow, the presence or absence of intrauterine peritrophoblastic flow, corpus luteal flow, and the presence or absence of peritrophoblastic flow in the adnexa. Pellerito and associates reported that colorflow imaging increased the sensitivity of detecting an ectopic pregnancy. Of 65 patients with surgically confirmed ectopic pregnancies, 36 (sensitivity 54%) cases were detected by endovaginal sonography alone, whereas 62 (sensitivity 95%) cases were detected by a combination of endovaginal sonography and color-flow imaging.

Dilation and Curettage

At one time, the histologic changes in the endometrium that accompany an ectopic gestation were routinely

confirmed by dilatation and curettage (D&C). Today, more accurate diagnostic methods—such as the immunoassay for β -hCG, transvaginal ultrasonography, and laparoscopy—exist. In this setting, a D&C may therefore not always be necessary. If, however, the plateau level of β -hCG is low, a D&C can be helpful to establish the presence of degenerating villi, and if a patient is bleeding excessively, a D&C may also be required. In either case, assessment of the removed material and findings of decidua without chorionic villi suggests the diagnosis of ectopic pregnancy. Such findings do not provide absolute proof, however, because they also occur with spontaneous abortion. To distinguish between an ectopic pregnancy and spontaneous abortion, Stovall and colleagues reported that if β -hCG concentrations did not decline $\geq 15\%$ within 8 to 12 hours following curettage, an ectopic pregnancy was likely.

P.778

If available, a frozen section may be obtained immediately after curettage, providing an opportunity to confirm the diagnosis within minutes while the patient is still in the operating room under anesthesia. If no chorionic villi are present, further assessment and treatment by laparoscopy may be considered. In a recent report of 87 consecutive frozen section samples taken from uterine curettings, Spandorfer and colleagues found that 93.1% of these specimens were identified correctly after further analyses of the tissue by permanent section.

The atypical epithelial changes of the gestational endometrium in a case of tubal pregnancy were first described by Polak and Wolfe in 1924, and these changes were further expanded on by Arias-Stella in 1954 ([Fig. 34.3](#)). These comprise a highly controversial set of histologic criteria that depend, for accuracy, on the precise definition of the particular cell type involved in the morphologic change, together with ill-defined physiologic events that reportedly produce the changes. Arias-Stella and others were convinced that these histologic changes are a progressive phenomenon resulting from the exaggerated proliferative and secretory endometrial responses to the elevated hormonal levels of pregnancy. Lloyd and Fienberg disagreed, maintaining that these endometrial changes are regressive and involutinal and are the result of declining hormonal levels. Whichever hypothesis is ultimately proven, similar endometrial changes may be seen with a normal pregnancy, spontaneous abortion, or ectopic pregnancy. Histologic endometrial criteria, therefore, seem to have limited value in the specific diagnosis of extrauterine pregnancies.

Culdocentesis

Culdocentesis is a diagnostic tool for identifying the presence of intraperitoneal bleeding. This simple procedure of inserting an 18-gauge spinal needle attached to a 50-mL aspirating syringe into the cul-de-sac between the uterosacral ligaments ([Fig. 34.4](#)) provides immediate clinical information when unclotted blood is aspirated from the cul-de-sac. The procedure cannot be used for a definitive diagnosis, of course, because a tubal pregnancy may not have ruptured or leaked into the peritoneal cavity. In addition, a culdocentesis does not provide information concerning whether the blood is from an ectopic pregnancy or from some other cause of intra-abdominal bleeding. The rupture of a corpus luteal hemorrhagic cyst, for instance, may cause a similar bleeding pattern.

FIGURE 34.3 Arias-Stella reaction in endometrial cells associated with ectopic pregnancy, showing nuclear enlargement, irregularity, and hyperchromasia with cytoplasmic vacuolization.

FIGURE 34.4 Culdocentesis. An 18-gauge spinal needle is inserted through the posterior fornix and enters the cul-de-sac between the uterosacral ligaments.

The availability of sensitive transvaginal ultrasonographic technology presently limits the usefulness of the culdocentesis procedure, such that it is rarely presently performed. Free intraperitoneal blood has a

characteristic ultrasonographic appearance and can be seen in nearly all cases in which a significant intraperitoneal hemorrhage has occurred. In the absence of the immediate availability of transvaginal ultrasonography or in an emergency setting, however, a culdocentesis may still be of potential value.

Laparoscopy

Laparoscopy remains the gold standard in the detection of ectopic pregnancy, although noninvasive diagnostic methods continue to improve. In addition to permitting the diagnosis of an ectopic pregnancy, it enables surgical treatment. Laparoscopy also provides an opportunity to visualize the entire pelvis and other peritoneal organs. In particular, the condition of the unaffected fallopian tube can be assessed, as well as the presence of pelvic adhesions and endometriosis. This information may be particularly valuable for those patients interested in future fertility. The disadvantage of laparoscopy is that it is an invasive procedure that carries some risk of complications. Using standard methods, it requires general anesthesia and an operating room setting, thereby contributing to increased medical costs. Recent investigators, however, have been exploring the potential of "microlaparoscopy," in which improved optics and smaller-diameter laparoscopes and trocars allow for a definitive diagnosis and possible treatment in the nonoperating room setting. Several authors have reported

P.779

the encouraging use of microlaparoscopy in the office setting, using local rather than general anesthesia. The specific utility of microlaparoscopy, however, for the primary evaluation and treatment of ectopic pregnancy remains to be established.

Laparoscopy may be useful when an ectopic pregnancy is suspected, but no signs of an ultrasonographically visualized extrauterine gestational sac are evident. This includes situations in which there is an inability to visualize an intrauterine gestational sac and serial β -hCG determinations are rising inappropriately. This also includes situations in which a D&C fails to identify products of conception. One must be careful, however, in settings in which the β -hCG determinations are very low or the gestational age is limited. In these settings, the ectopically implanted gestational mass may be so small that it is still not able to be seen at laparoscopy. The clinician and patient might therefore be falsely reassured by negative laparoscopic findings. All patients without a definitive diagnosis established at laparoscopy should continue to be followed closely.

Other Potential Diagnostic Aids

Gleicher et al. described the use of hysterosalpingography and selective salpingography in differentiating early (biochemical) intrauterine from failing intratubal gestations. A characteristic tubal opacification pattern was seen in the cases of early tubal pregnancy. Confino and coworkers reported that selective salpingography was useful in diagnosing early tubal pregnancies in some patients with equivocal clinical, laboratory, and sonographic findings. In addition, these investigators injected a single dose of MTX through the selective salpingography catheter after cannulation of the tubal ostia and identification of a characteristic ampullary radiolucency in seven patients. Each had subsequent complete resolution of the pregnancy without complication. Risquez and colleagues reported the successful visualization of two ectopic pregnancies by transcervical tubal cannulation and falloposcopy. The falloposcope is a microendoscopic instrument 0.5 mm in external diameter that is introduced by a 1-mm coaxial catheter. Although limited by the presence of blood in the tubal lumen, direct visualization of the ectopic pregnancies was accomplished in both cases and confirmed by concurrent laparoscopy. Other investigative teams have explored the potential of other imaging methods, such as magnetic resonance imaging (MRI), in the diagnostic workup for ectopic pregnancy. MRI might be useful if the sonographic image is inconclusive, although it is likely to be rarely needed, particularly if laparoscopy is generally considered in uncertain cases.

Summary of Diagnostic Methods for Detecting Tubal Ectopic Pregnancy

When a patient is seen with a clinical history suggestive of ectopic pregnancy, a careful examination is performed ([Fig. 34.5](#)). Quantitative serum β -hCG and rapid serum progesterone

P.780

levels (if available) are obtained. If the β -hCG titer is positive, a transvaginal ultrasound is performed. If an intrauterine sac is visualized with fetal heart activity, then the diagnosis of intrauterine pregnancy is established. If, however, there are no intrauterine sacs or there is a questionable intrauterine sac without fetal heart activity, then the asymptomatic patient may be expectantly treated awaiting further testing. If the serum progesterone level is, with certainty, below the threshold level for viability, then a uterine curettage can be performed. The subsequent failure to find chorionic villi on curettage is very suggestive, but not diagnostic, of an ectopic pregnancy. If the serum progesterone level is more than 25 ng/mL in the absence of ovulation induction, then there is a strong likelihood that a viable pregnancy is present. If the quantitative serum β -hCG level is above the discriminatory zone for a particular institution and no intrauterine gestational sac is apparent using transvaginal ultrasonography, then an ectopic pregnancy is likely. The level of hCG at which an intrauterine gestational sac should be visible varies, however, depending on the β -hCG assay and the method of pelvic ultrasonography. Many contemporary investigators report that with transvaginal ultrasonography, an intrauterine gestational sac should be identified at a β -hCG level of 1,500 IU/L (Third or Fourth IS) with high sensitivity and specificity.

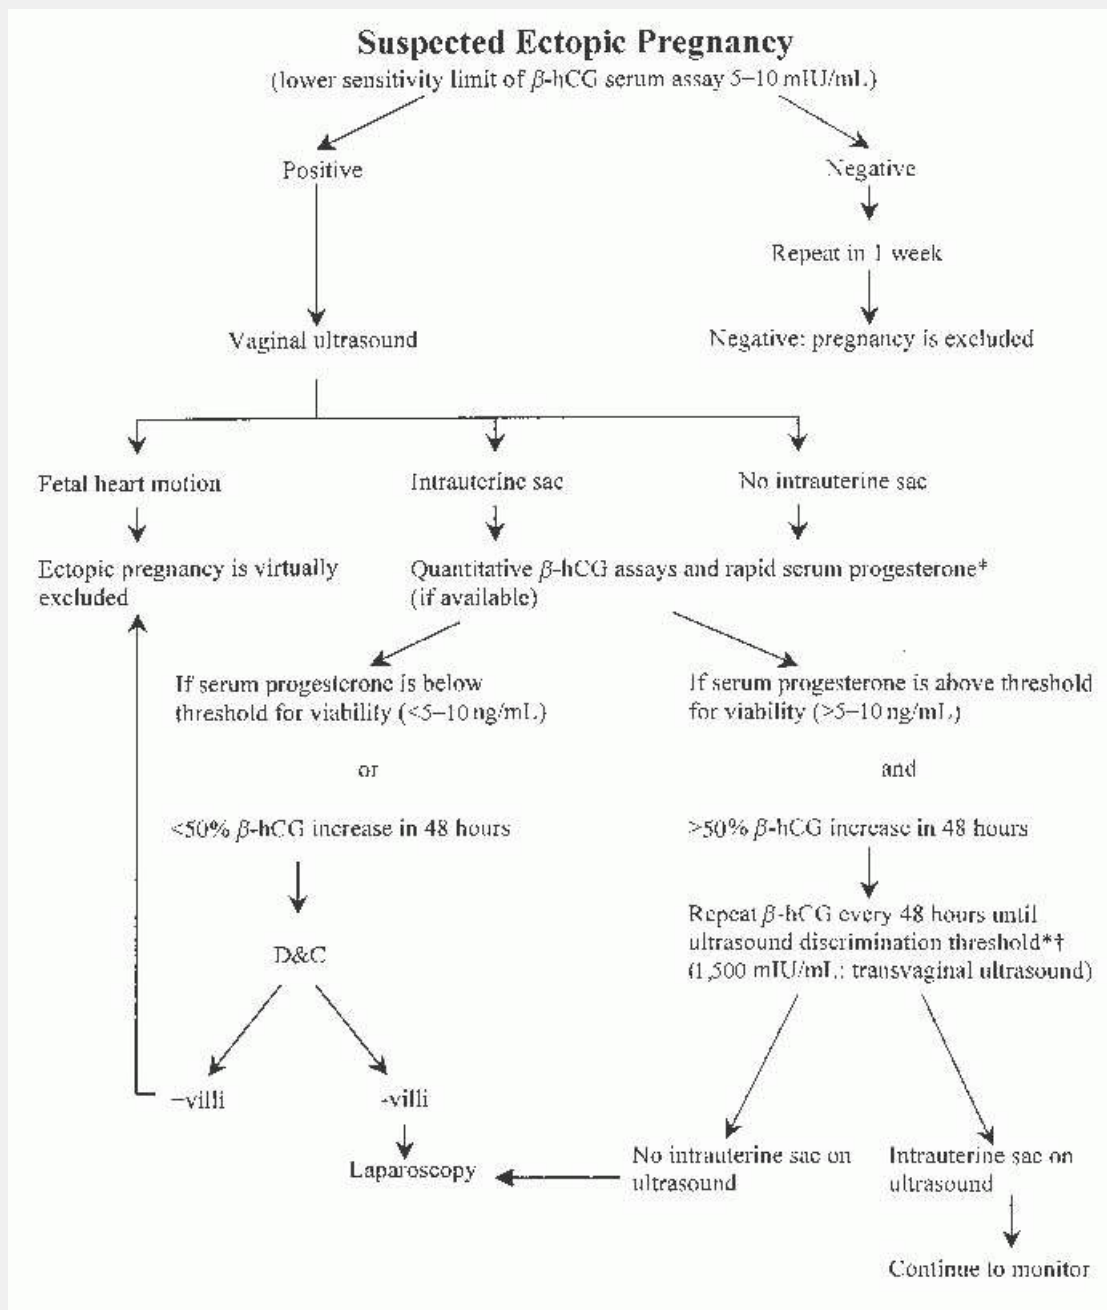

FIGURE 34.5 Evaluation of the stable patient with suspected ectopic pregnancy. *Hormonal parameters can vary depending on the assay technique and reference standard used. †The discriminatory threshold for sonographic detection of an intrauterine gestational sac must be established by each institution.

Commonly, results from initial testing are equivocal. The ectopic pregnancy can produce a low level of β -hCG from the aborting or degenerating trophoblast. The differential diagnosis should include spontaneous abortion or blighted ovum. When the diagnosis is uncertain and the patient is in an unstable condition or significant intraperitoneal fluid is seen, then evaluation should proceed immediately by laparoscopy and, if necessary, by laparotomy. If the patient is in stable condition, tests for serial β -hCG levels should be taken at 48-hour intervals, and the assays should be correlated with the patient's previous values. If the hCG level increases more than 50% within a 48-hour period, then the patient may have a normal intrauterine pregnancy and nonsurgical care (expectant management) is indicated. If the increase in the serial hCG level is less than 50% of the original value, then a nonviable pregnancy should be suspected. Ultrasound can often then corroborate the diagnosis of an ectopic pregnancy with the demonstration of a gestational sac in the adnexa or fluid in the cul-de-sac.

Initially, a normal increase in the β -hCG level may be observed. Over time, however, the level may slowly plateau, never reaching the discriminatory zone. If a potential intrauterine pregnancy is thought to be

nonviable, then a D&C can be performed. If there is any question of viability, however, laparoscopy is preferred to rule out ectopic pregnancy first. Once fetal heart motion is observed within the uterine cavity, the possibility of a tubal ectopic pregnancy is virtually excluded. Certain patients should continue to be observed closely, however, particularly after a superovulation regimen, which is associated with an increased risk of a simultaneous intrauterine and ectopic pregnancy. Nevertheless, the overall risk of the two existing simultaneously, even after a superovulation regimen, is quite small.

The use of vaginal ultrasonography with improved resolution and the potential addition of color Doppler flow analysis will invariably further define a lower discriminatory zone in the future. Both modalities appear to complement each other in attaining improved sensitivity and specificity in the diagnosis of ectopic pregnancy. Other investigative diagnostic techniques, such as selective salpingography and fallopscopy, should be considered strictly experimental.

TREATMENT FOR ECTOPIC PREGNANCY

Expectant Therapy

Before the advent of effective therapy for ectopic pregnancy, it was noted that the condition was not uniformly fatal and that some patients had spontaneous resolution of the ectopic gestation, through either spontaneous regression or tubal abortion. The natural history of ectopic pregnancy therefore suggests that a number of tubal pregnancies can resolve without treatment. In 1988, Fernandez and associates reported a spontaneous resolution of ectopic pregnancy in 64% of carefully selected patients. The mean time for resolution was 20 ± 13 days. Spontaneous resolution occurred more frequently when the initial hCG concentration was less than 1,000 mIU/mL. The authors observed that a β -hCG threshold of 1,000 mIU/mL and a hemoperitoneum of less than 50 mL with a hematosalpinx of less than 2 cm appeared to be most compatible with successful expectant management.

Subsequent larger studies have demonstrated similar results with expectant therapy. Korhonen and colleagues have published the largest series to date. Criteria for patient selection included decreasing β -hCG levels, an absent intrauterine pregnancy by transvaginal ultrasonography, and an adnexal mass of less than 4 cm without an embryonic heartbeat. Seventy-seven (65%) of one hundred and eighteen patients had spontaneous resolution of the ectopic pregnancy. The remaining patients had laparoscopy for increasing abdominal pain, increasing culde-sac fluid volume, or plateauing or increasing β -hCG levels. One patient required a salpingectomy for a ruptured ectopic pregnancy. Similar to other reports, these authors also noted an increased success rate with lower initial β -hCG concentrations.

Medical Treatment

Systemic Medical Therapy

MTX is a folic acid antagonist that can be administered to eradicate trophoblastic tissue in an ectopic pregnancy. MTX is the chemotherapeutic agent of choice in the treatment of gestational trophoblastic disease. Long-term follow-up of women who have taken MTX for gestational trophoblastic disease has failed to demonstrate an increase in congenital malformations, spontaneous abortions, or second tumors after chemotherapy.

Tanaka and colleagues reported the first use of systemic MTX for an ectopic pregnancy in 1982. This group successfully treated an interstitial pregnancy with a course of systemic MTX. Shortly thereafter, Farabow and coworkers described the use of systemic MTX in the treatment of a cervical pregnancy. Ory and associates reported the use of high-dose, short-course MTX therapy (plus citrovorum factor [CF]) to resolve small unruptured ectopic pregnancies without the need for conservative surgery. Six patients with ampullary pregnancies were treated, and resolution of the ectopic pregnancy was achieved in five patients. Surgical

intervention was required in the sixth patient. Two of the five patients who experienced resolution, however, had protracted courses and required blood transfusions. Sauer and associates also reported the use of systemic MTX and CF in 21 patients with ectopic pregnancy. Inclusion criteria included β -hCG levels that were reaching a plateau or slightly rising, laparoscopic confirmation of the ectopic pregnancy, and a tubal diameter of less than 3 cm with the tubal serosa intact and no evidence of bleeding. Treatment consisted of 1.0 mg/kg MTX administered intramuscularly on postoperative days 1, 3, 5, and 7, along with 0.1 mg/kg CF administered intramuscularly on postoperative days 2, 4, 6, and 8. Twenty of twenty-one pregnancies resolved without the need for laparotomy. Two patients

P.781

required blood transfusions, including one patient who required laparotomy and salpingectomy for a hemoperitoneum. In both of these cases, fetal heart activity in the adnexa was identified initially on ultrasound examination. This led the authors to suggest that MTX + CF can be safely used in selected cases of unruptured ectopic pregnancies that have not formed fetal elements that can be visualized by ultrasound.

In 1991, Stovall and colleagues reviewed the results of several series of tubal ectopic pregnancies treated with MTX + CF. Of 100 cases, 50 were diagnosed by laparoscopy, and 50 were diagnosed by a nonlaparoscopic algorithm. Complete resolution was achieved in 96 patients over a range of 14 to 92 days. In four patients, laparotomy was necessary because of tubal rupture; in one case, rupture occurred as late as 23 days after MTX administration. In five patients, cardiac activity was observed on ultrasound, and treatment was successful in four of them. Three patients experienced minor side effects. In 49 of 58 (84%) women who underwent subsequent hysterosalpingograms, tubal patency was demonstrated on the ipsilateral side. Of 56 patients desiring to conceive, 37 subsequently became pregnant; 33 of these were intrauterine pregnancies and 4 were repeat ectopic pregnancies.

Stovall and Ling later studied the efficacy and safety of a simplified regimen of single-dose systemic MTX. All patients were diagnosed with a nonlaparoscopic algorithm by the use of serial hCG titers, serum progesterone, transvaginal ultrasonography, and curettage. Patients were treated with a single dose of 50 mg/m² MTX intramuscularly if they were hemodynamically stable and the unruptured ectopic pregnancy did not exceed 3.5 cm in diameter. In the initial report, 120 patients were treated, including 14 (11.7%) with visualized cardiac activity. One hundred thirteen (94.2%) patients had complete resolution with treatment, with a mean time to resolution of 35.5 days. Four (3.3%) of the successfully treated patients required a second course of MTX on day 7. Seven (5.8%) patients required surgical management of the ectopic pregnancy, including two of the patients with cardiac activity. No major chemotherapy-related side effects were seen. Posttreatment hysterosalpingograms demonstrated tubal patency on the ipsilateral side in 51 of 62 (82.3%) patients. Of those attempting pregnancy, 79.6% subsequently became pregnant; 87.2% of these were intrauterine and 12.8% were ectopic.

Lipscomb and colleagues further reported on the expanded Memphis cohort of patients treated with single-dose MTX. They used similar inclusion criteria, with the exception of further allowing pregnancies up to 4.0 cm in diameter provided that ectopic cardiac activity was not present. In this series, 287 of 315 (90.1 %) patients were successfully treated with MTX. Forty-four patients with positive ectopic cardiac activity were treated with an 87.5% success rate. Of note, however, is that approximately 20% of these patients required more than one cycle of treatment. The authors' protocol reported that following the MTX dosing on day 1, serum chorionic gonadotropin was measured on days 1, 4, and 7. In many patients, they noted that β -hCG levels frequently continued to rise until day 4. If the chorionic gonadotropin levels then declined less than 15% between days 4 and 7, the MTX protocol was repeated. If the levels declined 15% or more between days 4 and 7, serum β -hCG was measured weekly until the level was less than 15 IU/L. If the chorionic gonadotropin level declined less than 15% during any subsequent week of follow-up, the MTX protocol was also then repeated. Other potentially

difficult issues with single-dose MTX therapy include the management of “resolution pain” (which may occur in 20% of patients) and the prolonged time to resolution sometimes seen.

A further review by Lipscomb and colleagues regarding the variables related to the success of single-dose MTX in the treatment of singleton ectopic pregnancy has been compiled. In this review, logistic regression analysis demonstrated that the serum chorionic gonadotropin level before treatment was the only factor that contributed significantly to the failure rate. Success rates were reported to be as high as 98% when serum chorionic gonadotropin concentrations were less than 1,000 IU/L, although were only 68% when serum chorionic gonadotropin concentrations were greater than 15,000 IU/L. Interestingly, the size and volume of the mass, the volume of hematoma, and the presence or absence of free peritoneal blood in the pelvis were not associated with a significant risk of treatment failure.

Comparisons of the multidose MTX and single-dose MTX regimens suggest that the multidose regimen may be slightly more effective although associated with greater side effects. Barnhart and coworkers reported a meta-analysis of 26 studies and reported an odds ratio for successful treatment of 1.71 (1.04 to 2.82 95% confidence intervals) favoring multidose MTX over single-dose MTX. The crude overall success rates for multidose MTX and single-dose MTX regimens were 92.7% and 88.1%, respectively. Clinical superiority of multidose MTX, however, was not demonstrated in two small prospective, randomized trials to date (Alleyassin and associates, Guven and coworkers). Barnhart and colleagues additionally described a hybrid protocol in which two equal doses of MTX (50 mg/m²) are administered intramuscularly on days 1 and 4 without leucovorin, which may offer an intermediate approach as compared to the multidose and single-dose MTX regimens.

Use of mifepristone as an adjunct to MTX treatment for ectopic pregnancy has also been assessed in two randomized controlled trials. In the first trial, Gazvani and colleagues reported both treatment approaches were successful, although the time to resolution was significantly faster in the group receiving MTX and mifepristone in comparison to the MTX alone group. In the subsequent multicenter randomized trial, Rozenberg and colleagues failed to demonstrate an overall benefit from the addition of mifepristone to MTX. These investigators, by contrast, demonstrated a higher efficacy of MTX and mifepristone in the subgroup of patients with higher initial serum progesterone levels (≥ 10 ng/L). Further studies are needed to define the role of mifepristone in combination with MTX in the treatment of ectopic pregnancy.

MTX has also been used to treat persistent ectopic pregnancy after conservative surgery. In these patients, persistent ectopic pregnancy results from proliferation of residual trophoblastic tissue remaining after a conservative surgical procedure. The trophoblast can be located within the muscular layer of the oviduct or between the muscularis and the serosa such that at the time of salpingotomy, only the portion of the trophoblast within the tubal lumen is removed. In those patients with persistent ectopic pregnancy described in the literature, the majority have been managed by a second operation and salpingectomy. Some patients, however, have been treated with either expectant management or MTX. Hoppe and colleagues have reported the largest MTX experience to date for persistent ectopic pregnancy. These authors noted successful treatment in all 19 patients treated following linear salpingotomy. All patients should therefore have a follow-up β -hCG titer 1 to 2 weeks after conservative surgery. If the titer is elevated, then serial β -hCG titers are indicated. If the titer then continues to fall, the patient can be treated expectantly. If the β -hCG level remains the same or increases, however, consideration should be given to a single dose of MTX or perhaps further surgery to remove the remaining portion of the ectopic pregnancy.

Systemic MTX is an alternative that can be used for the treatment of patients with small unruptured ectopic pregnancies or patients with persistent ectopic pregnancies following conservative surgery. Safeguards are necessary to enhance the success and minimize the toxicity of therapy. Patients should be carefully monitored with hematologic indices and liver chemistries. A history of active hepatic, renal, or peptic ulcer disease,

elevated baseline liver enzyme concentrations, and thrombocytopenia or neutropenia are contraindications to therapy. Patients should avoid exposure to the sun, because photosensitivity can be a complication. Patients should refrain from sexual intercourse during therapy. Patients should also avoid folate-containing vitamins. Appropriate candidates for systemic medical therapy should also be willing to accept a small risk of tubal rupture and participate in closely monitored follow-up.

Care and diligent effort should be made to definitively diagnose an ectopic pregnancy prior to MTX treatment. Medical treatment of an abnormal pregnancy of unknown location as a presumed ectopic pregnancy may expose a patient to MTX and its side effects unnecessarily, may result in future pregnancies being viewed as high risk for ectopic pregnancy, and may expose an intrauterine pregnancy to a known teratogen and abortifacient. Utilizing data derived from three North American Teratology Information Services between 2002 and 2010, Nurmohamed and associates reported the outcome of eight women exposed to high-dose MTX for the treatment of a presumed ectopic pregnancy and later identified to have a viable intrauterine pregnancy. Three patients miscarried shortly after exposure, three patients elected to terminate their pregnancies, and two patients had newborns with severe malformations.

Medical Therapy by Local Injection

In 1987, Feichtinger and Kemeter reported the direct injection of MTX under transvaginal ultrasound guidance into an ectopic gestational sac. They instilled 10 mg of MTX and observed resolution of the pregnancy within 2 weeks. Other investigators, including Kojima and colleagues, have reported the successful application of local MTX administered by direct injection at the time of laparoscopy. In 1993, Fernandez and colleagues reported a large series of patients who underwent intratubal MTX at a dose of 1 mg/kg under transvaginal sonographic control. Eighty-three of one-hundred patients were successfully cured; however, twenty-eight of the eighty-three successfully cured patients required additional MTX, which was subsequently given intramuscularly.

Direct injection of MTX has theoretic advantages over systemic treatment. The concentration of MTX at the site of implantation is many times higher after local injection than after systemic administration. With less systemic distribution of the drug, a smaller therapeutic dose might be necessary and toxicity would be less. Schiff and associates, however, evaluated the pharmacokinetics of MTX after local tubal injection and found that the peak serum level of MTX after local injection was not significantly lower than that of patients who were treated systemically with a similar dose of the drug. In addition, the success rates in practice appear to be unacceptably low. A review by Carson and Buster revealed that only 83% of the direct tubal injection procedures reported were successful.

Several trials have been conducted evaluating other intratubal agents administered for the treatment of ectopic pregnancy. Studies using prostaglandins (prostaglandin $F_{2\alpha}$, 15-methyl-prostaglandin $F_{2\alpha}$) were discouraging because of poor efficacy and serious adverse effects, including cardiac arrhythmia, malignant hypertension, and gastrointestinal symptoms. Other investigators have studied the use of hyperosmolar glucose, a less toxic agent, injected locally into the gestational sac of the ectopic gestation by either laparoscopy or transvaginal ultrasound-guided needle puncture. Lang and colleagues reported a 92% success rate using hyperosmolar glucose by laparoscopic puncture. Gjelland and associates reported successful treatment in 32 (82%) of 39 patients using local hyperosmolar glucose administered by transvaginal ultrasound guidance. They noted an inverse relationship between initial serum hCG concentrations and successful outcomes. Further larger trials are needed, however, to determine the precise clinical role, if any, of local injection therapies for ectopic pregnancy.

Surgical Treatment

Conservative Surgical Treatment

Conservative management of an unruptured ectopic pregnancy usually consists of one of two possible procedures: linear salpingotomy or segmental resection. A conservative surgical approach is possible when the diagnosis of ectopic pregnancy is made sufficiently early so that rupture of the oviduct has not yet occurred.

Linear Salpingotomy In women who wish to preserve their fertility, conservative surgery by linear salpingotomy is considered the gold standard for the management of a distal tubal pregnancy. Recent studies have reported that the uninvolved tube may be abnormal, either grossly or subclinically, in at least 50% of cases of ectopic pregnancy. Although there have been no randomized studies comparing the fertility outcome after conservative and radical surgery for ectopic pregnancy, most of the available information suggests that the subsequent intrauterine pregnancy rate is higher after conservative surgery (linear salpingotomy).

In 1898, Kelly was among the first to advocate conservative surgery for tubal gestation. He recommended drainage of the pregnancy per vaginum, particularly for chronic hemorrhage and formation of a pelvic hematoma. More than half a century elapsed before Stromme reported the first successful use of salpingotomy to treat a patient with tubal pregnancy. In 1973, Stromme reported his surgical experience with 36 cases of unruptured tubal pregnancy, 21 of which were treated by conservative salpingotomy. Five were performed when there was only one tube remaining. Only one term pregnancy ensued from the five single-tube procedures, but Stromme's work led to the development of more effective conservative surgical procedures. Stromme reported a rate of 13.5% repeat ectopic pregnancies, which was no higher than the repeat ectopic rate at the time for more radical procedures.

Since the time of Stromme's report, physicians have achieved good success with conservative linear salpingotomy. According to the review by Yao and Tulandi, of the 1,514 patients attempting to conceive following linear salpingotomy, 61.2% had a subsequent intrauterine pregnancy, whereas 15.5% had an ectopic recurrence. On the other hand, only 38.1% of the 3,584 patients attempting to conceive following salpingectomy had a subsequent intrauterine pregnancy, although the ectopic recurrence risk was likewise lower (9.8%). In 1993, Silva and colleagues reported a prospective cohort study in which the intrauterine pregnancy rates were 60.0% and 53.8% and recurrent ectopic rates were 18.3% and 7.7% in the conservative and radical surgery groups, respectively. Many of the available reports on linear salpingotomy unfortunately do not describe the condition of the uninvolved oviduct. Langer and associates did include a description of the uninvolved oviduct in their report of 30 patients undergoing salpingotomy. Of the patients in whom the contralateral tube was normal, 80% subsequently had normal pregnancies. When the contralateral tube was damaged or contained peritubal adhesions, only 11 (55%) patients later achieved a viable pregnancy.

Among recent reports of salpingotomy performed on a single remaining oviduct, an intrauterine pregnancy rate of about 50% has been achieved by several investigators, although the results are quite variable, and some reports have only a limited number of patients treated. The repeat ectopic pregnancy rate in the singletube salpingotomy patients appears to be about 20%, a slightly higher rate than that in series of patients with both oviducts.

In general, conservative salpingotomy is the preferred treatment for patients who desire further pregnancies. For results to be optimal, the oviduct should be unruptured and without serosal invasion, and the patient should be in a surgically stable condition.

STEPS IN THE PROCEDURE

Laparoscopic Salpingotomy

- Patient in dorsal lithotomy position following induction of general endotracheal anesthesia
- Placement of Foley catheter into bladder to gravity drainage
- Placement of intrauterine manipulator
- Establishment of pneumoperitoneum
- Placement of laparoscopic trocars (three-puncture technique) with patient additionally placed in moderate Trendelenburg position
- Evacuation of hemoperitoneum with large-bore suction irrigator, if present
- Infiltration of intended salpingotomy incision site with dilute solution of vasopressin (prepared by mixing 20 U of vasopressin with 100 mL of physiologic saline), utilizing a 22-gauge needle inserted either through the abdominal wall or through a 5-mm portal
- Performance of the salpingotomy incision in the area of maximal bulge on antimesenteric side of fallopian tube utilizing laser, unipolar needle electrocautery, or scissors
- Spontaneous extrusion of products of conception from the fallopian tube, or following hydrodissection or gentle tubal compression
- Removal of trophoblastic tissue in an endoscopic bag
- Careful irrigation of the fallopian tube and inspection for hemostasis
- Fallopian tube left to heal by secondary intention or sutured with fine suture

Transabdominal Conservative Procedure The procedure for linear salpingotomy starts by exposing, elevating, and stabilizing the tube. A linear incision is then made over the distended segment of the tube ([Figs. 34.6](#) and [34.7](#)). The incision is extended through the antimesenteric wall until entry is made into the lumen of the distended oviduct. When gentle pressure is exerted from the opposite side of the tube, the products of gestation are gently expressed from the lumen. Because a

P.784

certain amount of separation of the trophoblast has usually occurred, the conceptus generally can be easily removed from the lumen. Gentle traction by suction or by forceps teeth can be used if necessary, but care should be taken to avoid trauma to the mucosa. Any remaining fragments of the anchoring trophoblast should be removed by profuse irrigation of the lumen with warm lactated Ringer solution to prevent further damage to the mucosa.

FIGURE 34.6 Removal of ectopic pregnancy of the distal ampulla. **A:** Distal ampulla involved with ectopic pregnancy. **B:** Initial incision on the antimesenteric border. **C:** The gestational contents are carefully removed by use of blunt dissection. **D:** Tubal serosa and muscularis are closed as a single layer with 5-0 nonreactive suture material.

FIGURE 34.7 Removal of a midampullary ectopic pregnancy. **A:** Midampullary ectopic pregnancy. **B:** Antimesenteric incision with fine microdiathermy needle. **C:** The pregnancy is carefully removed by grasping the tissue and lifting while bluntly teasing the trophoblastic tissue away from the endosalpinx. **D:** The serosa and muscularis are closed with interrupted 5-0 nonreactive suture material.

Care must be taken to provide complete hemostasis in the tubal mucosa; failure to do so results in troublesome postoperative bleeding, which can lead to the formation of intraluminal adhesions. The small tubal vessels are easily identified while the tube is being irrigated, and loupe magnifying glasses can be used if necessary for better resolution. An operating microscope is usually not needed.

The mucosal margins are then closed with interrupted sutures, taking care that only the serosa and muscularis are approximated and that there is no undue tension. Care should be taken also to ensure that no suture material is retained on the mucosal surface, because even a small amount can produce a secondary inflammatory reaction with subsequent adhesion formation.

Laparoscopic Conservative Procedure Currently, most ectopic pregnancies are treated by laparoscopic surgery. In fact, most studies have suggested that laparoscopic surgery is superior to laparotomy in hemodynamically

stable patients. Advantages of laparoscopy include lower cost, shorter hospital stay, less surgical blood loss, less analgesia requirement, and a shorter postoperative convalescence. Not all patients, however, may be suitable for laparoscopic treatment. These include patients with an unstable hemodynamic status, those with severe pelvic adhesions, and those with a specific contraindication to laparoscopy.

The presence of a hemoperitoneum should not preclude laparoscopic treatment. Using a large-bore suction irrigator, the blood can be evacuated, and the pelvic organs irrigated with a crystalloid solution. Once the ectopic has been documented, two auxiliary puncture sites are made suprapubically to allow manipulation of the fallopian tube (**Fig. 34.8**). Using a 22-gauge injection needle inserted either directly through the abdominal wall or through a 5-mm portal, a dilute solution of vasopressin (prepared by mixing 20 U of vasopressin with 100 mL of physiologic saline) is injected into the tubal wall

P.785

at the area of maximal bulge. This step is crucial and allows for minimal bleeding and the precise removal of the ectopic pregnancy without damaging the surrounding mucosa. Laser, unipolar needle electrocautery, or scissors can then be used to make the salpingotomy incision. It is important to make the incision along the antimesenteric wall of the tube in the area of maximal distension and large enough to allow for complete extrusion of the products of conception without difficulty. It is also important to keep the fallopian tube taut. If the products of conception do not spontaneously extrude following

P.786

completion of the incision, either hydrodissection or gentle tubal compression with a blunt probe or suction irrigator will usually work. The tissue is then placed in an endoscopic bag and removed from the abdominal cavity. Special care is taken to remove all of the placental tissue, as it is known that persistent peritoneal implants of trophoblastic tissue following laparoscopic salpingotomy may occur. After the tissue is removed, the tube is irrigated carefully and checked for hemostasis. The tube is then either left to heal by secondary intention or sutured, with secondary intention being appropriate for most cases. A laparoscopic salpingotomy study by Fujishita and colleagues failed to demonstrate any benefit from suturing over the nonsuturing technique.

FIGURE 34.8 Laparoscopic salpingostomy for ectopic pregnancy. **A:** An incision is made with the fine monopolar diathermy needle along the antimesenteric border of the oviduct. **B:** The trophoblastic mass is removed with forceps. **C:** The lumen is allowed to heal by secondary intention.

The results of salpingotomy are very similar, whether performed by either laparotomy or laparoscopy. Yao and Tulandi reported that among the 811 patients attempting to conceive after the laparotomy approach, the intrauterine pregnancy rate was 61.4%, and the recurrent ectopic pregnancy rate was 15.4%. Similarly, of the 703 patients attempting to conceive following laparoscopy, 61.0% had an intrauterine pregnancy, and 15.5% had a repeat ectopic pregnancy.

Persistent Tubal Ectopic Gestation Persistent trophoblastic tissue can remain after linear salpingotomy. Although there can be an initial decrease in the β -hCG level after surgery, the level can then slowly rise, ultimately resulting in symptoms. For this reason, it is recommended to obtain weekly β -hCG measurements after linear salpingotomy. Yao and Tulandi reported that persistent ectopic pregnancy was encountered in 8.3% of patients treated by laparoscopic salpingotomy and in 3.9% of patients treated by a similar procedure at laparotomy. The incidence of persistent ectopic pregnancy following laparoscopy, however, was quite variable,

ranging from 3.5% to 20.0%. Pouly and colleagues achieved a relatively low 3.5% incidence of recurrent ectopic pregnancy in their series. Indeed, in many current practices, the incidence of persistent ectopic pregnancy appears to be low. There is a tendency for persistent trophoblastic tissue to be found in the proximal portion of the tube; therefore, special attention to this area is important. The use of hydrodissection to flush out the gestational products rather than removal of trophoblastic tissue piecemeal with forceps is recommended. One must, however, never assume that the chance for persistent trophoblast is entirely mitigated by the characteristics and ease of the procedure.

Risk factors for persistent ectopic pregnancy include small ectopic pregnancies (<2 cm diameter), early therapy (<42 days from last menstrual period), and high concentrations of β -hCG preoperatively. Rabischong and associates reported the outcome of 1,306 laparoscopic salpingotomy procedures and noted that a pretherapeutic hCG level of at least 1,960 IU/L was the only factor related to treatment failure. In high-risk cases, a single dose of MTX (1 mg/kg) can be administered postoperatively for prophylaxis. Graczykowski and Mishell demonstrated that the rate of persistent ectopic pregnancy was reduced to a rate of 1.9% using MTX prophylaxis in comparison with a rate of 14.5% among controls. Spandorfer and associates suggested that the postoperative day 1 serum β -hCG concentration can be used as a predictor of persistent ectopic pregnancy. They reported that a day 1 serum β -hCG decrease of less than 50% from preoperative levels may be predictive of persistent ectopic pregnancy. If day 1 serum β -hCG concentrations decreased greater than 50% of the preoperative value, there was more than an 85% probability that a persistent ectopic pregnancy would not occur.

Options for treatment of persistent ectopic pregnancy include reoperation and medical therapy. The choice of treatment can also include expectant therapy if the patient is asymptomatic and β -hCG levels are not rapidly increasing. MTX appears to be particularly effective in the setting of persistent ectopic pregnancy following linear salpingotomy. In the largest series reported to date, all 19 patients with persistent ectopic pregnancies were successfully treated with a single intramuscular dose of systemic MTX (50 mg/m²). The patient's reproductive prognosis does not appear to be particularly lessened following a persistent ectopic pregnancy. In a review of 50 cases, Seifer and colleagues reported that after 36 months of follow-up, there were 19 (59%) intrauterine pregnancies and no recurrent ectopic pregnancies in 32 such women attempting to conceive. Because of the chance for persistent ectopic pregnancies to present relatively late following initial appropriate decreases in β -hCG concentrations, it is recommended to obtain weekly β -hCG measurements until they return to the normal range.

Segmental Resection The optimal surgical approach to the isthmic ectopic pregnancy remains controversial. Three conservative operations have been described: segmental resection of the involved portion of oviduct with primary microsurgical anastomosis, segmental resection with reanastomosis at a later operation, and linear salpingotomy. In Sweden, Swolin initially advocated for segmental resection in 1967. Subsequently, other surgeons, including Stangel and Gomel as well as DeCherney and Boyers, have found segmental resection to be preferable to salpingotomy in most cases of isthmic pregnancy. In the isthmus, the tubal lumen is narrower and the muscularis is thicker than in the ampulla. Thus, the isthmus is more predisposed to severe postoperative damage, and the rate of proximal tubal obstruction seems to be higher following linear salpingotomy.

With segmental resection and end-to-end reanastomosis, the implantation site is removed so that it cannot be involved in a subsequent tubal pregnancy. A more normal architecture for the oviduct is consequently achieved. The anatomic restoration is a time-consuming process requiring special expertise and extensive microsurgical experience; *it should not be undertaken by an inexperienced surgeon*. The success of future pregnancies depends on the skill and precision of technique used in the procedure, and, once begun, the only alternative is total salpingectomy.

Segmental resection is best performed with loupe magnification or the operating microscope; the required

microsurgical techniques are identical to those discussed elsewhere in this text. Care must be taken to avoid trauma to the very vascular oviduct; only patients with minimal bleeding should be considered for the operation. The adjacent mesosalpinx must be incised and removed with care to avoid the formation of a hematoma in the broad ligament (**Fig. 34.9**). The muscularis sutures are placed with the use of magnification and no. 6-0 or 7-0 delayed absorbable material, and the serosa is secondarily supported by additional interrupted sutures. Patency of the oviduct is tested by insufflation of the uterine cavity with indigo carmine dye.

Radical Surgical Treatment

Total salpingectomy is required when a tubal pregnancy has ruptured and a substantial hemoperitoneum has occurred. In these cases, the intra-abdominal hemorrhage must be quickly controlled, and a conservative operation should not be attempted. Extensive hemoperitoneum places a patient in serious jeopardy of cardiopulmonary crises.

A salpingectomy may also be indicated for other reasons. These include a recurrent ectopic pregnancy in the same fallopian tube, an ectopic pregnancy in a severely damaged tube, and an ectopic pregnancy in a woman who has completed her family.

Some earlier reports advocated for the combined use of a prophylactic oophorectomy with salpingectomy. Theoretically,

P.787

removal of the ipsilateral ovary would cause the other ovary to ovulate more frequently, perhaps favoring future pregnancy. In reality, the benefits of removal of the contralateral ovary are outweighed by the consideration that any future oophorectomy would then mean castration. The high success rate of IVF is a further incentive to maintain functioning of both ovaries.

FIGURE 34.9 Segmental resection of midtubal ectopic pregnancy. **A:** A needle cautery is useful to resect the pregnancy. **B:** Care should be taken to approximate the mesosalpinx. Reanastomosis can be performed either immediately or in 3 to 5 months.

As stated earlier, most patients with an ectopic pregnancy currently are candidates for laparoscopic surgery. Radical surgical procedures, such as salpingectomy, are also easily adapted to laparoscopic surgery. Of course, certain patients remain noncandidates for laparoscopic surgery, including those with unstable hemodynamic status or severe pelvic adhesions. The latter patients are still best treated by laparotomy.

FIGURE 34.10 Salpingectomy for tubal pregnancy. A: The tube has been delivered, and the mesosalpinx is being clamped and cut with a succession of Kelly clamps.

At laparotomy, total salpingectomy with partial cornual resection has been criticized for providing a residual sinus tract that allows development of a subsequent interstitial pregnancy. This problem may not lie in the procedure per se but rather the surgeon's performance of the procedure. Complete peritonealization of the cornual incision and advancement of the round and broad ligaments over the uterine cornua (the modified Coffey technique of uterine suspension) should provide complete protection from recurrent interstitial pregnancy ([Fig. 34.10](#)). A too-vigorous resection of the uterine cornua can also cause problems. A residual myometrial defect can cause uterine rupture, interstitial recanalization, or placental encroachment during a subsequent intrauterine pregnancy and should be avoided by making certain that the interstitial resection includes less

than one third the thickness of the cornual portion of the myometrium.

FIGURE 34.10 (Continued) B: The mesosalpinx has been completely clamped and cut. The *dashed line* indicates the line of excision of the tube at the cornu. **Inset** shows the superficial wedge resection of the interstitial portion of the tube and the suture of the cornu. **C:** The method of placing a mattress suture for peritonealization is shown with anchoring of the medial portion of the broad ligament to the uterus, a little posterior and superior to the uterine incision. **D:** Peritonealization is completed by tying the mattress suture, which brings the broad and the round ligaments over the uterine cornu.

Dubuisson and colleagues reported the first large series of patients treated by total salpingectomy at laparoscopy for ampullary ectopic pregnancies. They used a three-puncture laparoscopic technique. They thermocoagulated the tubal isthmus, mesosalpinx, and tubo-ovarian ligament, followed by excision with hook scissors. The tube was subsequently removed with polyp forceps through one of the suprapubic punctures. They reported no immediate complications in 98 patients successfully treated at laparoscopy, although one patient experienced a postoperative deep venous thrombosis. Two patients initially intended for laparoscopy, however, required laparotomy because of either severe pelvic adhesions or significant intraperitoneal blood. In a later report, Dubuisson and associates advised opening the tube first to aspirate the trophoblast in cases in which the tube is large to more easily remove the tissue through a 12-mm trocar.

Technique of Salpingectomy at Laparotomy A suprapubic Pfannenstiel or low midline vertical abdominal incision is used, and the distended tube is elevated. The mesosalpinx is clamped with a succession of Kelly clamps as close to the tube as possible (**Fig. 34.10A**). The tube is then excised by cutting a small myometrial wedge at the uterine cornu (**Fig. 34.10B**). Care should be taken to avoid a deep incision into the myometrium. A figure-of-eight mattress suture of no. 0 delayed absorbable material is used to close the myometrium at the site of the wedge resection. The mesosalpinx is closed with interrupted ligatures of no. 2-0 delayed absorbable suture. Complete hemostasis is essential to avoid a hematoma of the broad ligament.

The fundus is held forward, and the round and broad ligaments are sutured over the uterine cornu (**Fig. 34.10C**). This procedure, the modified Coffey suspension, accomplishes complete peritonealization. Mattress sutures anchor the broad ligament to the uterus. The no. 0 delayed absorbable suture first penetrates the broad ligament from its anterior surface, just below the round ligament, at a distance of 2 to 3 cm from the cornu. The next “bite” is taken into the fundus of the uterus, a little posterior and superior to the uterine incision. The suture is then placed through the posterior aspect of the broad ligament, about 1 cm lateral to the previous suture. When this suture is tied, the cornual incision and the mesosalpinx are covered with mesothelium (**Fig. 34.10D**). If there is excessive tension on this suture, or if peritonealization is incomplete, then supporting sutures can be placed in the myometrium and the round ligament to ensure that the peritonealization suture will remain in place.

Technique of Salpingectomy at Laparoscopy Several methods have been successfully used for laparoscopic salpingectomy, including endoscopic stapling devices, endocoagulation, bipolar cautery, and pretied endoscopic ligatures. Following

P.789

placement of laparoscopic trocar ports (usually three-puncture technique), irrigation of the pelvis, and the evacuation of all blood clots, the involved tube is then grasped with a toothed grasper. One method then includes cauterizing the tubo-ovarian ligament first with bipolar forceps, followed by transection with scissors (**Fig. 34.11**) or the blade of a coagulation-cutting device. The mesosalpinx is similarly cauterized and transected, taking care to stay as close as possible to the fallopian tube. The proximal tubal isthmus is then cauterized and transected. Care should be taken such that excess cauterization of the uterine cornu does not occur because of concerns about the potential of interstitial sinus tracts or diminished myometrial integrity. The specimen is then placed in an endoscopic specimen retrieval bag and removed through a 12-mm port. Alternatively, the tube can be excised distal to a no. 0 polyglactin 910 (Vicryl) Endoloop ligature secured proximal to the ectopic implantation site, although this technique works optimally if the entire mesosalpinx is transected such that the Endoloop ligatures can be placed precisely at the tubal insertion at the cornua. Consideration may also be given to covering the proximal tubal pedicle with an absorbable adhesion prevention barrier.

FIGURE 34.11 Techniques of laparoscopic salpingectomy using bipolar cautery and excision.

Comparisons of Surgical and Medical Therapy

Several studies have compared conservative laparoscopic treatment with systemic MTX in the management of ectopic pregnancy. Saraj and associates reported a randomized trial comparing single-dose intramuscular MTX

(1 mg/kg) with laparoscopic salpingotomy. They reported similar immediate treatment success rates: 94.7% for MTX and 91.4% for laparoscopic salpingotomy. Additional MTX injections were required in 15.8% of women who were randomized to the single-dose MTX group. Initial serum hCG titers were higher for the patients who required additional MTX doses than for those who required only one dose. The mean times for serum progesterone and hCG concentrations to decrease to less than 1.5 ng/mL and 15 IU/L, respectively, were significantly less for laparoscopic salpingotomy. Fernandez and colleagues also reported a randomized trial of conservative laparoscopic treatment and MTX administration (by either transvaginal or intramuscular injection) and found similar immediate treatment success. Additional studies have also suggested that despite the increased number of posttreatment visits that are necessary, MTX therapy results in appreciable cost savings in comparison with laparoscopic treatment.

Hemodynamically stable patients who meet strict criteria, without excessively large or advanced ectopic pregnancies, may therefore be offered either medical or conservative surgical therapy. The immediate clinical and long-term outcomes in these selected patients appear to be similar.

INTERSTITIAL PREGNANCY

Interstitial (cornual) pregnancy is a rare condition that accounts for no more than 2% to 4% of all tubal pregnancies. The condition occurs once every 2,500 to 5,000 live births. An interstitial pregnancy should first be differentiated from an angular pregnancy. The latter entity was first described by Kelly in 1898. It occurs when an embryo implants in the lateral angle of the uterine cavity medial to the internal ostium of the fallopian tube. The clinical course of an angular pregnancy varies, although in many instances leads to asymmetric and symptomatic enlargement of the uterus.

Because the gestational sac is better protected in the interstitial than in other portions of the tube, it was felt that symptoms of interstitial ectopic pregnancies may manifest later (>12 gestational weeks). This general belief has recently been disputed, however, by Tulandi and Al-Jaroudi, who reported the results of an Interstitial Pregnancy Registry sponsored by the Society of Reproductive Surgeons (SRS). In this registry, 14 cases (43.7%) of rupture of interstitial pregnancy were reported, all at the time of initial diagnosis. Pelvic pain and vaginal spotting are common early symptoms. The developing chorionic villi may eventually erode into the blood vessels of the uterine cornu, causing a severe hemorrhage. Because the pregnancy occurs at the most richly vascularized area of the female pelvis—the junction of the uterine and ovarian vessels—rupture usually causes profound and sudden shock.

Before 1893, the only available reports on interstitial pregnancies were from autopsies. Since then, numerous cases have

P.790

been reported. Most of the same risk factors for interstitial pregnancy are similar to those for ectopic pregnancy in general, including PID, previous pelvic surgery, and the use of assisted reproductive technologies. Ipsilateral salpingectomy may be a unique risk factor for interstitial pregnancy, occurring in 37.5% of patients, according to the SRS Interstitial Pregnancy Registry. Earlier diagnosis and more experience in treating this disorder have reduced the present maternal mortality rate to approximately 2% to 2.5% of all interstitial pregnancies.

The diagnosis of interstitial pregnancy is made by critical evaluation of all the criteria used for other types of tubal pregnancy. The presentation often includes acute abdominal pain, intraperitoneal bleeding, a low hematocrit, and a positive serum or urine pregnancy test. Diagnostic tests include the sensitive β -hCG immunoassay and vaginal ultrasonography.

Asymmetry of the uterus, often indicative of an interstitial pregnancy, can be misinterpreted as a pregnancy in a bicornuate uterus or a myoma in a pregnant uterus instead of an interstitial pregnancy. Knowledge of the previous shape of the uterus can help to confirm or exclude the existence of a bicornuate or myomatous uterus.

A firm protrusion on the uterus suggests a myoma; a soft, tender asymmetric enlargement suggests an interstitial pregnancy.

Timor-Tritsch and colleagues established transvaginal ultrasonic criteria for interstitial pregnancy. These criteria include (a) an empty uterine cavity, (b) a chorionic sac seen separately and greater than 1 cm from the most lateral edge of the uterine cavity, and (c) a thick myometrial layer surrounding the chorionic sac. All of these parameters were relatively specific (88% to 93%) but lacked high sensitivity (only about 40%) for the diagnosis of interstitial pregnancy. Other investigators have described an “interstitial line sign.” This sign refers to the visualization of an echogenic line extending from the endometrial cavity into the cornual region and abutting the interstitial mass or gestational sac. Ackerman and associates reported that the “interstitial line sign” was 80% sensitive and 98% specific for the diagnosis of interstitial pregnancy.

Often, the difference between an interstitial pregnancy and an angular pregnancy is subtle. In addition, it may be easy to confuse an angular pregnancy with a pregnancy in a septated or bicornuate uterus. Because ultrasound cannot always confirm the position of the pregnancy, laparoscopy may be required to confirm the diagnosis. In cases of massive intra-abdominal bleeding, an immediate laparotomy should be performed.

Treatment for Interstitial Pregnancy

The choice of treatment for an interstitial (cornual) pregnancy depends on the extent of trauma that has occurred in the uterine wall and on the interest of the patient in preserving her childbearing function. Systemic MTX has been used in a limited number of patients with unruptured interstitial pregnancies. Tanaka and coworkers reported the first successful treatment of an interstitial pregnancy with systemic MTX. Since this report, according to Lau and Tulandi, there have been 40 additional published cases of interstitial pregnancies treated with the use of systemic or local MTX, or a combination of both. An overall success rate of 83% was reported.

If an interstitial pregnancy is observed when it is still small, it might be excised using conservative laparoscopic techniques. In their review, Lau and Tulandi noted 22 successful cases of laparoscopic treatment of interstitial pregnancy. Techniques used varied from cornuostomy with careful extraction of the products of conception to a more formal cornual resection. Hemostatic methods have included ligation of the ascending branches of the uterine vessels, intracorporeal and extracorporeal suturing, and surgical stapling. A further review by Moawad et al. reported 164 successful cases of laparoscopic management of interstitial pregnancies out of 192 attempted procedures. Although the immediate efficacy of laparoscopic conservative procedures for interstitial pregnancy is high, the risk of uterine rupture in a subsequent pregnancy is unknown. Uterine rupture can occur at the site of a previous interstitial pregnancy. Patients treated by conservative laparoscopic techniques should therefore be carefully counseled about this risk. The risk of uterine rupture also emphasizes the importance of proper suturing of the uterine cornu during conservative surgical treatment of an interstitial pregnancy.

For many surgeons, cornual resection and repair of the defect by laparotomy remains the standard conservative surgical procedure for interstitial pregnancy. Provided that uterine rupture has not occurred, this is technically feasible in most cases. Unfortunately, in many cases in which uterine rupture has occurred or a very large interstitial pregnancy is present, a hysterectomy may be required. Hysterectomy remains the treatment of choice for pregnancies advanced to such a stage that repair of the cornu would be technically difficult and medically hazardous.

Excision of Interstitial Pregnancy by Cornual Resection and Salpingectomy

Whenever possible, the ovary should be saved. A cornual resection and salpingectomy are performed by first ligating the ascending uterine vessels where they approach the cornu ([Fig. 34.12A](#)). Each is ligated separately with a figure-of-eight suture. One may also consider the use of a dilute solution of vasopressin (prepared by mixing 20 U of vasopressin with 30 mL of physiologic saline) injected in the intended myometrial incisional line to

further optimize intraoperative hemostasis. The interstitial pregnancy is excised in a V-shaped manner, and the myometrium is approximated with a figure-of-eight closure using no. 0 delayed absorbable suture (**Fig. 34.12B**). The remainder of the fallopian tube is excised. If it becomes necessary, the round ligament can be cut and resutured to the cornu and the uterine serosa by use of interrupted sutures (**Fig. 34.12C**). The round and broad ligaments are brought over the incision with mattress sutures (the modified Coffey suspension) (**Fig. 34.12D**), and additional interrupted sutures of no. 2-0 or no. 3-0 delayed absorbable material can be used to secure the serosa of the round ligament to the serosa of the uterus to maintain the operative site in a permanent retroperitoneal position.

OVARIAN ECTOPIC PREGNANCY

Because IUDs protect the endometrium and, to a lesser extent, the proximal oviducts from implantation, it was expected that when IUDs were introduced, future reports of extrauterine pregnancies might show an increased rate of ovarian involvement. Data from the Cooperative Statistical Program of the Population Council show that 1 of every 9 ectopic pregnancies among IUD users is an ovarian pregnancy. Of total pregnancies among IUD users, 4.3% are extrauterine.

There are several reviews in the English literature on the subject of primary ovarian pregnancy. Boronow and associates summarized 62 cases in a review of the literature between 1950 and 1963. Campbell and associates brought the list up to date through 1973 with 91 cases, including three new cases of their own. Pratt-Thomas and colleagues reported an additional 10 new cases in 1974. Grimes and associates summarized the major reviews through 1980 and added 18 previously unreported cases of primary ovarian pregnancy from the records of six hospitals. Their combined data from this review,

P.791

the hospital cases, and four other recent reports totaled 34 cases of primary ovarian pregnancy among 236,983 deliveries, a rate of 1 ovarian pregnancy in 7,000 deliveries.

FIGURE 34.12 Salpingo-oophorectomy with resection of interstitial pregnancy. **A:** The dotted line denotes the line of excision. **B:** Tube, ovary, and the cornual pregnancy have been excised. The myometrium is being approximated with figure-of-eight sutures of no. 0 delayed absorbable suture. Note that the uterine vessels have been ligated separately. **C:** The round ligament, which was cut, is being resutured to the cornu. The ovarian vessels have been ligated, and the broad ligament has been closed with a continuous lock stitch. Serosa of the uterine wound is closed with a simple continuous stitch. **D:** The cornual wound is covered with the round and broad ligaments.

In an intrafollicular ovarian pregnancy, the second stage of meiosis, ovum capacitation, and fertilization each occur within the follicle. Only 15% of cases of ovarian pregnancy are intrafollicular in origin. In an intrafollicular pregnancy, a wellpreserved corpus luteum can be identified in the wall of the gestational sac. Four other criteria presented by Spiegelberg for identifying an intrafollicular pregnancy are that the tube, including the fimbria ovarica, is intact and is clearly separate from the ovary; that the gestational sac definitely occupies the normal position of the ovary; that the sac is connected to the uterus by the utero-ovarian ligament; and that ovarian tissue is unquestionably demonstrated in the wall of the sac.

Diagnosis of Ovarian Pregnancy

Early diagnosis of an ovarian pregnancy, of all the diagnoses relating to extrauterine gestations, is perhaps the most difficult. As stated previously, the classic symptoms of a tubal gestation are abdominal pain, amenorrhea, and bleeding; however, persistent pelvic pain alone, a symptom not always easily related to its cause, is the most frequent clinical manifestation of an ovarian gestation. Although an adnexal mass is palpable in as many as 60% of ovarian pregnancies, the mass is frequently confused with a leaking corpus luteum hematoma.

All of the test criteria used for diagnosing a tubal pregnancy are helpful in diagnosing a primary ovarian

pregnancy. In particular, the highly sensitive β -hCG immunoassay is effective for identifying the presence of low hCG levels. The test can confirm the presence of a gestational process, but knowing the β -hCG level does not help to precisely locate the gestation. Incomplete spontaneous abortion with a leaking corpus luteum hematoma, one of the most common complications of pregnancy, mimics an ovarian pregnancy. In such cases, a D&C will often show the remnants of trophoblastic villi responsible for the low levels of β -hCG.

A tubal pregnancy can easily be ruled out with laparoscopy, but an ovarian pregnancy is sometimes difficult to differentiate from a leaking corpus luteum hematoma by gross appearance. Ultrasonography can be helpful, but only in advanced ovarian pregnancy will the ultrasound image show a discrete gestational sac, therefore confirming an ovarian pregnancy.

Critical evaluation of all of the diagnostic studies, particularly the sensitive β -hCG immunoassay and vaginal ultrasonography, is necessary in making the diagnosis. When the β -hCG is positive, ultrasonography shows no intrauterine gestational sac, and free blood exists in the peritoneal cavity, a laparoscopy should be performed to confirm or refute a diagnosis of suspected ovarian pregnancy.

Treatment for Ovarian Pregnancy

Raziel and Golan, as well as Chelmow and colleagues, reported cases in which an intact ovarian pregnancy was diagnosed by laparoscopy and systemic MTX treatment was successful. In many cases, an ovarian pregnancy is diagnosed after a significant hemoperitoneum has occurred and medical therapy is contraindicated. An ovarian pregnancy is easily confused with a leaking corpus luteum hematoma. For this reason, a safe approach is to proceed with localized surgical resection of the bleeding mass with conservation of the ovary, if possible. Unless the diagnosis is made late, the ovary can usually be preserved. In 1997, Seinera and colleagues reported successful laparoscopic treatment of ovarian pregnancy in eight patients over a 12-year time span. Einkenkel and associates even reported the successful conservative resection of an ovarian pregnancy in a patient with ovarian hyperstimulation. The concomitant increased ovarian size, fragility, and vascularity presented an additional surgical challenge for these authors, although the use of intraoperative ultrasound

P.792

greatly facilitated the precise localization of the ectopic pregnancy within the ovary.

Only rarely is the hemorrhage so profuse that oophorectomy is required to control bleeding. Even if the last trophoblastic villus cannot be removed in the ovarian resection, the ovary should be preserved. Any remaining trophoblastic tissue will usually degenerate rapidly or respond to postoperative MTX therapy and therefore should produce no long-standing clinical problem.

ABDOMINAL ECTOPIC PREGNANCY

An abdominal pregnancy is perhaps both the rarest and the most serious type of extrauterine gestation. Reports of the frequency of abdominal pregnancy vary, ranging from 1 in 3,371 deliveries to greater than 1 in 10,200 deliveries. Stafford and Ragan reported an incidence of 1 abdominal pregnancy in 7,269 deliveries, a figure that is representative of the reports in the literature.

Abdominal pregnancies are classified as primary or secondary. Most are secondary, the result of early tubal abortion or rupture with secondary implantation of the pregnancy into the peritoneal cavity. To be considered a primary abdominal pregnancy, the pregnancy must meet the three criteria defined by Studdiford in 1942:

1. Both tubes and ovaries must be in normal condition with no evidence of recent or remote injury.
2. No evidence of uteroperitoneal fistula should be found.
3. The pregnancy must be related exclusively to the peritoneal surface and be early enough to eliminate the possibility that it is a secondary implantation following a primary implantation in the tube.

Secondary abdominal pregnancy occurs when a tubal gestation attaches itself to other viscera as the enlarging placenta spreads through the wall of the tube or is aborted through the fimbriated end. The placenta probably retains some tubal attachment, which supplies blood for the gestation to continue developing in the new peritoneal site. Rare types of secondary abdominal pregnancies have occurred after spontaneous separation of an old cesarean section scar, after uterine perforation during a therapeutic or elective abortion, and after subtotal or total hysterectomy.

Diagnosis of Abdominal Pregnancy

Early diagnosis of an abdominal pregnancy is difficult but critical, because a catastrophic hemorrhage can result from separation of the placenta later in pregnancy. A history of recurrent abdominal discomfort, fetal movement beneath the abdominal wall, and the presence of fetal movements high in the upper abdomen should alert the clinician to the possibility of an abdominal implantation. Other clinical clues include cessation of fetal movement, vomiting late in pregnancy, fetal malposition, a closed and uneffaced cervix, or the failure of oxytocin to stimulate the gestational mass.

Confirmation of the diagnosis requires demonstration of the fetus outside the uterine cavity. In their review of 199 cases, Costa and colleagues reported that only in 68 cases (40.2%) was a mass adjacent to or distinct from the uterus found. The radiologic finding of fetal small parts in the lateral position overlying the maternal spine was first noted by Weinberg and Sherwin in 1956; this finding is a fairly reliable sign of an abdominal pregnancy. A radiologic examination of the abdomen, including anterior, posterior, and lateral views, is also helpful in defining malposition of the fetus, which is most often discovered to be in the transverse position. Ultrasound, however, is the most effective method for diagnosing an abdominal pregnancy. Ultrasound can usually identify an abdominal gestation as separate from the nonpregnant uterus. Ultrasonography can be expected to have high diagnostic accuracy in most cases. In those cases in which ultrasonography is equivocal, MRI may be useful.

The maternal mortality risk from abdominal pregnancy in the United States is 7.7 times greater than the maternal mortality risk from tubal ectopic pregnancy and 90 times greater than that with intrauterine pregnancy. Reported maternal mortality rates in the literature have varied in the past from 4% to 29%. Maternal morbidity can also be substantial, with high incidences of pelvic abscess, peritonitis, and sepsis caused by retained placental remnants. Rare instances of massive rectal bleeding or rectal passage of fetal bones secondary to the formation of celo-intestinal fistulae have also been reported. Fetal mortality is notoriously high, ranging from 75% to 95% of all cases.

Management of Advanced Abdominal Pregnancy

Recent techniques of fetal monitoring serve as diagnostic adjuncts to the management of the advanced abdominal pregnancy. Fetal assessment—including repeated ultrasonography to measure biparietal diameter, nonstress testing, monitoring of fetal movements, and biophysical profiles—can provide clinical evidence of fetal maturity and fetal welfare. Despite the use of these diagnostic tools, fetal death occurred in all of the 15 cases of abdominal pregnancy reported by Martin and associates. Clark and Jones reported a fetal salvage rate of only 11.4% in a study of 35 advanced abdominal pregnancies.

One of the major factors in fetal survival is the condition of the fetal membranes. If the membranes rupture, the fetus usually dies from respiratory distress in the peritoneal cavity within a short time of the rupture. When the volume of amniotic fluid is significantly decreased or absent, the incidence of fetal malformations increases significantly, pressure deformities occur, and pulmonary hypoplasia precludes the possibility of delivering a viable fetus. In situations in which the pregnancy is advanced and there is sufficient volume of amniotic fluid, there exists a reasonable possibility of a good fetal outcome. In rare instances, there may be justification for postponed surgery to allow for further fetal maturity and a better perinatal prognosis.

Preoperative preparation of a patient with an advanced abdominal pregnancy should include an adequate supply of compatible blood and blood products and appropriate intravenous infusion lines that can deliver large amounts of fluid quickly. The use of a cell-saver or MAST (military antishock trouser) suit has been reported in the management of patients experiencing massive hemorrhage and shock. A surgical team should be standing by that is capable of handling the possible bowel, vascular, or genitourinary complications that may arise.

Following incision into the amniotic sac and delivery of the fetus, the management of the placenta still remains a controversial issue. Most clinicians believe the best treatment is to clamp the cord, to leave the placenta in situ, and to close the abdomen, but to allow retroperitoneal drainage if possible. The placenta can be removed after complete cessation of function is demonstrated by quantitative β -hCG titers. The placenta should be removed during laparotomy only if it is accessible and if its removal can be accomplished without excessive blood loss. In case of doubt, the placenta should be left in place. Thompson has reported leaving the placenta in

P.793

the peritoneal cavity for a period of 13 years without physical harm to the patient. MTX has been used occasionally to hasten trophoblastic degeneration, but it leads to the accelerated accumulation of necrotic placental tissue, which may become infected. For this reason, it is currently felt best not to administer MTX in this clinical setting.

CERVICAL ECTOPIC PREGNANCY

The cervix is a rare but hazardous site for placental implantation because the trophoblast can penetrate through the cervical wall and into the uterine blood supply. Cervical gestations have, until recently, received little attention in the literature, but increased awareness of the condition has resulted in a number of recent reports.

The following three criteria for the diagnosis of cervical pregnancy were established by Rubin in 1911:

1. Cervical glands must be opposite the placental attachment.
2. Placental attachment to the cervix must be situated below the entrance of the uterine vessels or below the peritoneal reflection of the anterior and posterior surfaces of the uterus.
3. Fetal elements must be absent from the corpus uteri.

Because strict anatomical and histologic criteria necessitate a hysterectomy for a complete study of the entire uterus, Paalman and McElin proposed five more clinically practical criteria for the diagnosis of this condition:

1. Uterine bleeding without cramping pain following a period of amenorrhea
2. A soft, enlarged cervix equal to or larger than the fundus (the "hourglass" uterus)
3. Products of conception entirely confined within and firmly attached to the endocervix
4. A closed internal cervical os
5. A partially opened external cervical os

The incidence of this rare entity varies. The Mayo Clinic reported 1 in 16,000 pregnancies. The highest incidence, 1 in 1,000 pregnancies, was reported from Japan. The high incidence of elective abortion in Japan is probably a factor in the higher rates. D&C seems to be a predisposing factor for cervical pregnancy. Shinagawa and Nagayama noted that in 18 of 19 cases of cervical pregnancy, there was a history of legal abortion. In the review by Ushakov and associates, 68.6% of patients with a cervical pregnancy had a previous uterine curettage. It has also been suggested that a previous cesarean section may play a role in the etiology of cervical pregnancy.

Cervical gestation is frequently confused with a neoplastic process because of the marked vascularity and friable

appearance of the cervix. Profuse bleeding can occur if the placenta is mistaken for a tumor and a biopsy is taken. A cervical gestation also can be mistaken for a spontaneous abortion in which the products of conception were retained within the cervical canal (**Fig. 34.13**).

Treatment for Cervical Pregnancy

The treatment for a cervical pregnancy is surgical, and the condition often requires an abdominal hysterectomy. In selected patients, conservative evacuation of an early cervical pregnancy may be accomplished by skillful D&C, although the procedure has the potential to be complicated by profuse hemorrhage. Further preoperative preparations directed to reduce the vascularity of the uterine cervix—such as transvaginal ligation of cervical branches of the uterine arteries, a Shirodkar-type cerclage, angiographic uterine artery embolization (UAE), or intracervical vasopressin injection—may reduce operative morbidity. In a review by Ushakov and colleagues, of the 16 cases in which one of these methods was employed, 15 had minimal (50 to 200 mL) blood loss, one patient had a hemorrhage of 1,200 mL requiring transfusion, and no patient required laparotomy or hysterectomy. Among 41 cases in which D&C was performed without cervical preparation, minimal bleeding occurred in just five cases (12.2%),

P.794

massive bleeding (1,200 to 5,000 mL) occurred in 70.7%, and hysterectomy was performed in seven cases (17.1%). Laparotomy with bilateral internal iliac artery ligation or bilateral uterine artery ligation was also required in an additional five (12.2%) of these patients. To control postevacuation bleeding, several authors, including Kuppuswami and colleagues and Werber and associates, have described the successful use of a Foley catheter balloon to tamponade the cervical implantation site in patients who continued to have blood loss after cervical pregnancy evacuation. A 26-French Foley catheter with a 30-mL balloon is preferably used and left inflated for 0.5 to 6 days, as clinically indicated.

FIGURE 34.13 Differential diagnosis of cervical pregnancy. **A:** In the cervical phase of uterine abortion, the placenta is mainly within the expanded cervix, and the external and internal ora are dilated. **B:** In a cervical abortion (abortion into the cervix), because of stenosis of the external os, spontaneous rupture of the cervical wall can cause severe hemorrhage. **C:** Ragged, friable cervix seen in cervical pregnancy mimics carcinoma of the cervix. (Redrawn from Rothe DJ, Birnbaum SJ. Cervical pregnancy: diagnosis and management. *Obstet Gynecol* 1973;42:675, with permission. Copyright © 1973 The American College of Obstetricians and Gynecologists.)

Medical therapy can also be considered for the primary treatment of cervical pregnancy or as an adjunct to surgical therapy through decreased vascularization of the mass. Kung and Chang reviewed the use of MTX administration for cervical ectopic pregnancy from 1983 to 1997. Among 35 cases of viable cervical ectopic pregnancies less than 12 weeks gestation, 63% of patients received either systemic MTX alone or a combination of systemic MTX with a local (intra-amniotic or intracervical) injection of either MTX or potassium chloride. Among the 23 cases of nonviable cervical pregnancy less than 12 weeks gestation, 96% of women required systemic MTX alone. The ultimate success rate of uterine preservation was similar (94% for the viable pregnancy group; 91% for the nonviable pregnancy group), although the patients in the viable pregnancy group required a significantly higher number of concomitant additional surgical procedures (43% vs. 13%).

Zakaria and associates reported successful nonsurgical conservative management of 15 cases of cervical ectopic pregnancy. Five patients were treated with multidose MTX and leucovorin rescue, six patients were treated with multidose MTX and bilateral UAE, and four patients were treated with multidose MTX and bilateral UAE with intra-amniotic potassium chloride additionally administered prior to UAE.

CESAREAN SCAR PREGNANCY

With the increasing utilization of cesarean section for delivery, there has been recent identification of an increasing number of abnormal (ectopic) pregnancies in which there is implantation of the gestational sac in the hysterotomy scar. It is felt that endometrial and myometrial disruption due to poor healing can predispose to abnormal pregnancy implantation in this area, although it has also been speculated that implantation may occur through a microscopic tract into the myometrium. Fylstra reported a review of the English literature from 1966 until 2002 and identified 19 cases. Since this time, numerous additional reports have appeared in the literature, including a series of 96 cases reported by Zhang and associates.

The diagnosis may be difficult, and a false-negative diagnosis has the potential for a major complication, including profound hemorrhage and the need for hysterectomy. Timor-Tritsch and colleagues proposed the following transvaginal ultrasonographic criteria for cesarean scar pregnancy:

1. Visualization of an empty uterine cavity as well as an empty endocervical canal.
2. Detection of the placenta and/or a gestational sac embedded in the hysterotomy scar.
3. In early gestations (≤ 8 weeks), a triangular gestational sac that fills the niche of the scar; at ≥ 8 postmenstrual weeks, this shape may become rounded or even oval.
4. A thin (1 to 3 mm) or absent myometrial layer between the gestational sac and the bladder.
5. A closed and empty cervical canal.
6. The presence of embryonic/fetal pole and/or yolk sac with or without heart activity.
7. The presence of prominent and at times rich vascular pattern at or in the area of cesarean delivery scar in the presence of a positive pregnancy test.

Treatment for Cesarean Scar Pregnancy

A wide variety of conservative, fertility-sparing treatment approaches for cesarean scar pregnancy have been reported, including resection and uterine scar dehiscence repair by both laparotomy and laparoscopy approaches. Successful resection by either hysteroscopy or curettage has also occurred following bilateral UAE and systemic MTX. Curettage alone has been attempted, but secondary salvage treatments were necessary to resolve these pregnancies. Curettage alone appears contraindicated due to the trophoblast location being outside of the realm of the uterine cavity (beyond the reach of the curette) as well as due to the potential risk of uterine rupture and hemorrhage. Systemic MTX as primary treatment, bilateral UAE alone, and bilateral UAE

combined with systemic MTX have all also been reported in the treatment of cesarean scar pregnancy.

Timor-Tritsch and colleagues reported on a series of 19 patients between 6 and 14 postmenstrual weeks who were successfully treated for cesarean scar pregnancy. Each patient had 50 mg of MTX injected into the gestational sac, with 25 mg into the area of the embryo and 25 mg into the placental area. An additional 25 mg of MTX was administered intramuscularly. It was speculated that intragestational sac injection may be more effective, as a cesarean scar pregnancy may potentially have inefficient drug delivery following systemic MTX alone due to its being surrounded by fibrous scar rather than a normally vascularized myometrium.

HETEROTOPIC PREGNANCY

Heterotopic pregnancy (coexistence of intra- and extrauterine pregnancies) is rare. The incidence has been estimated to be about 1 in 30,000 spontaneous pregnancies. With the use of assisted reproductive technologies, the incidence is higher, as high as 0.75% to 1.5% of pregnancies.

Although the precise cause of a combined pregnancy is frequently obscure, most of the risk factors are the same as those associated with other forms of ectopic pregnancy. The use of ovulation-inducing agents has increased the incidence of multiple gestations and heterotopic pregnancies. Berger and Taymor reported an incidence of combined pregnancy in as many as 1 in 100 stimulated patients. The most common predisposing anatomic finding associated with heterotopic pregnancies is preexisting tubal disease.

Abdominal pain, an adnexal mass, peritoneal irritation, and an enlarged uterus together constitute the major clinical features associated with a heterotopic pregnancy. Additional diagnostic findings include the presence of two corpora lutea found at the time of laparotomy or laparoscopy, hemoperitoneum, acute abdominal pain after the termination of an intrauterine pregnancy, and the persistence of an enlarged uterus with amenorrhea after excision of an ectopic pregnancy.

As opposed to solely extrauterine pregnancies, which are presently diagnosed and treated electively at an early preclinical stage, heterotopic pregnancies are still mostly diagnosed after clinical signs develop. In their review, Rojansky and Schenker report that nearly half of the cases present with

P.795

rupture, hemorrhage, and emergency intervention. This is due to the fact that serial β -hCG determinations and transvaginal ultrasonography are often not helpful in establishing an early diagnosis of heterotopic pregnancy.

The majority of heterotopic pregnancies consist of a single tubal gestation combined with an intrauterine pregnancy. Rarer varieties include combined cervical-intrauterine, ovarian-intrauterine, abdominal-intrauterine, and interstitial-intrauterine pregnancies.

Treatment for Heterotopic Pregnancy

Laparoscopy has been employed with reasonable success for the treatment of combined tubal and intrauterine pregnancies. Louis-Sylvestre and associates reported treating 13 patients laparoscopically, 10 by salpingectomy and 3 by salpingostomy. Subsequently, 60% of the patients with a viable intrauterine pregnancy at the time of surgery had a favorable outcome. On the other hand, in cases in which hemodynamic instability or an interstitial-intrauterine pregnancy is present, a laparotomy is indicated. Expectant management does not seem to have a role in the care of a patient with a heterotopic pregnancy. This is due to the fact that the specific course of the extrauterine component cannot be monitored by serial β -hCG determinations. Likewise, either local or systemic MTX therapy would be contraindicated in the presence of a viable intrauterine gestation. The use of a local injection of potassium chloride into the extrauterine gestational sac, however, has been used successfully in a few cases. There are very rare cases in which extrauterine abdominal pregnancies progress simultaneously with intrauterine pregnancies to viability. In their review of the world's literature, Reece and associates found only 13 cases in which both pregnancies reached term and both infants were delivered and survived the neonatal period.

In the absence of such rare circumstances, the outcome for the intrauterine pregnancy is optimized by immediate therapy of the extrauterine pregnancy.

Rh IMMUNOGLOBULIN USE AFTER ECTOPIC PREGNANCY

Grimes has reported that Rh-negative mothers were recognized and administered Rh immunoglobulin in only 36% of cases. Fetomaternal hemorrhage associated with ectopic pregnancy can sensitize Rh-negative women at risk. A dose of 50 µg Rh immunoglobulin is usually sufficient to prevent Rh sensitization.

BEST SURGICAL PRACTICES

- The benefits derived from the early diagnosis of an ectopic pregnancy include the potential use of medical and conservative surgical procedures that optimize future fertility. Early diagnosis may also preclude ectopic pregnancy rupture and therefore result in lower patient morbidity and mortality.
- The astute clinician is aware of the risk factors for ectopic pregnancy, thereby increasing the level of suspicion in the appropriate clinical context. Risk factors for ectopic pregnancy include chronic PID, prior tubal surgery, surgical sterilization, use of an IUD, previous ectopic pregnancy, DES exposure, progestin-only contraceptives, assisted reproductive technologies, infertility, tubal developmental anomalies, multiple sex partners, early age at first intercourse, cigarette smoking, and vaginal douching.
- The classic presentation of pain and uterine bleeding with the finding of an adnexal mass is present in only 14% of patients with ectopic pregnancy. Even when present, these classic signs and symptoms are not entirely specific for ectopic pregnancy.
- Highly sensitive β -hCG assays have greatly aided in the early diagnosis of ectopic pregnancies. Serum hCG concentrations increase in an exponential fashion in early pregnancy. During the period of gestation in which the hCG concentration is less than 10,000 IU/L, the time required for doubling of hCG levels remains consistent, with a mean of 1.9 days. The slowest minimal hCG rise for a normal viable intrauterine pregnancy is 53% in 2 days. Transvaginal ultrasonographic evidence of an intrauterine pregnancy can be expected to be seen with very high sensitivity when β -hCG concentrations exceed 1,500 IU/L.
- Serum progesterone assays are useful in the early diagnosis of an ectopic pregnancy. In one large study, 98% of patients with a normal intrauterine pregnancy had progesterone levels greater than 10 ng/mL, and 98% of patients with an ectopic pregnancy had progesterone levels less than 20 ng/mL. Diagnostic limitations of the serum progesterone assay included the fact that 31% of viable intrauterine pregnancies, 23% of abnormal intrauterine pregnancies, and 51% of ectopic pregnancies had progesterone levels between 10 and 20 ng/mL in this study. In another large trial, the lowest serum progesterone concentration associated with a viable pregnancy was 5.1 ng/mL.
- A D&C procedure is helpful when β -hCG assays and transvaginal ultrasonography are nondiagnostic and a nonviable pregnancy is suspected. Appropriate indications include (a) a failure of β -hCG concentration rise of greater than 50% in 2 days, (b) a serum progesterone level less than 5 ng/mL, and (c) a failure to visualize an intrauterine gestational sac by transvaginal ultrasonography when the β -hCG concentrations exceed 1,500 IU/L. An ectopic pregnancy is suspected after uterine curettage if chorionic villi are not present on frozen section or if β -hCG concentrations do not fall by at least 15% 8 to 12 hours after the procedure.
- Laparoscopy remains the gold standard for the diagnosis of ectopic pregnancy, although it still has a low rate of falsenegative and false-positive outcomes.
- Systemic MTX is an alternative that can be used for the treatment of patients with small, unruptured ectopic pregnancies or patients with persistent ectopic pregnancies following conservative surgery. A history of active hepatic, renal, or peptic ulcer disease; elevated liver enzyme concentrations; and thrombocytopenia or

neutropenia are contraindications to MTX therapy. Appropriate candidates for systemic MTX therapy should be willing to accept a small risk of tubal rupture and participate in closely monitored follow-up.

- In women who wish to preserve their fertility, conservative surgery by linear salpingotomy is the preferred treatment of a distal unruptured tubal pregnancy. Contraindications to conservative tubal surgery include an extensive hemoperitoneum and potentially compromised cardiovascular status, a recurrent ectopic pregnancy in the same fallopian tube, an ectopic pregnancy in a severely damaged tube, and an ectopic pregnancy in a woman who has completed her family.
- During laparoscopic salpingotomy, it is important to make the incision along the antimesenteric wall of the tube in the area of maximal distension and large enough to allow for complete extrusion of the products of conception without difficulty. Following laparoscopic salpingotomy, healing by secondary intention is felt appropriate in most cases.

P.796

- During laparoscopic salpingectomy, take care to stay as close as possible to the fallopian tube during transection of the tubo-ovarian ligament and mesosalpinx. If cautery and transection of the proximal tubal isthmus are used, care should be taken such that excess cauterization of the uterine cornu does not occur because of concerns about the potential of interstitial sinus tracts or diminished myometrial integrity.
- All Rh-negative patients with an ectopic pregnancy should be offered at least 50 µg of Rh immunoglobulin to prevent Rh sensitization caused by fetomaternal hemorrhage.

Chapter 35A

Surgical Management of Obstetric Complications

Kelly A. Bennett

DEFINITIONS

B-Lynch stitch—A uterine body compression suture used to control postpartum hemorrhage resulting from uterine atony. A deep suture is placed vertically on the side of the uterus from 3 cm below the end of the uterine incision to 3 cm above the incision. The suture is then taken over the fundus, and a horizontal bite is taken on the posterior wall of the uterus below the level of the uterine vessels entering the myometrium on the same side as the anterior stitch. The suture is again passed over the fundus on the opposite side, and a deep suture is placed starting 3 cm above the other end of the anterior uterine incision and exiting 3 cm below the incision. This large four-corner mattress suture is then tightly tied down, compressing the fundus.

Cervical insufficiency—Premature, painless dilation of the cervix leading to midtrimester delivery if not treated. The etiology of the condition is poorly understood and may be due to prior cervical trauma and/or an inherent cervical defect.

Cerclage—A purse-string suture placed around the cervix to treat or prevent premature cervical dilation without labor.

Late postpartum hemorrhage—Hemorrhage occurring more than 24 hours following delivery.

McDonald suture—Surgical treatment for cervical insufficiency. A purse-string suture of heavy caliber is placed around the cervix at the level of the internal os.

Placenta accreta—Abnormal invasion of the placenta into the decidual layer lining of the endometrial cavity with no plane of separation.

Placenta increta—The placenta penetrates into the myometrium.

Placenta percreta—The placenta penetrates through the whole thickness of the myometrium up to the serosal surfaces or beyond to surrounding organs.

Postpartum hemorrhage—Blood loss is difficult to estimate accurately; the American Congress of Obstetricians and Gynecologists has arbitrarily defined postpartum hemorrhage as blood loss of greater than 500 mL with a vaginal delivery or greater than 1,000 mL with a cesarean section. Other definitions describe a 10% drop in the hematocrit or the need for blood transfusion (as defined by CA Combs in 1991).

Shirodkar suture—A thick suture or mesh band is placed submucosally around the cervix to treat cervical insufficiency.

Surgery in the pregnant patient presents several unique challenges. There is, of course, the added complexity of caring for two patients simultaneously. Illness and surgery both affect the fetus and the mother, and every decision to recommend surgery and when that surgery should be done requires weighing the risks and benefits to both patients. In many cases, there may be some urgency required to prevent or reduce maternal or fetal morbidity or mortality. In addition, the physiologic and anatomic changes of pregnancy may complicate diagnosis and alter the surgeon's normal operative field. The size of the uterus and increased vascularity of the pelvis may make it significantly more difficult to perform routine gynecologic procedures during pregnancy.

PHYSIOLOGIC CHANGES OF PREGNANCY

Profound physiologic changes of the cardiovascular, respiratory, renal, and coagulation systems occur during pregnancy. It is important for the surgeon to understand these changes in order to understand normal from abnormal findings because they can affect laboratory interpretation, blood product replacement, and surgical approach.

Cardiovascular System

During pregnancy, maternal blood volume increases by 45% to 50% above nonpregnant volumes. Placental hormone production stimulates maternal erythropoiesis, increasing red cell mass by approximately 20%. Because plasma volume increases disproportionately to the increase in red blood cell mass, physiologic hemodilution occurs, manifested as a physiologic anemia. Pregnancy should be considered a hypervolemic state. A mild increase in maternal heart rate begins early in pregnancy and continues until term. In late pregnancy, maternal heart rate is increased by approximately 20% over antepartum values, often resulting in mild tachycardia.

Systemic vascular resistance decreases by 20%, but gradually increases near term. This results in a decrease in systolic and diastolic blood pressure during pregnancy, with a gradual recovery to nonpregnant values by term. As there is increased pressure in the venous system, there is decreased return from the lower extremities, resulting in dependent edema.

Respiratory System

In pregnancy, minute volume is increased, while functional residual volume is decreased. This is primarily the result of upward displacement of the diaphragm. It seems intuitive that lung volume would be decreased during pregnancy, but an increase in minute volume in association with an expansion of the anterior and posterior diameter of the chest results in increased tidal volume, thereby also increasing minute ventilation. These changes result in a compensated respiratory alkalosis. Normal P_{CO_2} in pregnancy ranges from 28 to 35 mm Hg. P_{O_2} is usually greater than or equal to 100 mm Hg. Oxygen consumption and basal metabolic rate are also increased during pregnancy by approximately 20%.

These physiologic changes result in less pulmonary reserve for the acutely ill pregnant patient; therefore, this reduces the time interval from respiratory distress to respiratory failure. Because of this, early recognition and intervention in patients with respiratory challenge is mandatory.

Gastrointestinal Tract

During pregnancy, there is a decrease in gastrointestinal motility. This is caused by mechanical changes in the abdomen with the enlarging uterus and smooth muscle relaxation induced by high production of progesterone in pregnancy. Gastric emptying may be delayed for up to 8 hours; therefore, pregnant women should be considered to have a functionally full stomach at all times. In addition, a decrease in large intestine motility may result in constipation severe enough to cause significant abdominal pain.

Coagulation Changes

Pregnancy is a hypercoagulable state. Fibrinogen is increased approximately 30% over baseline values. The hypercoagulable

P.800

state of pregnancy is associated with increased risk of deep venous thrombosis and pulmonary embolus. This is particularly compounded when bed rest or immobilization occurs during the gestational period.

Renal Changes

Pregnancy increases blood flow to the renal pelvis approximately 60% to 80%. This results in an increased

glomerular filtration rate accompanied by frequent urination. Serum creatinine is approximately 40% less than in a nonpregnant state. Therefore, a creatinine of 1 mg/dL during gestation should be considered to be at the upper limits of normal.

Ureteral diameter increases in pregnancy secondary to compression and smooth muscle relaxation. Peristalsis is delayed, and reflux occurs freely from the bladder into the lower ureteral segment. This results in an increased incidence of pyelonephritis during pregnancy, making treatment of significant asymptomatic bacteriuria mandatory.

IMAGING TECHNIQUES

The most common imaging technique used during pregnancy is *ultrasonography*. Ultrasound is considered safe and primarily is used for fetal assessment. In patients with abdominal pain, an ultrasound should be considered the first-line diagnostic imaging test. During ultrasound, the presence of an intrauterine pregnancy should be documented and the size and other pertinent parameters of fetal well-being should be recorded. Evaluation of the cul-de-sac for fluid, the ureter for dilatation or stones, the gallbladder for the presence of gallstones, and the placenta for abnormalities should also be noted in the report.

Magnetic resonance imaging can be safely used during pregnancy. There are no data to suggest any increased fetal risk from this modality. Magnetic resonance imaging is now used to diagnose fetal abnormalities, especially abnormalities of the central nervous system. It may be particularly important for the diagnosis of appendicitis in pregnancy.

Although there are theoretical risks associated with ionizing radiation, fortunately, most *diagnostic x-ray procedures* are associated with minimal or no risk to the fetus. While unnecessary, multiple, or recurrent x-ray exposure should be avoided, existing evidence suggests that there is no increased risk of fetal congenital malformations, growth restriction, or abortion from x-ray procedures that expose the fetus to doses of 5 rads or less. The American Congress of Obstetricians and Gynecologists has published guidelines regarding diagnostic imaging during pregnancy. Women should be reassured that concern about radiation exposure should not prevent medically indicated diagnostic procedures. It cannot be stressed enough that maternal well-being is of the utmost importance, and appropriate diagnostic procedures should be obtained to facilitate a rapid diagnosis.

POSTPARTUM HEMORRHAGE

Postpartum hemorrhage is poorly defined by estimation of blood loss; therefore, it is difficult to accurately determine actual or percentage of blood loss at the time of delivery. Additionally, blood volume expansion is variable during pregnancy and can be affected by several factors including hypertension, renal disease, maternal body mass index, and the presence of multifetal gestations. The potential effects of blood loss largely depend on the degree of blood volume expansion. For example, blood loss of 1,000 mL during cesarean section is generally well tolerated by healthy pregnant women. A blood loss of 500 to 750 mL, however, may not be tolerated in a woman with minimal volume expansion or one who is hemoconcentrated secondary to severe preeclampsia or eclampsia. The American Congress of Obstetricians and Gynecologists has noted that a number of definitions have been used to define hemorrhage, including a blood loss greater than 500 mL with a vaginal delivery or greater than 1,000 mL during a cesarean section or a drop in hematocrit of 10% regardless of the amount of documented blood loss.

Gilstrap and Ramin have defined clinically significant hemorrhage as that amount of bleeding “that produces signs and symptoms of hemodynamic instability or that is likely to produce such if left unabated.”

Incidence and Etiology

Although the exact incidence of hemorrhage associated with pregnancy is unknown, it remains one of the leading

causes of maternal mortality in this country. Kaunitz and associates reported that 13% of more than 2,000 maternal deaths were secondary to hemorrhage, and one third of these occurred postpartum. Rochat and colleagues reported a similar incidence of 11% of maternal deaths resulting from hemorrhage.

In a randomized trial conducted in the United States, birth weight, labor induction and augmentation, chorioamnionitis, use of magnesium sulfate, and a maternal history of previous obstetrical hemorrhage were associated with increased risk of postpartum hemorrhage. A large population-based study supported these findings, with significant risk factors identified using multivariate analysis. Risk factors associated with an increased risk of postpartum hemorrhage were retained placenta (odds ratio [OR] 3.5; 95% confidence interval [CI]: 2.1 to 5.8), failure to progress during the second stage of labor (OR 3.4; 95% CI: 2.4 to 4.7), placenta accreta (OR 3.3; 95% CI: 1.7 to 6.4), vaginal or perineal lacerations (OR 2.4; 95% CI: 2.0 to 2.8), instrumental delivery (OR 2.3; 95% CI: 1.6 to 3.4), large-for-gestational-age newborn (OR 1.9; 95% CI: 1.6 to 2.4), hypertensive disorders (OR 1.7; 95% CI: 1.2 to 2.1), induction of labor (OR 1.4; 95% CI: 1.1 to 1.7), and augmentation of labor with oxytocin (OR 1.4; 95% CI: 1.2 to 1.7).

Diagnosis and Medical Management

The most important aspects in the management of postpartum hemorrhage are prompt recognition and treatment of the condition. Recognition of external bleeding is straightforward and almost always can be controlled with medical or minor surgical means. Tachycardia, decreased urine output, and, finally, hypotension without obvious external blood loss are important signs of potential internal bleeding, and many such instances will require surgical intervention to arrest the hemorrhage. If the etiology of the hemorrhage is not determined quickly, coagulopathy may complicate the clinical presentation, thereby making diagnosis and treatment more difficult.

Uterine atony is readily recognizable by palpation of the uterus. If atony is not present, the cervix and vagina should be carefully inspected for lacerations. The placenta also should be inspected for missing fragments, and careful manual palpation of the uterine cavity should be performed. If the source of bleeding still is not obvious or if bleeding is seen around venipuncture or catheter sites, then the patient should be evaluated for coagulopathy. A thrombin clot (clot retraction test) tube will reveal gross disruption in coagulation within minutes. Useful laboratory tests include prothrombin time, partial thromboplastin time, platelet count, fibrinogen, and fibrin degradation product levels. The clinician should note that d-dimer levels may be abnormal during pregnancy even in patients without coagulopathy. Before surgical intervention, an ultrasound

P.801

examination of the uterine cavity may prove useful for the identification of an accessory placental lobe or fragment.

Medical management of postpartum hemorrhage consists of volume replacement and uterotonics, including intravenous oxytocin and parenteral methylergonovine and prostaglandins. Volume can be maintained with crystalloid and blood or blood products. Invasive monitoring, such as with a pulmonary artery catheter, generally is not necessary and may be dangerous in the presence of a coagulopathy. Its use should be reserved for those patients who do not respond to usual and expected therapy. As a general rule, monitoring of urine output, vital signs, and oxygen saturation will be sufficient. Volume replacement generally is adequate when the blood pressure is maintained at 90 to 100 mm Hg systolic, pulse rate is less than 100 beats per minute, and urine output is at least 25 to 30 mL per hour. When a patient has required transfusion of packed red blood cells, it is important to transfuse coagulation factors to replace those lost in the hemorrhage. Calcium also should be replaced in these patients because of risk of complications such as hypotension related to hypocalcemia in patients receiving massive transfusions. Fluid overload generally can be detected with a stethoscope and an oxygen monitor in conjunction with clinical signs and symptoms. Diuretics should only be used to remove excess fluid if the patient becomes hypoxic related to volume overload. A medical management protocol for postpartum

hemorrhage is summarized in [Table 35A.1](#).

Surgical Management

Lower genital tract lacerations usually are best managed by suturing. The rare case of uterine rupture also is managed surgically. Other techniques to control hemorrhage include uterine and utero-ovarian artery ligation, hysterectomy, or uterine or hypogastric artery embolization.

Uterine packing, which until recently had been abandoned by most clinicians, may allow adequate time for blood and fluid replacement before surgical intervention. Maier described the use of a packing device called a Torpin packer. The device uses a plunger to place several yards of 4-inch-wide gauze into the uterine cavity and has been used successfully to control postpartum hemorrhage. Uterine packing allows time for volume replacement and slows bleeding enough to allow for surgical techniques short of hysterectomy. In many cases, it may stop the bleeding so that no further treatment is necessary. Other methods of uterine tamponade reported in the literature have included the use of a Foley catheter with a 30- to 50-mL balloon or a Sengstaken-Blakemore tube with the esophageal balloon inflated with 50 mL of normal saline and, more recently, the use of the Bakery balloon. The choice of a specific surgical technique to control bleeding depends on several factors, including the degree of hemorrhage, the hemodynamic status of the patient, parity, and the desire for future childbearing. An undoubtedly important factor in achieving a favorable outcome in control of postpartum hemorrhage is the experience of the surgeon.

TABLE 35A.1 Medical Management Protocol for Postpartum Hemorrhage

General
Large-bore intravenous line Foley catheter
Drugs
Oxytocin, dilute solution of 20 U in 1,000 mL of normal saline or Ringer solution, given as IV infusion Methylergonovine, 0.2 mg IM 15-Methyl PGF _{2α} , 0.25 mg IM or intramyometrially every 15-60 min as indicated
Volume Replacement
Crystalloid, 3 mL/mL of estimated blood loss (maintain urine output ≥30 mL/h) Packed red blood cells Fresh frozen plasma, platelets, or cryoprecipitate, as indicated

Arterial Embolization

Angiographic arterial embolization has been described for the successful control of obstetric and gynecologic bleeding. Small metal coils, Gelfoam, polyvinyl alcohol dehydrated particles, and other substances have been

used for such embolizations. Pelage and associates, in two separate reports, describe use of arterial embolization in patients with primary or secondary postpartum hemorrhage, defining primary postpartum hemorrhage as that which occurs within 24 hours after delivery. Twenty-seven women were identified, including two who had already undergone hysterectomy in an unsuccessful attempt to control the hemorrhage. Following transcatheter embolization, immediate decrease or cessation of bleeding occurred in all patients. Two patients required repeat embolization the next day with no further complications. Fourteen women were diagnosed with secondary postpartum hemorrhage after the first 24 hours following delivery. All of these patients had complete resolution of bleeding with embolization with no further complications. Arterial embolization can be performed quickly and safely; therefore, it should be strongly considered in patients with postpartum hemorrhage who are stable enough to be managed in the radiology suite. There have been reports of successful pregnancies following embolization, which makes it an especially attractive alternative to hysterectomy in the patient who desires preservation of fertility.

Uterine Artery Ligation

STEPS IN THE PROCEDURE

Uterine Artery and Utero-Ovarian Artery Ligation (O'Leary Stitch)

- First-line treatment to control postpartum hemorrhage at the time of cesarean delivery.
 - Advance bladder before placement of sutures is important to avoid bladder injury.
 - Absorbable suture no. 0 chromic or polyglycolic acid suture is placed through the lateral aspect of the lower uterine segment, 2 to 3 cm medial to the uterine vessels through the myometrium, and then back through the broad ligament just lateral to the uterine vessels.
 - The suture is tied *to compress the vessels*.
 - Placement of second ligature at junction of the uteroovarian ligament and uterus.
-

Uterine artery ligation is a relatively safe procedure that can be performed by most obstetricians. It also allows for future childbearing. The technique consists of ligating the uterine artery and vein at the lower uterine segment 2 to 3 cm below the level of the transverse uterine incision. An

P.802

absorbable ligature is placed 2 to 3 cm medial to the uterine vessels through the myometrium (to obliterate any intramyometrial ascending branches) and then lateral to the vessels through the broad ligament. It is imperative that the bladder be advanced before placement of the suture to prevent bladder injury. Because of collateral flow from the ovarian artery, some recommend that a second ligature be placed at the junction of the utero-ovarian ligament and uterus. The technique of uterine artery ligation is shown in [Figures 35A.1](#) and [35A.2](#).

In a review of 90 women who underwent uterine artery ligation (30 were for uterine atony), O'Leary reported that only six (7%) procedures resulted in failure. There were no major complications from the procedure itself. In a follow-up review of 265 women who underwent uterine artery ligation, O'Leary reported a greater-than-95% success rate.

This technique is most useful (and successful) when hemorrhage is of a moderate degree and originates from the lower uterine segment. Such an example is bleeding from a low placental implantation site. Uterine artery ligation also can prove beneficial for lower segment extensions or lacerations, in addition to slowing bleeding for a uterine artery laceration. Philippe and associates reported a vaginal approach to ligation of the uterine arteries in two patients after vaginal delivery, but a larger case series would have to be performed to determine the

feasibility of this approach.

B-Lynch Suture

STEPS IN THE PROCEDURE

B-Lynch Suture Placement

- The B-Lynch suture is an effective method for reducing uterine blood loss related to uterine atony.
 - A large Mayo needle with absorbable suture is used to enter and exit the uterine cavity laterally in the lower uterine segment.
 - The initial placement is anteriorly at one angle of the uterine incision.
 - The suture is passed over the uterine fundus.
 - A deep transverse bite is taken in the posterior lower uterine segment.
 - The suture is then passed back over the fundus to enter the anterior lower uterine segment opposite and parallel to the initial bite.
 - The free ends are pulled tightly and tied down securely to compress the uterus.
-

B-Lynch and colleagues also described five cases in which hemorrhage was controlled by placing an absorbable suture vertically from 3 cm below the uterine incision to 3 cm above the uterine incision on the right side of the uterus ([Fig. 35A.3](#)). The stitch is then taken vertically over the fundus and placed horizontally in the posterior uterus at the same level as the anterior suture. The suture is threaded over the left side of the uterus to place another stitch on the left from 3 cm above the uterine incision to 3 cm below the uterine incision. The long suture is tied, compressing the fundus. A large suture, such as no. 1 Prolene on a large needle, is used. The uterine incision is closed in the usual fashion. There are several case series in the literature supporting the efficacy of the B-Lynch stitch for the treatment of uterine atony. In all series, the suture has been reported to be effective. It has been suggested that the B-Lynch be considered in all cases of severe postpartum hemorrhage before resorting to hysterectomy.

Hypogastric Artery Ligation

STEPS IN THE PROCEDURE

Hypogastric Artery Ligation: Ligation Performed Bilaterally

- Open the peritoneum overlying the common iliac artery.
 - Identify the ureter and retract medially.
 - Longitudinally open the sheath covering the internal iliac (hypogastric) artery.
 - A right angle clamp is passed lateral to the medial direction with blunt dissection.
 - Two nonabsorbable 2-0 silk sutures are placed 2 cm distal to the bifurcation.
 - Hypogastric artery ligation should be performed bilaterally to adequately decrease pressure to the uterus.
-

FIGURE 35A.1 Uterine artery ligation.

P.803

FIGURE 35A.2 Uterine artery ligation. **A:** Lateral view demonstrating ligature placement. **B:** Anatomic relation of ligature to uterine wall and vessels. (Reprinted from Floyd RC, Morrison JC. Postpartum hemorrhage. In: Plache WC, Morrison JC, O'Sullivan MJ, eds. *Surgical obstetrics*. Philadelphia, PA: WB Saunders, 1992:272, with permission. Copyright © 1992, Elsevier.)

The major blood supply to the uterus and pelvis comes from the internal iliac artery, often called the hypogastric artery. Bilateral ligation of this artery can effectively control significant bleeding and thus prevent the need for hysterectomy and permanent sterilization. Burchell has aptly described the physiology of internal iliac artery

ligation. It appears that ligation of this artery controls bleeding by converting an arterial system into a venous system, which decreases the pulse pressure by as much as 85%. This allows pressure and packing to produce clotting. Hypogastric artery ligation probably interferes little, if at all, with subsequent pregnancies. Mengert and colleagues reported successful pregnancies in five women who had undergone internal iliac artery ligation. This technique also may prove useful for controlling bleeding in patients with large hematomas of the broad ligament or for a lacerated artery that has retracted into the broad ligament. Such vessels or active bleeding sites often are difficult to identify. If the bleeding is from the hypogastric vein, ligation of the hypogastric artery will decrease venous pressure which makes the bleeding easier to control.

The technique of hypogastric artery ligation is illustrated in **Figure 35A.4**. The peritoneum overlying the external iliac artery is divided directly above the artery between the infundibulopelvic ligament and the round ligament of the uterus. The internal iliac (hypogastric) artery is identified as it arises and runs from the common iliac artery posteriorly into the pelvis just beneath the infundibulopelvic ligament. The ligation should be performed about 2 cm distal to the bifurcation to avoid disrupting the posterior division of the hypogastric, which can lead to ischemia and necrosis of the skin and subcutaneous tissue of the gluteus. A right angle clamp is gently passed under the artery in the lateral to medial direction with blunt dissection. Great care must

P.804

be taken not to perforate the internal iliac vein, and the clamp is passed lateral to medial to avoid injury to the vein by the tip of the clamp. Two nonabsorbable sutures of 2-0 silk should be used for ligation. It is important that hypogastric artery ligation be performed bilaterally to adequately decrease systolic pressure to the uterus. Clark and associates reported on the successful control of bleeding in 8 (42%) of 19 women who underwent hypogastric artery ligation. In a review of hypogastric artery ligation from three series, Clark reported that this procedure prevented hysterectomy in about half of the patients associated with uterine atony and placenta accreta. Interestingly, in this series, the success of hypogastric artery ligation did not appear to be related directly to the conditions for which it was performed. It must be noted, however, that the number of patients in each category is small.

FIGURE 35A.3 Technique of B-Lynch suture placement. A: The initial bite is placed anteriorly at one angle of the

uterine incision (see inset). B: After the anterior B-Lynch suture is placed, the suture is passed over the fundus, a deep transverse bite is taken in the posterior lower uterine segment, and the suture is passed back over the fundus.

FIGURE 35A.4 Ligation of the right hypogastric artery. The clamp is passed laterally to medial, and the ligature is placed around the anterior division of the hypogastric artery. Note the ureter is attached to the peritoneum, which is reflected medially.

Although this procedure is successful in about 50% of patients and does not interfere with subsequent fertility, it is not technically easy to perform and requires special skill and experience. Many obstetricians have little, if any, experience with this procedure, especially in the presence of a surgical emergency. Moreover, potential complications of hypogastric artery ligation include laceration of the iliac vein, ligation of the external iliac artery, ureteral injury, and death.

Hysterectomy

Because of the lack of experience and skill with the technique of hypogastric artery ligation, many clinicians prefer to do a hysterectomy to control postpartum hemorrhage. Peripartum hysterectomy is extensively discussed later in this chapter. Hysterectomy usually is the safest procedure and also the quickest that can be performed for refractory bleeding. For example, Clark and associates reported that patients undergoing hypogastric artery

ligation who subsequently required hysterectomy had an increased incidence of cardiac arrest secondary to blood loss. The increased morbidity associated with hypogastric artery ligation followed by hysterectomy may be secondary to a delay resulting from attempted conservative management short of hysterectomy. Hypogastric artery ligation was attempted before hysterectomy 64% of the time in nulliparous women, compared with 10% of the time for multiparous patients. Lack of experience with hypogastric artery ligation adds to the overall time required to attempt the procedure and overall blood loss.

In a review of 70 women who underwent emergency hysterectomy for postpartum hemorrhage, Clark and colleagues reported that almost all required blood transfusion, and 50% had postoperative febrile morbidity. The most common indication for hysterectomy in this series was uterine atony, followed by placenta accreta. Of the 70 procedures, 60 were performed after cesarean delivery. Mean operating time was 3.1 hours, and mean blood loss was 3,575 mL.

ABNORMAL PLACENTATION

Placenta accreta occurs when the placenta attaches abnormally to the underlying uterine wall. It is believed to occur due to an abnormal attachment of the chorionic villi to the myometrium due to an absence of decidua basalis and incomplete

P.805

development of the fibrinoid layer. Placenta increta occurs when the placenta extends in to the myometrium, and placenta percreta occurs when the placenta invades through the myometrium and serosa with possible involvement of adjacent organs. Because of the abnormal attachment to the myometrium, there is a risk of life-threatening hemorrhage often requiring massive transfusion of blood products and hysterectomy. The maternal mortality rate was reported in 1996 by O'Brien and his group to be as high as 6% to 7%.

Flood and his group reported in 2009 that the incidence of placenta accreta has increased from approximately 0.8 per 1,000 deliveries in the 1980s to 3 per 1,000 in the past decade. The rising incidence of placenta accreta parallels the rising cesarean section rate. Important risk factors include prior history of placenta previa, previous cesarean delivery, increasing parity and maternal age, and prior uterine surgery. Antepartum diagnosis of placenta accreta is best accomplished by ultrasound, with a reported sensitivity of 77%, specificity of 71%, and a positive predictive value of 65%. Sonographic findings that may be associated with accreta include loss of normal hypoechoic retroplacental myometrial zone, thinning of the uterine serosa-bladder interface, and increased vascularity at the interface of the uterus and bladder. Magnetic resonance imaging may be helpful if there is suspicion that the placenta has invaded the parametrium or surrounding organs.

LATE POSTPARTUM HEMORRHAGE

Late postpartum hemorrhage is defined as occurring more than 24 hours after delivery. The etiology of such bleeding includes placental site subinvolution, infection, coagulopathy, and retained products of conception. Initial therapy for this complication is the same as for early hemorrhage. If infection is present, antibiotics should be used. Endometrial curettage may be necessary for retained placental fragments. Angiographic embolization may prove especially useful in the case of late postpartum hemorrhage. Uterine artery ligation, hypogastric artery ligation, and hysterectomy are rarely required for control of late postpartum hemorrhage.

PERIPARTUM HYSTERECTOMY

Horatio Storer performed the first cesarean hysterectomy in 1869. Initially, the procedure was performed only for emergency situations, but in the early 20th century, it became an accepted means of sterilization. In the modern obstetrical age, elective cesarean hysterectomy is rarely performed, except in cases of cervical neoplasia.

Peripartum hysterectomy can be performed in conjunction with a cesarean delivery (e.g., cesarean hysterectomy) or after a vaginal delivery for complications such as postpartum hemorrhage. In a recent review of

a nationwide sample of deliveries from 1998 to 2003, Whiteman and colleagues estimated that the rate of peripartum hysterectomy in the United States is 0.77 per 1,000 deliveries.

Although there is little controversy regarding peripartum hysterectomy for emergency conditions, there is significant debate in modern obstetrics regarding an elective hysterectomy performed at the time of cesarean delivery. There has been legitimate concern about increased morbidity related to peripartum hysterectomy—including damage to the ureters, bladder, and rectum—and an increased rate of reoperation. However, Plaque has pointed out that morbidity often is associated with the conditions leading to the hysterectomy and not necessarily the procedure itself. Lower morbidities have been reported for elective cesarean hysterectomies when compared with emergency hysterectomies. However, there is inherent bias in these retrospective reviews. Emergent surgery for lifesaving maternal indications would be expected to have higher morbidities, such as blood loss and injury to surrounding structures. In a retrospective study, Castaneda and colleagues observed that over the years the indications for peripartum hysterectomy have changed from predominately elective to almost exclusively emergent indications. In their series, the average blood loss was 3,009 mL in emergent cases and 1,262 mL in nonemergent cases. They concluded that, at the present time, peripartum hysterectomy is almost always emergent in nature and associated with a significant blood loss. As might be expected, there are no randomized prospective studies of elective cesarean hysterectomy, and it is unlikely that such a study could ever be done given the ethical dilemma involved.

Emergency Peripartum Hysterectomy

Obstetric hemorrhage secondary to a variety of etiologies is a common indication reported for peripartum emergency hysterectomy. The three most common reasons are uterine rupture, abnormal placentation, and uterine atony. Although the exact incidence of emergency peripartum hysterectomy is not known, several authors have reported widely varying rates of 0.004 to 1.5 per 1,000 deliveries.

Clark and associates reviewed 70 cases of emergency hysterectomy for obstetric hemorrhage and found that 60 (86%) of these procedures were performed after cesarean delivery and 10 (14%) were performed after vaginal delivery. Uterine atony and placenta accreta accounted for almost three fourths of the cases. Other indications were uterine rupture, extension of the uterine incision, and fibroids precluding closure of the uterine incision.

It is clear from the literature that *abnormal adherent placentation or placenta accreta (with or without hemorrhage) is emerging as the most common condition leading to an emergency hysterectomy*. In three studies from 1993 to the present, 156 (56%) of the 279 emergent peripartum hysterectomies were performed for placenta accreta. These studies are outlined in [Table 35A.2](#). *The increase in placenta accreta is related to the high rate of cesarean deliveries*, which has risen in the United States from 5% in the early 1960s to 30% at the present time. A recent study of more than 60,000 deliveries at the University of Chicago by Wu et al. found that the rate of placenta accreta had increased to 3 per 1,000 deliveries in 2003. They observed that this was directly associated with the increase in cesarean section rate. Clarke and colleagues found that in the presence of a placenta previa, the risk of having placenta accreta increased from 24% in women with one prior cesarean delivery to 67% in women with 3 or more prior cesareans.

Cesarean Hysterectomy

STEPS IN THE PROCEDURE

Cesarean Hysterectomy

- Midline skin incision.
- Cesarean delivery with dissection of bladder flap.
- Placenta removal unless placental invasion exists.
- If accreta is suspected, clamp cord and leave placenta in situ.
- Close the uterine incision with a no. 1 suture placed in a running locking fashion.
- Ligate the round ligament close to the uterus using 0 Vicryl.
- Open the peritoneum superiorly.
- Identify the ureters crossing the iliac artery at the level of the bifurcation in the medial leaf of the broad ligament.
- Identify the utero-ovarian ligaments, then clamp, cut, and ligate bilaterally.
- With upward traction on the uterus, identify and clamp the uterine vessels bilaterally (using a Heaney or Zeppelin clamp); vascular pedicles are double ligated.
- Using a straight or slightly curved clamp, clamp, cut, and tie the cardinal and uterosacral ligaments at the level of the cervix.
- Remove the uterus by clamping across the vagina on each side and incising the vaginal mucosa.
- Secure the lateral vaginal fornix to the cardinal and uterosacral ligaments.
- Close the vaginal cuff with interrupted figure-of-eight sutures.
- Inspect all pedicles for bleeding.
- Close the abdominal incision.

TABLE 35A.2 Indications for Emergency Hysterectomy for Obstetric Hemorrhage

INDICATION	CLARK ET AL. (1984) (<i>n</i> = 70)	BAKSHI ET AL. (2000) (<i>n</i> = 39)	STANCO ET AL. (1993) (<i>n</i> = 123)	ZELOP ET AL. (1993) (<i>n</i> = 117)
Uterine atony/hemorrhage	30 (43%)	11 (28%)	44 (35.9%)	25 (21.3%)
Placenta accreta/percreta	21 (30%)	20 (51%)	61 (49%)	75 (64.1%)
Uterine rupture	9 (13%)	5 (15%)	14 (11.5%)	—
Extension of uterine incision	7 (10%)	—	—	—
Leiomyomata	3 (4%)	2 (5%)	3 (2.4%)	—
Uterine infection	—	—	—	17 (14.5%)
Other	—	1 (1%)	1 (1.2%)	—

Although a number of conditions have been reported as indications for elective cesarean hysterectomy, currently accepted indications are usually limited to microinvasive or invasive cervical cancer. In retrospective reviews that go back to the 1950s and 1960s, sterilization, menstrual abnormalities, and uterine fibroids are listed as

indications; however, most practitioners would not consider these appropriate indications for such an invasive surgical procedure in the 21st century.

Morbidity and Mortality of Hysterectomy

The conditions leading to emergency hysterectomy also are responsible for much of the morbidity reported with the procedure. Two other important factors associated with morbidity, both of which are difficult to quantify, are training and experience (or surgical skill) of the surgeon. Chestnut and associates reported statistically significant reductions in operative time, estimated blood loss, intraoperative and total blood replacement, and length of hospital stay if the patient was in the care of an experienced surgeon. It seems reasonable, however, to conclude that morbidity and complications are also higher in women undergoing emergency versus elective procedures despite the skill of the surgeon.

Zelop and associates reported 102 (87%) of the patients in their series required transfusion of blood products. Complications of three series, totaling 279 cases of emergency peripartum hysterectomy, are summarized in Table 35A.3. Maternal mortality rates in these studies varied between 0% and 4.5%. As with morbidity, mortality is better correlated with the specific complication than with the hysterectomy per se.

In a review of 80 women undergoing elective cesarean hysterectomy, McNulty reported that only 5 (6%) experienced febrile morbidity and 15 (19%) received blood transfusion. Four (5%) women sustained bladder injuries, and 4 (5%) women developed broad ligament hematomas. Yancey and colleagues compared the outcomes in 43 women undergoing scheduled cesarean hysterectomy with those of 86 women who underwent cesarean delivery and subsequent scheduled delayed postpartum hysterectomy. Although women in the cesarean hysterectomy group were more likely to need a blood transfusion than were women in the subsequent hysterectomy group (OR 3.4; 95% CI: 1.4 to 8.4), they were less likely to have other complications, such as infection (OR 0.34; 95% CI: 0.25 to 0.45). The overall postoperative complication rate was the same in both groups (51%). Thus, it appears from the older literature that *elective* cesarean hysterectomy is not associated with an increased risk of complications or morbidity compared with a cesarean delivery followed by an elective hysterectomy at a later time. However, in a healthy population, one must weigh the risk of blood transfusion versus the benefit of the combined procedure. As pointed out by Baker and D'Alton, there is little doubt that elective cesarean hysterectomy is associated with increased morbidity when compared with a cesarean delivery and a tubal ligation.

Emergency versus Elective Hysterectomy

In two studies comparing emergency with elective peripartum hysterectomy, morbidity was greater with the emergency procedure. Estimated blood loss, number of women transfused, and operating time were all higher in the emergency group.

P.807

It is important to remember that many of the patients who undergo emergent delivery have already had significant blood loss and hemorrhage before the decision is made to proceed with hysterectomy.

TABLE 35A.3 Complications of 279 Cases of Emergency Peripartum Hysterectomy

COMPLICATION INCIDENCE (%)			
CLARK ET AL. (n = 70)	BAKSHI ET AL. (n = 39)	STANCO ET AL. (n = 123)	ZELOP ET AL. (n = 117)

Coagulopathy	6	2.5	5.7	27
Urologic injury	4	7.7	13	10.2
Death	1	0	0	0

Cesarean Hysterectomy Technique

Elective cesarean hysterectomy can be accomplished through either a midline or low transverse (Pfannenstiel) skin incision. Often, it is more prudent to use a midline skin incision, which affords better surgical exposure.

After the cesarean delivery, the placenta is quickly removed unless there is a contraindication to do so. *No attempt is made to remove the placenta in cases of placenta accreta because significant life-threatening hemorrhage can ensue.* In cases of placenta percreta involving the posterior wall of the bladder, a partial cystectomy may be required. In these cases, the bladder trigone and ureteral orifices must be carefully identified, and urologic consultation may be needed. In cases of anterior placenta previa and suspected placenta accreta, it is prudent to arrange for urologic support preoperatively. In cases of suspected accreta, some interventional radiologists may place bilateral hypogastric artery balloons preoperatively. When inflated, these balloons have significantly decreased operative blood loss in our experience.

The uterine incision can be closed with a running no. 1 suture in a locking fashion. The bladder flap should be dissected well down before the start of the hysterectomy. This is best accomplished at the time of the cesarean delivery. The bladder should be dissected off the anterior, lower uterine segment with sharp dissection if firm adhesions are encountered. Firm adhesions often are present in patients who have undergone multiple cesarean deliveries. If bleeding is a problem, further dissection of the bladder from the lower uterine segment can be accomplished after ligation of the uterine artery. If significant difficulty or bleeding is encountered in dissection of the bladder flap, a supracervical hysterectomy should be considered. Bleeding may also be diminished after the uterine arteries have been ligated bilaterally, so another attempt to dissect the bladder off of the anterior cervix may be considered at this time.

The actual hysterectomy is begun by ligating the round ligament close to the uterus and ligating the distal stump with a 0 Vicryl suture ligature. The vesicouterine serosa, where the bladder was attached before its dissection, then is extended laterally to the severed round ligaments.

FIGURE 35A.5 A: The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tube, utero-ovarian ligaments, and ovarian vessels. **B:** These are then doubly clamped close to the uterus and severed. (From Cunningham FG, MacDonald PC, Gant NF, et al. *Caesarean section and caesarean hysterectomy*. In: *Williams obstetrics*, 19th ed. Norwalk, CT: Appleton & Lange, 1993:591, with permission from The McGraw-Hill Companies, Inc.)

The peritoneal incision should be extended superiorly. Because the ureters are dilated in pregnancy, they should be identified quickly to avoid injury. The ureter can be seen crossing the iliac artery at the level of the bifurcation in the medial leaf of the broad ligament and is most easily identified at this location. The utero-ovarian ligaments can be secured by first making a “window” through the posterior leaf of the broad ligament and then doubly clamping, cutting, and ligating the utero-ovarian ligament bilaterally (**Fig. 35A.5**). This step is easy and uncomplicated in the nonpregnant patient, but the dilated vasculature of pregnancy requires the surgeon to carefully select a clear window and handle the tissues gently to avoid troublesome bleeding from easily torn veins. The uterine vessels are skeletonized as in the nonpuerperal

P.808

hysterectomy. These vessels are large and easy to identify. Dissection is made easier with continuous upward traction of the uterus. If possible, the uterine vessels are clamped bilaterally (usually with a Heaney or Zeppelin clamp) before the vessels are cut. If there is room, we prefer to place three large clamps on each side and divide the pedicle between the first and second clamp (**Fig. 35A.6**). This provides two clamps on the active vessels for security and one back clamp to prevent back bleeding from the enlarged, blood-engorged uterus. The vascular pedicles are doubly ligated with 0 synthetic absorbable sutures, and we generally prefer to suture ligate the back bleeders also, so that the back clamps can be removed from the field. This provides better exposure and reduces the risk of tearing the uterine tissues by excessive traction on these clamps. Once the uterine vessels are secured bilaterally, bleeding should be decreased and the situation should be reevaluated. Taking into account the indication for the hysterectomy in the first place, the stability of the patient, the blood loss to this point and an

estimation of additional blood loss, and the pelvic anatomy, the surgeon may elect to complete the total hysterectomy or decide that, if the bleeding is now well controlled but the patient is unstable or further pelvic dissection risks urinary tract injury or hemorrhage, a supracervical hysterectomy may be advisable. As with all hysterectomies, care must be exercised in identifying and avoiding the ureter.

The next pedicles encountered should be the broad ligament, the base of which is the cardinal ligament. A slightly curved or a straight clamp, whichever fits the anatomy best, can be used for these ligaments. It is better to take several small pedicles instead of one large bite, because an excessively large pedicle can slide out of a clamp or suture. This is especially true with the edematous tissues associated with pregnancy. Once the cardinal and uterosacral ligaments have been clamped, cut, and tied at the level of the cervix, the specimen can be removed by clamping across the vagina on each side and incising the vaginal mucosa ([Fig. 35A.7](#)). It may be difficult to identify the lower extent of the cervix, especially if the cervix is effaced. The cervix can be grasped with a thumb anteriorly and the hand wrapping around the cervix with the fingers posteriorly. The cervix is then pinched between the thumb and middle finger as the hand slowly slides down the cervix toward the vagina. Usually, it is possible to feel the lower end of the cervix in this way. If there is any doubt, it may also be helpful to make an incision into what is believed to be the anterior vagina just below the cervix using the electrosurgical blade. A finger can be inserted into the vagina, and the cervix palpated directly to confirm its location. Once the specimen has been removed, the cervix should be inspected to ensure that it has been removed completely.

After removal of the uterus and cervix, each of the angles of the lateral vaginal fornix is secured to the cardinal and uterosacral ligaments with a figure-of-eight 0 delayed absorbable suture. There is no unanimity of opinion regarding whether the vaginal cuff should be run and left open or closed. The vaginal cuff can be closed with interrupted figure-of-eight sutures. If there is continued oozing, as with a coagulopathy or in the presence of purulent amniotic fluid, then the vaginal cuff is left open to allow for adequate drainage. Hemostatic agents such as Gelfoam, with or without topical thrombin, or Surgicel can be considered. Reperitonization of the pelvis is not necessary in most cases. All pedicles should be closely inspected for bleeding before the abdominal incision is closed.

P.809

Subtotal versus Total Hysterectomy

Some clinicians have a tendency to perform a subtotal or supracervical hysterectomy in most cases of emergency peripartum hysterectomy. There is a general belief that both operating time and blood loss are significantly lower with the subtotal technique. In addition, the risk of bladder or ureteral injury may be decreased. There is no question that in the select patient who has been or is hemodynamically unstable, it may be prudent to perform a supracervical hysterectomy, especially if all bleeding has been controlled to that point. However, it is necessary to remove the cervix in cases of placenta previa or placenta accreta involving the lower uterine segment.

Despite the reputed advantages of a supracervical hysterectomy, there is evidence that performance of a complete hysterectomy with removal of the cervix adds little to either operating time or blood loss. Clark and associates reported no significant differences in mean values for blood loss and operating time in obstetric patients undergoing emergency total hysterectomy versus supracervical hysterectomy. Mean hospital stay also was not significantly different. However, the women in this study were not randomized to supracervical versus total hysterectomy. In 1998, Zorlu and associates also reported no significant difference between total and supracervical hysterectomy in operative time, blood transfusion, and mean hospital stay. It is important to separate emergency cesarean hysterectomy for hemorrhage, and so on, from elective peripartum hysterectomy for indications such as microinvasive cervical cancer because the blood loss and other morbidity are generally significantly greater for the emergency procedure. It is important for the surgeon to appreciate his or her experience; the stability of the patient; the operative team, including the anesthesiologists and the availability of operative consultation such as other gynecologic surgeons or urologists; and the postoperative support of a good intensive care unit and possible interventional radiology. A combination of good surgical judgment as well as surgical skill is required to achieve the best result.

EPISIOTOMY

An episiotomy is a surgical incision into the perineal body for the purpose of either aiding the actual delivery process or preventing tears and lacerations.

Indications

The routine use of episiotomy with vaginal delivery has been strongly challenged. A recent Practice Bulletin from the American Congress of Obstetricians and Gynecologists stated that the previously held ideas that episiotomy facilitated vaginal delivery, especially difficult or operative vaginal delivery, or improved neonatal outcome when expeditious delivery was indicated are *not* supported by current evidence. Studies by Myles and Santolaya and Bodner-Adler and colleagues failed to show any reduction in anal sphincter damage, rectal mucosal tears, or improved neonatal outcomes in women who underwent episiotomy.

In the past, it was thought that episiotomy prevented vaginal and perineal damage that led to subsequent pelvic relaxation. However, there is little evidence to support the premise that “prophylactic” episiotomy prevents cystocele, rectocele, enterocele, uterine prolapse, vaginal prolapse, or stress urinary incontinence. Röckner and associates evaluated pelvic floor muscle strength using vaginal cones and found that women with episiotomies had less strength than those with spontaneous vaginal deliveries. Neural testing of the

perineal musculature in other studies showed that the amount of denervation was associated with weight of the baby and the length of the second stage of labor and was unrelated to episiotomy. Sleep and Grant looked at deliveries in those who restricted use of episiotomy and those who reported liberal use of episiotomy. Over 3 years of follow-up, there was little difference between the two groups in severity of incontinence or the reported incidence of incontinence. These studies indicate that episiotomy does not appear to prevent the physical/anatomic or symptomatic changes of pelvic relaxation.

In addition, there are no good data to support prophylactic episiotomy for the prevention of “trauma” to the fetus, especially the preterm fetus. Although there is no evidence that the risk of shoulder dystocia can be decreased by the use of an episiotomy, many experts feel that a generous episiotomy may help in the management of a shoulder dystocia when it presents.

In summary, current opinion does not support the routine use of episiotomy for vaginal delivery. Previous ideas that suggested episiotomy decreased the risk of perineal injury, reduced trauma of operative delivery, or improved neonatal outcome have not been supported by recent studies. An episiotomy undoubtedly provides more room for a difficult vaginal delivery. Such deliveries are inherently associated with an increased risk of fetal distress and maternal trauma. The obstetrician must individualize each patient and weigh the potential advantages of an episiotomy against the known risks of episiotomy or vaginal delivery without an episiotomy or even cesarean delivery.

Midline versus Mediolateral Episiotomy

There is little question that the midline perineal incision is easier to perform and repair and is associated with less postoperative pain than is the mediolateral episiotomy. In general, it is also associated with less blood loss and better anatomic results. Midline perineal incisions are used more frequently in the United States, whereas mediolateral episiotomy is used more commonly in Europe. The major disadvantage of midline episiotomy is an increased risk of third- and fourth-degree lacerations. Owen and Hauth report that 20% of primiparous women with a midline episiotomy had a third- or fourth-degree laceration, compared with 9% of women with a mediolateral incision and only 1% when no episiotomy was performed. Of interest, multiparous women with a midline episiotomy had fewer third- and fourth-degree lacerations than those with a mediolateral episiotomy. Although these data appear to favor performing either a mediolateral episiotomy or no episiotomy at all, caution must be exercised when interpreting the data because this was not a randomized, prospective study, and it does not control for possible confounding factors. For example, patients who underwent episiotomy may well have had larger babies, a higher incidence of forceps assistance, or other characteristics resulting in an increased risk of laceration.

Although the mediolateral episiotomy may be associated with fewer third- and fourth-degree lacerations (at least in the primiparous patient) ([Table 35A.4](#)), there are several disadvantages to this technique. Blood loss is greater, and mediolateral episiotomies are more difficult to repair. Postoperative pain also is more common and can be very troublesome.

In the absence of good, prospective, randomized trials, the decision to perform a mediolateral or midline episiotomy must be based on clinical judgment and experience. A mediolateral episiotomy may provide more room for a difficult delivery

P.810

with a lower risk of third- and fourth-degree laceration, but it also results in more blood loss and a greater risk of long-term dyspareunia.

TABLE 35A.4 Relation of Lacerations to Type of Episiotomy in 7,675 Primiparous Women

LACERATION TYPE	TYPE OF EPISIOTOMY		
	MIDLINE (<i>n</i> = 4,822)	MEDIOLATERAL (<i>n</i> = 79)	NONE (<i>n</i> = 2,774)
Second degree	1,425 (30%)	26 (33%)	375 (14%)
Third or fourth degree	968 (20%)	7 (9%)	52 (1%)

Episiotomy Repair

STEPS IN THE PROCEDURE

Episiotomy Repair

- Closure of the vaginal mucosa and submucosa with a continuous running locking 2-0 absorbable suture.
- Closure of the fascia and muscle of the perineal body with interrupted sutures using absorbable suture material.
- Closure of the skin of the perineum can be closed with a continuous subcuticular stitch using 3-0 or 4-0 suture. An alternate method to close skin is to use interrupted sutures of 3-0 or 4-0 absorbable suture.
- For sphincter repair, carefully approximate with several interrupted 2-0 sutures through the muscle and fibrous capsule.
- For repair of the rectum, approximate the edges of the rectal mucosa with a running submucosal 3-0 or 4-0 delayed absorbable suture, followed by a second reinforcement layer of the rectovaginal septal tissue.

An episiotomy can be repaired in numerous ways. One popular method is to close the vaginal mucosa and submucosa with a continuous locking suture of 2-0 synthetic delayed absorbable suture, followed by closure of the fascia and muscle of the perineal body with three or four interrupted sutures of similar suture material. The skin of the perineum can then be closed with a continuous subcuticular stitch or by interrupted sutures of 3-0 or 4-0 synthetic absorbable or chromic suture through the subcutaneous tissue and skin. In cases of fourth-degree lacerations, it is important to approximate the edges of the rectal mucosa with a running submucosal 3-0 or 4-0 delayed absorbable or chromic suture, followed by a second reinforcing layer of the rectovaginal septal tissue. If the external anal sphincter is severed, it should be carefully reapproximated with several interrupted 2-0 sutures

through the muscle and fibrous capsule. The technique for primary episiotomy closure is illustrated later in this chapter and is also discussed in [Chapter 40](#).

Complications of Episiotomy

Extensions and Fistula Formation

The major complications of episiotomy include infection, hematoma, breakdown, and fistula formation. Probably the single most common complication is extension (i.e., third- or fourth-degree laceration). Extensions in turn can lead to incontinence of flatus and stool, rectovaginal fistula, and infection. The association of extensions with the type of episiotomy has been discussed already. In the report by Harris, 11.6% of the more than 7,000 women with midline episiotomies had a third- or fourth-degree laceration. In the women with these lacerations, 2% subsequently had poor sphincter tone, and 0.1% developed a rectovaginal fistula. Signorello and colleagues performed a retrospective cohort study to evaluate the relationship between midline episiotomy and anal incontinence postpartum. Women with episiotomies had a higher risk of fecal incontinence 3 months and 6 months postpartum. Episiotomy tripled the risk of fecal incontinence at 3 months and 6 months postpartum and doubled the risk of flatus incontinence compared with women with spontaneous lacerations. In a prospective evaluation of 16,583 deliveries, Walsh and colleagues found that 0.56% of deliveries were complicated by third-degree lacerations. Lacerations were not prevented by episiotomy but were associated with forceps delivery. Of the 81 patients followed, 30 had abnormal anorectal examination, 7% were incontinent of stool, and 12% were incontinent of flatus.

Fistula is fortunately an uncommon complication of episiotomy. Causes include unrecognized lacerations in the rectovaginal septum at the time of episiotomy repair or infected hematoma. Risk factors for fistula formation include obesity, poor hygiene, malnutrition, anemia, history of inflammatory bowel disease, connective tissue disease, or prior exposure to radiation therapy. Half of these fistulae spontaneously heal, but repair should be considered if the patient is bothered by symptoms.

Dehiscence

The exact incidence of episiotomy dehiscence is unknown, but it appears to occur infrequently. In a review of 390 women with fourth-degree perineal lacerations, 18 (4.6%) experienced a dehiscence, and 11 of these were associated with infection.

P.811

Several predisposing factors have been reported to be associated with episiotomy dehiscence, including infection, human papillomavirus, cigarette smoking, hematoma, or trauma. Infection is probably the most common factor. In the study by Ramin and associates, 86% of patients with midline episiotomy dehiscence and 69% of patients with mediolateral episiotomy dehiscence had evidence of infection that was based on the presence of fever or purulent discharge. Infection with human papillomavirus also has been reported by some to be associated with dehiscence. Although inadequate or “faulty” repair has been reported to be associated with dehiscence, this is a rare cause.

Early Repair of Dehiscence In the past, it had been taught that repair of episiotomy dehiscence should be delayed for several months to allow for revascularization and healing. However, current surgical opinion supported by recent data strongly favors early repair. Delayed repair is an inconvenience for the woman and may be associated with fecal incontinence and loss of sexual function. Delay also can increase the hospital stay and cost, and increase risk of litigation.

There are many advantages to early repair of episiotomy dehiscence. Hauth and colleagues reported on the efficacy and safety of early repair in eight women who had a dehiscence of a fourth-degree midline episiotomy. Early repair was successful in seven of the eight women. One woman developed a pinpoint rectovaginal fistula 4

days after early repair. This was fixed with a 1-cm rectal flap 4 months later.

Monberg and Hammen reported on the successful resuturing of episiotomy breakdown in 20 women with infection, dehiscence, or both. Although four of the women had superficial reseparation, all subsequently healed spontaneously.

Hankins and associates updated the initial report by Hauth and colleagues to include 22 women with dehiscence of an initial fourth-degree repair, 4 with dehiscence of a third-degree repair, and 5 with breakdown of a mediolateral repair. Initial success of early repair was achieved in 29 (94%) of 31 women. Two women with a pinpoint rectovaginal fistula were subsequently repaired with a rectal flap procedure. Of the 27 women with a follow-up of 1 year or greater, all were continent and had resumption of normal coital activity. The follow-up of the 22 women with early repair of episiotomy dehiscence revealed no complications in 18 patients. Occasional incontinence of flatus and stool, dyspareunia, dyschezia, and numbness occurred in the remaining patients. All of the symptoms resolved by 9 months, except for 2 patients who had persistent dyspareunia.

Ramin and coworkers reported on the early repair of 34 women with episiotomy dehiscence, most of whom were infected ([Table 35A.5](#)). These women received care from a large urban hospital serving primarily an indigent population. The timing of repair for dehiscence ranged from 3 to 13 days. Two women with initial third-degree episiotomy dehiscence had unsuccessful repairs. Thus, successful repairs were accomplished in 32 (94%) of the women. The average time from delivery to subsequent discharge after repair of the dehiscence was 15.5 days. This is similar to the time reported by Hankins and colleagues. This time probably can be shortened significantly with outpatient management of the wound and repair in ambulatory care units.

Secondary Repair Technique Before attempting a closure, it is important to prepare the wound for repair. The first step is cleaning and debridement of the episiotomy site. This can be accomplished either on the ward with intravenous sedation or local anesthesia or in the operating room under regional anesthesia. All necrotic tissue and suture fragments should be removed and the wound irrigated with a diluted povidone-iodine solution or half-strength Dakin solution. Broad-spectrum antibiotics are indicated for overt infection or significant cellulitis. After initial debridement, the wound should be scrubbed and cleaned at least twice daily. Scrub brushes impregnated with povidone-iodine or gauze dressing pads can be used. A 1 % lidocaine jelly is applied to the wound several minutes before cleansing, and analgesics should be used as necessary. The liberal use of sitz baths helps keep the wound clean.

TABLE 35A.5 Characteristics of 34 Patients with Episiotomy Dehiscence and Subsequent Early Repair

CHARACTERISTIC	MIDLINE	MEDIOLATERAL
Total number of patients	21	13
Type of delivery		
Spontaneous	11	0
Outlet forceps	3	3
Low forceps	7	10

Extension

None	1	5
Third degree	9	6
Fourth degree	11	2
Evidence of infection	18 (86%)	9 (69%)
Early repair failures	1	1

Reprinted from Ramin SM, Ramus RM, Little BB, et al. Early repair of episiotomy dehiscence associated with infection. *Am J Obstet Gynecol* 1992;167:1104, with permission. Copyright © 1992, Elsevier.

Secondary repair of the episiotomy is not attempted until the wound is free of exudate and covered by granulation tissue. A mechanical bowel preparation with an oral electrolyte solution should be administered the evening before surgery for fourth-degree breakdowns. Prophylactic antibiotics are recommended for all repairs. One to three doses of a first-generation cephalosporin generally proves satisfactory.

The first step in the surgical repair of dehiscence is debridement of granulation tissue and dissection to ensure good tissue mobility. If the anal sphincter muscle has been severed, extensive retraction usually has occurred. It is important to identify the fibrous capsule and mobilize the muscle and capsule for successful reapproximation. If the rectal mucosa has been lacerated, it should be reapproximated as described in this chapter. In a prospective, randomized trial, Fitzpatrick and colleagues compared 55 women who underwent a sphincter overlap procedure with 57 women who underwent staple approximation repair of third-degree lacerations. In this study, there were no significant differences in anal manometry or endoanal ultrasound in the two groups. Therefore, either approach is acceptable. The rest of the closure is the same as for a secondary episiotomy repair. The secondary repair of a fourth-degree episiotomy breakdown is shown in [Figures 35A.8](#) to [35A.11](#).

Postoperatively, women can be placed on a regular diet if the rectal mucosa is not involved. If the rectal mucosa is involved, a low-residue diet should be used for several days and advanced to a regular diet. Stool softeners are recommended, but diarrhea should be avoided because of the increased likelihood of infection.

Postoperative care should also include sitz baths and a heat lamp.

The care and repair of a mediolateral episiotomy dehiscence are the same as for a midline repair. More extensive tissue mobilization may be required with the repair of a mediolateral episiotomy dehiscence.

FIGURE 35A.8 Secondary closure of fourth-degree episiotomy breakdown. The rectal mucosa has been closed with 4-0 running chromic submucosal suture and reinforced with a second layer of 3-0 chromic suture through the rectovaginal septum.

FIGURE 35A.9 The anal sphincter muscle has been reapproximated end to end with several interrupted 2-0 chromic sutures through the muscle and capsule.

FIGURE 35A.10 The vaginal mucosa and bulbocavernosus muscle have been closed with 2-0 chromic suture.

CERVICAL CERCLAGE

Premature dilation of the uterine cervix is a major cause of loss or delivery in midpregnancy. Although the pathophysiology of *cervical insufficiency* is poorly understood and the diagnosis challenging, concepts continue to evolve regarding this complex situation. The concept of cervical insufficiency, its diagnosis, and its management have been well reviewed in a Practice Bulletin issued by the American Congress of Obstetricians and Gynecologists. Although a variety of diagnostic criteria—including prior midtrimester losses and history of cervical surgery (including loop electrode excision procedure or cone biopsy) and painless dilatation of the cervix—have been used in the past and serve as useful clinical risk factors, today *ultrasound monitoring of cervical length and funneling are usually used to make a diagnosis of cervical insufficiency*.

Shirodkar first described cerclage placement in 1955 as a new method to prevent habitual abortion in the second trimester. McDonald, in 1957, reported a simplified technique. The technique for the abdominal approach for cerclage was described by Benson and Durfee in 1965. Data regarding the efficacy of cerclage placement has been conflicting. The Cervical Incompetence Prevention Randomized Cerclage Trial (CIPRACT) concluded that serial ultrasounds for evaluation of cervical insufficiency with secondary intervention are a safe alternative to traditional prophylactic cerclage. Studies have supported the uses of cerclage for pregnancy prolongation in singleton gestations; however, there are conflicting data about its utility in multiple gestations. Cerclage is rarely performed after 24.5 weeks gestation because the risks of surgery are outweighed by the benefits of bed rest for a few weeks to achieve improved fetal survival.

Zaveri and colleagues noted that transabdominal cerclage may be associated with a lower risk of perinatal death, but has a higher risk of intraoperative complications. Data suggest that an abdominal cerclage may be preferable in patients in whom a transvaginal cerclage has failed. The abdominal approach is also indicated in patients whose cervix has been shortened significantly by cone biopsy or other surgery. Laparoscopic transabdominal suture insertion during and before pregnancy has recently been described. Recent case reports suggest that placement of the abdominal cerclage by a laparoscopic approach is safe and may reduce maternal recovery time; however, its efficacy over the additional abdominal approach has not been examined.

Technique

STEPS IN THE PROCEDURE

Cervical Cerclage: Transvaginal

- Modified Shirodkar
 - Make a transverse incision in the vaginal mucosa of the anterior cervix to allow for displacement of the bladder upward.
 - A posterior incision is made in a similar fashion to avoid entry into the rectum.
 - The lateral angles of the anterior and posterior incisions are then expanded with blunt dissection of the lateral cervix.
 - A 5-mm woven Mersilene tape on a large needle is then passed through the submucosal tunnel from anterior to posterior on both sides of the cervix, then tied posteriorly.
- McDonald approach
 - Placement of a suture of 5-mm Mersilene or other type of heavy monofilament suture (Prolene) around the cervix in a purse-string fashion and securely tied anteriorly

STEPS IN THE PROCEDURE

Cervical Cerclage: Abdominal

- Low, transverse abdominal incision (Pfannenstiel technique)
- Transverse incision of the vesicouterine peritoneum to allow for bladder retraction
- Placement of 5-mm Mersilene suture through the broad ligament close to the cervical stroma and tied securely
- Delivery by cesarean section

FIGURE 35A.12 Modified Shirodkar cerclage. An incision in the mucosa is made anteriorly and posteriorly to advance the bladder and rectum. A 5-mm Mersilene suture on a large needle is placed in a submucosal tunnel around the cervix and tied posteriorly.

The modified Shirodkar and the McDonald procedure are performed using the transvaginal approach. In the *modified Shirodkar approach*, a transverse incision is made in the vaginal mucosa of the anterior cervix to allow for upward displacement of the bladder to avoid injury. A posterior incision is made in similar fashion to avoid entry into the rectum. The lateral angles of the anterior and posterior incisions are then expanded with blunt fingertip dissection of the lateral cervix (**Fig. 35A.12**). A 5-mm woven Mersilene tape on a large needle (Ethicon, USA) is then passed through the submucosal tunnel from anterior to posterior on both sides of the cervix. It is preferable to avoid entering the cervical canal because the tape may irritate the fetal membranes; this can be done by placing an index finger in the cervical canal as the needle is passed through the lateral cervix. The lateral cervical mucosa at 3 and 9 o'clock can also be grasped with an Allis clamp or ring forceps as shown in **Figure 35A.12** to facilitate placement of the sutures. After the suture is placed on both sides of the cervix, the knot is tied in the posterior defect. The defects are then closed with 3-0 Vicryl in figure-of-eight fashion. We usually leave a whisker of the Mersilene band extending through the closure so that it can be grasped and the suture exposed and cut when the patient goes into labor.

The *McDonald* approach requires no dissection into the cervical tissues. A suture of braided Mersilene or a heavy monofilament suture (Prolene) may be placed around the cervix in purse-string fashion and tied securely (**Fig. 35A.13**).

FIGURE 35A.13 Placement of suture for McDonald cervical cerclage. **A:** We use a double-headed Mersilene band with four “bites” in the cervix, avoiding the vessels. **B:** The suture is placed high upon the cervix close to the cervical-vaginal junction, approximately the level of the internal os.

Proponents of the modified Shirodkar feel that cervical dissection assists in placing a higher cerclage, but Rozenburg and associates noted that the anterior colpotomy associated with the modified Shirodkar cerclage only increased the distance from the external os by 2.7 mm. Rust and colleagues noted that the length of the cervix below the level of the cerclage does not affect the rate of preterm delivery.

Placement of the *abdominal cerclage* traditionally has required a low transverse abdominal incision, usually

performed by Pfannenstiel technique. The vesicouterine peritoneum is incised in transverse fashion to allow for retraction of the bladder inferiorly. A suture of 5-mm Mersilene is placed through the broad ligament close to the cervical stroma with care taken to avoid the uterine vessels. The suture is then tied securely. Unlike the transvaginal cerclage, the suture cannot be removed vaginally; thus, the patient requires a cesarean delivery. This suture may be left in place until childbearing is complete.

BEST SURGICAL PRACTICES

- The anatomic and physiologic changes of pregnancy may make diagnosis and surgical management more complex. Ultrasound and magnetic resonance imaging are safe and useful diagnostic imaging techniques that can be used in the pregnant patient.
- Postpartum hemorrhage may be a life-threatening emergency. It may be due to an obstetric laceration, retained products of conception, uterine atony, or coagulation defects. Aggressive fluid replacement and oxytocic agents are indicated while a diagnostic evaluation is undertaken. Uterine packing has recently been rediscovered as an effective way to treat hemorrhage from uterine atony.
- Transcatheter arterial embolization may be very effective to control postpartum hemorrhage. Bilateral uterine artery or hypogastric artery embolization is recommended. This technique is highly effective, preserves the uterus, and does not preclude future pregnancies.
- Surgical techniques for the management of peripartum hemorrhage include uterine artery ligation, hypogastric artery ligation, B-Lynch compression sutures, and hysterectomy. Emergency hysterectomy for hemorrhage is associated with a significantly increased risk of complications, including urinary tract injury and infection. It is not clear whether elective hysterectomy performed at the time of a scheduled cesarean delivery is associated with increased morbidity, but blood loss and risk of transfusion are increased, and delivery followed by hysterectomy 3 to 6 months later may be considered as an alternative.
- The use of episiotomy has declined significantly in recent years. Recently, studies have not shown any benefit of episiotomy in reducing the risk of third- and fourth-degree lacerations, reducing the risk of long-term pelvic support defects, or improving neonatal outcome. Episiotomy should not be used routinely. Median episiotomy is associated with a higher risk of anal sphincter and rectal injury. Mediolateral episiotomy is associated with increased blood loss and perhaps an increase in postpartum pain and longterm dyspareunia. Repair of episiotomy, especially if there is rectal or sphincter injury, should be done meticulously, using good surgical technique with adequate anesthesia and sterile technique.
- Surgical treatment of cervical insufficiency is complicated by a poor understanding of the pathophysiology of the condition. Painless dilatation and effacement of the cervix in the second trimester, usually documented by ultrasound, is an indication for treatment. Both the McDonald and Shirodkar techniques have been used successfully. An abdominal cerclage may be considered if the cervix has been shortened or damaged by surgery or trauma.

Chapter 35B

Ovarian Tumors Complicating Pregnancy

Jack Basil

Kristin Coppage

James Pavelka

DEFINITIONS

Hyperreactio luteinalis—A benign, frequently large (15 to 20 cm), usually bilateral ovarian enlargement caused by an increased sensitivity to human chorionic gonadotropin (hCG). These masses are composed of numerous luteinized follicular cysts and are more common in conditions in which the hCG is increased (e.g., hydatidiform mole, multiple gestation). This condition is benign and resolves spontaneously after pregnancy.

P.817

Luteoma of pregnancy—A benign neoplasm of the ovary caused by the hormonal effects of pregnancy. It is usually solid and unilateral. It is most often asymptomatic and found incidentally. It may cause virilization and complications if torsion occurs. It resolves spontaneously after pregnancy.

Pulsatility index (PI)—An arterial waveform index that has been shown to be useful in discriminating benign from malignant adnexal masses. A PI > 1.0 is almost always associated with a benign mass. A PI < 1.0 is suggestive of malignancy but can be seen in a corpus luteum cyst or an inflammatory mass.

The coexistence of an adnexal mass with pregnancy presents problems to both the clinician and the patient, the most serious being that of malignancy. The care of the patient must balance the competing risks and benefits of the mother and fetus. Through a multidisciplinary approach of specialists in gynecologic oncology, maternal fetal medicine, pathology, and neonatology, the best plan of action, observation versus intervention, can be determined. Therapeutic implications including loss of the current pregnancy and loss of future fertility result in an emotionally charged environment, which must be skillfully navigated by all members of the health care team.

EPIDEMIOLOGY

Cancer complicates 1:1,000 pregnancies in the United States. The most common malignancies seen in pregnancy include malignant melanoma (2.6:1,000), Hodgkin lymphoma (1:1,000-6,000), breast cancer (1:3,000-10,000), cervical cancer (1.2:10,000), ovarian cancer (1:10,000-100,000), colorectal cancer (1:13,000), and leukemias (1:75,000-100,000).

The lifetime risk of developing ovarian cancer is 1.4% (14 per 1,000), the highest risk occurring after menopause. Women of reproductive age have a low risk approximating 0.2% to 0.4%. Benign ovarian tumors are the most common complicating pregnancy. The exact incidence, however, depends on whether one considers simple cysts noted on ultrasound examination (1 in 50 live births), during pelvic examination (1 in 80 live births), or those that ultimately require laparotomy (1 in 1,000 to 1 in 1,500 live births). Hill and colleagues reported findings for ovarian cysts found at the time of second and third-trimester ultrasound. Ovarian cysts were diagnosed in 4.1% of second- or third-trimester ultrasounds. Most of these cysts were less than 3 cm and resolved spontaneously. Eighteen of the 7,996 patients had an exploratory laparotomy, which was equivalent to one surgery in 444 deliveries. All of these lesions were benign on pathologic examination. Ueda and Ueki

reported 106 patients who required ovarian surgery during pregnancy. Of these patients, 31 (29.2%) had physiologic ovarian cysts, 70 (66%) were benign tumors, and 5 (4.7%) were malignant. More recent observations by Schlemmer et al. have noted that adnexal masses greater than 5 cm were observed in 63 patients (0.05%), with 4 patients (6.8% of masses and 0.0032% of deliveries) diagnosed as malignant. Finally, these tumors may also be an incidental finding at the time of cesarean. Koonings and colleagues noted the incidence of ovarian tumors complicating cesarean section to be about 1 in 200 cesarean births. Dede et al. also observed a 0.8% incidence of masses greater than 5 cm at the time of cesarean section.

DIAGNOSIS

The definitive diagnosis of an ovarian tumor can only be made by pathologic examination. This places the clinician in a difficult dilemma during pregnancy. Until the widespread use of ultrasound, ovarian masses often remained unrecognized, as their symptoms frequently mimic common symptoms of pregnancy. Over time, clinicians have realized that there are windows of opportunity to evaluate the adnexa. These include the initial pelvic examination in the first trimester (palpable masses), any ultrasound performed, and careful evaluation at the time of operative intervention (cesarean section or postpartum tubal ligation). A thorough pelvic examination at the time of termination of pregnancy is another opportunity to evaluate the ovaries.

The increasing (nearly routine) use of ultrasound examination in pregnancy affords an excellent opportunity for the diagnosis of coexistent ovarian pathology; it is for this reason that such an examination should always include the adnexa ([Fig. 35B.1](#)). The results of ultrasound, although potentially very useful in the relatively rare patient with an ovarian malignancy, may create a difficult dilemma for the clinician who must decide how to proceed when an ovarian cyst is diagnosed in pregnancy. Perkins and coworkers evaluated 1,001 patients with first-trimester ultrasound and determined that a simple ovarian cyst was seen in 29% of these patients. The incidence of ovarian cysts decreased after 8 weeks, and absence of a cyst was more often associated with blighted ovum.

Bromley and Benacerraf evaluated the accuracy of sonographic diagnosis of adnexal masses during pregnancy. They evaluated all patients with an adnexal mass measuring 4 cm or greater noted beyond 12 weeks gestation. One hundred and thirty-one lesions were noted; of these, 89.3% were accurately diagnosed as benign. Fourteen of the 131 lesions (10.7%) had sonographic characteristics of malignancy. One of 14 (7%) of these patients had ovarian cancer, for a 0.8% malignancy rate in this study. Lavery and colleagues, in a review of 3,918 ultrasound examinations at 20 weeks gestation, noted cyst formation greater than 2 cm in 2.4% of examinations. Only nine patients (0.23%) required surgical intervention. Hogston and Lifford, in a review of 26,000 patients who received routine ultrasound, noted an incidence of cyst formation of 0.52%. All complex cysts and those greater than 6 cm were operated on primarily (10%). Eighty-five percent of the remaining patients who were followed conservatively showed spontaneous resolution, with the exception of 5 patients who ultimately required laparotomy.

Doppler sonography has been evaluated for use in complex adnexal masses in pregnancy. Wheeler and Fleischer evaluated 34 pregnant patients with complex adnexal masses. Diagnosis made by color Doppler sonography was compared with actual histopathologic diagnosis. Three malignant and five low malignant potential tumors were correctly identified with a sensitivity of 0.89 and a mean pulsatility index (PI) of 0.71. The mean PI for benign lesions was greater than 1, and the negative predictive value for $PI > 1$ was 0.93. The positive predictive value for $PI < 1$ was 0.42, indicating that some benign lesions were incorrectly classified as malignant when a $PI < 1$ is used as a cutoff for possibly malignant tumors. However, color Doppler appears to be highly predictive of a benign lesion when the PI is greater than 1.

FIGURE 35B.1 This is a midline picture from a first-trimester ultrasound. Both the intrauterine pregnancy on the right and maternal adnexal mass on the left are visualized.

P.818

Epithelial tumor markers such as CA-125, CEA, CA-19-9, and CA-15-3 demonstrate some fluctuation during pregnancy and should be interpreted with caution. However, median levels are still typically within established norms for premenopausal women. Alpha-fetoprotein levels rise during pregnancy. High MSAFP (maternal serum alpha fetoprotein) levels can be seen with germ cell tumors. These levels are significantly higher (MoM of 24) than are those seen in neural tube defects or abdominal wall defects as shown in a study by Elit and colleagues. Alpha-fetoprotein is heterogeneous, and the yolk sac variant can be separated by affinity chromatography to determine if the elevation is due to the yolk sac or liver variant. Another chemical marker is LDH (lactate dehydrogenase). Ovarian dysgerminomas may have significantly elevated levels of LDH in pregnancy as shown by Buller and colleagues. Pregnancy LDH is usually in normal range unless preeclampsia/HELLP syndrome has been diagnosed. Inhibin is a chemical made by the placenta and can be used to assess risk for chromosomal anomalies. Therefore, inhibin cannot be used during pregnancy to help to diagnose cell tumors, as it does in a nonpregnant patient. Finally, human chorionic gonadotropin (hCG) is used to follow some germ cell tumors such as choriocarcinoma; however, it again is not useful in pregnancy. Composite tests, such as the newer OVA-1 test, have no established data in pregnant women; include components such as transferrin, which are altered in pregnancy; and are therefore not recommended.

From a treatment standpoint, the first trimester is clearly the best time to diagnose an adnexal mass complicating pregnancy. Because tumors are rarely symptomatic during this period, most such tumors are discovered by ultrasound examination. With the increasing incidence of ultrasound evaluation and use of cesarean section, recent articles suggest that only about 50% of ovarian tumors complicating pregnancy are symptomatic. When symptomatic, the patient typically presents with abdominal pain, abdominal distention, and vague gastrointestinal symptoms. All these symptoms can be directly attributable to pregnancy itself; therefore, it is not surprising that most pregnant women with these symptoms are not evaluated for an ovarian tumor.

A successful outcome for both mother and fetus depends on a high index of suspicion with early diagnosis. One should consider an ovarian mass in any woman who experiences abdominal pain in pregnancy. Furthermore, torsion, rupture, infection, or hemorrhage of an ovarian tumor should be included in the differential diagnosis of any catastrophic abdominal obstetric event. This is particularly true during times of rapid change in uterine size or position (e.g., 8 to 16 weeks), during termination of pregnancy, during labor

and delivery, or in the immediate postpartum period.

The incidence of torsion complicating an ovarian tumor in the nonpregnant state is about 2%. Torsion complicating an ovarian tumor during pregnancy is much higher. One report by Ueda and Ueki showed a 21.8% rate of torsion in ovarian tumors in pregnancy. Further, it is clear that the previously unrecognized symptomatic ovarian tumor complicating pregnancy can become catastrophic. Wang and colleagues retrospectively evaluated 174 patients who underwent surgery for ovarian masses during pregnancy. These patients were divided into two groups: those with emergency surgery (32 patients) and those with elective surgery (142 patients). They found in the emergency surgery group that half of the surgeries occurred in the first trimester, they contributed to 75% of total fetal wastage and 87% of spontaneous fetal loss, and tumor sizes were significantly larger. In their experience, tumors less than 5 cm in size never caused symptoms requiring surgery. Therefore, size of tumor, ultrasound characteristics, color Doppler flow, serum analytes, and symptoms are important in determining the management of pregnant patients with adnexal masses.

PATHOLOGY

Benign neoplasms complicating pregnancy include two tumorlike conditions with which every gynecologist should be familiar. *Hyperreactio luteinalis* (first described by Burger in 1938 as a grossly multicystic, usually bilateral ovarian enlargement, often 15 to 20 cm in size) is a term used to describe numerous luteinized follicular cysts of the ovary complicating pregnancy. Microscopically, one notes extensive luteinization of the theca and granulosa cell layers. Bradshaw and associates suggest that the hyperandrogenicity seen in this condition is related to increased ovarian sensitivity to hCG. Therefore, it is seen in conditions in which the hCG is elevated, such as hydatidiform mole, multiple gestations, choriocarcinoma, and erythroblastosis fetalis. *Hyperreactio luteinalis* also has been associated with normal pregnancy, and, in these patients, it has not been associated with fetal virilization. These tumors spontaneously regress after delivery but may take up to 6 months to resolve. *Hyperreactio luteinalis* also may occur in subsequent pregnancies.

Luteoma of pregnancy is a specific benign, usually unilateral, solid lutein cell tumor of the ovary found in late pregnancy, often noted at cesarean section (**Fig. 35B.2A, B**). First described by Sternberg in 1966, this tumor is grossly bosselated, soft, fleshy, yellow, or hemorrhagic. Microscopically, it exhibits an acidophilic granular cytoplasm with sparse lipid formation and a distinctive reticular pattern. It is likely the most common cause of maternal virilization during pregnancy. The etiology is unknown, but theories have included luteinized stromal cells present before pregnancy that respond to hCG or “hyperluteinized” theca cells, granulosa cells, or a combination of the two. Fifty percent of female infants born to virilized mothers with pregnancy luteoma exhibit signs of virilization.

The important clinical implication with both of these lesions is that if they are recognized or suspected, simple biopsy without further surgery is adequate therapy, because both invariably resolve spontaneously.

The most common benign neoplasm of the ovary in pregnancy is the *benign cystic teratoma*, which accounts for about one third of all benign ovarian tumors seen in pregnancy (**Fig. 35B.3A, B**). The second most common group of ovarian tumors complicating pregnancy is that of cystadenomas (**Fig. 35B.4**). These represent about 15% of tumors. Endometriomas, simple cysts, corpus luteal cysts, tubal cysts, myomas, and other miscellaneous lesions constitute the remaining types of tumors seen in pregnancy (**Table 35B.1**).

Malignant ovarian tumors constitute only about 1% to 2% of all adnexal masses that complicate pregnancy and require

surgical exploration. The single most common malignant ovarian tumor complicating pregnancy probably is *dysgerminoma*. Malignant tumors of epithelial origin as a group, however, are more common (**Fig. 35B.5**);

tumors of low malignant potential occur most frequently (**Fig. 35B.6**). Sex-cord stromal tumors are the third most common primary malignant ovarian neoplasms, representing about 17% to 20% of such tumors. Krukenberg and other metastatic tumors represent about 12% to 13% of malignant ovarian neoplasms complicating pregnancy (**Fig. 35B.7**).

FIGURE 35B.2 A: Luteoma of pregnancy. The left ovary is enlarged with a lobulated smooth surface. These are usually unilateral. **B:** In this gross photograph, the ovary is bivalved and 5 reddish-brown leuteomas are clearly visible within the yellowish ovarian stroma. Leuteomas usually resolve spontaneously within several weeks of delivery. (With permission of Ed Uthman, MD.)

Whether malignant or benign, most ovarian tumors complicating pregnancy are unilateral. Karlen and associates reported 90% of dysgerminomas in pregnancy to be unilateral, and Young and colleagues reported 35 of 36 sex-cord stromal tumors to be unilateral when complicating pregnancy. Even malignant tumors of epithelial origin noted during pregnancy are unilateral in 90% of cases. The rarer germ cell tumors, such as endodermal sinus tumors, virtually always are unilateral as well. It is also interesting that most bilateral tumors occurring in pregnancy are not malignant; these include benign cystic teratoma, endometriosis, and hyperreactio luteinalis. The most common bilateral malignant ovarian tumors are the metastatic Krukenberg types. Somewhat less common are primary malignant tumors of epithelial origin.

FIGURE 35B.3 A: Benign cystic teratoma (dermoid cyst) of the right ovary in a 15-week pregnant woman. (Reprinted from Shah K, Anjurani S, Bhat P, et al. Ovarian mass in pregnancy: a review of six cases treated with surgery. *Internet J Gynecol Obstet* 2000;14, with permission. Available at <http://www.ispub.com>.) **B:** Gross appearance of a bisected benign cystic teratoma with a large amount of oily hair. The small cyst contained oil and thick sebaceous material.

FIGURE 35B.4 Serous cyst adenoma of the left ovary. This patient presented to the emergency department with severe lower abdominal pain. She reported several missed periods and on exam had a tender mass up to the umbilicus. Ultrasound demonstrated a 10-week pregnancy plus a separate 22-cm smooth-walled, simple cystic

mass with no ascites. *Note:* The pregnant uterus should be manipulated as little as possible during surgery.

Virilization secondary to an ovarian tumor sometimes complicates pregnancy. The classic painting titled *Magdalena Ventura with Husband and Son*, painted in 1631 by Ribera, documents such a problem ([Fig. 35B.8](#)). Magdalena, after having several children, became virilized at age 37, with apparent infertility thereafter. However, when she was 52, a son was born. One would speculate that she probably had an ovarian Sertoli-Leydig cell tumor. Young and colleagues have noted that although about 50% of Sertoli-Leydig cell tumors in the nonpregnant state are functional, only about 15% of those complicating pregnancy result in maternal virilization. They proposed two possible explanations for this apparent decrease in virilization. The first is that the most active of such tumors result in anovulation; therefore, women with virilizing tumors rarely become pregnant. The second is that the placenta may aromatize the tumor-produced androgens into estrogens. In any event, Sertoli-Leydig cell tumors are not the most common tumors in pregnancy associated with

virilization. This distinction falls to those tumors associated with a functioning ovarian stroma. The most common virilizing ovarian tumor that complicates pregnancy is the luteoma, followed by Krukenberg tumors and mucinous epithelial tumors ([Table 35B.2](#)).

FIGURE 35B.5 The approximate relative frequency of the most common malignant ovarian tumors.

The clinical implications of virilizing tumors complicating pregnancy are somewhat different from those of such tumors in the nonpregnant state. Virilization usually occurs late in pregnancy, is of short duration, and usually is reversible. The majority of such cases, as mentioned, are secondary to luteoma; therefore, they resolve spontaneously. If sex-cord stromal or epithelial tumors are present, the ultimate outcome remains quite good. However, patients with Krukenberg lesions have a poor outcome.

Malignancies also can be metastatic to the placenta or products of conception. Although this is an uncommon occurrence, tumors that may metastasize to the placenta include malignant melanoma, leukemias and lymphomas, breast carcinoma, lung carcinoma, and some sarcomas.

FIGURE 35B.7 This MRI depicts a fetus and intrauterine pregnancy at 32 weeks. Anterior to the uterus is a large adnexal mass that was removed at the time of cesarean section. Final pathology revealed a Krukenberg tumor.

FIGURE 35B.6 Ultrasound of a complex 7-cm left adnexal mass that was noted during pregnancy. The size of the mass and the ultrasound characteristics of papillary projections were concern for malignancy. Final pathology revealed a mucinous tumor of low malignant potential.

FIGURE 35B.8 The painting by Ribera titled *Magdalena Ventura with Husband and Son* (1631). The most common virilizing tumors of the ovary complicating pregnancy are those with functioning stroma.

THERAPY

The first successful oophorectomy for an ovarian tumor complicating pregnancy was performed in 1846 by Bund. Although the woman survived, the fetus aborted at 12 weeks gestation. At about the same time, J. Marion Sims was the first to successfully remove an ovarian tumor in a pregnant woman and to have both the woman and fetus survive. As late as 1906, McKerran reported a 21 % maternal mortality rate and a 50% fetal mortality rate with surgical management of ovarian tumors in pregnancy. While contemporary surgical management of adnexal masses in pregnancy carries significantly lower risk to both the patient and her fetus, a thorough understanding of potential pitfalls will improve outcomes.

In general, one should avoid elective surgery in the first trimester, because many ovarian lesions represent the cystic corpus luteum of pregnancy and resolve spontaneously. Therefore, ultrasound should be repeated in 6 weeks to determine if the mass is persistent before considering surgical intervention. Buttery and colleagues noted an abortion rate of about 30% in those patients operated on in the first trimester, so first-trimester procedures are high risk. Nevertheless, highly symptomatic masses with suspicion of torsion or masses with solid and cystic conformation or other findings such as ascites, which would correlate with a high suspicion of malignancy, should be operated on immediately ([Fig. 35B.9](#)). Preoperative evaluation should include careful clinical evaluation and pelvic ultrasound examination. Studies relying on ionizing radiation such as barium enema, computed tomography, and other such studies are best avoided. Magnetic resonance imaging has a well-established track record of safety in pregnancy and, with newer imaging techniques, can help in the evaluation of adnexal masses and other abdominal pathologies.

The optimum time for surgical intervention is 16 to 18 weeks. In general, the first trimester should be avoided if possible because of the naturally occurring high rate of spontaneous abortion. Additionally, disruption of the corpus luteum in the first trimester could lead to fetal wastage unless progesterone supplementation is provided. In any case, it is difficult to avoid the conclusion that any pregnancy loss occurring within a short time of surgery is related to the surgery, so that if it is possible to wait until the second trimester, the risk of an unrelated spontaneous abortion is decreased. Patients in whom the asymptomatic mass is noted at or near term may be considered for delivery by cesarean section with careful intraoperative evaluation of the adnexa. Vaginal delivery in this situation has been associated with torsion, rupture, and hemorrhage that can occur during labor or immediately postpartum. The size and ultrasound characteristics of the mass will help to guide the clinician's decision concerning the best route of delivery. Caspi and colleagues described *conservative management* of 63

patients who had dermoid cysts ≤ 6 cm. None of these patients had an increase in size of the dermoid during pregnancy. In this study, 55 patients had normal vaginal deliveries, and none had complications related to the cyst.

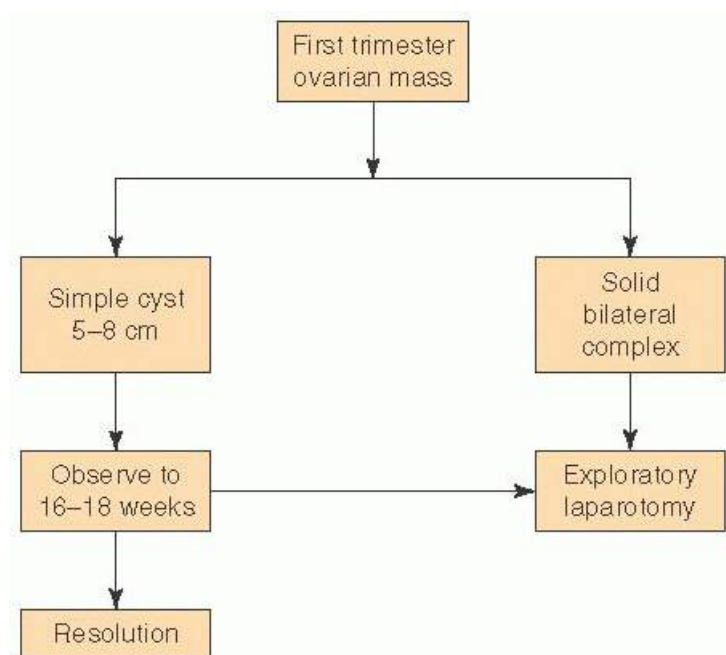

FIGURE 35B.9 Algorithm for the surgical management of ovarian tumors complicating pregnancy in the first trimester. Symptomatic, solid, bilateral, and complex lesions should be operated on when discovered.

General anesthesia is the anesthesia of choice, although a combination of epidural and general anesthesia can be considered. One should remember that delayed gastric emptying and esophageal reflux can occur in pregnancy; therefore, appropriate precautions are necessary. One also should be aware of and prevent compression of the vena cava and aorta by proper patient positioning.

The next consideration is *laparoscopy versus laparotomy* as primary surgical management. Several case series have evaluated the safety and efficacy of laparoscopic management of adnexal masses in pregnancy. These studies have shown that a laparoscopic approach can be employed without increased risk to mother or fetus. Laparoscopy should be considered early in the second trimester if the mass is mobile and accessible and does not have characteristics of malignancy such as ascites or carcinomatosis. Left upper quadrant or open laparoscopic entry should be considered to minimize risk of unintentional uterine or adnexal trauma. If laparotomy is the chosen surgical approach, a vertical incision is preferred due to the flexibility it offers to complete staging, if necessary, and because after 16 weeks gestation the ovary becomes an abdominal rather than pelvic structure. The incision should be placed higher than usual.

P.823

Regardless of surgical approach, thorough evaluation of peritoneal cavity and all contents should be performed, along with pelvic washings. The involved ovary should be sent for frozen section to establish a preliminary diagnosis. The contralateral ovary should be carefully inspected. Biopsy or wedge resection of the contralateral ovary should be avoided if no gross evidence of involvement is present. One possible exception is if the primary tumor is a dysgerminoma, because these tumors can involve the contralateral ovary in a clinically undetectable, microscopic manner. If the frozen section demonstrates a malignant germ cell tumor, an epithelial ovarian cancer, or low malignant potential tumor, staging should be performed to include omentectomy, peritoneal biopsies, and pelvic and aortic lymph node dissection. Malignant ovarian stromal tumors rarely spread to retroperitoneal nodes, and the value of routine lymphadenectomy in these patients is questioned. While it has been argued historically that routine appendectomy should be performed in the case of a mucinous ovarian tumor, recent data suggest

that a visibly normal appendix is extremely unlikely to harbor pathology.

The uterus should be handled gently in any case, and frequent irrigation should be used to prevent the tissue from drying. When ovarian cystectomy is required, simple hemostasis is sufficient, and ovarian closure is unnecessary and may lead to iatrogenic bleeding. If closure is required, an internal closure with use of a 4-0 absorbable is recommended.

Before the decision is made to perform oophorectomy, one must always consciously exclude hyperreactio luteinalis and luteoma of pregnancy. Furthermore, because most malignant ovarian tumors are unilateral, total abdominal hysterectomy and bilateral salpingo-oophorectomy are rarely indicated (**Fig. 35B.10**). Total hysterectomy and removal of ovaries should never be performed on the basis of a frozen section diagnosis of borderline or low-grade malignancy unless the patient has clearly expressed a desire to abort this pregnancy and does not wish to preserve fertility and ovarian function.

When faced with a clearly malignant bilateral or metastatic tumor, one usually treats the patient as if she were nonpregnant, with bilateral salpingo-oophorectomy, pelvic and abdominal washings, omentectomy, and pelvic and aortic node biopsies. Hysterectomy should be performed in a desired pregnancy only when gross involvement of the uterus is appreciated and after appropriate preoperative consultation. Although other tumors are known to metastasize rarely to either the placenta or fetus, primary ovarian tumors almost never do so.

Preoperative discussion with the patient and her family is of paramount importance. All the possible findings at surgery and possible surgical management options should be carefully discussed, and a good understanding of the planned therapy should be agreed on by all. A complete preoperative note about the discussion should be made in the patient's chart. The family should be informed of the findings and plans during

P.824

the course of surgery, and consultation should be obtained if necessary.

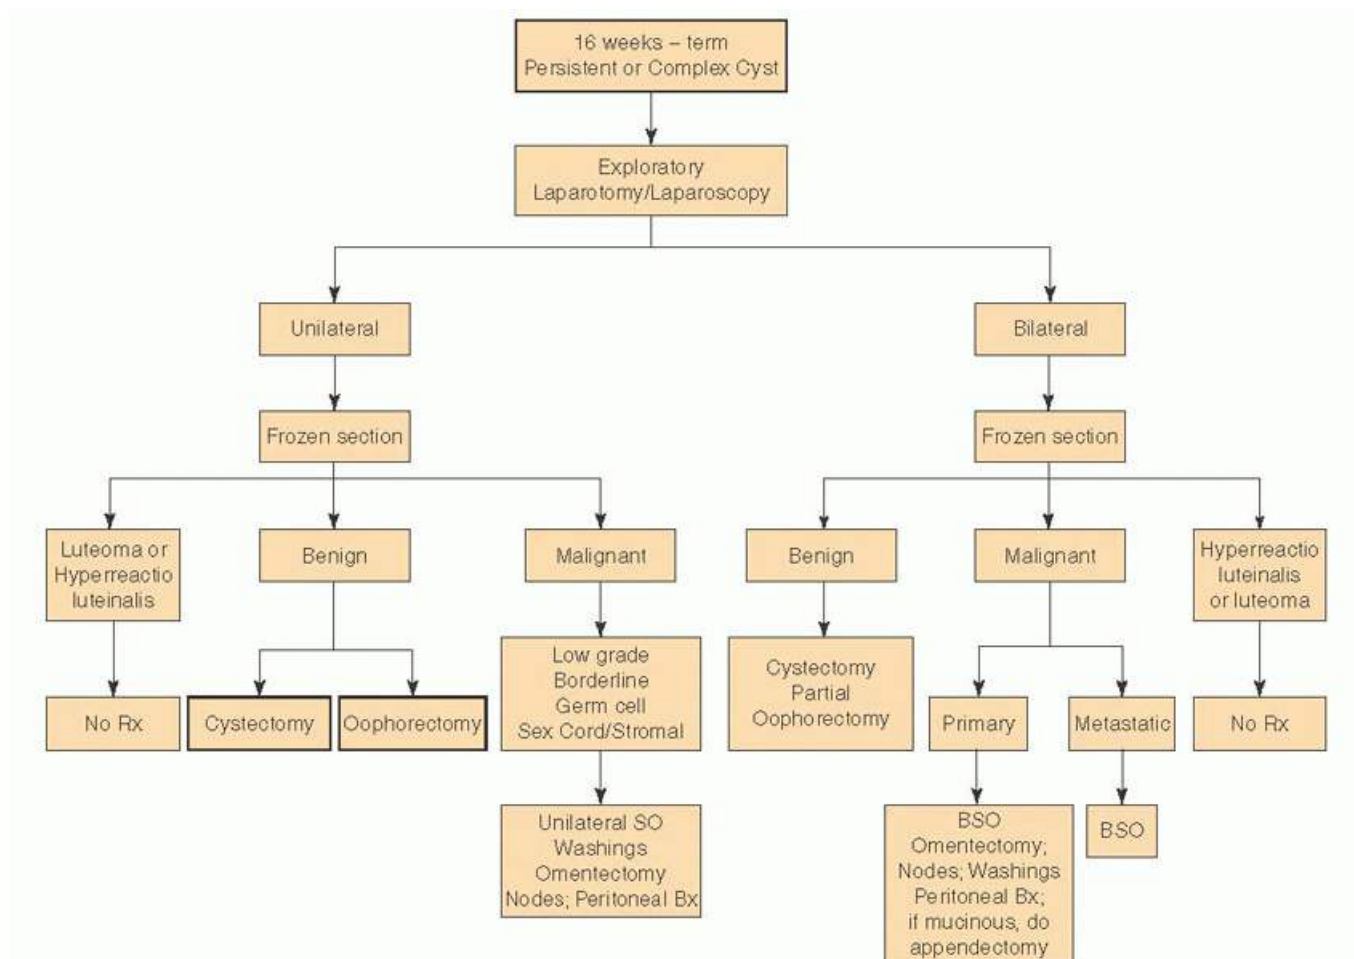

FIGURE 35B.10 Algorithm for the surgical management of ovarian tumors occurring after 16 weeks gestation. (BSO, bilateral salpingo-oophorectomy; SO, salpingo-oophorectomy; TAH, total abdominal hysterectomy; Bx, biopsy; Rx, treatment.)

The role of progesterone to prevent labor in the postoperative period is unclear but should be considered if the surgery occurs in the first trimester and the corpus luteum is disrupted. The patient should have fetal heart tones checked preoperatively, immediately postoperatively, and periodically through the postoperative period. If contractions occur, these can be treated with hydration, indomethacin (if before 32 weeks), or standard tocolytic therapy for symptom relief.

TREATMENT OUTCOME

For benign disease, the patient's surgical outcomes should be excellent. With malignant disease, the overall 5-year survival rate depends on histology, stage, and treatment choices. In a classic paper on ovarian cancer in pregnancy, Novak and associates reported a 5-year survival rate of 75% from the Johns Hopkins Hospital. In a review of 27 dysgerminomas, Karlen and associates reported a tendency toward local recurrence with conservative treatment but an overall 5-year survival rate of 90%. Young and coworkers, in a review of 36 sexcord stromal tumors, noted a 5-year survival rate of 100%, although they cautioned that granulosa cell tumors are prone to late recurrence. However, patients with Krukenberg tumors or metastatic disease have a poor prognosis.

Fetal mortality also should be minimal with early diagnosis and appropriate surgical intervention. Although Karlen and associates reported a fetal mortality rate of 25%, two of the five deaths were secondary to hysterotomy. Young and colleagues reported three fetal deaths in 36 cases, two of which resulted from hysterectomy. Ueda and Ueki reported on 106 surgeries with a spontaneous abortion rate of 10%. Two patients desired termination of pregnancy in the second trimester owing to ovarian diagnosis, and one fetus died despite intensive efforts.

CYTOTOXIC CHEMOTHERAPY DURING PREGNANCY

At no time is the treatment of cancer during pregnancy more complicated than when adjunctive therapy is indicated. Can such therapy be given safely during pregnancy? The relative safety of cytotoxic chemotherapy to a developing fetus depends on many variables, including choice of drug, relative dose intensity and dose density, maternal metabolism, and especially gestational age. Although single-agent or combination chemotherapy may be teratogenic in the first trimester, it is now apparent that cytotoxic chemotherapy can for the most part be used safely in the second and third trimesters.

Antimetabolite therapy, including both aminopterin and methotrexate, seems to pose the greatest risk to a developing fetus and has been reported to be associated with a fairly high rate of congenital abnormalities. The aminopterin syndrome—which consists of cranial dysostosis, hypertelorism, anomalies of the external ear, micrognathia, and cleft palate—has occurred in the fetuses of about 20% of patients treated in the first trimester. In the reported literature, when methotrexate is given in the early first trimester for an erroneous diagnosis of ectopic pregnancy, spontaneous abortion or severe malformations will occur in a majority of cases. The alkylating agent chlorambucil has been associated with congenital abnormalities—namely, renal aplasia, cleft palate, and skeletal anomalies—but only with first-trimester exposure.

If drugs outside the antimetabolite class are administered in the second or third trimester, the safety profile is fairly sound. Cisplatin and carboplatin have a well-established record of use in this setting, with no apparent teratogenicity significantly above the baseline observed. Some hearing loss and transient renal effects have been reported with in utero exposure to cisplatin. Antitumor antibiotics such as bleomycin, doxorubicin, and daunorubicin have shown no adverse fetal outcomes. Vincristine and vinblastine cause malformations in animals, but the effects have not been reported in humans. Paclitaxel is very effective in treatment of epithelial ovarian

malignancies, and there are several reports in the literature of its successful use during pregnancy without significant negative fetal effects. Besides such congenital abnormalities and spontaneous abortions, other concerns with the use of chemotherapy in pregnancy include sterility, low birth weight, pancytopenia, delayed cognitive development, and carcinogenesis. The risk and benefits to the fetus and mother must be considered before beginning therapy. Of course, cytotoxic chemotherapy has other effects, including hematopoietic depression and infection. For this reason, the timing of chemotherapy in relation to anticipated delivery must be assessed carefully so that delivery does not occur when the patient is pancytopenic.

OTHER ISSUES SURROUNDING MALIGNANCY

Symptom control is very important in pregnant patients with malignancy. Symptoms commonly seen in malignancy include pain, nausea, vomiting, anorexia, dyspnea, fatigue, and depression. Oxycodone and hydrocodone with acetaminophen can be used safely for pain. Codeine should be avoided in the first trimester because of possible fetal malformation. Opiates can be used, but with long-term usage or usage in close proximity to delivery, the neonate should be monitored for withdrawal. For nausea, options include ondansetron, chlorpromazine, prochlorperazine, prednisone, and metoclopramide. Morphine and albuterol have been successfully used to control dyspnea in patients with malignancy. Many patients with advanced cancer have depression. Tricyclic antidepressants, bupropion, and selective serotonin reuptake inhibitors with the exception of paroxetine have been used safely in pregnancy; the risks and the benefits should be discussed with these patients before starting them on medications. The use of monoamine oxidase inhibitors is discouraged in pregnant patients.

BEST SURGICAL PRACTICES

- Symptomatic adnexal masses may require surgery at any time during pregnancy. Women with asymptomatic masses may be diagnosed at the time of routine second-trimester ultrasound examination. Color Doppler blood flow characteristic, size, and morphology on ultrasound may be helpful in deciding which masses need surgical management.
- Elective surgery is best avoided in the first trimester. Benign corpus luteum cysts are common and so is spontaneous miscarriage unrelated to the adnexal mass. Many masses detected in the first trimester will resolve spontaneously; therefore, ultrasound should be repeated in 6 weeks to determine if the mass is persistent before considering surgical intervention.
- The best time for surgery is 16 to 18 weeks gestation. General anesthesia is recommended. Laparoscopy may be preferable if laparoscopy would be used for similar findings in a nonpregnant patient. If laparotomy is the chosen surgical approach, a vertical incision is preferred due to the flexibility it offers to complete staging, if necessary, and because after 16 weeks gestation the ovary becomes an abdominal

P.825

rather than pelvic structure. A conservative approach is advised. Most ovarian masses in pregnancy are benign. In the absence of obvious metastatic cancer, if a malignancy is found, unilateral oophorectomy with conservative staging should be performed, and final treatment plans are deferred pending a definitive pathology diagnosis.

- Even if unilateral dysgerminoma or a sex-cord stromal tumor is diagnosed, conservative therapy offers a good prognosis. Delivery may be delayed, and further surgery may be unnecessary.
- If metastatic cancer is diagnosed, a debulking surgery can be performed and pregnancy continued while the patient is started on chemotherapy. Careful consideration of all options should be discussed with a multidisciplinary approach including the gynecologic oncologist, the maternal fetal specialist, the pathologist, the neonatologist, and the patient and her family.

Chapter 36

Pelvic Organ Prolapse: Basic Principles

Carl W. Zimmerman

The judgment as to surgical correction should depend upon a correlation of the history and physical findings. Even marked prolapse in the absence of complaint should rarely be corrected. The patient should ask the gynecologist for relief; the gynecologist should not urge the patient to have corrective surgery if she does not feel sufficiently uncomfortable to request it.

—Richard Te Linde, 1966

DEFINITIONS

Endopelvic fascia—The deep endopelvic connective tissue located between the dependent portion of the pelvic peritoneum and the superior fascia of the pelvic diaphragm. This continuum of tissue serves to support, suspend, and separate the central pelvic organs.

Kegel exercise—Voluntary contraction of the pelvic diaphragm, primarily the puborectalis muscle, and the external anal sphincter.

Interspinous diameter—The distance between the ischial spines. The narrowest diameter in the human pelvis. The components of the deep endopelvic connective tissue suspend the cervix and pericervical ring within this plane in normal anatomy.

Pelvic diaphragm—The skeletal muscles of the pelvic floor and their parietal fasciae. These muscles cover the majority of the pelvic outlet. These muscles originate on the pelvic sidewall and insert on the sacrum, coccyx, or sacrococcygeal raphe.

Rugae—Transverse creases in the vaginal wall that signify the presence of deep endopelvic connective tissue. Conversely, the absence of rugae implies the absence or a disruption of deep endopelvic connective tissue.

Urogenital hiatus—The large central opening in the pelvic diaphragm. The vagina, urethra, and anus exit the pelvis through this area.

Uterosacral ligaments—A named component of the endopelvic fascia. The primary apical suspensory elements of the uterovaginal complex. They extend from the pericervical ring to the presacral periosteum and probably the anterior parietal fascia of the piriformis muscles. These ligaments hold the cervix behind the posterior margin of the urogenital hiatus and over the sacrococcygeal raphe.

Valsalva maneuver—Pressure exerted downward on the pelvic floor by fixing the respiratory diaphragm and the anterior abdominal wall.

BASIC CONCEPTS

Pelvic organ prolapse is the downward displacement of central pelvic organs that are normally located at the level of or adjacent to the vaginal vault. Because these displacements are each associated with defects in integrated connective tissue structures, they may each be considered a pelvic hernia. These conditions are common and affect a progressively larger percentage of women as age advances especially in the

postmenopausal years. Whereas mortality from this condition is negligible, significant morbidity or deterioration of lifestyle may be associated with prolapse. Women in developed countries who have access to modern health care can benefit from the advances that have been made in nonsurgical and surgical treatments for pelvic organ prolapse. If the problem is viewed from a worldwide perspective, however, the scope of suffering is much greater. In areas of high parity and little or no access to health care, countless women suffer from problems associated with pelvic organ prolapse with no real possibility of resolution. The direct effect that these conditions have on urinary, gastrointestinal, and sexual functions can only be appreciated by those women burdened with these problems on a daily basis.

Treatment of pelvic organ prolapse and the associated symptoms constitutes a major subject in gynecology. Especially in the advanced state, management of these conditions is one of the most challenging problems a pelvic surgeon can face. Indeed, success in treating prolapse is frequently used to judge the overall skill of those surgeons. Providing permanent relief from this classic malady by restoring normal anatomy and maximum physiologic function always tests the ingenuity of gynecologists. As medical sophistication has progressed, so has the ability to understand more completely and better treat pelvic organ prolapse.

A brief review of the history of treatment of prolapse is helpful in understanding modern treatments and current concepts of these conditions. Because it was mentioned in the writings of Hippocrates and Galen, prolapse was clearly known to the ancients. Early treatments may seem quaint by today's standards. Yet some of these interventions continue to be used today. Fortunately, others have not survived. Vaginal packing, tampons, massages, and exercises were used with some success. Other patients were suspended from their feet for a period of 24 hours to treat prolapse. Rodericus A. Castro advised that prolapse should be attacked with a red hot iron as if to burn it, "when fright would cause it to recede into the vagina." Various caustics were used, including silver nitrate, nitric acid, acid nitrate of mercury, hot metal, and sulfuric acid.

Perhaps, the first real advance in treatment was the development of pessaries. These devices functioned as trusses. Their fitting and placement became a desirable skill. They continue to bring relief to a large number of women and seldom do any serious harm. They were especially popular in the middle of the 19th century. Some were held in place by waistbands. In some cases, pessaries were deliberately left in place until erosions of the vaginal epithelium occurred. The subsequent healing

P.828

was expected to reduce the caliber of the vagina with scarification adding to support, but serious complications could occur. Reports exist of neglected pessaries being retrieved from the peritoneal cavity and bladder. Fistulae may also occur in various locations, especially the bladder and anorectum.

The earliest surgical attempts to relieve prolapse were relatively simple. These procedures included labial suturing and removing portions of the vaginal epithelium to reduce the caliber of the vagina. Although Heming operated on the anterior vaginal wall in 1831, surgery for uterovaginal prolapse was not common until the advent of anesthesia and antisepsis later in the 19th century. The first vaginal hysterectomy for prolapse was performed by Samuel Choppin of New Orleans in 1861. Many years passed before this surgical technique became common. By the beginning of the 20th century, European and American reports of hysterectomy, colporrhaphy, cervical amputation, transposition/interposition operations (Manchester-Fothergill), cervical ligament plications, colpocleisis (Le Fort), ventral fixation of the uterus to the abdominal wall, and trachelorrhaphy for procidentia were being published. The timing of this ingenious variety of operations is certainly consistent with the development of anesthesia and various surgical techniques in all fields of medicine.

During the 20th century, advances in understanding and treatment of prolapse have progressed at an ever-increasing rate. In 1909, George R. White of Georgia published an account of cystocele repair using a transvaginal paravaginal approach. His correct perspective on the importance of lateral vaginal support took

nearly 50 years to be rediscovered by mainstream gynecologic surgeons. The paravaginal repair was not widely known and accepted at the time because it was overshadowed by the work of Howard A. Kelly of Johns Hopkins. This great and influential surgeon popularized the concept of fascial attenuation. Midline anterior and posterior plications were touted as the correct surgical approach to the problem of prolapse. The Kelly-Kennedy anterior plication and levator ani plication of the posterior vaginal wall remain as commonly performed procedures today, despite the fact that more contemporary surgical techniques described in this chapter more effectively correct the anatomic defects of pelvic prolapse and achieve better clinical results with fewer long-term side effects.

In the 1950s, Milton L. McCall of Louisiana developed a culdoplasty technique that emphasized the important suspensory function of the uterosacral ligaments. He believed this operation prevented enteroceles and posthysterectomy vaginal vault prolapse when it was performed at the time of hysterectomy. Currently, the restitution of vaginal vault support at the time of any type of hysterectomy is considered a very important step in prevention of future prolapse.

In the 1960s, Baden and Walker of Texas began to systemize a new defect-specific approach to pelvic organ prolapse repair. Page 1 of their 1992 book, *Surgical Repair of Vaginal Defects*, stated: "In a sense, the defect approach reverses the prior evolution toward 'compensatory' reparative techniques—our goal is to return all vaginal supports to their original anatomic status." Many other surgeons have contributed to this powerful concept of pelvic reconstructive surgery. A. Cullen Richardson and associates of Georgia developed the concept of classifying fascial defects as proximal, distal, central, and lateral. This observation and the teaching of such master surgeons as David H. Nichols of New England encouraged gynecologists to not only identify and repair each vaginal defect but to return support attachments to their original anatomic location. Emphasis was focused on the hernial nature of prolapse and led to the abandonment of absorbable suture in favor of permanent suture in critical locations in these repairs. In the 1990s, pelvic anatomist, John O.L. DeLancey of Michigan, published a biomechanical analysis of normal vaginal anatomy. His observations have the precision of an engineer's work and identify specific structural goals for each of three vaginal levels of support. Proximal (apical) vaginal suspension, midvaginal lateral attachment, and distal vaginal fusion to the perineum and urogenital diaphragm are the basic concepts that modern pelvic surgeons must satisfy to successfully complete a prolapse surgery.

In the 1980s, hernia repair literature began to demonstrate better long-term results with the use of bolsters. For that reason, autografts, allografts, xenografts, and various synthetic meshes achieved frequent use in surgical techniques for prolapse in the first decade of the 2000s. Because of an increasing number of reported problems and lack of strong data to support their use, the Food and Drug Administration has issued two statements urging caution in the use of these bolsters, especially polypropylene meshes. Considerable debate exists regarding the indications for their use (if at all) and the type, amount, and best location for pelvic support grafts.

A fusion of anatomic, physiologic, and biomechanical principles has allowed surgeons to offer their patients better treatments for prolapse than have historically been available. This brief and incomplete historical discussion outlines the evolution of our current understanding of a complex topic. Historically ineffective treatments of the presurgical era gave way to surgical approaches for advanced cases. As surgical sophistication has increased, anatomically distorting operations have gradually been replaced by anatomically restoring procedures. Many interesting aspects of the historical development of this subject are described in previous editions of this book and in the bibliographic selections at the end of this section.

A better understanding of a problem always leads to more questions that deserve answers. For example, the process of childbirth is regarded as an important cause of vaginal prolapse. Little or no effort has been made to analyze the forces of childbirth as they relate to specific patterns of damage to the deep endopelvic connective tissue. Delineation of these patterns would assist the surgeon in recognizing defects and undoubtedly improving operative outcome. Precise knowledge of the effects of labor and delivery on the pelvic floor would likely lead to new surgical techniques and create the potential for better obstetrical decisions designed to reduce the

potentially damaging effects of childbirth. The concept of prolapse prevention is underused in the practice of gynecology. Teaching patients about physical therapy of the pelvic floor, better lifestyle, and proper evacuation habits should be part of the gynecologist's job. The long-term benefits of an organized program of prolapse prevention have never been evaluated.

Controversy exists as to the best surgical management for specific cases of female pelvic organ prolapse. In fact, now that reparative options are no longer limited to midline plications, more procedures are available than ever before. Vaginal, abdominal, laparoscopic, robotic, minimally invasive devices, and combined approaches each have their advocates. The necessary randomized trials with matched controls will likely never be done to generate true evidence-based outcomes, especially because two of the most powerful variables are surgical skill and experience. The necessary long-term follow-up is rarely available in the pelvic surgery literature. New concepts and techniques appear before the older ones can properly be compared in studies. Surgical techniques for prolapse must be carefully evaluated so that anatomic and functional results will continue to improve.

The authors of the following chapters of this section describe interventions and operations that gynecologic surgeons should consider when managing pelvic organ prolapse. Each of these surgeons possesses a combination of operative skill, experience,

P.829

and special interest in their topics that have led to their selection. The operative techniques presented should be combined with appropriate clinical evaluation and skillful technical performance to obtain maximum benefit for the patients.

ANATOMIC CONSIDERATIONS

The normal position, support, and suspension of the uterus, vagina, bladder, and rectum rely on an interdependent system of bony, muscular, and connective tissue elements. This entire system is three dimensional, and even subtle alterations in one part may lead to stresses in other parts that eventually lead to alteration or failure of normal anatomy. An understanding of normal applied pelvic anatomy is imperative in the repair of pelvic organ prolapse.

The bony pelvis has a central opening that is necessary for reproductive function. During evolutionary transition to upright bipedal posture, the potential for prolapse became more likely because of gravitational stress. In the human female, a lordosis of the lumbosacral portion of the spine places the pelvic inlet in an oblique orientation reminiscent of the pelvic posture of a quadruped. The physical result of this shift is that the posterior aspect of the pelvic inlet is approximately 60 degrees above the anterior aspect with the promontory of the sacrum placed in a vertical plane above the pubic symphysis (**Fig. 36.1**). This partially vertical orientation of the pelvic inlet deflects force onto the superior symphysis pubis rather than directly on the pelvic outlet and urogenital hiatus. Consequently, the pelvic outlet is partially shielded from downward stresses in the anatomically normal woman.

FIGURE 36.1 The relationship between the pelvic floor and the abdominal cavity. Notice the lordosis of the lumbosacral spine and the almost vertical orientation of the pelvic inlet. (The original illustration is in the Max Brödel Archives in the Department of Art as Applied to Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD. Used with permission.)

FIGURE 36.2 The pelvic diaphragm viewed from below.

The muscles of the pelvic diaphragm primarily provide pelvic support. These muscles form a basin or covering of the pelvic outlet and are often grouped together as the levator ani or levator sling (**Fig. 36.2**). Within this diaphragm is the urogenital hiatus, an opening large enough to allow childbirth. This large central opening in the muscular pelvic floor explains why prolapse is such a significant problem in humans. The most medial portion of the pelvic diaphragm is formed by the puborectalis muscle, the muscular boundary of the urogenital hiatus. The obstetric axis of the pelvis passes through the urogenital hiatus medial to the puborectalis muscle. In the standing patient, the puborectalis muscle is horizontal and is palpable as a 2- to 2.5-cm band of voluntary muscle on each lateral side of the distal one third of the vagina. When well innervated and contracted, the puborectalis muscle closes the distal vagina and displaces the posterior wall of the rectum anteriorly creating the anorectal angle. Forming the bulk of the pelvic diaphragm, the

P.830

pubococcygeus and iliococcygeus muscles cover the posterior and lateral portions of the pelvic outlet (**Fig. 36.3**). The superior insertion of the iliococcygeus muscles is an important landmark in pelvic support anatomy. These insertions are thickenings of the pelvic sidewall parietal fascia of the obturator internus muscle that extend from the ischial spines posteriorly to points on the pubic bone known as the pubic tubercles. These lines of insertion are known as the arcus tendineus levator ani or muscular arches (**Figs. 36.4 and 36.5**). Immediately inferior to the muscular arches are thickenings of the parietal fascia of the bellies of the iliococcygeus muscles known as the arcus tendineus fasciae pelvis (fascial arches) or white lines. These structures are the lateral attachment points for the pubocervical septum and apical rectovaginal septum. The white line serves the function of midvaginal lateral support. Paravaginal and apical pararectal defects are located immediately medial to the white line. In the standing patient, the white line is nearly horizontal; in the standard lithotomy position, it is nearly vertical.

FIGURE 36.3 Muscles of the pelvic floor, lateral view.

FIGURE 36.4 The pelvic diaphragm viewed from above.

During paravaginal repair, the white lines are palpable as stringlike structures that extend between the ischial

spines and the pubic arch. Another fascial thickening has been described that runs posteriorly from the white line to the structures of the lateral perineal body and serves as lateral support for the distal rectovaginal septum of the posterior vagina. This structure

P.831

has been named the arcus tendineus fasciae rectovaginalis (**Fig. 36.6**). The lateral supports of the anterior and posterior vaginal septa merge and are not separate in the apical half of the vagina. Superior to the muscular arch is the uppermost portion of the obturator internus muscle and the parietal obturator fascia. The obturator internus muscles qualify as pelvic muscles because they form the lateral borders of the upper portion of the pelvic basin. Posterior to the iliococcygeus, the pelvic floor is covered by the coccygeus muscle and the closely associated sacrospinous ligament (**Fig. 36.5**). These structures pass between the ischial spine and the terminal sacrum and coccyx. The most posterior portion of the pelvis is bounded by the piriformis muscle. The midline confluence of the levator muscles forms a particularly strong band of connective tissue between the coccyx and the posterior anus known as the levator plate or sacrococcygeal raphe. This plate is oriented horizontally in the standing patient. The vagina and the rectum are suspended by the endopelvic fascia (primarily the uterosacral ligaments) directly over the levator plate. Myopathies or neuropathies cause weakness of the pubococcygeus and iliococcygeus muscles and may allow the levator plate to sag and descend permanently. This descent causes the genital hiatus to remain open as it does during defecation. This increased opening changes the normal horizontal axis of the apical vagina to a more vertical orientation and predisposes the central pelvic organs to prolapse.

FIGURE 36.5 Sagittal view of the pelvis.

FIGURE 36.6 The lateral attachments of the pubocervical fascia (PCF) and the rectovaginal fascia (RVF) to the pelvic sidewall. Also shown are the arcus tendineus fascia pelvis (ATFP), arcus tendineus fasciae rectovaginalis (ATFRV), and ischial spine (IS).

The pudendal nerve is an important motor and sensory nerve of the pelvic floor and perineum. It descends through the pelvic diaphragm between the coccygeus and piriformis muscles in the area posterior to the ischial spine into Alcock canal. Alcock canal is located in the ischiorectal fossa immediately adjacent to the fascia of the obturator internus muscle on the lateral wall of this space. Because of its location, the pudendal nerve is subjected to significant stretch and pressure particularly in the area adjacent to the ischial spines during the descent of a fetus through the pelvis. The muscles of the pelvic diaphragm are also subjected to great pressure and stretch during labor. Magnetic resonance imaging studies have demonstrated atrophy and breaks in the levator muscles of parous women. Neuropathy of the pudendal nerve and myopathy of the levator muscles are believed to be significant contributing factors in the development of pelvic organ prolapse.

P.832

Unfortunately, at this time, no treatments are available for myopathies and neuropathies of this type. For that reason, surgical treatment of pelvic organ prolapse is limited largely to manipulation of the deep endopelvic connective tissues.

The connective tissues of the pelvis are collectively known as the endopelvic fascia. This fibroelastic connective tissue matrix contains varying amounts of smooth muscle. It supports and invests all the midline organs and structures of the pelvis. Only the ovaries and fallopian tubes lie outside this investment. At various locations, the endopelvic fascia manifests different characteristics. These forms include loose areolar tissue capable of distention; neurovascular sheaths; septa and ligaments that support, suspend, and separate the pelvic organs; and dense skeletal muscle investments. In the central pelvis, the visceral peritoneum drapes over the midline structures, dipping into recesses but not descending into direct contact with the muscular pelvic floor. The irregular space between the pelvic diaphragm, the muscular pelvic sidewall, and the visceral peritoneum is the location of the endopelvic fascia. The endopelvic fascia may be divided into three parts: parietal fasciae, visceral fasciae, and deep endopelvic connective tissue.

The parietal fasciae of the endopelvic fascia are relatively dense membranes investing the pelvic surface of the skeletal muscles of the pelvic sidewall ([Table 36.1](#)). They are similar in structure, form, and function to other

parietal fasciae of the body, for example, the rectus abdominis fasciae. At muscular margins, they blend with the various periosteal of the bony pelvis.

The visceral pelvic fasciae are loose, highly elastic, and relatively ill-defined encasements of the central pelvic organs, taking the form of sheaths and sleeves (Table 36.2). These structures allow for the high degree of physiologic distention necessitated by the intestinal, urinary, and reproductive functions of the pelvic organs. The visceral fasciae blend intimately with the organs that they encase, are not easily separable from those organs, and are not useful for support and suspension purposes in surgery.

The deep endopelvic connective tissue is of central importance in the clinically applied anatomy of the pelvis and is especially significant to the pelvic reconstructive surgeon. This structure is part of a continuum of retroperitoneal connective tissue that extends from the respiratory diaphragm in the upper abdomen to the pelvic diaphragm. Included in this continuum of structures are the mesenteries and ligaments of the upper abdomen. Anatomists debate whether the condensations of this connective tissue should be considered as true ligaments and fasciae or septa. Part of this debate stems from the fact that some of these structures contain a significant muscular component and others serve as neurovascular conduits. Certainly, from a functional standpoint in the pelvis, they meet criteria for being so named. The endopelvic connective tissue is continuous from one part to the other. Separate portions serve different functions, take various forms, and therefore are given different names. The named structures of the deep endopelvic connective tissue include six ligaments, two septa, and one ring. Important anatomic details of these elements are summarized in the following tables.

TABLE 36.1 Parietal Pelvic Fasciae

Obturator fascia

Particularly well defined in the area superior to the arcus tendineus levator ani and below the linea terminalis. This fascia may represent a vestigial portion of the levator ani whose origin has been lowered through evolution to the level of the muscular arch.

Levator ani fascia (Superior fascia of the pelvic diaphragm)

This fascia is continuous across the pelvic floor, blending laterally with the obturator fascia at the arcus tendineus levator ani and centrally with the levator plate and the visceral fasciae at the urogenital hiatus.

Coccygeus fascia (Sacrospinous ligament)

This important pelvic support structure extends from the ischial spine laterally to the sacrum medially and is an important alternative source of proximal support when the uterosacral ligament is unavailable or insufficient.

Piriformis fascia

This fascia is the thinnest and most posterior of the parietal fasciae of the pelvis.

Ovaries

TABLE 36.3 Components of the Deep Endopelvic Connective Tissue: Uterosacral Ligaments

Origin

Periosteum of sacral vertebrae 2, 3, and 4

Insertion

The points of insertion are on the posterior and lateral supravaginal cervix at the 5-o'clock and 7-o'clock positions. The ligaments are continuous with and form part of the pericervical ring.

Neurologic content

Uterosacral plexus of autonomic nerves

Vascular content

Minimal

Muscular content

Rectouterine muscle

Function

These structures are the primary proximal suspensory elements of the uterovaginal complex. They hold

the cervix behind the urogenital hiatus in the posterior pelvis at the level of the ischial spines with the uterus in ante flexion and the vagina suspended over the levator plate.

Synonym

Rectal pillar

At their insertion into the pericervical ring, the uterosacral ligaments blend as continuous structures superiorly and laterally with the cardinal ligaments and distally with the proximal rectovaginal septum.

The six pericervical ligaments form the paracolpium ([Tables 36.3](#), [36.4](#), and [36.5](#)). The net effect of these structures is the suspension of the cervix in the posterior pelvis and the consequent placement of the vagina directly over the levator plate and away from direct exposure to the urogenital hiatus. In the normal anatomic position, pressure from above tends to close

P.833

the apical vaginal vault by compressing it against the sacrococcygeal raphe with no tendency toward prolapse. This compression of the vagina is a flap valve type of mechanism and is aided by the anchoring of the cervix by the uterosacral ligaments.

TABLE 36.4 Components of the Deep Endopelvic Connective Tissue: Cardinal Ligaments

Origin

The hypogastric root with fibrous connections to the lateral abdominal and pelvic walls

Insertion

The points of insertion are on the lateral supravaginal cervix at the 3-o'clock and 9-o'clock positions. This insertion is continuous with and forms part of the pericervical ring.

Neurologic content

Portions of the uterosacral plexus

Vascular content

Uterine artery and veins

Muscular content

Minimal smooth muscle content with no named component

Urinary

The distal ureter passes under the uterine artery within the superior portion of the cardinal ligament.

Function

These ligaments are the primary vascular conduits of the uterus and vagina, providing lateral stabilization to the cervix at the level of the ischial spines. They are similar in structure, content, and function to the mesenteries of the abdomen.

Synonyms

Mackenrodt ligament, lateral cervical ligament, and proper cervical ligament

TABLE 36.5 Components of the Deep Endopelvic Connective Tissue: Pubocervical Ligaments

Origin

Inferior surface of the superior pubic ramus medially and the arcus tendineus fascia pelvis laterally

Insertion

The points of insertion are on the anterior and lateral supravaginal cervix at the 11-o'clock and 1-o'clock positions. This insertion is continuous with and forms part of the pericervical ring.

Vascular component

Artery and veins of the bladder pillar

Function

These ligaments are the least well developed of the pericervical ligaments, serving as a vascular conduit and for a minimal degree of cervical stabilization.

Synonym

Bladder pillar

TABLE 36.6 Components of the Deep Endopelvic Connective Tissue: Pubocervical Septum or Fascia

Shape

Trapezoidal with the narrow end located distally

Contents

Fibroelastic connective tissue and smooth muscle

Function

Anterior vaginal support, including support of the bladder

Synonyms

Vesicovaginal septum or fascia, pubovesicocervical septum or fascia

Boundaries

Distal: Pubic tubercles laterally and the pubic arch centrally fusing with the urogenital diaphragm

Lateral: Arcus tendineus fascia pelvis or white line

Proximal: Pericervical ring centrally and both pubocervical and cardinal ligaments laterally

Superior: Visceral fascia of the bladder

Inferior: Epithelium of the vagina

TABLE 36.7 Components of the Deep Endopelvic Connective Tissue: Rectovaginal Septum or Fascia

Shape

Trapezoidal with the narrow end located distally

Contents

Fibroelastic connective tissue and smooth muscle

Function

Posterior vaginal support and suspension, stabilization of the rectum, and perineal suspension. The vaginal suspensory axis consists of the perineum, rectovaginal septum, pericervical ring, uterosacral ligaments, and presacral periosteum. The rectovaginal septum also guides the leading edge of a descending bowel movement into the anus.

Synonym

Denonvilliers fascia

Boundaries

Distal: Fusion with the proximal perineal body at the central tendon of the perineum

Lateral: In the distal half of the vagina, the lateral boundary is the arcus tendineus fasciae rectovaginalis; in the proximal half of the vagina, the lateral boundary is the arcus tendineus fascia pelvis.

Proximal: Uterosacral ligaments laterally and the pericervical ring centrally

Superior: Epithelium of the vagina

Inferior: Visceral fascia of the rectum

Two septa or fasciae ([Tables 36.6](#) and [36.7](#)) are located within the deep endopelvic connective tissue. These condensations of fibroelastic connective tissue are in close contact with the vaginal epithelium and visceral fasciae of the adjacent organs. Clinically, they are separate from their adjacent structures. When the septa and their supports are intact, the vaginal and rectal axes have a posterior angle of approximately 130 degrees at the anterior point of their suspension over the levator plate due to the action of the puborectalis muscle. Distal to the puborectalis muscle, the vagina is nearly vertical as it

P.834

passes through the urogenital hiatus. The apical or proximal two thirds of the vagina is nearly horizontal and is suspended over the levator plate. The normal vaginal axis is oriented posteriorly toward a point just above the center of the fourth sacral vertebra. This area of the anterior sacrum corresponds to the exact area of the origin of the uterosacral ligaments.

TABLE 36.8 Components of the Deep Endopelvic Connective Tissue: Pericervical Ring

Shape

Collar of connective tissue encircling the supravaginal cervix

Contents

Fibroelastic connective tissue

Function

Cervical stabilization within the interspinous diameter by connecting with all other named components of the deep endopelvic connective tissue

Synonym

Supravaginal septum

Connections

Anterior: The pericervical ring is located between the base of the bladder and the anterior cervix, where it connects with the pubocervical ligaments at the 11-o'clock and 1-o'clock positions and the proximal pubocervical septum centrally.

Lateral: Cardinal ligaments at the 3-o'clock and 9-o'clock positions

Posterior: The pericervical ring is located between the rectum and the posterior cervix, where it connects with the uterosacral ligaments at the 5-o'clock and 7-o'clock positions and the proximal rectovaginal septum centrally.

The pericervical ring ([Table 36.8](#)) is the single location where all deep endopelvic connective tissue support structures converge. *Simply stated, the goal of the defect-specific pelvic reconstructive surgeon is the restitution of the anatomical connections of the pericervical ring within the interspinous diameter.* If the dissection and reconstructive efforts during such a surgery do not extend apically to the interspinous diameter, the surgery is likely to fail because that diameter is the normal location of the pericervical ring. Because the cervix is located on the apical anterior vaginal wall, the pubocervical septum is shorter than the rectovaginal septum by a length equal to the diameter of the pericervical ring. If one carries this line of reasoning further, an inherent structural problem is present in the posthysterectomy prolapse patient. If the cervix and its surrounding support tissues are absent, no completely anatomic method to reconstruct the proximal anterior vaginal support exists. Some form of anatomic distortion (e.g., shortening of the vagina or plication) or bolstering is necessary to compensate for this defect. Likely, this dilemma is the reason that the most frequently encountered support defect in the posthysterectomy patient is most frequently in the apical anterior location.

The three-dimensional structure of the endopelvic fascia has another distinguishing anatomic characteristic that is of interest to the pelvic surgeon. Outside the confines of the named condensations of this tissue are avascular potential spaces (**Table 36.9**). When properly used, these spaces give the surgeon access to important support structures deep within the pelvis. Gynecologic oncologists base their surgical training around mastering the surgical manipulation of these spaces, usually from the abdominal approach. These spaces are not only available to the vaginal reconstructive surgeon, but they are also critical in identification of pelvic support landmarks.

FIGURE 36.7 Three-dimensional view of the endopelvic fascia. Notice the location of the cervix in the proximal anterior vaginal segment. (Adapted from DeLancey JO. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717, with permission. Copyright © 1992, Elsevier.)

DeLancey's biomechanical analysis of normal uterovaginal support by the deep endopelvic connective tissue helps to unify the anatomic principles pertinent to pelvic organ prolapse (**Fig. 36.7**). These concepts of support and suspension also help to define a set of goals for the reconstructive

P.835

surgeon. Each goal must be satisfied for the long-term success of a prolapse surgery. DeLancey divided vaginal support into three levels (**Fig. 36.8**). *Proximal or apical vaginal level I support is attributed to suspension by the ligaments of the paracolpium primarily the uterosacral ligaments.* Damage to level I support results in uterovaginal prolapse, posthysterectomy vaginal prolapse, and enterocele. The cause for level I support problems is necessarily at or above the level of the ischial spines. The primary load-bearing elements are the uterosacral ligaments and, to a lesser extent, the cardinal ligaments. This fact is consistent with cadaver observations made many years ago by Mengert showing that prolapse occurred only after 85% of the integrity of the paracolpium was severed. *Midvaginal level II support is due to lateral attachment of the fascial septa to the pelvic sidewalls.* The septa attach to the arcus tendineus fascia pelvis and the arcus tendineus fasciae rectovaginalis. Damage at this level results in paravaginal and pararectal defects. *Distal Level III support is attributed to fusion of the deep endopelvic connective tissue septa to the urogenital diaphragm anteriorly and to the proximal perineum posteriorly.* Damage at these sites can result in urinary incontinence anteriorly and in perineal body deficits and defecatory dysfunction posteriorly. Historically, cystocele and rectocele were believed to be central defects within the fabric of the pubocervical and rectovaginal septa. These defects are now

believed to be due to displacements of the respective endopelvic septa originating at the margins of those structures, not centrally.

FIGURE 36.8 The endopelvic fascia of a posthysterectomy patient divided into DeLancey's biomechanical levels: level I, proximal suspension; level II, lateral attachment; level III, distal fusion. (Adapted from DeLancey JO. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717, with permission. Copyright © 1992, Elsevier.)

FIGURE 36.9 Suspensory axis of the uterovaginal complex.

Another useful concept is the suspensory axis of the uterovaginal complex. This concept is consistent with DeLancey's various levels, but views the connective tissue structures as a continuum. The posterior suspensory axis includes the structures between the perineum and presacral periosteum. From inferior to superior, these elements are the perineal body, rectovaginal septum, posterior pericervical ring, uterosacral ligaments, and presacral periosteum. The posterior axis is the primary load-bearing structure of the uterovaginal complex. The anterior axis extends from the urogenital diaphragm, through the pubocervical septum, cervix, and pericervical ring merging with the posterior suspensory axis at the level of the ischial spines. Disruption of this continuum occurs due to childbirth at the level of the interspinous diameter during the process of childbirth ([Fig. 36.9](#)).

P.836

ETIOLOGY AND PREVENTION

In the vast majority of women who will develop pelvic organ prolapse, the process begins with their first *vaginal delivery*. Each subsequent vaginal delivery contributes to the likelihood that a clinically symptomatic prolapse will occur at some point in her lifetime. The normal process of labor and vaginal delivery are certainly desired, necessary, and important physiologic events. Nonetheless, childbirth does have a traumatic aspect by contributing to the development of pelvic organ prolapse. Commonly, many years pass, and other factors contribute to the progression of prolapse before such patients present for evaluation.

During labor, the fetal presenting part (about 95% are vertex) must overcome a significant amount of soft tissue resistance presented by the lower uterine segment and cervix, the endopelvic fascia, and the muscular pelvic floor. Because of the lordosis of the lumbosacral spine, the obstetric axis of the pelvis is noticeably angled, differing by 90 degrees between the inlet and outlet. This right angle occurs at the level of the ischial spines and causes the baby's head to extend sharply beginning at the level of the interspinous diameter in order to rotate under the pubic arch while following the anterior concavity of the sacrum. Thus, the fetus is driven by strong uterine contractions through a low-velocity, high-pressure, arcing transit through the pelvis. Labor aided by maternal pushing and, at times, by physician traction has a damaging effect on the intricately constructed support structures of the pelvis. Fortunately, the majority of women who deliver are capable of overcoming the stresses on their internal pelvic structures and never experience prolapse.

In the initial phase of a nulliparous labor, the fetal head engages, flexes, and descends to a point immediately apical to the interspinous diameter. Clinical examination at this stage commonly finds the cervix held in a far posterior position as a result of the strength and suspensory function of the uterosacral ligaments. In this situation, great pressure is placed on the anterior vaginal segment. The most common fetal presentation, the left occipitoanterior position, places the rotating arc of the fetal head in the maternal right hemipelvis. As the fetal head overcomes the resistance of the pubocervical septum, significant downward pressure is placed on the maternal right pelvic sidewall. This event likely explains the preponderance of full-length right paravaginal paravesical defects and apical transverse separation of the pubocervical septum as the most common fascial defects in anterior vaginal relaxation. As further fetal descent occurs, the cervix rotates anteriorly, representing uterosacral ligament damage apical to the interspinous diameter. The fetus then usually rotates into the occipitoanterior position as it encounters the interspinous diameter. This diameter is the narrowest in the female human pelvis and therefore is the plane of greatest pressure during labor and delivery. The fetal head then flexes to allow passage under the pubic symphysis. The anterior sacrococcygeal curvature is concave. As the fetus passes under the pubic arch, this concavity makes it necessary for the fetal head to extend to complete labor. This change in orientation places intense pressure on the posterior pericervical ring. The result is further uterosacral stress and a transverse apical detachment of the rectovaginal septum at its junction with the pericervical ring and uterosacral ligaments. As extension of the head progresses, displacement of the rectovaginal septum toward the perineum results in the creation of a nidus for apical vaginal enterocele and midvaginal rectocele formation. If the rectovaginal septum is displaced far enough distally, pararectal defects

form as the septum is sheared away from its lateral attachments. The process of rectovaginal detachment and displacement also weakens the apical support for the perineal body and predisposes to perineal descent. Note that rectocele, enterocele, and perineal descent are all explained by the disruption of the posterior suspensory axis at the level of the interspinous diameter. Subsequent deliveries progressively contribute damage to the endopelvic fascia. During complete dilation of the uterine cervix, descent and extension, the fetus passes through the urogenital hiatus. During this process, pressure is transmitted to the levator muscles and the pudendal nerve. If a patient dilates completely, pushes in an attempt to deliver, and then receives a cesarean section, she may have much of the same fascial damage as a woman with a successful vaginal delivery. A nulliparous patient with prolapse would likely suffer from isolated failure of the paracolpium, with the pericervical ring and fascial septa remaining intact.

A major shortcoming of the profession is that the effect of labor and delivery on the female pelvis has not been more completely objectified. Only recently has the study of pudendal neuropathy and levator myopathy been brought under scientific scrutiny. Even less has been done to determine the most common overall patterns of fascial and ligament damage during parturition. The pattern described in the previous paragraph is simply the most common one encountered. Other fetal presentations would result in different patterns of damage. Any experienced prolapse surgeon recognizes the variations in pattern of herniation, leading to the adage that no two patients are exactly alike. However, knowledge of the common pattern does help the surgeon who is new to the defect-specific approach know where to look to identify fascial edges and visually discriminate between the various tissues in the dissection field.

Fortunately, most women who bear children will not suffer a significant symptomatic degree of prolapse. Parturition then is a necessary cause but not a sufficient cause for the vast majority of prolapse cases. Other factors work over time and in combination with the damage caused by childbirth to convert incipient prolapse into a clinically apparent problem.

Prolapse becomes more common with *advancing age*. The likely cause is general weakening of tissues, including the pelvic floor muscles. Passage of time increases the cumulative effect of contributing causes on the pelvic floor. Most cases of prolapse become evident after the age of menopause. Virtually all the tissues of the pelvis possess estrogen receptors, and the *atrophic changes* that occur in the absence of estrogen are a contributing cause for prolapse. With age and a prolonged hypoestrogenic state, osteoporosis may develop. The kyphotic changes in the spine that result from osteoporosis displace the pelvic inlet into a more horizontal plane. This change in the pelvic inlet allows the weight of the abdominal contents to act more directly on the pelvic floor and on the urogenital hiatus.

Lifestyle may contribute to prolapse. Lifting objects heavy enough to require a Valsalva maneuver or fixation of the respiratory diaphragm displaces stress directly down on the pelvic floor. This process may be aided by shoulder, back, and extremity weakness. Defecation and micturition are commonly assisted with straining. This straining occurs when the pelvic diaphragm is intentionally relaxed. This action places substantial force on a passive pelvic floor and open urogenital hiatus several times a day. Straining has essentially the same effect as heavy lifting. Obesity, which is epidemic in the United States, directly increases the load on the pelvic floor and decreases mobility as well as the ability to do muscle strengthening exercises.

Medical conditions and their complications may contribute to the development of prolapse. A few examples suffice to illustrate how a *chronic medical condition* or the treatments for medical problems may affect the pelvic floor. The natural

history of diabetes mellitus includes neuropathy and obesity, both of which contribute to the tendency to prolapse. Chronic cough accompanying asthma, bronchitis, or smoking places repeated stresses on the pelvic floor. The effects of repeated or paroxysmal coughing help to convert incipient prolapse into a clinical problem.

Smoking also has antiestrogenic properties, contributes to vascular disease, and creates a chronic hypoxic state. Corticosteroid therapy is used in many chronic medical conditions. The weakening effect of these medications on connective tissue is well known. People with constitutional connective tissue disorders have been shown to be at increased risk for prolapse. Ehlers-Danlos syndrome, for example, is characterized by generalized fascial and connective tissue weaknesses. The pelvic floor is also affected by these deficits. More subtle connective tissue weakness, such as joint hypermobility, has been suspected to increase the long-term risk for prolapse. Development of ascites may cause a rapid increase in the degree of prolapse. This list is by no means complete. Any condition that affects the physical load on the pelvic floor or the integrity of the muscular and connective tissues of the pelvis will increase the likelihood that symptomatic prolapse will develop.

Some medical conditions may reduce the tendency to develop prolapse. This is the case for any condition that causes an inflammatory reaction in the paracervical or parametrial tissues with subsequent tissue fibrosis. Pelvic inflammatory disease, puerperal or postabortal sepsis, endometriosis, and pelvic radiation therapy are conditions that could lead to such a circumstance. Pelvic adhesions, regardless of the cause, might be dense and numerous enough to secondarily suspend a prolapse. Large uterine leiomyomata or other pelvic masses can mechanically prevent the development and descent of prolapse.

The list of contributing causes to pelvic organ prolapse is varied. *Prevention* should begin early in a woman's life and be continued into the later years. Many of the measures discussed as preventions also have a positive effect on a woman's general health. Any discussion of pelvic organ prolapse prevention must include the obstetric management of childbirth. Vaginal delivery undoubtedly has a primary and profound effect on pelvic support anatomy. Debates have occurred for decades about the wisdom of operative vaginal deliveries, optimal length for the second stage of labor, management of macrosomia, usefulness of episiotomy, and multiple other obstetric practices. In truth, little evidence-based information exists regarding these concepts as they relate to the subsequent development of prolapse. The most likely major contributing factor is simply vaginal delivery. The pelvis is contoured so that even in a normal labor and delivery, substantial forces are applied to the endopelvic fascia, muscular floor of the pelvis, and pudendal nerve. The greatest forces generated are at the level of the interspinous diameter. This plane is the location of the singularly important pericervical ring and its junction with every other septa and ligament associated with normal vaginal support and suspension. For example, an episiotomy may shorten the second stage of labor but is unlikely to have any effect on the stresses generated in the interspinous diameter. Does prophylactic cesarean section represent the ultimate in prolapse prevention? This tactic certainly has attained popularity in some parts of the world. One might argue that if vaginal delivery is a necessary cause for prolapse, then this strategy would be preventative. This topic has generated an active and emerging debate in obstetrics and gynecology. Evidence-based resolutions to these questions are unlikely to ever be available. In my opinion, prophylactic cesarean section will never be widely applied. Replacing a desired physiologic process with a major surgery is illogical when the consequence to be prevented is relatively uncommon and not life threatening. However, occasional patients may present convincing arguments in favor of prophylactic cesarean section. The individual practitioner and patient must resolve the course of action in the privacy of the consultation room.

In the adult parous woman, strategies to prevent the development of prolapse center on efforts that decrease physical stress on the urogenital hiatus and strengthen the pelvic floor. Physical therapists have known for years that protection of the lower back is improved by strengthening the shoulder girdle, quadriceps muscles, and abdominal muscles, as well as the muscles of the low back. These same concepts are valid for protection of the pelvic floor. A program of exercise that develops strength in all these muscle groups allows women to accomplish the activities they desire without straining or using the assistance of a Valsalva maneuver. Care must be taken to respect the urogenital hiatus so that during such training, undue stress is not repeatedly placed on the pelvic floor. Likewise, in daily activity, the proper techniques to lift, push, and pull objects should be learned and

practiced. The control of obesity must be considered part of the effort to reduce the load placed on the pelvic floor. Osteoporotic spinal changes cause a gradual kyphosis, replacing the normal lumbosacral lordosis. The net effect is to rotate the pelvic brim into a more horizontal position. This shift places more stress on the pelvic floor. Estrogen therapy not only helps to prevent osteoporosis but also has positive effects on the various estrogen-sensitive tissues of the pelvis. Hormone replacement therapy is complicated, controversial, and beyond the scope of this discussion. Other effective treatments for osteoporosis exist.

Pelvic floor strengthening by voluntary contraction of the muscles innervated by the pudendal nerve was popularized by Arnold Kegel. The associated exercises have been known by his name ever since. Many women know this term because it is used frequently in postpartum instructions. Several different strategies help to remind patients to do their Kegel exercises. One of the most effective techniques is briefly outlined below. The Kegel contraction should be confirmed during a pelvic examination to ensure that the patient understands the correct muscles to contract. Frequently, patients will either perform a Valsalva maneuver or tighten the gluteus maximus muscle instead of the external anal sphincter and levator ani muscles. The proper time to Kegel is after micturition. After the bladder is emptied, the patient is instructed to lean as far forward as her stability allows. While leaning forward, she performs three or more isometric Kegel exercises by tightening the muscles until they voluntarily relax on their own. The dependent portion of a cystocele is below the level of the internal urethral orifice. The forward tilt physically elevates the bladder floor and allows for more complete emptying. The muscular action of the Kegel contractions also aids the process of emptying. Coupling this activity with voiding habituates the patient to perform the exercises several times a day. The result is the combination of more complete emptying and a strengthened pelvic floor, both of which are advantageous for the patient. The patient may then be able to use the Kegel contraction during physical stress to prevent incontinence or to protect against the pelvic floor impact of sudden increases in abdominal pressure. If the patient knows how to use Kegel muscles that are strong and easily controlled, they become an asset in her daily life.

Splinting is particularly effective in alleviating the dysfunctional defecation related to symptomatic rectoceles. If a significant rectocele/enterocele herniation is present, patients frequently experience entrapment of the leading edge of the descending bowel movement in the resulting anterior rectal pocket. Entrapment leads to straining, which further enhances

P.838

the entrapment. Often, patients in this circumstance will strain until the bowel movement fragments and allows partial defecation and descent of another segment of stool into the rectal pocket. Several trips to the toilet and a large segment of the day may be required to complete this process. This unfortunate problem may be avoided if the patient simply places upward pressure with her fingertips against the perineum or the area lateral to the perineum during the initial urge to defecate. Occasionally, the patient needs to place one or two fingers against the posterior vaginal wall. These maneuvers effectively reduce the rectocele pocket, allowing the stool to evacuate while bypassing the rectocele. This “digital defecation” or splinting technique may avoid surgery and certainly empowers the patient to be in better control of her daily activities. I encourage the use of this technique postoperatively to protect the suspended posterior vaginal segment against undue strain. This protective maneuver is particularly important while acute healing is under way.

Control of chronic diseases and habits are helpful preventative strategies. Effective treatment of persistent cough may decrease incontinence and prevent progression of prolapse. Cessation of smoking certainly may be considered part of the preventative effort. Diabetic complications such as obesity, myopathy, and neuropathy may be prevented by modern management strategies.

The prevention of pelvic organ prolapse involves care of the entire body. A healthy, fit, and well-nourished patient who is aware of ways to actively protect her pelvic floor is less likely to experience this potentially disabling problem. Many of the strategies outlined in this section should be part of the care of patients from their

obstetric years onward. Prevention is always preferable to intervention in the operating room.

CLINICAL EVALUATION

The correct management of pelvic organ prolapse depends on a careful evaluation of each patient. Only after a thorough history and physical examination is the practitioner able to develop an effective treatment plan for the individual patient.

The *history* should begin with the patient's perception of the problem. This information helps to determine what specific goals the patient may have. The patient might be afraid that the prolapse could rupture or that it may be caused by a malignant growth. Reassurance may suffice if any of these are her major concern. Patients may or may not be interested in coital function, further childbearing, or simply knowing that the vagina is present if social circumstances change. Some women have grown accustomed to advanced prolapse and may describe very little inconvenience related to the herniation. These people may simply want to know if the prolapse represents any threat to their longevity. Other women are very conscious of an anatomically minor prolapse or may have pain unrelated to the prolapse. The patient may have unrealistic expectations or may be ready for intervention before the physician's operative criteria are met. In this situation, the pelvic reconstructive surgeon needs to be honest and forthright in discussing what will or will not improve after a surgery. A careful micturition, defecation, and sexual history may be invaluable in developing a treatment plan. Validated evaluation forms are available for each of these aspects of function. Patients must be placed at ease and reassured during the evaluation before a full history concerning the details of pelvic functions can be obtained. Stress, urge, and neurogenic urinary incontinence may be differentiated by history. Obviously, the evaluations and treatments differ for each of these conditions. The complex topic of urinary incontinence is covered in detail elsewhere in this book. The mechanics involved in defecation are important. Determine the number of trips to the toilet and the compensatory measures necessary to complete evacuation. Fecal incontinence is a condition that patients are notoriously reluctant to discuss. This condition may or may not be due to physical damage to the anal continence control mechanism. The patient may be continent or incontinent of gas, liquid, or solids. Each patient may safely be presumed to desire urinary and bowel continence. Marked variation exists in patients' sexual goals. The practitioner should learn about these goals in a respectful and nonjudgmental way. Collecting sexual function information is an art, critical to the development of a management plan.

The past surgical history helps the surgeon assess the status of the patient in general and of the pelvis in particular. Specific interest should be placed on previous attempts to correct pelvic organ prolapse. Before her visit, the patient may be asked to prepare a list of previous surgeries so that none are overlooked. The route of hysterectomy and the indications for the procedure may be helpful. If previous prolapse surgery has been performed, the physician should try to obtain the operative notes. The anatomic details, type of suture used, and other details of the operative technique may help predict problems such as the likely location of anatomic distortion (previous plications) or the location of previously placed foreign bodies (e.g., meshes). Multiple previous attempts at repair necessitate a combination of caution and experience to achieve a successful outcome.

The medical history should be used to determine whether medical conditions exist that would likely interact with surgery or recovery. A complete pelvic reconstructive surgery may last several hours, involve significant blood loss, and even require combined vaginal and abdominal or endoscopic approaches. Obviously, the patient needs the physical reserve to withstand this degree of stress. Patients with morbid obesity, limited pulmonary and cardiac function, thromboembolic risks, entrenched tobacco addiction, or limited mobility are not ideal candidates for this type of surgery. A complete list of current medications, including herbals and over-the-counter preparations, and treating physicians is also helpful.

The proper *physical examination* of the prolapse patient requires that the examining physician have a working

knowledge of normal pelvic anatomy. Older systems for recording physical findings related to prolapse relied on subjective terms such as *mild*, *moderate*, and *severe*. These terms have a limited ability to accurately describe prolapse and restrict effective communication between examiners. Two systems are currently in use that encourage a complete prolapse examination and that more objectively record anatomic detail. Each of these systems has strengths and weaknesses. The Baden-Walker Halfway System is user friendly, is easy to record, and maximizes the amount of detail that can be recorded in a very brief space. Proponents of this system maintain that the essence of the prolapse examination is recorded after writing six numbers and some editorial notes. Critics note that the abbreviation of detail means that some compromises are made along the way. The second system is the Pelvic Organ Prolapse-Quantification or POP-Q system. This is a more complex system incorporating more specific detail of the physical findings. Even for those clinicians accustomed to its use, the number of measurements needed requires additional time to acquire. The beauty of this system is that, theoretically, physician-to-physician variation is minimized. The POP-Q is currently used in many academic papers on the subject of prolapse. Interested physicians should become familiar with both of these systems. More important than any system is an accurate and anatomically based assessment of the patient at the time of examination.

TABLE 36.10 Primary and Secondary Symptoms at Each Site Used in the Baden-Walker Halfway System

ANATOMIC SITE	PRIMARY SYMPTOMS	SECONDARY SYMPTOMS
Urethral	Urinary incontinence	Falling out
Vesical	Voiding difficulties	Falling out
Uterine	Falling out	Heaviness and so forth
Cul-de-sac	Pelvic pressure (standing)	Falling out
Rectal	True bowel pocket	Falling out
Perineal	Anal incontinence	Too loose (gas/feces)

Reprinted from Baden WF, Walker T. *Surgical repair of vaginal defects*. Philadelphia, PA: JB Lippincott, 1992:12, with permission. Copyright © 1992 Wolters Kluwer Health.

Baden-Walker Halfway System

The extent of prolapse is recorded using a number (0 to 4) at each of six defined sites in the vagina. There are two sites on the anterior, superior, and posterior walls of the vagina. [Table 36.10](#) lists the anatomic sites and the associated symptoms. The six numbers are recorded as a measure of descent. For all sites except the perineum, the hymen is used as a fixed anatomic reference point. Zero indicates normal anatomic position for a site, whereas 4 represents maximum prolapse. Between these extremes, the intervening numbers grade descent using a halfway system. The examination is performed with the patient straining so that maximum descent is

attained. The patient may wish to stand or use other maneuvers in order to demonstrate maximum descent.

The perineum is graded with the familiar perineal laceration system used in obstetrics. The patient is asked to hold or Kegel to evaluate the amount of muscular and fascial compensatory support. Editorial comments may include the site of dominant prolapse, location of scars, palpable plications from previous surgery, and the type of efforts necessary to demonstrate maximum prolapse. Strength of the levator contraction may be recorded as 0 to 4.

Example: 12/44/32. A dominant complete apical prolapse is noted with enterocele, significant cystocele and rectocele, and perineal attenuation to the level of the external anal sphincter. 2/4 levator strength is present.

Although this type of notation encodes much information in a small space, no specific location of fascial defects is indicated.

Pelvic Organ Prolapse-Quantification (POP-Q) System

This system was developed as an effort to introduce more objectivity into the quantification of pelvic organ prolapse. For example, measurements in centimeters are used instead of subjective grades. Nine specific measurements are recorded as indicated in **Figure 36.10**. Point Aa is defined as being 3 cm proximal or apical to the external urethral meatus on the anterior vaginal wall. Point Ap is defined as being 3 cm proximal to the hymen on the posterior vaginal wall. Points Ba and Bp are defined as points of maximum prolapse excursion on the anterior and posterior vaginal walls, respectively. Measurements are recorded as negative numbers when proximal or apical to the hymen and positive numbers when distal to the hymen. POP-Q sites C (cervix or hysterectomy scar) and D (cul-de-sac of Douglas) are identical in location to Baden-Walker sites 3 and 4 in the apical vagina. In addition, measurements of the total vaginal length, genital hiatus, and perineal body are taken. All measurements are recorded on a tic-tac-toe style grid (**Fig. 36.11**). When combined with sagittal line drawings, a fairly complete picture of prolapse is attained (**Fig. 36.12**). Ordinal stages of pelvic organ prolapse are then assigned from stage 0 (no prolapse) to stage IV (complete prolapse) so that the outcome of cases of like magnitude may be compared.

FIGURE 36.10 The nine specific sites of measurement used in the Pelvic Organ Prolapse-Quantification (POP-Q) system. (gh, genital hiatus; pb, perineal body; tvl, total vaginal length.) (Adapted from Bump RC, Mattiasson A, Bø K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:10, with permission. Copyright © 1996, Elsevier.)

This system is a physical examination tool and does not assign the specific location of fascial defects.

Pelvic Examination

After a general physical examination is performed, the prolapse may be evaluated. Any surgical scars on the abdomen should be correlated with the surgical history. Patients frequently forget procedures that may have an impact on the treatment plan. The physician should pay particular attention to the suprapubic region where previous incontinence procedure incisions may be located.

The pelvic examination is initiated with the patient in the lithotomy position. Hip mobility should be evaluated because adequate abduction and flexion of the thighs is required for a vaginal procedure. Thigh and buttock obesity may also be limiting factors related to surgical access. If exposure is limited, an extended procedure performed vaginally is not in the patient's or surgeon's best interest.

The labia are opened for introital inspection. Prolapse may be internal or incomplete (proximal to the hymen) or external, that is, complete (distal to the hymen), at rest. The extent of the prolapse may change considerably if the patient is asked to

P.840

strain or stand. This difference may be especially pronounced in patients with healthy pelvic floor muscles and an undescended levator plate. These two structures may help hold a prolapse in place. The patient may give a history of a prolapse that is not apparent on examination or not as large as she describes. In such a case, the patient is examined while she is in the standing position; or she may be asked to perform the maneuvers necessary to demonstrate the full extent of the prolapse.

The dominant prolapse is considered to be the first hernia to descend or the most dependent part of a prolapse that has previously descended. Proper identification of the dominant prolapse provides key clues about where the most significant fascial damage is located. The dominant prolapse is located and replaced to examine the remainder of the vaginal vault. A large dominant prolapse often fills the urogenital hiatus and introitus, preventing incipient hernias from fully developing. Usually, an anterior prolapse is easily replaced by placing a tongue blade or Ayre spatula in each anterior lateral sulcus. If an apical transverse or lateral paravaginal defect is present, this maneuver replaces the anterior vaginal wall. If this maneuver does not reduce the hernia, a central anterior defect is likely present. A dominant posterior segment prolapse may be replaced with the posterior blade of a disjoined Sims speculum. A dominant superior segment prolapse may be replaced with a large cotton swab or a sponge stick or, in advanced cases, by attaching a tenaculum to the cervix. After replacement of the dominant prolapse, the secondary sites of prolapse become more apparent. An isolated single-site prolapse is not the norm. The location of the cervix or hysterectomy scar helps determine the location of the dominant prolapse. Frequently displaced, either anteriorly or posteriorly, these sites are often not at the most dependent part of the prolapse. The posthysterectomy scar is commonly a transverse fibrous band that may be slightly retracted. To either side of the band are dimples in the epithelium corresponding to the location of the insertion of cardinal and uterosacral ligament remnants. Incomplete prolapse evaluation may lead to incomplete repair and result in recurrent prolapse in a different location and multiple trips to the operating room. The support structures of all vaginal segments and levels are interdependent. Complete restoration of all defects is necessary for a successful outcome.

Careful inspection of the vaginal epithelium reveals the location of rugae. The presence of these transverse folds implies that endopelvic fascia is adherent to the epithelium in that location. The lateral vaginal sulci are the location of the junction of the pubocervical and rectovaginal septa to their respective lateral arcuate attachments. The pattern of rugae and the condition of the sulci should correlate with the pattern of fascial breaks found at

surgery. The vaginal epithelium should also be inspected for atrophy created by the absence of the effects of estrogen. Local or systemic administration of estrogen before surgery assists in dissection and subsequent healing. Occasionally, an external prolapse may develop pressure ulcers as a result of entrapment when the patient is sitting. These lesions must be properly evaluated to rule out malignancy.

Rectovaginal examination assists in the evaluation of the posterior and superior vaginal segments. The uterosacral

P.841

ligaments may be palpable immediately medial to each ischial spine, especially if the uterus is present. The uterosacral ligaments are usually more easily palpated with traction placed on the cervix. Anterior displacement of the rectal examining finger toward the vagina helps to distinguish between rectocele and enterocele. During the rectal examination, the patient is asked to strain. If an enterocele is present, it bulges down in the nonrugated vaginal epithelium proximal to the tip of the examining finger. Palpating the transversely detached proximal edge of the rectovaginal septum is possible during this maneuver. This sharp border may retract distally all the way to the perineum. Perineal descent is also evaluated at the time of rectal examination. The levator plate is immediately posterior to the rectum and should be horizontal and immovable. The perineum is evaluated last. The perineum is triangular in the sagittal plane. The base is on the rectal side and the apex at the hymen. Perineal attenuation is very common in parous women. Apposition of the thumb of the examining hand while the index finger is in the rectum proximal to the anterior aspect of the external anal sphincter allows for evaluation of the integrity of this muscle. Voluntary contraction of the sphincter may be helpful. The S3 neurologic segment is necessary to contract this muscle and controls the ability to spread and dorsiflex the toes. If the patient cannot perform these tasks, the integrity of that neural segment is in question. The mechanical strength of the pelvic diaphragm is directly correlated with the ability to voluntarily contract these muscles. This ability is best tested clinically with light pressure placed on the posterior vaginal wall by the examining digits. The patient may need coaching to elicit a response. This time is an excellent opportunity to instruct the patient in the importance of postvoiding Kegel exercises and perineal support (splinting) during defecation.

If muscle activity is elicited, it may be subjectively graded from 0 to 4. If no muscle activity is detected, a more formal neurologic and medical workup should be considered. Pudendal nerve motor latency studies may reveal significant neuropathies. Magnetic resonance imaging of these patients has revealed the presence of advanced muscle atrophy and muscular detachments as well. Neuropathy and myopathy erode the surgeon's ability to correct prolapse. If the patient cannot properly move her toes and cannot contract the levator muscles, a spinal cord or central nervous system lesion must be considered.

The presence of urinary incontinence should be noted during any part of the evaluation of prolapse. In an advanced prolapse, assessment of incontinence should be conducted with the prolapse in a reduced state. A pessary or loose vaginal packing may be helpful in accomplishing this goal. Incontinence may be masked by a hypotonic bladder or reverse kinking of the urethra if a cystocele is large. Repair of a large prolapse may be followed by the appearance of urinary incontinence if the preoperative evaluation is not performed with the prolapse reduced.

When a large prolapse is present, the trigone of the bladder is often located outside the vaginal introitus. In this degree of displacement, one may deduce the location of the trigone as being directly adjacent to the location of a Foley catheter bulb. The course of the ureter in a large prolapse arcs from the superior and lateral aspect of the anterior prolapse to the area of the trigone. The ureter may often be palpated in this location. If the prolapse is chronic and advanced, hydroureter and even hydronephrosis may be present. In this circumstance, the ureters lose their cordlike consistency and are more difficult to palpate or recognize at the time of surgery. A large external prolapse makes the ureter more susceptible to surgical injury. Intraoperative placement of ureteral catheters may be helpful in such a patient. Postoperative documentation of ureteral patency is required.

FIGURE 36.13 Key elements of pelvic support anatomy. Three dimensions are reduced to two by dividing the vagina at the 3-o'clock and 9-o'clock positions. Baden-Walker vaginal support profile sites: 1, urethral; 2, vesical; 3, uterine; 4, cul-de-sac; 5, rectal; 6, perineal. (PT, pubic tubercle; ATFP, arcus tendineus fascia pelvis; ATFRV, arcus tendineus fasciae rectovaginalis; IS, ischial spines; U, urethra; Cx, cervix; A, anus.)

A patient may present with the cervix near the level of the hymen. If no other signs of prolapse are present, the alert examiner is aware of the possibility of an elongated cervix. Sometimes, surgery is not necessary in these patients. If surgery is performed, the technique of hysterectomy needs to take into consideration the elongation of the cervix. Often, the paracolpium is properly placed in the interspinous diameter in these patients.

The examiner should not underestimate the value of an examination under anesthesia prior to the initiation of a planned surgical procedure to supplement information that has been gathered preoperatively. With the patient and her pelvic diaphragm relaxed, the full extent of prolapse may become more apparent. Deep structures of importance, such as the ischial spines and uterosacral ligaments, may be more easily palpated. An examination under anesthesia should be performed before initiating a prolapse surgery.

A number of ways may be used to summarize the array of clinical findings discussed in this section. My preference is to use a pelvic organ prolapse map (Figs. 36.13 and 36.14). Key anatomic landmarks are schematically outlined. The three-dimensional structure of the vagina is reduced to two dimensions as if the vagina were divided at the 3-o'clock and 9-o'clock positions. A Baden-Walker profile can be recorded vertically on the map with numbers placed beside the appropriate anatomic location. As seen in Figure 36.15, fascial defects can be sketched on the map at their suspected or known location. Editorial notes regarding the prolapse can be recorded in the space provided. A POP-Q evaluation may be used as well. The pattern that is noted in Figure 36.15 is the one most commonly seen in pelvic organ prolapse surgery; however, many

variations on this theme are encountered (Fig. 36.16). Another diagram may be drawn to indicate the exact locations of fascial defects at the time of surgery.

FIGURE 36.14 Key elements of posthysterectomy pelvic support anatomy. Three dimensions are reduced to two by dividing the vagina at the 3-o'clock and 9-o'clock positions. Baden-Walker vaginal support profile sites: 1, urethral; 2, vesical; 3, uterine; 4, cul-de-sac; 5, rectal; 6, perineal. (PT, pubic tubercle; ATFP, arcus tendineus fascia pelvis; ATFRV, arcus tendineus fasciae rectovaginalis; IS, ischial spines; U, urethra; HS, hysterectomy scar; A, anus.)

FIGURE 36.15 The most frequently encountered pattern of fascial damage in pelvic organ prolapse: (a) full-length right paravaginal defect; (b) transverse proximal detachment of the pubocervical septum; (c) transverse proximal detachment of the rectovaginal septum. This pattern of damage is consistent with the mechanics of a left occipitoanterior delivery. Baden-Walker vaginal support profile sites: 1, urethral; 2, vesical; 3, uterine; 4, cul-de-sac; 5, rectal; 6, perineal. (PT, pubic tubercle; ATFP, arcus tendineus fascia pelvis; ATFRV, arcus tendineus fasciae rectovaginalis; IS, ischial spines; U, urethra; Cx, cervix; A, anus.)

FIGURE 36.16 An infrequently encountered inverted “V” anterior central fascial defect. Posteriorly, the proximal detachment of the rectovaginal septum has retracted toward the perineum, creating an enterocele and rectocele. Notice the bilateral pararectal defects. Baden-Walker vaginal support profile sites: 1, urethral; 2, vesical; 3, uterine; 4, cul-de-sac; 5, rectal; 6, perineal. (PT, pubic tubercle; ATFP, arcus tendineus fascia pelvis; ATFRV, arcus tendineus fasciae rectovaginalis; IS, ischial spines; U, urethra; HS, hysterectomy scar; A, anus.)

A thorough history and physical examination improves the treatment of the prolapse patient. The physical findings must be recorded in an anatomically accurate and understandable way.

CHOICE OF TREATMENT

Vaginal reconstructive surgery is concerned with the return of abnormal organ relationships to a usual or normal state. There is no one site or degree of damage that must be repaired or restored; there are many and they occur in various combinations at various times of life, from different etiologic factors, in varying degrees, and with varying degrees of symptoms and disability.

—Nichols and Randall, 1989

Patients with pelvic organ prolapse have highly individualized perceptions of their situation. The single most

important concept in the treatment of these conditions is to understand the patient's symptoms, concerns, and limitations related to the prolapse. Her quality of life should be of paramount concern in the decision-making process. The patient's expectations and her ability to tolerate surgery should be expertly evaluated. The physician's job is to educate the patient regarding options of treatment. After informed consent is given, the appropriate course of action is usually obvious to both the doctor and the patient. If the chosen course of action fails or becomes inappropriate over the course of time, the clinical evaluation and decision process can be revisited.

P.843

Nonsurgical Management

Regardless of the degree of prolapse, no surgery should be done unless the patient experiences a sufficient degree of morbidity. Most symptoms relate to quality-of-life issues. Generally, preventative measures should be the most widely applied techniques. Pelvic floor exercises, weight loss, treatment of chronic diseases, physical therapy, cessation of smoking, and estrogen therapy are all considerations in the conservative treatment of pelvic organ prolapse. These interventions have been discussed in the previous section of this chapter and should be used regardless of whether expectant management or surgical intervention is the plan. During expectant management, periodic examinations should be done to determine the status of pelvic organ support and the degree of progression. Symptoms and the ability to participate in daily activities may be reviewed to reinforce the patient's motivation to continue preventative measures.

Pessaries are ingenious devices that have been used in one form or another for much of recorded history. They were originally the product of an age when surgery was not an option for the prolapse patient. They are available in a variety of shapes and sizes, depending on the needs of the patient. In general, the greater the degree of prolapse and the more strenuous the daily activities of the patient, the less likely it is for a pessary to be a permanent solution. As the prolapse expands, occupies the urogenital hiatus, and dilates the introitus, the pressure of the prolapse tends to expel the pessary. A pessary may be valuable for a patient to wear to feel more comfortable during a specific activity, such as exercise. If a patient of limited activity and acute-onset advanced prolapse can be successfully fitted with a pessary, it may prevent progression and result in longterm improvement in intestinal and urinary function. Pessaries are discussed in detail in [Chapter 40](#).

Surgical Principles and Management

The management of advanced and symptomatic prolapse is primarily surgical. In 1997, 226,000 women underwent pelvic organ prolapse surgery in the United States. This condition is one of the most common indications for major surgery. Eleven percent of all women will experience some type of prolapse surgery during their lifetimes, and 30% of these women will undergo another operation for recurrence of prolapse or a complication related to surgery. Prolapse is a high-incidence problem that commands a substantial expenditure of health care dollars. Only those patients who request relief should be considered surgical candidates. Once the decision is made to operate, quality-of-life goals need to be established. If the patient can tolerate a lengthy operation and especially if she desires coital function, a reconstructive operation should be considered. The restoration of normal anatomy (form) maximizes the potential that symptoms and limitations (function) will be corrected or significantly improved. Restoration of normal anatomy automatically addresses the questions of vaginal axis, caliber, and depth. If the patient does not desire coital function, an occlusive procedure, such as colpocleisis, might be the best choice. Colpocleisis, with or without vaginectomy, has a very low failure rate; however, the end does not justify the means in all patients because these operations render the patient permanently acoital.

Choosing the correct operation for prolapse is critical for success. The general plan for the procedures that will best correct the problems of the individual patient may be developed from details gathered during the

preoperative history and pelvic examination and even the examination under anesthesia. Specific details become evident only during the intraoperative dissection. The goals of the operation are the restoration of normal form and function. Isolated areas of prolapse are uncommon. Childbirth places damaging pressure on all segments of suspension and support during the various phases of labor and delivery. Restricting an operative procedure to the repair of a single dominant or symptomatic site of prolapse may simply transfer the physical stress to a different vaginal segment. An incomplete reconstruction may result in a secondary prolapse descending as a new dominant prolapse. Sometimes, prolapse can return quickly postoperatively. Perhaps, the best known example of this phenomenon was the observation by Burch that many patients developed an enterocele after his anterior urethropexy procedure. An active search for potential and undeveloped defects must be done at the time of prolapse surgery. Site-specific repair of all segments and levels is the best insurance against failure.

The route of operation is a matter of debate. Vaginal surgery is the historical hallmark of the gynecologic surgeon. Although surgical training in vaginal techniques has eroded in recent years, a resurgence of interest in these operations is occurring. The vaginal approach requires either limited or no access to the peritoneal cavity and is surgically less stressful on the patient.

During the last three decades, a significant change has occurred in the way prolapse surgery is conceptualized and performed. Anatomically distorting distal plications have been replaced by defect-specific anatomic restorations. Several aspects of the defect-specific method favor the vaginal approach. Fascial defects can be best identified when the full extent of the vaginal segment to be repaired is dissected and exposed. Such dissections are only possible vaginally. The detached fascial edge of a paravaginal defect may retract across the midline to the contralateral side of the body. This retraction leaves the fascial edge in a position that is impossible to reach from the abdominal or endoscopic approach. No one questions that a paravaginal defect can be seen from the abdominal or endoscopic operative approach. A question does remain about whether the retracted fascial edge can be accessed and reattached to the white line using the abdominal or endoscopic approach. Likewise, a proximal rectovaginal septal defect that has retracted distally to the perineum would be very difficult to find and resuspend from above. All the major support anatomic landmarks and tissues are accessible vaginally. These points include the arcus tendineus fascia pelvis, arcus tendineus fasciae rectovaginalis, ischial spines, uterosacral ligaments, sacrospinous ligaments, and virtually all components of the deep endopelvic connective tissue. During childbirth, the named components of the endopelvic fascia are displaced away from the interspinous diameter. Reconstructive efforts must be centered in this diameter for a permanently successful outcome. Access to torn fascial edges is best attained by complete dissections of the vesicovaginal and rectovaginal spaces. Midvaginal lateral defects can easily be repaired by this route. Additionally, apical suspension can also be performed to complete the restoration of central pelvic organ suspension. For most primary reconstructions, the vaginal operative route is superior to any other approach. The vaginal route is also preferred for patients with failures from previous operations. This approach is especially useful when a previous operation did not use the defect-specific approach and did not include the use of permanent suture for critical support sites.

The discussion and opinions in the previous paragraphs do not preclude the use of abdominal and endoscopic techniques for certain problems in pelvic reconstructive surgery. Procedures to correct stress urinary incontinence are discussed extensively in [Chapter 41](#). Anterior urethropexy approached through the prevesical space with a suprapubic incision or endoscopic technique has some advantages when compared with a suburethral sling urethropexy. No iatrogenic paravaginal defect is necessary during anterior urethropexy, for example. Such defects are made with pubovaginal sling

procedures of all types. Some intentionally created defects are larger than others. To spend time and effort to reconstruct the pubocervical fascia anatomically from white line to white line and then to destroy part of the

paravaginal support intentionally to allow passage of the sling material into the prevesical space does not make good sense. The primary prevesical space approach avoids this destructive necessity. Kelly-Kennedy plications and paravaginal repairs have been shown to be ineffective as incontinence procedures. New minimally invasive sling operations represent an effective totally vaginal operation to cure stress incontinence. Vaginal incontinence operations that avoid iatrogenic paravaginal damage and an abdominal or laparoscopic incision are ideal.

The abdominal approach is useful in some cases of prolapse in which one or more previous pelvic support operations have failed. Abdominal sacral colpopexy is an option in this situation. This operation also has its proponents as a primary procedure. Outcome data have generally been good with low recurrence rates. Colpopexy may be useful in a circumstance in which considerable scar is present from previous surgery. For example, consider a patient with a previous aggressive distal plication and a proximal support failure. Significant adhesiolysis would be necessary to gain access to the proximal structures necessary to repair the prolapse. A rescue abdominal sacral colpopexy may more easily and effectively correct the prolapse. Occasional patients whose support has failed following a sitespecific operation with permanent suture may also benefit from this operation. Abdominal sacral colpopexy is not a sitespecific operation; however, it provides substantial proximal apical support and protects vaginal length. Sacral colpopexy may be accomplished laparoscopically with or without robotic assistance in a less invasive manner, but should be considered equivalent only if the technique is not substantially altered.

During a prolapse surgery, the surgeon may determine that adequate support or repair is not attainable through the primary approach. No harm is done in using a combined approach. If support is not satisfactory after a vaginal procedure, an abdominal sacral colpopexy can be done at that time. Conversely, a vaginal examination should be performed after an abdominal sacral colpopexy to determine if the vaginal axis, caliber, and depth have been restored to an acceptable state. The patient with proper informed consent would likely prefer a combined procedure to subsequent surgery.

Suture selection for pelvic reconstruction has changed with the realization that prolapse surgery is really a series of herniorrhaphies. No surgeon would consider performing a repair of an inguinal or ventral hernia with absorbable suture. In the days of distal plications, the use of absorbable suture was common. Today, fascial defects are repaired with permanent suture. In an attempt to compromise, some surgeons use delayed absorbable sutures. They reason that the suture material is not needed after healing has been completed. No evidence exists in the hernia literature to support the use of anything other than permanent suture for these repairs. Monofilament and polyfilament sutures are acceptable. Monofilament sutures occasionally erode and cause an unpleasant whisker effect in the vagina. If erosion occurs, the suture can be removed. My choice of suture is interwoven braided polyester for fascial repairs. This suture is affordable and easily tied, has no sharp end, and infrequently causes a reaction or exposure. If exposure occurs, suture material should be removed in its entirety.

All prolapse patients should be carefully evaluated for concomitant vaginal, uterine, adnexal, pelvic, or abdominal disease. Coexisting pathology may change the operative approach selected for correction of prolapse. Orthopedic problems and obesity must be factored into the decision-making process because adequate surgical access is important.

Young patients with uterovaginal prolapse may request preservation of their fertility. Unless the problem is severe, these patients should be advised to complete their childbearing so that a definitive operation can be performed. Ring-type pessaries may provide temporary relief. They permit intercourse and may be worn at the discretion of the patient during exercise or strenuous activity and on other occasions. A unilateral sacrospinous ligament fixation with the uterus in place may be beneficial and does not prohibit subsequent vaginal childbirth. Various abdominal or endoscopic uterine suspensions may also be considered. In general, retention of the uterus when a significant degree of prolapse is present compromises the long-term operative result. The cervix

limits access to the structures of the paracolpium that are necessary to achieve proper proximal suspension of the vaginal vault. At the same time, removal of the cervix creates an inherent defect in the proximal anterior vaginal wall. The posthysterectomy vault prolapse is in many instances a result of this cervical defect. Care must be taken to compensate for this weakness at the time of hysterectomy. This area is the location of the pericervical ring whose proper attachments are so important to normal vaginal suspension. No totally anatomic method to close this space exists. To achieve a satisfactory result is easier at hysterectomy than at subsequent posthysterectomy repair. Plication of the cardinal ligaments and McCall culdoplasty are necessary components of hysterectomy cuff repair. Permanent suture material may be used for McCall culdoplasty.

Various grafts, bolsters, and synthetic meshes can be valuable tools in prolapse surgery. For example, in a posthysterectomy prolapse, a small piece of foreign material used to bolster the weak area left by the absence of the cervix may decrease the amount of anatomic distortion needed to support the apical anterior vaginal wall. These materials are useful and often necessary in abdominal sacral colpopexy. However, the overzealous use of grafts and meshes is unnecessary and may predispose to the troublesome problems of exposure and erosion. Procedures that require the use of foreign materials to compensate for absent fasciae should be viewed with suspicion. Even in an advanced prolapse, the fascia is present in most cases. Fasciae, unlike muscles, do not atrophy. They may be retracted and scarred but are available for dissection and reattachment if the surgeon is trained in the proper techniques. Bolstering of site-specific repairs is acceptable. At no time should bolsters, grafts, and meshes be used as a substitute for meticulous surgical technique. Foreign materials should be used to strengthen anatomically restorative repairs. The Food and Drug Administration has issued two notifications indicating that complications related to bolsters used to correct prolapse are not rare and that care should be exercised in the use of these materials. Informed consent is essential.

Complications occurred in 15.5% of prolapse surgeries performed in the United States in 1997 (Table 36.11). The majority of these complications can be addressed in the operating room. Gynecologic surgeons have been well trained to irrigate inside the abdomen. The same principles are applicable when operating vaginally. In the operating room after the surgical prep and draping are completed, a vaginal lavage rinses the vagina of nonadherent bacteria. Intraoperative irrigation at frequent intervals also helps to prevent infection. Irrigation as described and prophylactic antibiotics greatly help reduce the incidence of postoperative infection. A vaginal pack may help initial adherence of the vaginal epithelium to the endopelvic fascia and may reduce hematoma formation. Packs should be removed the day after surgery.

The pelvis is a busy place anatomically. The deep dissections necessary for the correction of prolapse predispose the patient to injury to adjacent structures. Development of proper surgical planes helps to minimize the potential for such injuries.

P.845

Vascular injuries are usually immediately apparent and can be corrected during the operation. Intestinal and urinary injuries are often more subtle. The surgeon should not conclude the operative procedure without some reassurance of the integrity of these structures. Cystoscopy is a valuable skill that should be used by the pelvic support surgeon. A high rectal examination may suffice for intestinal reassurance unless damage is suspected higher than the examination extends.

TABLE 36.11 Frequency and Percentage of Morbidity Associated with Pelvic Organ Prolapse Surgery, 1997

MORBIDITY	FREQUENCY	PERCENT OF ALL SURGERIES ^a
-----------	-----------	---------------------------------------

Infections	14,824	5.4
Bleeding complications	13,945	5.4
Surgical injury	9,546	4.2
Pulmonary complications	3,024	1.3
Cardiovascular complications	2,407	1.1
Wound complications	1,368	0.6
Cerebrovascular complications	249	<0.1
Other complications	165	<0.1
Total morbidity	45,528	15.5

^aN = 225,964 women undergoing prolapse surgery. Reprinted from Brown JS, Waetjen LE, Subak LL, et al. Pelvic organ prolapse in the United States, 1997. *Am J Obstet Gynecol* 2001;186:712, with permission. Copyright © 2002, Elsevier.

Preoperative and postoperative care is discussed elsewhere in this text. Early ambulation and thrombosis prophylaxis are particularly important in the usual prolapse patient. The patient should be at sexual pelvic rest for approximately 6 weeks. The patient may be quite anxious about sexual activity. Sexual rehabilitation may require time, reassurance, and the helpful advice of the physician. Straining to void and defecate should be minimized. The act of perineal splinting postoperatively helps to protect the perineum from downward displacement during defecation. Lifting should be restricted to those things that can be accomplished with available strength in the shoulders, back, and legs.

The care of patients with pelvic organ prolapse can be equally challenging and rewarding. Attention to the details of anatomy, physical diagnosis, reconstructive surgical techniques, and good medical care will yield the best results.

BEST SURGICAL PRACTICES

- Pelvic organ prolapse affects a patient's quality of life. Any decision regarding treatment of prolapse should ultimately be made with significant input from the patient.
- A careful physical examination documenting the defects in pelvic supportive structures is useful in selecting the appropriate treatment to correct the anatomic defect responsible for the patient's symptoms and physical exam findings.
- Pelvic reconstructive surgeries should be designed to restore maximally the normal biomechanical support and suspension of the central pelvic organs. This concept is called site-specific repair of pelvic support defects. Restoration of normal anatomy maximizes the potential for normal urinary, intestinal, and sexual functions.
- Principles of hernia repair should be followed in prolapse surgery. Use of permanent suture is standard. Judicious use of meshes, bolsters, and grafts may be indicated; however, these products should be used to

enhance rather than replace sound surgical technique.

- Complex pelvic surgery and dissection into the deep pelvic spaces require that ureteral patency be documented before leaving the operating room.
- Precise anatomical knowledge of deep pelvic anatomy is necessary for performance of pelvic organ prolapse surgery.

Chapter 37

Reconstruction of the Anterior Vagina for Prolapse

Mark D. Walters

Matthew D. Barber

DEFINITIONS

Anterior vaginal wall prolapse—Descent of the anterior vaginal wall. Most commonly, this would be due to bladder prolapse (cystocele: either central, paravaginal, or a combination). Higher-stage anterior vaginal wall prolapse will generally involve uterine or vaginal vault (if uterus is absent) descent. Occasionally, there might be anterior enterocele (hernia of peritoneum and possibly abdominal contents) after prior reconstructive surgery.

Arcus tendineus fasciae pelvis—The white line of the pelvic sidewall. This thickening of the pelvic sidewall fascia extends from the ischial spine posteriorly to the pubic tubercle anteriorly. It is the site of lateral attachment of the pubocervical fascia.

Paravaginal defect—When the pubocervical fascia becomes detached from, or torn just medial to, its lateral attachment to the arcus tendineus fasciae pelvis (white line).

P.847

Pelvic organ prolapse—The descent of one or more of the anterior vaginal wall, posterior vaginal wall, the uterus (cervix), or the apex of the vagina (vaginal vault or cuff scar after hysterectomy). The presence of any such sign should be correlated with relevant prolapse symptoms. More commonly, this correlation would occur at the level of the hymen or beyond.

Pubocervical fascia—A trapezoid-shaped fascia that provides support for the anterior vagina under the bladder. It is attached superiorly to the pericervical ring, distally to the pubic ramus, and laterally to the arcus tendineus fasciae pelvis (white line).

Anterior vaginal wall prolapse occurs commonly and may coexist with disorders of micturition. Mild anterior vaginal prolapse often occurs in parous women but usually presents few problems. As the prolapse progresses, symptoms may develop and worsen, and treatment becomes indicated. The anterior vaginal wall is the most common segment of the vagina to prolapse and the segment that is most likely to fail long term after surgical correction. This chapter reviews the anatomy and pathology of anterior vaginal wall prolapse, with and without stress incontinence, and describes methods of surgical repair.

TERMINOLOGY

Anterior vaginal wall prolapse (cystocele) is defined as pathologic descent of the anterior vaginal wall and overlying bladder base. According to the International Continence Society (ICS) standardized terminology for prolapse grading, the term “anterior vaginal prolapse” is preferred to “cystocele.” This is because information obtained at the physical examination does not allow the exact identification of structures behind the anterior vaginal wall, although it usually is, in fact, the bladder. A more recent joint report on terminology by the International Urogynecological Association (IUGA) and International Continence Society (ICS) states that anterior vaginal wall prolapse is most commonly due to bladder prolapse (cystocele: either central, paravaginal, or a combination). Higher stage of anterior vaginal prolapse generally involves some amount of uterine or vaginal apex descent. Rare anterior enteroceles can also be found. Most gynecologists are generally comfortable with

the terms cystocele, rectocele, vaginal vault prolapse, and enterocele. Coupled with the brevity of these terms and their clinical usage for up to 200 years, the inclusion of these terms is appropriate.

Some regard it as important to surgical strategy to differentiate between a central cystocele (central defect with loss of rugae due to stretching of the pubocervical and subvesical connective tissue and the vaginal wall) and a paravaginal defect (rugae preserved due to detachment of the lateral vagina from the arcus tendineus fasciae pelvis). Surgical procedures for each of these types of anterior vaginal wall prolapse are presented, although data specifically addressing the comparative efficacy of these various repairs are scarce.

ANATOMY AND PATHOLOGY

The etiology of anterior vaginal wall prolapse is not completely understood, but it is probably multifactorial, with different factors implicated in prolapse in individual patients. Normal support for the vagina and adjacent pelvic organs is provided by the interaction of the pelvic muscles and connective tissue. The upper vagina rests on the levator plate and is stabilized by superior and lateral connective tissue attachments. The midvagina is attached to the arcus tendineus fasciae pelvis (ATFP; white lines) on each side, and the apical portion of the anterior vagina is attached to the web of the endopelvic fascia, including pubocervical fascia, and the cardinal and uterosacral ligaments. Pathologic loss of lateral and/or apical support may occur with damage to or impairment of the pelvic muscles, connective tissue attachments, or both.

Nichols and Randall described two types of anterior vaginal prolapse: distension and displacement. Distension was thought to result from overstretching and attenuation of the anterior vaginal wall, caused by overdistention of the vagina associated with vaginal delivery or atrophic changes associated with aging and menopause. The distinguishing physical feature of this type was described as diminished or absent rugal folds of the anterior vaginal epithelium caused by thinning or loss of midline vaginal fascia. The other type of anterior vaginal prolapse—displacement—was attributed to pathologic detachment or elongation of the anterolateral vaginal supports to the ATFP. It may occur unilaterally or bilaterally and often coexists with some degree of distension cystocele, with urethral hypermobility, or with apical prolapse. Rugal folds may or may not be preserved.

Another theory ascribes most cases of anterior vaginal prolapse to disruption or detachment of the lateral connective tissue attachments at the ATFP, resulting in a paravaginal fascial defect and corresponding to the displacement type discussed earlier. This was first described by White in 1909 and 1912, but disregarded until reported by Richardson in 1976. Richardson also described transverse defects, midline defects, and defects involving isolated loss of integrity of pubourethral ligaments. Transverse defects were said to occur when the pubocervical fascia separated from its insertion around the cervix, whereas midline defects represented an anteroposterior separation of the fascia between the bladder and the vagina. A contemporary conceptual representation of vaginal and paravaginal defects is shown in [Figure 37.1](#).

There have been few systematic or comprehensive descriptions of anterior vaginal prolapse based on physical findings and correlated with findings at surgery to provide objective evidence for any of these theories of pathologic anatomy. In a study of 71 women with anterior vaginal wall prolapse and stress incontinence who underwent retropubic operations, DeLancey described paravaginal defects in 87% on the left and 89% on the right. The ATFP were usually attached to the pubic bone but detached from the ischial spine for a variable distance. The pubococcygeal muscle was visibly abnormal with localized or generalized atrophy in over half of the women.

Improvements in pelvic imaging are leading to a greater understanding of normal pelvic anatomy and the structural and functional abnormalities associated with prolapse. Magnetic resonance imaging (MRI) holds great promise, with its excellent ability to differentiate soft tissues and its capacity for multiplanar imaging. The pelvic organs, pelvic muscles, and connective tissues can be identified easily with MRI. Various measurements can be made that may be associated with anterior vaginal prolapse or urinary incontinence, such as the urethrovesical

angle, descent of the bladder base, quality of the levator muscles, and the relationship between the vagina and its lateral and apical connective tissue attachments. Aronson et al. used an endoluminal surface coil placed in the vagina to image pelvic anatomy with MRI and compared four continent nulliparous women with four incontinent women with anterior vaginal prolapse. Lateral vaginal attachments were identified in all continent women. In **Figure 37.2**, the “posterior pubourethral ligaments” (bilateral attachment of ATRP to posterior aspect of the pubic symphysis) are clearly seen. In the two subjects with clinically apparent paravaginal defects, lateral detachments were evident (**Fig. 37.3**). More recent studies based on MRI analysis and computer modeling suggest that apical support abnormalities are at least as important as, if not more important than, paravaginal defects; the degree of apical decent can explain about half of anterior wall descent. Other factors, such as levator muscle impairment, levator avulsion, greater anterior wall length, and widened levator hiatus, also contribute to anterior vaginal prolapse.

P.848

FIGURE 37.1 Three different defects can result in anterior vaginal wall prolapse. Lateral or paravaginal defects occur when there is a separation of the pubocervical fascia from the ATRP, midline defects occur secondary to attenuation of fascia supporting the bladder base, and transverse defects occur when the pubocervical fascia separates from the vaginal cuff or uterosacral ligaments and represents paravaginal, midline, and transverse defects. P.849

Anterior vaginal prolapse commonly coexists with stress urinary incontinence (SUI). Some features of pathophysiology may overlap, such as loss of anterior vaginal support with bladder-base descent and urethral hypermobility; other features, such as sphincteric dysfunction, may occur independent of vaginal and urethral support. The pathophysiology and surgical treatments of stress incontinence are covered more fully in [Chapter 41](#).

EVALUATION

History

When evaluating women with pelvic organ prolapse or urinary or fecal incontinence, attention should be paid to all aspects of pelvic organ support. The reconstructive surgeon must determine the specific sites of damage for each patient, with the ultimate goal of restoring both anatomy and function. Patients with anterior vaginal prolapse complain of symptoms directly related to vaginal protrusion or of associated symptoms such as urinary incontinence or voiding difficulty. Symptoms related to prolapse may include the sensation of a vaginal mass or bulge, pelvic pressure, low back pain, and sexual difficulty. SUI commonly occurs in association with anterior vaginal prolapse, particularly when it is mild. In contrast, women with anterior vaginal prolapse that extends beyond the hymen are less likely to complain of stress incontinence and more likely to have obstructed voiding

symptoms such as urinary hesitancy, intermittent flow, weak or prolonged stream, feeling of incomplete emptying, the need to manually reduce (splint) the prolapse to initiate or complete urination, and, in rare cases, urinary retention. The mechanism for this appears to be mechanical obstruction resulting from urethral kinking that occurs with progressively worsening anterior vaginal prolapse.

Physical Examination

The physical examination should be conducted with the patient in the lithotomy position, as for a routine pelvic examination. The examination is first performed with the patient supine. If physical findings do not correspond to symptoms or if the maximum extent of the prolapse cannot be confirmed, the woman is reexamined in the standing position.

The genitalia are inspected, and if no displacement is apparent, the labia are gently spread to expose the vestibule and hymen. The integrity of the perineal body is evaluated, and the approximate size of all prolapsed parts is assessed. A retractor or Sims speculum can be used to depress the posterior vagina to aid in visualizing the anterior vagina. After the resting examination, the patient is instructed to strain down forcefully or to cough vigorously. During this maneuver, the order of descent of the pelvic organs is noted, as is the relationship of the pelvic organs at the peak of straining.

It may be possible to differentiate lateral defects, identified as detachment or effacement of the lateral vaginal sulci, from central defects, seen as midline protrusion but with preservation of the lateral sulci, by using a pair of curved forceps placed in the anterolateral vaginal sulci directed toward the ischial spine. Bulging of the anterior vaginal wall in the midline between the forceps blades implies a midline defect; blunting or descent of the vaginal fornices on either side with straining suggests lateral paravaginal defects. Studies have shown that the physical examination technique to detect paravaginal defects is not particularly reliable or accurate. In a study by Barber et al. of 117 women with prolapse, the sensitivity of clinical examination to detect paravaginal defects was good (92%), yet the specificity was poor (52%); despite an unexpectedly high prevalence of paravaginal defects, the positive predictive value was poor (61%). Less than two thirds of women believed to have a paravaginal defect on physical examination were confirmed to possess the same at surgery. Another study by Whiteside et al. demonstrated poor reproducibility of clinical examination in detecting specific anterior vaginal wall defects. Thus, the clinical value of determining the location of midline, apical, and lateral paravaginal defects remains unknown.

Anterior vaginal wall descent usually represents bladder descent with or without concomitant urethral hypermobility. In 1.6% of women with anterior vaginal prolapse, an anterior enterocele mimics a cystocele on physical examination (Tulikangas et al., 2004). Other uncommon conditions, such as anterior vaginal cysts or myomas, can also mimic anterior vaginal prolapse.

Diagnostic Tests

After a careful history and physical examination, a few diagnostic tests are needed to evaluate patients with anterior vaginal prolapse. A urinalysis should be performed to evaluate for urinary tract infection if the patient complains of any lower urinary tract dysfunction. Hydronephrosis occurs in a small proportion of women with severe prolapse; however, even if identified, it usually does not change management in women for whom surgical repair is planned. Therefore, routine imaging of the kidneys and ureters is not necessary.

If urinary incontinence is present, further diagnostic testing is indicated to determine the cause of the incontinence. Urodynamic (simple or complex), endoscopic, or radiologic assessments of filling and voiding function are generally indicated only when symptoms of incontinence or voiding dysfunction are present. Even if no urologic symptoms are noted, voiding function should be assessed to evaluate for completeness of bladder emptying. This procedure usually involves a timed, measured void, followed by urethral catheterization or bladder ultrasound to measure postvoid residual urine volume.

In women with severe prolapse, it is important to check urethral function after the prolapse is repositioned. Women with severe prolapse may be paradoxically continent because of urethral kinking; when the prolapse is reduced, urethral dysfunction may be unmasked with occurrence of incontinence (occult stress incontinence). A pessary, vaginal retractor, or vaginal packing can be used to reduce the prolapse before office bladder filling or electronic urodynamic testing. If urinary leaking occurs with coughing or Valsalva maneuvers after reduction of the prolapse, the urethral sphincter may be incompetent, even if the patient is normally continent. This is reported to occur in 17% to 69% of women with stage III or IV prolapse. In this situation, the surgeon should choose an antiincontinence procedure in conjunction with anterior vaginal prolapse repair. If stress incontinence is not present even after reduction of the prolapse, an antiincontinence procedure probably is not indicated, although this is a subject of ongoing research.

P.850

SURGICAL REPAIR TECHNIQUES

General Considerations

The transvaginal operative procedures begin with the patient supine, with the legs elevated and abducted in stirrups and the buttocks placed just past the edge of the operating table. Antibiotics should be given within 60 minutes of incision to achieve minimal inhibitory concentrations in the skin and tissues by the time the incision is made. This typically means a first-generation cephalosporin (cefazolin) or combination regimens (500-mg metronidazole and 400-mg ciprofloxacin) if the patient has an allergy to penicillin. In general, all patients undergoing apical prolapse surgery are at moderate risk for thromboembolic events and require a prevention strategy. Low-dose unfractionated heparin (5,000 units every 12 hours) or low molecular weight heparins (e.g., 40-mg enoxaparin or 2,500 units of dalteparin), an intermittent pneumatic compression device, or a combination of these are recommended. Either form of heparin should be started 2 hours before surgery and the compression stockings placed on the patient in the operating room before incision. These treatment approaches should be continued until the patient is ambulatory.

Paravaginal Defect Repair: Transvaginal Approach

The aim of paravaginal defect repair for anterior vaginal prolapse is to reattach the detached lateral vagina to its normal place of attachment at the level of the ATFP. This can be accomplished using a vaginal or open or laparoscopic retropubic approach.

The preparation for vaginal paravaginal repair and for anterior colporrhaphy is similar. The abdomen, vagina, and perineum are sterilely prepped and draped, and a 16-French Foley catheter with a 10-mL balloon is inserted for easy identification of the bladder neck. A weighted speculum is placed into the vagina. Hemostatic solution (such as 0.5% lidocaine with 1:200,000 epinephrine) or saline may be injected below the epithelium along the midline of the anterior vaginal wall to decrease bleeding and to aid in dissection. If a vaginal hysterectomy has been performed, the incised apex of the anterior vaginal wall is grasped transversely with two Allis clamps and elevated. Otherwise, a transverse or diamond-shaped incision may be made in the vaginal epithelium near the apex. A third Allis clamp is placed about 2 cm below the posterior margin of the urethral meatus and pulled up. If a midurethral sling is to be done, then the incision is only made to the bladder neck. Additional Allis clamps may be placed in the midline between the urethra and the apex.

Marking sutures are placed on the anterior vaginal wall on each side of the urethrovesical junction, identified by the location of the Foley balloon after gentle traction is placed on the catheter. In patients who have had a hysterectomy, marking sutures are also placed at the vaginal apex. If a culdoplasty or apical suspension procedure is being performed, the stitches are placed but not tied until completion of the paravaginal repair and closure of the anterior vaginal wall. As for anterior colporrhaphy, vaginal flaps are developed by incising the

vagina in the midline and dissecting the vaginal muscularis laterally. The dissection is performed bilaterally until a space—the paravaginal space—is developed between the vaginal wall and obturator internus muscle. Blunt dissection using the surgeon's index finger is used to extend the space anteriorly along the ischiopubic rami, medially to the pubic symphysis, and laterally toward the ischial spine. If the defect is present and dissection is occurring in the appropriate plane, one should easily enter the retropubic space, visualizing retropubic and paravaginal adipose tissue. The ischial spine then can be palpated on each side. The ATRP coming off the spine can be followed to the back of the symphysis pubis (**Fig. 37.4B**). After dissection is complete, midline plication of the bladder adventitia is usually performed, either at this point or after placement and tying of the paravaginal sutures.

On the lateral pelvic sidewall, the obturator internus muscle and the ATRP are identified by palpation and then visualization. Retraction of the bladder and urethra medially is best accomplished with a Breisky-Navratil retractor, and posterior retraction could be provided with a lighted right-angle retractor. Using No. 0 nonabsorbable or delayed absorbable suture on a CT-2 needle, the first stitch is placed around the tissue of the white line just anterior to the ischial spine. Alternatively, a Capio device (Boston Scientific, Natick, MA) works well to facilitate suture placement. If the white line is detached from the pelvic sidewall or clinically not felt to be durable, then the attachment should be to the fascia overlying the obturator internus muscle. The placement of subsequent sutures is aided by placing tension on the first suture. A series of three to six stitches are placed and held, working anteriorly along the white line from the ischial spine to the level of the urethrovesical junction (**Fig. 37.4A**). Starting with the most anterior stitch, the surgeon picks up the edge of the periurethral tissue (vaginal muscularis or pubocervical fascia) at the level of the urethrovesical junction and then the tissue from the undersurface of the vaginal flap at the previously marked sites. Subsequent stitches move posteriorly until the last stitch closest to the ischial spine is attached to the vagina nearest the apex, again using the previously placed marking sutures for guidance. Stitches in the vaginal wall must be placed carefully to allow adequate tissue for subsequent midline vaginal closure. After all the stitches are placed on one side, the same procedure is carried out on the other side. The stitches are then tied in order from the urethra to the apex, alternating from one side to the other. This repair is a three-point closure involving the vaginal epithelium, vaginal muscularis and endopelvic fascia (pubocervical fascia), and lateral pelvic sidewall at the ATRP (**Fig. 37.4B, C**). There must be tissue-to-tissue approximation between these structures. Suture bridges must be avoided by careful planning of suture placement. Vaginal tissue should not be trimmed until all the stitches are tied. The vaginal flaps are trimmed and closed with a running subcuticular or interlocking delayed absorbable suture.

Paravaginal Defect Repair: Retropubic Approach

The object of the retropubic paravaginal defect repair is to reattach, bilaterally, the anterolateral vaginal sulcus with its overlying endopelvic fascia to the pubococcygeus and obturator internus muscles and fascia at the level of the ATRP. The retropubic space is entered laparoscopically or through a small, low transverse incision, and the bladder and vagina are depressed and pulled medially to allow visualization of the lateral retropubic space, including the obturator internus and levator muscles, and the fossa containing the obturator neurovascular bundle. Blunt dissection can be carried dorsally from this point until the ischial spine is palpated. The ATRP is often visualized as a white band of tissue running over the pubococcygeus and obturator internus muscles from the back of the lower edge of the symphysis pubis toward the ischial spine. A lateral paravaginal defect representing avulsion of the vagina

off the ATRP or of the ATRP off the obturator internus muscle may be visualized (**Fig. 37.5**).

FIGURE 37.4 Surgical steps for vaginal paravaginal (3-point) repair. **A:** Numerous sutures are passed through the white line on the fascia over the obturator internus muscle (point 1). **B:** Each suture is passed through the lateral edge of the detached fascia (point 2). **C:** Each suture is passed through the full thickness of the vaginal wall excluding the epithelium (point 3). (Reprinted from Karram MM. *Surgical management of pelvic organ prolapse*. Philadelphia, PA: Elsevier/Saunders, 2013, with permission. Copyright 2013 Saunders, an imprint of Elsevier, Inc.)

The surgeon's nondominant hand is inserted into the vagina. While gently retracting the vagina and bladder medially, the surgeon elevates the anterolateral vaginal sulcus. Starting near the vaginal apex, a suture is placed, first through the full thickness of the vagina (excluding the vaginal epithelium) and then deep into the obturator internus fascia or ATRF, 1 to 2 cm anterior to its origin at the ischial spine. After this first stitch is tied, additional (three to five) sutures are placed through the vaginal wall and overlying fascia and then into the obturator internus at about 1-cm intervals toward the pubic ramus ([Fig. 37.5](#)). The most distal sutures should be placed as close as possible to the pubic ramus, into the pubourethral ligament; alternatively,

Burch colposuspension sutures can be placed bilaterally at the level of the bladder neck and urethra if the patient has stress incontinence. No. 2-0 or 0 nonabsorbable suture on a mediumsized, tapered needle usually is used for the paravaginal repair.

FIGURE 37.5 Abdominal paravaginal defect repair reattaches the pubocervical fascia to the white lines bilaterally. **A:** A patient with bilateral paravaginal defects. The repair has been started on the left with sutures at the two extremes of the defect. **B:** The repair is complete on the left side. **C:** Both sides are repaired. (Reprinted from Shull BL. How I do abdominal paravaginal repair. *J Pelvic Surg* 1995;1:43, with permission. Copyright © 1995 Wolters Kluwer Health.)

This procedure leaves free space between the symphysis pubis and the proximal urethra but secure support so that rotational descent of the proximal urethra and bladder base is prevented with sudden increases in intra-abdominal pressure. According to Turner-Warwick, it avoids overcorrection and fixation of the periurethral fascia, which might compromise the functional movements of the urethra and bladder base and lead to obstruction and voiding difficulty. This principle may explain why the paravaginal defect repair usually results in spontaneous voiding on the first or second postoperative day.

Anterior Colporrhaphy

The objective of anterior colporrhaphy is to plicate the layers of vaginal muscularis and adventitia overlying the bladder ("pubocervical fascia") or to plicate and reattach the paravaginal tissue in such a way as to reduce the central protrusion of the bladder and vagina. Modifications of the technique depend on how lateral the dissection is carried, where the plicating sutures are placed, and whether additional layers (natural or synthetic grafts) are placed in the anterior vagina for extra support.

FIGURE 37.6 Classic anterior colporrhaphy. **A:** Initial midline anterior vaginal wall incision is demonstrated. **B:** The midline incision is extended using scissors. **C:** Sharp dissection of the bladder off the vaginal wall should be lateral to the superior pubic ramus, and the base of the bladder should be dissected off the vaginal cuff or cervix to the level of the preperitoneal space of the anterior cul-de-sac. **D:** The bladder has been completely mobilized off the vagina. **E:** Initial plication layer is placed. **F:** Second plication layer is placed, which commonly requires further mobilization of vaginal muscularis off of the vaginal epithelium. The most proximal stitch involves plication of the inside of the vaginal wall at the level of the vaginal apex or upper portion of the cervix.

Operative setup and preparation are as for a vaginal paravaginal defect repair. A scalpel is used to open the anterior wall in the midline (**Fig. 37.6A**). Alternatively, the points of a pair of curved Mayo scissors are inserted

between the vaginal epithelium and the vaginal muscularis, or between the layers of the vaginal muscularis, and gently forced upward while being kept half-opened/half-closed (**Fig. 37.6B**). Countertraction during this maneuver is important to minimize the likelihood of perforation of the bladder. The vagina is incised in the midline, and the incision is continued to the level of the midurethra (or bladder neck if a sling is being done). As the vagina is incised, the edges are grasped with Allis or T-clamps and drawn laterally for further mobilization. Dissection of the vaginal flaps is then accomplished by turning the clamps back across the forefinger and incising the vaginal muscularis with a scalpel or Metzenbaum scissors, as shown in **Figure 37.6C**. An assistant maintains constant traction medially on the remaining vaginal muscularis and underlying

P.854

vesicovaginal adventitia. This procedure is performed bilaterally until the entire extent of the anterior vaginal prolapse has been dissected; in general, the dissection should be carried further laterally with more advanced prolapse (**Fig. 37.6D**). The spaces lateral to the urethrovesical junction are sharply dissected toward the ischiopubic rami. It is also important to use sharp dissection to mobilize the bladder base from the vaginal apex, if necessary.

FIGURE 37.6 (Continued) G: The completed second plication layer and the trimming of excess vaginal mucosa are demonstrated. **H:** Closure of vaginal mucosa is demonstrated. (Reprinted from Karram MM. *Surgical management of pelvic organ prolapse*. Philadelphia, PA: Elsevier/Saunders, 2013, with permission. Copyright 2013 Saunders, an Imprint of Elsevier, Inc.)

Some surgeons routinely perform a bladder neck plication (Kelly-Kennedy plication; **Fig. 37.7**) at the time of anterior colporrhaphy, particularly when a concurrent midurethral sling is not planned. Vesical neck plication was used to treat mild SUL in the past, but is no longer done for that indication. It may, however, help to prevent the later development of de novo stress incontinence in the patient. Once the vaginal flaps have been completely developed, the urethrovesical junction can be identified visually or by pulling the Foley catheter downward until the bulb obstructs the vesical neck. Repair should begin at the urethrovesical junction, using No. 2-0 or 0 delayed absorbable suture. The first plicating stitch is placed into the periurethral endopelvic fascia and tied. One or two additional stitches are placed to support the length of the urethra and urethrovesical junction.

In a standard anterior colporrhaphy, stitches using No. 2-0 or 0 delayed absorbable sutures are placed in the vaginal tissue (muscularis and adventitia) medial to the vaginal flaps and plicated in the midline without excessive tension. Depending on the severity of the prolapse, one or two rows of plication sutures or a purse-

string suture followed by plication sutures are placed (**Fig. 37.6E-G**). Excess vaginal epithelium is then trimmed from the flaps bilaterally, and the remaining anterior vaginal wall is closed with a running No. 2-0 subcuticular or locking suture (**Fig. 37.6H**).

Anti-incontinence operations are often performed at the same time as anterior vaginal prolapse repair to treat coexistent or occult stress incontinence. More advanced anterior vaginal prolapse often also has anterior-apical prolapse and requires a concurrent colpopexy procedure. Surgical judgment is required to perform the bladder plication tightly enough to reduce the anterior vaginal prolapse sufficiently, yet preserve some mobility of the anterior vagina. If anterior colporrhaphy is combined with a sling procedure (midurethral or bladder neck), the cystocele should be repaired before the final tension is set for the sling. A midurethral sling, such as a tension-free vaginal tape or transobturator sling, is best done through a separate midurethral incision after the cystocele repair is complete.

Anterior Prolapse Repair with Grafts

A prosthetic material can be used to provide support in the anterior vagina, but this remains controversial. This can be done in a number of ways, and the surgical techniques continue to evolve. Graft materials may include synthetic absorbable grafts (e.g., polyglactin 910 mesh), synthetic permanent meshes (e.g., polypropylene), and biologic materials. Biologic materials that have been used include autografts of harvested rectus fascia and fascia lata, human allografts including fascia lata and dura mater, and xenografts such as porcine dermis, porcine small intestinal submucosa, and bovine pericardium. In 2010, approximately 25% of surgeries for pelvic organ prolapse in the United States included transvaginal placement of biologic or synthetic mesh, but this rate of use has decreased in recent years. Many surgeons use transvaginal graft placement in an attempt to increase the efficacy and durability of their surgical repair. For anterior prolapse, studies have demonstrated improved anatomic outcomes after transvaginal placement of permanent synthetic mesh when compared to anterior colporrhaphy without mesh ("native tissue repair"). However, this comes at the expense of an increased rate of complications unique to synthetic mesh placement including vaginal mesh exposure or extrusion, mesh erosion or perforation into an adjacent organ (bladder, urethra, or rectum), and vaginal mesh tension or contraction with associated pain and dyspareunia. Concerns over increased adverse events from transvaginal mesh placement led to two separate FDA notifications. In October 2008, the FDA issued a Public Health Notification (PHN) to inform clinicians and patients of adverse events related to urogynecologic use of surgical mesh and to provide recommendations on how to mitigate risks and counsel patients. In July 2011, the FDA provided an updated PHN on urogynecologic surgical mesh and reported that the complications of mesh used transvaginally are not rare.

When considering the use of transvaginal mesh for anterior prolapse, surgeons and patients must balance improved anatomic support of the anterior vaginal wall against the cost of the devices and increased complications such as mesh erosion, exposure, or extrusion; pelvic pain; groin pain; and dyspareunia. In a joint Committee Opinion published in December 2011, the American Urogynecologic Society and the American Congress of Obstetricians and Gynecologists recommended that pelvic organ prolapse vaginal mesh repair should

P.855

be reserved for high-risk individuals in whom the benefit of mesh placement may justify the risk, such as individuals with recurrent anterior prolapse or with medical comorbidities that preclude more invasive and lengthier open and endoscopic procedures. They also noted that surgeons placing vaginal mesh should undergo training specific to each device and have experience with reconstructive surgical procedures and a thorough understanding of pelvic anatomy.

FIGURE 37.7 Anterior colporrhaphy with Kelly-Kennedy plication: **A:** Vaginal mucosa is opened, and interrupted sutures are started under the urethra; **B:** Completed colporrhaphy uses midline plication with interrupted sutures. Preferential support is provided to the proximal urethra over that provided to the bladder. (Reprinted from Karram MM. *Surgical management of pelvic organ prolapse*. Philadelphia, PA: Elsevier/Saunders, 2013, with permission. Copyright 2013 Saunders, an Imprint of Elsevier, Inc.)

Prior to considering treating anterior vaginal prolapse with graft or mesh, patients should undergo a thorough informed consent process including discussion of risks, benefits, and both surgical and nonsurgical alternative treatments. There are several situations where mesh use is contraindicated. Many surgeons would not consider the use of mesh in a patient who has had a previous mesh complication. Mesh augmentations should not be used in pregnant women or women who are contemplating future pregnancy, as the mesh does not stretch significantly as the patient grows. In patients who have had pelvic radiation, mesh placement is not recommended because of the risk of poor wound healing. Similarly, preexisting local or systemic infection is a contraindication for vaginal mesh placement, particularly nonabsorbable synthetic mesh. Many surgeons would not recommend the use of nonabsorbable synthetic mesh if colorectal surgery is being performed concurrently. Chronic steroid use, smoking, uncontrolled diabetes mellitus, or other causes of a compromised immune system can impair wound healing, and many would consider these conditions to be relative contraindications to vaginal mesh placement. Pelvic pain syndromes such as endometriosis, vulvodynia, interstitial cystitis, fibromyalgia, and

dyspareunia should be evaluated preoperatively to allow for comprehensive counseling as to the best surgical and nonsurgical form of treatment.

Currently, there are three general categories of transvaginal mesh or graft placement options for the management of anterior vaginal prolapse: (a) self-tailored mesh, (b) commercially available trocar-guided mesh kits that use a transobturator approach, and (c) commercially available mesh kits that use a transvaginal fixation method rather than a trocar (nontrocar kits). No matter what placement option is used, the general surgical approach to treat anterior vaginal wall prolapse is fixation of mesh to the ATFP or the coccygeus muscle. The initial incision for anterior vaginal mesh placement usually involves significant hydrodissection and a deeper colpotomy incision than usually performed for a traditional native tissue anterior colporrhaphy so that the perivesical space is entered. The mesh is spread laterally toward the ATFP proximally and distally and, in many of the newer nontrocar kits, attached apically to the sacrospinous ligament. Despite the lack of evidence that any one placement technique is best in managing a

P.856

patient's symptoms, most experts would agree on some basic perioperative tenets:

- The bladder should be drained with a transurethral catheter.
- A well-estrogenized vaginal wall is preferred prior to surgery. (We use intravaginal estrogen cream daily [0.5 to 1.0 g/day] for 2 to 3 weeks preoperatively if the patient is eligible and willing to use estrogen.) A vaginal pessary should be removed 1 to 2 weeks prior to surgery to limit vaginal epithelium irritation.
- All patients require perioperative prophylactic antibiotics and efforts to prevent venous thromboembolic events, as noted earlier.
- Avoid making inverted "T-shaped" incisions from a concurrent hysterectomy and colporrhaphy, if possible.
- Exposure of the correct vesicovaginal space is performed with hydrodissection of 20 to 80 mL of 0.5% lidocaine with 1:200,000 epinephrine, dilute Pitressin (20 units in 60 to 100 mL of saline), or normal saline. The correct space for dissection is found using a "loss of resistance" technique similar to that used by an anesthesiologist placing an epidural. A wheal or blanching illustrates incorrect intraepithelial placement of the fluid. Hydrodissection in the correct plane will create a fluid bubble in the avascular vesicovaginal and rectovaginal spaces.
- As opposed to an anterior colporrhaphy where the vaginal epithelium and muscularis are split for plication, mesh should be placed underneath the vaginal muscularis. It is vital that the surgeon perform a full-thickness dissection deep into the vesicovaginal and rectovaginal spaces to avoid erosion of the mesh postoperatively. Proper hydrodissection, as described above, facilitates the identification of the proper dissection plane.
- It is unknown whether or not the bladder wall should be plicated in the midline below the graft.
- Place the graft loosely because mesh can contract by up to 20% following placement, compromising vaginal length and caliber. Allow enough room for Mayo scissors to be easily placed between the mesh and the vagina. Also, ensuring that the mesh is placed flat and with minimal tension will improve fibroblast growth and minimize complications of pain or erosion.
- The vaginal epithelium should not be trimmed. Trimming the vaginal epithelium can lead to discomfort, and it may also contract. The colpotomy incision is closed utilizing a nonlocking continuous absorbable suture.
- Cystourethroscopy with assessment of urine flow from both ureters should be performed routinely after anterior mesh placement to identify potential urethral, bladder, or ureteral injury.

Self-Tailored Mesh Placement

Self-tailored mesh can be customized by the surgeon to match the size and shape of each patient's individual pelvic anatomy. Mesh is cut into a trapezoid multiarmed shape for compartment augmentation and fixed to sacrospinous ligaments, obturator fascia, ATFP, and/or the distal bladder neck (**Fig. 37.8**). This type of surgery requires a strong set of vaginal surgical skills as it involves dissections similar to sacrospinous ligament fixation, iliococcygeus suspension, uterosacral suspension, and vaginal paravaginal defect repair. No studies have compared standard repair techniques using self-tailored mesh with other mesh placement techniques.

Trocar-Based Mesh Kits

Trocar-guided devices can be used to suspend mesh by passing needles through the transobturator and/or ischiorectal fossa. Trocar-based mesh kits were the first commercially available transvaginal mesh products, but some are no longer marketed by their respective companies. In general, the technique for placement of these products is similar, and the vesicovaginal spaces are dissected as described previously. First, a weighted speculum, self-retaining retractor, or Deaver retractors are placed in the vagina. As the vesicovaginal dissection plane is advanced superiorly, loose areolar tissue is encountered until the ischial spine, the ATFP, and, depending upon the kit, the sacrospinous ligaments are exposed. A number of different trocar types are available including helical shaped trocars similar to those for transobturator slings and flexible straight trocars. Cutaneous incisions that are 4 to 7 mm in length are made over the appropriate locations for the obturator foramen and/or gluteus trocars. When placing multiple mesh arms through the transobturator space, the superior and inferior puncture sites should be at least 3 cm apart so the mesh can lay flat. Two fingers placed into the vagina can retract the colon, elevate the bladder, and minimize deviation of the trocar tip with direct palpation. For anterior compartment mesh, the surgeon immediately identifies the incoming trocar passing through the ATFP. The prosthesis is loosely placed in a "tension-free" manner because mesh can contract by up to 20% following placement, creating tension and compromising vaginal length and caliber. A finger should be kept inside the vagina whenever tensioning the graft. This provides countertraction and splints the tissue at the points of fixation. Stay sutures can be used to help the mesh lay flat against the vagina. If the surgeon conserves the uterus, then permanent sutures can be placed into the cervical stroma to stabilize the mesh and prevent enterocele. Cystoscopic and rectal examinations before, during, and after each portion of the surgery can be helpful. Once adequate hemostasis is obtained, the vaginal epithelium is closed with a continuous nonlocking stitch of delayed absorbable suture. Placing a lubricated vaginal pack may minimize bleeding and keep the mesh flat during healing. After desired tensioning, all ends of the mesh arms should be trimmed below the surface of the skin, and the incisions closed. Concurrent procedures, such as a midurethral sling, should be done through a separate vaginal incision at this time.

Nontrocar Mesh Kits

The nontrocar or "single-incision" mesh kits have become increasingly popular and have largely replaced trocar-based kits. The products avoid the potential complications associated with blind trocar passage through the transobturator space and ischiorectal fossa and allow mesh fixation via direct visualization. Additionally, most currently available nontrocar kits provide apical fixation to the sacrospinous ligaments bilaterally as well as anterior vaginal support. The technique for the nontrocar kits begins similarly to the technique for trocar-guided kit placement. After the vesicovaginal space is dissected, pertinent fixation points are identified including the ischial spines, ATFP, and sacrospinous ligaments. For apical fixation, the surgeon palpates the location of interest then identifies the sacrospinous ligament at least one fingerbreadth medial to the ischial spine. The ligament is penetrated using the surgeon's device of choice. The ATFP mesh arms provide lateral fixation. An index finger placed into the vagina palpates the ATFP from the ischial spine to the posterior pubis. The mesh can be passed through the upper third of the ATFP using the same fixation methods. The mesh arms are slowly and individually adjusted to a loose tension; then, the mesh is sutured flat. Cystoscopy is performed to ensure integrity of the bladder and ureters. The colpotomy is closed and the vagina packed as described above.

FIGURE 37.8 Cystocele repair with mesh: **A:** The bladder is dissected bilaterally and off the vaginal apex. **B:** Midline plication is completed. **C:** After entering the left paravaginal space and exposing the ATFP (*white line*) if desired, the self-styled prosthetic mesh is sewn in place. **D:** The mesh is attached bilaterally, and all sutures are tied, supporting the bladder. (Reprinted from Karram MM. *Surgical management of pelvic organ prolapse*. Philadelphia, PA: Elsevier/Saunders, 2013, with permission. Copyright 2013 Saunders, an Imprint of Elsevier, Inc.)

Cystoscopy

Cystoscopy with direct observation of urine flow from both ureters is usually performed after cystocele repair, especially if slings, mesh, or apical suspension procedures are also being performed. The purpose is to ensure that no sutures or mesh have been placed in the bladder and to verify patency of both ureters. The rate of ureteral obstruction after simple anterior colporrhaphy is only about 0.4%, but the rate increases with the addition of some types of apical suspension. Intraoperative release of the offending sutures almost always releases the ureteral obstruction without further sequelae.

RESULTS

The main indication for surgical repair of anterior vaginal prolapse is to relieve symptoms when they exist or

as part of a comprehensive pelvic reconstructive procedure for multiple sites of pelvic organ prolapse, with or without SUI. Few studies have addressed the long-term success of surgical treatments for anterior vaginal wall prolapse. While the majority of studies evaluating anterior vaginal prolapse repairs are uncontrolled series, an increasing number of randomized surgical trials have been done in recent years. Success rates vary considerably depending upon the outcome measure used to define success. Historically, most studies evaluating the treatment of pelvic organ prolapse have focused exclusively on anatomic success without considering other important areas such as symptoms, vaginal compliance, quality of life, sexual function, or socioeconomic outcomes. For an individual patient, the most important outcome of a surgical procedure is the relief of her symptoms and improvement in her quality of life, yet until recently these areas have largely been ignored. Reported success rates for native tissue anterior colporrhaphy range from 37% to 100% with most cohorts reporting success rates greater than 80%.

No randomized trials have been performed evaluating the efficacy of paravaginal defect repair for the treatment of anterior vaginal wall prolapse. Single-center uncontrolled case series suggest

P.858

good anatomic results for both open retropubic (success rate 75% to 97%) and vaginal (success rate 67% to 100%) approaches. However, the vaginal approach appears to be associated with high risk of hemorrhage, with one series reporting a 21% blood transfusion rate. Few data are available on the efficacy or safety of the laparoscopic or robotic paravaginal defect repair.

In 2001, Weber et al. studied three variations of anterior colporrhaphy using a prospective randomized study design and a strict definition of success (Aa and Ba points at -3 or -2 cm; stage 0 or I). Standard anterior colporrhaphy resulted in 30% of patients with an optimal or satisfactory anatomic result, anterior colporrhaphy with polyglactin 910 mesh overlay had a 42% optimal or satisfactory result, and ultralateral plication under tension had a 46% optimal or satisfactory result. No difference was seen in anatomic or functional outcomes, and most patients reported satisfaction with their symptom improvement. The low success rates found in the trial are used as evidence that anterior colporrhaphy should either be augmented by synthetic mesh or another approach used (e.g., sacrocolpopexy) for treatment of anterior vaginal prolapse. More recently, Chmielewski et al. reanalyzed the data from this trial using more clinically relevant definitions of success and reported considerably better outcomes with only 10% of subjects developing anatomic recurrence beyond the hymen, 5% of subjects developing symptomatic recurrence, and less than 1% having another surgery for prolapse at 23 months' follow-up. In general, it appears that native tissue anterior colporrhaphy commonly results in asymptomatic anterior vaginal descent to within 1 cm of the hymen (POPQ stage 2); however, prolapse beyond the hymen, development of symptomatic prolapse (e.g., vaginal bulging symptoms), and reoperation for recurrent prolapse are uncommon events in the first 2 to 3 years after surgery. Long-term results of anterior colporrhaphy are largely unknown, although Gotthart et al. reported only 13 reoperations for prolapse (2.9%) after 10 years in 456 patients who had vaginal hysterectomy and colporrhaphy. The median interval from the first surgery to the second was 5.5 years.

TABLE 37.1 Randomized Trials of Transvaginal Synthetic Permanent Mesh-Augmented Anterior Vaginal Repair to Anterior Colporrhaphy

AUTHOR	YEAR	GRAFT	NO.	REVIEW MONTHS	SUCCESS	COMPLICATIONS
Nguyen et al.	2008	AC	38	24	18/38 (47%)	Blood loss greater for mesh, 6% exposure

Adapted from Maher C, Baessler K, Barber M, et al. Surgery for pelvic organ prolapse. In: Abrams P, Brubaker L, Cardozo C, Wein A, eds. *5th International Consultation on Incontinence*. Paris: Health Publications, Ltd., 2013.

Two studies evaluated the use of absorbable polyglactin 910 mesh to augment anterior colporrhaphy and reported mixed results. The Weber et al. trial described above found no benefit, while a randomized trial by

Sand et al. found a 75% success rate 1 year after surgery in those receiving absorbable mesh compared with a 57% success in those receiving native tissue anterior colporrhaphy. To date, six trials have compared biologic graft overlay to anterior colporrhaphy, and two trials have compared biologic graft to permanent synthetic graft. Based on a meta-analysis of these trials, a Cochrane review concluded that overall use of a biologic graft overlay is associated with a lower risk of anatomic failure than anterior colporrhaphy alone (failure rate, anterior colporrhaphy 25% vs. biologic graft 14%; RR 1.44 [95% CI: 1.20 to 2.63]), but no difference was found in subjective cure or improvement in quality of life. Given the different characteristics of many of the biologic grafts, it seems likely that results will vary depending upon the specific biologic graft used; however, no head-to-head comparisons have been performed. Two clinical trials have found inferior anatomic outcomes for porcine dermis when compared to polypropylene graft. Six randomized trials have compared the efficacy of mesh augmentation with polypropylene to native tissue anterior colporrhaphy for the treatment of anterior vaginal prolapse (see [Table 37.1](#)). The 2012 Cochrane review concluded that use of permanent synthetic mesh for anterior prolapse repair was associated with a decreased anatomic failure rate when compared to anterior colporrhaphy alone (14% vs. 49%; RR 3.50, 95% CI: 2.71 to 4.52), but no differences were found in the reoperation rate for prolapse or for improvement in quality of life measures. Of note, use of mesh in the anterior vaginal wall appeared to predispose to prolapse in the apical and posterior segments in these trials compared to native tissue repair. The Cochrane reviewers also found that anterior vaginal mesh placement was

P.859

associated with greater operating time, greater blood loss, and a tendency for more cystotomies and de novo SUI.

Vaginal mesh erosions can be a particularly difficult problem, and a small but significant number require reoperation for mesh removal due to chronic discharge, bleeding, pain, and other serious complications. The average rate of mesh exposure reported in the literature in the 1st year after transvaginal mesh placement for pelvic organ prolapse is 10.9%. More than half of the women who experienced erosion or exposure from nonabsorbable synthetic mesh after transvaginal placement require surgical excision in the operating room with some women requiring multiple operations. Creation of thicker vaginal flaps with an attached fibromuscularis, limiting vaginal trimming and avoiding inverted “T” colpotomy incisions or concurrent vaginal hysterectomy, probably decreases the mesh erosion rate. Treatment of vaginal atrophy and cessation of smoking may also help to decrease the mesh erosion rate.

It is worth emphasizing that the great majority of clinical trial evidence available for anterior transvaginal mesh placement studied trocar-based mesh products that are no longer commercially available. In recent years, there has been a significant shift toward the non-trocar-based mesh kits for which there are currently few data. As of the writing of this chapter, no clinical trials comparing nontrocar-based mesh kits for anterior vaginal prolapse have been published.

Risk factors for failure of anterior vaginal prolapse repair have not been specifically studied separate from studies of total prolapse. Vaginal prolapse in general recurs with increasing age and length of follow-up, but the actual frequency is unknown and tends to vary with different definitions of prolapse. Recurrence of anterior prolapse is more likely to occur with more severe initial prolapse and probably with transvaginal, compared to abdominal, repairs. Recurrence may represent a failure to identify and repair all support defects, or weakening, stretching, or breaking of patients’ tissues, as occurs with advancing age and after menopause. Sacrospinous ligament suspension of the vaginal apex, with exaggerated retrosuspension of the vagina, may predispose patients to recurrence of anterior vaginal prolapse. Other characteristics that may increase chances of recurrence are genetic predisposition, subsequent pregnancy, heavy lifting, chronic pulmonary disease, chronic straining at stool, smoking, and obesity.

COMPLICATIONS

Intraoperative complications are uncommon with native tissue anterior vaginal prolapse repair. Excessive blood loss may occur, requiring blood transfusion, or a hematoma may develop in the anterior vagina; this is probably more common after vaginal paravaginal repair than anterior colporrhaphy. The lumen of the bladder or urethra may be entered in the course of dissection. Accidental cystotomy should be repaired in layers at the time of the injury. After repair of cystotomy, the bladder is generally drained for 7 to 14 days to allow adequate healing. Ureteral damage or obstruction occurs rarely (0% to 2%), usually with very large cystoceles or with apical prolapse. Other rare complications include intravesical or urethral suture placement (and associated urologic problems) and fistulae, either urethrovaginal or vesicovaginal.

Complications unique to synthetic mesh use in the vagina include vaginal mesh exposure or extrusion; mesh erosion or perforation into an adjacent organ including the bladder, urethra, and rectum; and vaginal mesh contraction with associated pain and dyspareunia. Complications that can occur with any reconstructive pelvic surgery but that can be made more severe or complicated by the presence of synthetic mesh include bleeding, infection, fistulas, pelvic pain, sexual dysfunction, and dysfunction of the lower urinary and lower gastrointestinal tract. While many of these complications can be managed nonsurgically, a significant proportion will require surgical excision of some or all of the mesh. The incidence of these complications varies from 3% to 39%. A systematic review of 110 studies by Abed et al. found the average rate of graft erosion or exposure to be 10.3% with permanent synthetic grafts and 10.1% after biologic grafts. Wound granulation was seen in 7.8%. Approximately two thirds of women with a mesh exposure after permanent synthetic mesh placement require some surgery to correct the exposure; in some cases, multiple procedures are required.

De novo stress incontinence occurs in 15% to 59% of women after anterior vaginal prolapse repair. This risk is higher in women who demonstrate a positive cough stress test with prolapse reduction prior to surgery than those who do not. However, performance of an antiincontinence procedure such as a midurethral sling or Burch colposuspension decreases this risk whether the preoperative stress test is positive or not.

Voiding difficulty can occur after anterior vaginal prolapse repair. This problem may occur more often in women with subclinical preoperative voiding dysfunction, especially if a suburethral plication is done. Treatment is bladder drainage or intermittent self-catheterization until spontaneous voiding resumes, usually within 6 weeks. Urinary tract infections are common (especially with concurrent catheter usage), but other infections such as pelvic or vaginal abscesses are uncommon.

Sexual function may be positively or negatively affected by vaginal operations for anterior vaginal prolapse. Most prospective studies demonstrate that sexual function either does not change or improves in the majority of women after vaginal reconstructive surgery for pelvic organ prolapse; however, worsening sexual function can be seen in some patients. As many as 50% of patients with advanced prolapse report dyspareunia prior to surgery. In general, dyspareunia rates go down after prolapse surgery; however, de novo dyspareunia can be seen in as many as 18%, especially if a posterior colporrhaphy is also performed. Vaginal length and caliber appear to have little relationship with postoperative sexual satisfaction. In a comprehensive study by Kuhn et al. of male and female sexual function after primary repair of vaginal prolapse without the use of mesh, female patients reported improvement in sexual desire, arousal, lubrication, pain, and overall satisfaction, but not orgasm. De novo dyspareunia only occurred in 2 of 70 women. Male partner function improved as well in domains of interest, sexual desire, and overall satisfaction. One prospective comparison of patients undergoing vaginal versus nonvaginal (open or robotic) prolapse repair found that sexual function improved overall after surgery with no difference between

groups. Comparisons of sexual outcomes between native tissue and mesh-augmented repairs have had mixed results with some showing worse sexual function after mesh repairs, and others show no difference between the groups. The Cochrane reviewers found no difference in postoperative de novo dyspareunia between native tissue prolapse repair and those augmented with synthetic or biologic grafts.

BEST SURGICAL PRACTICES

- Anterior vaginal wall prolapse can involve prolapse of the bladder, prolapse of the uterus or vaginal apex, and even anterior enterocele.
- Anterior vaginal wall prolapse can adversely affect quality of life, sexuality, voiding function, and urinary continence.
- The goal of the operative repair of a paravaginal defect is to reattach the pubocervical fascia to the ATFP and to the fascia overlying the obturator internus muscle.
- Using an open retropubic technique, the bony landmarks of the pelvis are identified by palpation; then, tissue forceps are used to develop the space between the pelvic sidewall

P.860

fascia and the bladder and urethra. Care is taken to avoid venous bleeding in this area. After the white line and the lateral edge of the pubocervical fascia have been identified, a series of interrupted 2-0 permanent sutures are placed about 1 to 2 cm apart to reapproximate the fascial edge to the white line of the pelvic sidewall fascia.

- When a transvaginal approach is used, the retropubic space is opened and cleared back to the ischial spine and the important landmarks visualized as with an anterior retropubic approach. Starting near the ischial spine, a series of sutures are placed in the white line and held with the needles in place. Then, in reverse order, starting with the most distal suture, a bite is taken in the edge of the pubocervical fascia and the undersurface of the vaginal mucosa. The process is repeated, advancing deeper into the pelvis until the highest suture is placed. The sutures are then tied, starting with the one closest to the vaginal introitus and proceeding to the vaginal apex. The vaginal mucosa is then closed in the midline.
- Women with anterior vaginal prolapse should be evaluated for symptomatic or occult SUI, and, if SUI is found, consideration of placing a concurrent antiincontinence procedure should be made.
- Cystoscopy with assessment of both ureters is usually performed after cystocele repair, especially if slings, mesh, or apical suspension procedures are also being performed. The purpose is to ensure that no sutures or mesh have been placed in the bladder and to verify patency of both ureters.
- The 2012 Cochrane review concluded that use of permanent synthetic mesh for anterior prolapse repair was associated with a decreased anatomic failure rate when compared to anterior colporrhaphy alone (14% vs. 49%; RR 3.50, 95% CI: 2.71 to 4.52), but no differences were found in the reoperation rate for prolapse or for improvement in quality-of-life measures. Also, the overall rate of reoperations including reoperation for recurrent prolapse, de novo stress incontinence, or mesh exposure is almost two times higher after anterior vaginal mesh than native tissue repair (10.2% vs. 5.8%).

Chapter 38

Posterior Compartment Defects

Oz Harmanli

Keisha Jones

DEFINITIONS

Constipation—The following criteria must be present for the last 3 months with symptom onset at least 6 months before diagnosis and must include two or more of the following being present during at least 25% of defecations: straining during defecation, lumpy or hard stools, sensation of incomplete evacuation, sensation of anorectal obstruction/blockage, manual maneuvers to facilitate at least 25% of defecations (e.g., digital evacuation, support of the pelvic floor), or fewer than three defecations per week. Loose stools are rarely present without the use of laxatives. There are insufficient criteria for irritable bowel syndrome.

Defecatory dysfunction (DD)—A heterogeneous term used to describe any difficulty with defecation, excluding anal incontinence. DD is often used synonymously with constipation.

Defecatory dyssynergia—A phenomenon whereby the puborectalis and external anal sphincter muscles contract paradoxically during defecation or fail to relax.

P.862

Defecography—A dynamic evaluation that provides a twodimensional view to assess defecation in real time, using fluoroscopy. It may identify a rectocele, sigmoidocele, rectal intussusception, and rectal prolapse and can help to exclude pelvic floor dysynergy.

Endopelvic fascia—A network of connective tissue composed of collagen, elastin, and nonvascular smooth muscle strands that connect pelvic support structures.

Incomplete emptying—Complaint that the rectum does not feel empty after defecation.

Midline plication/traditional posterior colporrhaphy—The operation that plicates the posterior vaginal wall fibromuscular layer, usually from the vaginal apex to the perineal body.

Pelvic diaphragm—The muscular support structure, which forms the pelvic floor posteriorly and laterally and includes the levator ani and coccygeus muscles that originate from the pubic and ischial rami at the level of the arcus tendineus levator ani.

Pericervical ring—The location where the endopelvic connective tissue connects to support the structures surrounding the cervix and vaginal apex.

Perineal body—A midline, fibromuscular confluence between the urogenital and anal triangles where perineal membrane and several muscles including the bulbocavernosus and deep and superficial transverse perineal and external anal sphincter muscles are attached.

Perineal descent—A bulge in the perineum where the perineum descends greater than or equal to 2 cm below the ischial tuberosities at rest or with straining.

Perineal membrane—The inferior fascia of the urogenital diaphragm, which is dense and instrumental in the stability of perineal body and support of the rectum. Some recent anatomic descriptions have begun using the terms, perineal membrane and urogenital diaphragm, interchangeably.

Perineorrhaphy—Reapproximation of torn dense perineal connective tissue including the bulbocavernosus and perineal muscles in an effort to restore the perineal body.

Rectocele and enterocele—The terms used historically to describe protrusion of rectum (rectocele) and

other intestines (enterocele) through posterior vaginal wall defects. This is no longer the preferred terminology as the examiner cannot identify the origin of the prolapse accurately with physical examination alone.

Rectovaginal septum (RVS) or fascia—A misnomer for the dense fibromuscular layer of the vaginal wall between the vaginal epithelium and the rectal wall. This structure, which is not a true histologic fascia or septum, is dense distally and becomes adipose with bundles of fibrous tissue and elastic fibers toward the vaginal apex.

Site-specific repair of the posterior vaginal compartment—Identification of the specific defects of the posterior vaginal wall and subsequent repair of these localized defects.

Splinting/digitation—Complaint of need to digitally replace the prolapse or to otherwise apply pressure, for example, to the vagina or perineum (splinting) or to the vagina or rectum (manual evacuation/digitation) to assist voiding or defecation.

Urogenital diaphragm—The fibromuscular structure that spans from one ischiopubic ramus to the other. It is divided in the middle by the genital hiatus, which contains the urethra and the vagina. Urogenital diaphragm includes deep transverse perineal and sphincter urethra muscles and is covered by fascia on both sides like other muscles in the body.

EPIDEMIOLOGY

Pelvic floor disorders are a prevalent problem that increases cumulatively with age. It is the indication for over 400,000 surgeries annually, representing only a small fraction of those affected by prolapse. The reported prevalence of rectocele varies from 13% to 20% depending on the population studied. Posterior vaginal wall descent is found in approximately 80% of women who have documented prolapse, with isolated rectoceles occurring in 7% of women. Posterior compartment repair is performed in about 40% to 70% of all pelvic floor repairs.

Posterior compartment prolapse can present with symptoms of impaired structure and/or function. Structural abnormalities may manifest as bulge symptoms or sensation of pressure, while functional disorders will usually include defecatory dysfunction (DD). DD is generally used synonymously with constipation, the prevalence of which is estimated as 10% to 15% in most studies and between 9% and 60% in women seen in urogynecology practices. Anal incontinence may also be present but is not typically related to posterior compartment prolapse. The term anorectal dysfunction includes anal incontinence and DD. For the purposes of this chapter, we will focus on DD because anal incontinence is not a typical symptom of posterior compartment prolapse.

Posterior vaginal wall prolapse, the recommended term for bulging that presents in the posterior wall of the vagina, could potentially lead to a protrusion of the anterior wall of the rectum into the vagina (rectocele), small bowel (enterocele), perineal body (perineocele), or the rare entity of the sigmoid colon (sigmoidocele). Bump et al. recommended the term posterior vaginal wall prolapse as the examiner cannot identify with certainty the organs that are protruding through the posterior vaginal wall. This distinction can generally be made once the patient is brought to the operating room.

HISTOLOGY

The vaginal wall is comprised of four layers: a nonkeratinized stratified squamous epithelium; subepithelium, which contains collagen and elastin; lamina propria, a smooth muscle layer; and a loose connective tissue layer, the adventitia. Multiple researchers have investigated the potential alterations that occur in collagen that may result in prolapse; studies have variably concluded that there was overall a lower amount of collagen or a change in the predominant type of collagen in patients with prolapse. In addition, the smooth muscle content of

the posterior vaginal wall is disorganized and significantly reduced in women with pelvic organ prolapse.

Histologic studies of the posterior vaginal wall reveal that the rectum with its outer and inner muscular layers, lamina propria and rectal mucosa, lies immediately adjacent to the vaginal adventitia. There is no evidence of a continuous sheet of dense collagen that would qualify histologically as fascia (**Figs. 38.1** and **38.2**). The layer that supports the vaginal walls is the fibromuscular layer of the vagina, which is rich in elastin. Though technically inaccurate, it has been commonly named “rectovaginal fascia,” “rectovaginal septum,” or “Denonvilliers fascia.” In the proximal vagina, this so-called rectovaginal septum contains mostly adipose tissue, while the most distal 3 to 3.5 cm is dense connective tissue without a true cleavage plane.

P.863

FIGURE 38.1 Histologic layers of the posterior vaginal wall. Hematoxylin and eosin (H&E) horizontal section. (A) Vaginal epithelium, (B) lamina propria of the vagina, (C) fibromuscular wall of the vagina, (D) adventitia, (E) outer muscular wall of the rectum, (F) inner muscular wall of the rectum, (G) lamina propria of the rectum, (H) rectal mucosa. (Reprinted from Kleeman SD, Westermann C, Karram MM, et al. Rectocele and the anatomy of the posterior vagina wall: revisited. *Am J Obstet Gynecol* 2005;193:2050-2055, with permission. ANATOMY

Due to the interdependent nature of the tissues of the pelvic floor, a thorough understanding of the anatomy of posterior vagina is prudent for the gynecologic surgeon planning repair of the posterior compartment.

Identification of all anatomic defects is essential when planning surgery for durable outcomes. Pelvic organ support is provided by the vagina, which is supported by the physiologically complex interactions between the levator ani muscles, surrounding fascia, the arcus tendineus fascia pelvis, the uterosacral ligaments, the connective tissue attachments of the vagina to the bony pelvis, the perineal body, and the perineal membrane (**Fig. 38.3**). The network of connective tissue that envelops the pelvic structures including the vagina is known

as the endopelvic fascia. Its integrity is critical for pelvic floor support. It is made of collagen, elastin, and smooth muscle fibers. The smooth muscle strands in the endopelvic fascia are long and wavy unlike those that form part of the intestinal and bladder wall. The pelvic diaphragm provides the muscular support and includes the levator ani muscles and coccygeus muscles, which originate at the pubic rami at the level of the arcus tendineus levator ani and create the pelvic floor posteriorly and laterally.

In the presence of normal support, the vagina is pulled posteriorly toward the sacrum by uterosacral ligaments and to a lesser degree cephalad by cardinal ligaments, resulting in an almost horizontal orientation in its proximal two thirds (**Fig. 38.4**). Damage to any of the apical vaginal support will lead to a more vertical position of the vagina over the levator ani muscles, predisposing to abnormal distribution of pressures to these muscles, and the subsequent development of prolapse.

FIGURE 38.2 Layers of posterior vaginal wall.

The urogenital diaphragm closes the anterior portion of the pelvic outlet. It spans from one ischiopubic ramus to the other and is divided in the middle by genital hiatus, which contains the urethra and the vagina. The urogenital diaphragm, which includes deep transverse perineal and sphincter urethra muscles, is covered by fascia on both

sides similar to other muscles in the body. The fascia on the superior surface is thin and unremarkable, whereas the inferior fascia is dense and deserves a specific name, the perineal membrane (**Fig. 38.5**).

As described by DeLancey, support of the posterior vaginal wall can also be divided into three levels. The perineal body and its lateral attachments make the most distal level, level III. The perineal body is the key anchoring point where

P.864

P.865

the perineal membrane and deep transverse perineal muscles attach from each side. There is a debate among anatomists whether deep transverse perineal muscles truly exist because it is difficult to dissect a distinct striated muscle in the dense connective tissue of the urogenital diaphragm, which contains significant amount of smooth muscle fibers as well. The distal rectum lies against the dense connective tissue of the perineal body. The fibers of the perineal membrane contract and resist further displacement when the distal rectum is subjected to increased downward force. The structural integrity of the perineal body is crucial in maintaining resistance to downward displacement as it connects the right and left sides of the perineal membrane. When the perineal body is attenuated, as is often seen following obstetrical trauma, the distal rectum becomes vulnerable to pressure and may prolapse (**Fig. 38.6**). The bulbocavernosus muscle, which in some anatomic descriptions is referred to as the urethrovaginal sphincter, is a thin, flat muscle with an about 5-mm width that extends dorsally along the lateral vaginal introitus immediately deep to the cephalic edge of the vestibular bulb. Its fibers interdigitate with its counterpart dorsal to the vagina within the perineal body, and as a result, level III support maintains a U configuration. Individual muscles of the perineum are not always easy to identify even in a nulliparous woman. The perineal body is thickest at the distal end of the vagina, but continues as a substantive structure for a distance of approximately 2 to 3 cm cephalad to the hymenal ring (**Fig. 38.7**).

FIGURE 38.3 Pelvic floor support demonstrating the levator ani muscles and the lateral attachments of the vagina.

FIGURE 38.4 In the presence of normal support, the vagina is pulled posteriorly toward the sacrum by uterosacral ligaments and to a lesser degree cephalad by cardinal ligaments, resulting in an almost horizontal orientation in the proximal two thirds.

FIGURE 38.5 Urogenital diaphragm and perineal membrane.

FIGURE 38.6 The perineal body is the anchoring point where the perineal membrane and deep transverse perineal muscles attach from each side. When perineal body is attenuated, as is often seen with obstetrical trauma, the distal rectum becomes vulnerable to pressure and may protrude.

The support of the posterior midvagina (level II) is continuous with the level III support. Level II support is provided by the endopelvic fascia fibers that extend from the superior surface of the pelvic diaphragm on either side of the rectum. Tension generated by these fibers in a dorsal direction creates bilateral posterior vaginal sulci and a W configuration in level II posterior compartment. Together with the levator plate formed by the pubococcygeus component of levator ani muscles, these endopelvic fascia fibers keep the posterior midvagina in a horizontal plane. A rectocele may form if these fibers are detached, as may occur with birth trauma. Any damage to the levator muscles may also result in rectocele by weakening these lateral attachments. Finally, the upper portion of the posterior vagina is attached to the lateral condensations of the endopelvic fascia, namely, the uterosacral and cardinal ligaments or level I support. The final shape of the vagina is determined by the interaction of these three levels of support.

Contrary to the general perception, the vagina is not a cylinder. Level I support makes the vagina wider at its

proximal end. The vagina becomes narrower as it extends distally. Its upper two thirds is flattened horizontally due to the intricate balance of the forces controlled by level II support. In addition, the bulbocavernosus muscles practically behave almost as a sphincter at the introitus, making the distal vagina the narrowest portion. Pendergrass and her colleagues demonstrated this well by casting the vaginas of women without pelvic floor defects. Most women were shown to have conical shaped vaginas with a width of 5 to 6 cm at the apex and 3 cm at the introitus (**Fig. 38.8**). The average vaginal length is 10 cm with a range from 9 to 12 cm, and it is distensible to approximately 11.5 cm.

Through cadaver studies and clinical analysis, Richardson identified various locations in the posterior vaginal wall where breaks were commonly observed. He concluded that breaks of the fibromuscular network would cause pelvic

P.867

P.868

organ prolapse (**Fig. 38.9**). Rectoceles were formed as a result of discrete “rectovaginal fascia” tears at various points along the posterior vagina. His work demonstrated that the most common defect was a transverse separation of the rectovaginal fascia from the perineal body, resulting in a low (distal) rectocele. With similar frequency, he and other researchers identified midline vertical defects that were caused by poorly repaired or healed lacerations or episiotomies. In addition, a high (proximal) rectocele or an enterocele may result from detachment of the vaginal fibromuscular layer from the pericervical ring.

FIGURE 38.7 Sagittal view of the perineal body.

FIGURE 38.8 Most women were shown to have conical-shaped vaginas with a width about 5 to 6 cm long at the apex and 3 cm at the introitus. (After Pendergrass PB, et al. Comparison of vaginal shapes in Afro-American, Caucasian, and Hispanic women as seen with vinyl polysiloxane casting. *Gynecol Obstet Invest* 2000;50(1):54-59.)

FIGURE 38.9 The formation of rectocele most likely results from discrete tears occurring in the rectovaginal fascia at various points along the posterior vagina.

The anatomic findings of Richardson's work correlate well with the different types of rectoceles encountered in clinical practice. Identification of these defects intraoperatively is paramount for a lasting, successful repair. Defects in midvaginal support can give rise to a rectocele, which may occur in the middle of the vagina despite normal levator function and an intact perineal body. This condition must be addressed not by plicating the rectovaginal fascia but by retrieving and reuniting the separated fibers of the perineal body. If the perineal body has separated from the level II support, they must be reunited.

EVALUATION

History

Pelvic organ prolapse is usually mildly symptomatic or even asymptomatic. It is often discovered by the gynecologists during a routine visit or an encounter for another reason. Prolapse generally becomes symptomatic once it has passed the hymenal ring. Severely symptomatic prolapse usually represents only a

small group of patients.

Prior to the first visit, all patients in our practice are sent an intake form for general information including medical history, medications, previous surgeries, obstetrical and gynecologic history, and social history along with standardized condition specific questionnaires. This is reviewed by the physician prior to the patient encounter. Obtaining initial patient data through these forms facilitate the discussion at the first visit as patients with pelvic organ prolapse often have a difficult time discussing some of their symptoms and concerns due to their sensitive nature.

Patients with posterior vaginal wall prolapse usually complain of a sense of pelvic pressure or bulge and difficulty with initiating and completing evacuation. They often report a need

P.869

for digitation for bowel movements and pressure on the posterior vagina or perineum in an effort to complete rectal evacuation. Pain during intercourse may also be a consequence of a posterior vaginal wall prolapse.

Symptoms of DD should be carefully delineated in all women with pelvic organ prolapse, especially in the posterior compartment. When the patient reports constipation, a thorough understanding of stool frequency and consistency is important as the definition of constipation can vary. When evaluating a patient with DD, one must first exclude systemic causes including metabolic, neurologic, endocrine, or psychiatric abnormalities. In addition, if a functional disorder, that is, dysmotility, irritable bowel syndrome, colonic inertia, or functional constipation, is suspected, the appropriate studies should be performed with referral to a gastroenterologist. In cases of obstructed defecation, it is prudent to exclude gastrointestinal abnormalities that could result in these symptoms including rectal prolapse, colorectal tumors, hemorrhoids, or fecal impaction. Defecatory dyssynergia should also be ruled out in patients with a functional abnormality. On defecography or anal manometry, the findings would include contraction or failure to relax the puborectalis and/or the external anal sphincter muscles with attempted defecation. The gynecologic surgeon is then left with a patient with obstructed defecation that is likely due to the anatomical abnormalities associated with posterior compartment prolapse. In many cases, symptoms generally do not correlate with the severity of prolapse. It is not unusual to see a severely symptomatic woman with only mild anatomic defects. A recent cross-sectional study failed to identify an association between symptoms of incomplete evacuation and straining. In addition, the patient should understand that surgery may not improve chronic constipation, and, in fact, constipation may contribute to the return of a rectocele if not managed aggressively after surgery.

Information regarding fecal incontinence, which may present with pelvic organ prolapse, is not always volunteered due to embarrassment. When it is present, the physician must consider appropriate investigation to rule out dysfunction of the anorectal sphincteric mechanism, neurologic abnormality, a bowel lesion, or a rectal mass. Patients may also describe coital discomfort or a sensation of obstruction in the vagina by their partner. This can be due to prolapse in any compartment, but may often be seen when the couple attempts intercourse in the presence of a rectocele and hard stool in the vault. It is important to remember that pelvic organ prolapse is frequently complex; in addition to a careful history of DD, a complete history of any urinary voiding dysfunction should be obtained.

Physical Examination

Physical examination should begin with a brief mental status exam, assessment of cranial nerve integrity, and cerebellar control. Deep tendon reflexes and muscle strength should be assessed in the lower extremities. Once this is complete, the remainder of the exam takes place in a dorsal lithotomy position. Sensory function may be quickly evaluated from dermatomes L2 through S3 by testing for sensation to pinprick or light touch. The integrity of S3 is elicited by swabbing the perineum and observing for a contraction of the external anal sphincter. The Pelvic Organ Prolapse-Quantification exam is performed using a measuring spatula, which can be marked with

centimeter markings to improve precision. First, the genital hiatus and perineal body are measured. Then, a lubricated speculum is inserted in the vagina for inspection of the entire vagina and the cervix. At this time, the measuring spatula is placed in the posterior fornix to measure total vagina length when the patient is at rest. The patient is then asked to perform a Valsalva maneuver with the spatula in the vaginal apex to quantify vaginal apical descent. This is followed by inspection and measurement of the descent of each vaginal wall under maximum Valsalva effort when the posterior blade of the split speculum is used to support the opposite compartment.

The examiner should avoid excessive support, especially apically, as this can lead to underestimation of the extent of the prolapse. A bimanual examination is then performed to assess the size and position of the uterus and the adnexa; this can also be used to reassess apical descent as it is of paramount importance in any surgical planning for pelvic organ prolapse. Before the fingers are removed, they are rotated 180 degrees to evaluate the integrity and strength of the levator muscles. The patient is asked to perform a “Kegel” contraction for assessment of the patient’s ability to control these muscles. It is important that the patient believes that the extent of prolapse demonstrated in the office is consistent with what she feels on a regular basis. If the examiner is unable to elicit the maximum extent of her prolapse, the exam should be repeated in a standing position with Valsalva. It may sometimes be helpful to leave the patient alone in the room for her to reproduce a physical activity or position that aggravates the prolapse. If these efforts fail, the exam can be repeated on a different day.

Once the maximum descent of each compartment is ascertained, the focus is turned to delineate exact location of the defects of each compartment. Typically, smoothening and loss of rugae in any part of the posterior wall may indicate an area that lacks fibromuscular support. As reviewed in the anatomy section of this chapter, a common defect seen in the posterior compartment occurs because of separation and retraction of perineal muscles and disruption of so-called rectovaginal septum from the perineal body. This is reflected on physical examination as a finding of skin-fold-like perineal body that has lost its fibromuscular elements including bulbocavernosus muscles in the midline; formation of a dimple between this fold and the most protruding part of the distal posterior vaginal wall; and, commonly, an increased genital hiatus measurement, which often occurs at the expense of perineal body (**Fig. 38.10**). A longitudinal defect along the rectovaginal fascia, with lateral disruption of the fascia on either side, may present itself as a false and asymmetric longitudinal sulcus. Proximal posterior vaginal wall prolapse, which is a result of an apical detachment of the rectovaginal fascia from the pericervical fascia, also causes loss of rugae and flattening of vaginal surface in the defective area. The perineum is then carefully examined at rest and with straining. If a 2-cm or more descent of the perineum below the ischial tuberosities is identified, there is perineal body descent. A shortened distance between hymenal ring and rectum indicates perineal body deficiency.

Posterior vaginal wall examination is incomplete until a thorough bimanual rectovaginal examination is performed. Rectal examination begins with inspection of the anus. Then, the examiner inserts one index finger into the rectum first to assess the internal and external anal sphincter tone. Identification of any incidental rectal masses or lesions is crucial. The rectal examination should also include palpation of the rectal wall with simultaneous palpation and observation of the posterior vagina with the other index finger (**Fig. 38.11**). If the rectal-examining finger contains the entire posterior vaginal bulge, a rectocele is likely present. However, a significant defect above the examining finger likely represents an enterocele or possibly a sigmoidocele.

FIGURE 38.10 The most common defect is a transverse separation of the rectovaginal fascia from the perineal body, resulting in a low (distal) rectocele. **A:** This is reflected on physical examination as a finding of skin-fold-like perineal body and formation of a dimple between this fold and most protruding part of the distal posterior vaginal wall. **B:** Shows the same defect dissected. Allis clamp is pulling the torn edge of vaginal muscularis.

Ancillary Testing

Identification of a rectocele is generally made clinically. Ancillary testing is not a standard part of the rectocele evaluation. We perform simple cystometry on all patients with advanced prolapse, including those without urinary loss as occult incontinence may often be present. With the bladder filled to capacity, after the rectocele is reduced with two scopettes or a half speculum, stress testing with Valsalva maneuver and a cough is performed in the supine and standing position. When apical or anterior descent is also identified, urodynamic studies are performed on patients prior to surgery because urinary incontinence is often coincident in these cases.

Multiple ancillary tests may be appropriate in patients with surgical failure or atypical presentations. For any patient with DD, collaboration with a gastroenterologist is prudent in order to assess problems associated with endocrine or metabolic conditions, malabsorption, colonic motility, and dietary issues. Consultation with a colorectal surgeon and colonoscopy may be indicated for rectal abnormalities such as hemorrhoids, prolapse, and anal fissures.

Imaging studies that can be useful in posterior vaginal wall prolapse include defecography and dynamic magnetic resonance imaging; however, radiologic diagnosis of rectocele has not been standardized. Defecography is a fluoroscopic study performed after insertion of radiopaque contrast material into the colon. Defecography provides dynamic visualization of defecation under fluoroscopy. It may assist identification of the location and size of a rectocele, rectal prolapse, intussusception, and sigmoidocele. In addition, there should be a coordinated relaxation of the puborectalis and external anal sphincter muscles with defecation, the absence of which may indicate dysynergy of the pelvic floor. There are, however, no studies indicating that the information obtained with defecography will alter management or clinical outcomes.

Dynamic magnetic resonance imaging (MRI) will provide the highest-quality images of the posterior vagina and surrounding structures, without exposure to radiation. However, this test may not demonstrate the true extent of prolapse as it is performed in a supine position. The clinical utility of MRI, which is costly and not performed at all centers, is also debatable.

Anal manometry is used to assess rectal function by measuring the resting and squeeze sphincter pressure as well as the functional length of the anal canal. Functional anal canal length is the length of the anal canal over which resting pressure exceeds that of the rectum by greater than 5 mm Hg. Rectal compliance reflects the capacity and distensibility of the rectum. Higher compliance indicates lower resistance to distention.

Electrophysiologic studies of bowel function such as electromyography and nerve conduction velocity, especially those measuring individual muscle responses, have generally been abandoned by physical therapists and gastroenterologists because of the tests' inability to measure clinically significant parameters.

Endoanal ultrasound can be used for the diagnosis of anal sphincter defects in patients presenting with fecal incontinence but has limited utility for managing rectoceles.

P.871

FIGURE 38.11 The rectal examination should also include palpation of the rectal wall with simultaneous palpation and observation of the posterior vagina with the other index finger. If the rectal examining finger contains the entire posterior vaginal bulge, a rectocele is likely present. However, a significant defect above the examining finger likely represents an enterocele or possibly a sigmoidocele.

MANAGEMENT

Conservative Management

Asymptomatic patients may be managed expectantly. For most patients, reassurance and review of precautions and lifestyle changes, which may prevent progression of prolapse, is sufficient. We recommend a follow-up visit to monitor the changes in the symptoms and pelvic floor in 6 to 12 months.

For patients who have symptoms related to pelvic organ prolapse, the most common nonsurgical approach is use of a pessary. Unfortunately, data on pessaries are limited. There is no specific pessary that works best for patients with rectoceles. The examiner should decide which pessary is appropriate based on the patient's vaginal length, genital hiatus, sexual activity, and severity of prolapse. Clemons et al. found that a vaginal length of 6 cm or less and an introitus greater than 4 fingerbreadths were risk factors for an unsuccessful pessary trial. In addition, prior pelvic surgery and previous hysterectomy were also associated with increased failure of pessary trial. We generally begin with a supportive pessary such as a ring pessary with a platform and attempt multiple sizes. If the patient cannot retain the pessary, it is uncomfortable, or

P.872

the pessary does not provide enough support, we generally will move to the Gellhorn pessary, a space-occupying pessary. Donut and cube pessaries are rarely used, if ever, in our practice as we find they often result in ulcerations and copious vaginal discharge and are very difficult to insert and remove.

Pelvic floor physical therapy and biofeedback have both been shown to improve symptoms from pelvic organ prolapse, especially in early stages. Its greatest role may be in the treatment of dysynergy of the pelvic floor. It should also be utilized for patients with fecal incontinence with the addition of biofeedback.

SURGICAL MANAGEMENT

Informed Consent

The preoperative office visit is crucial for a detailed discussion of natural history, treatment options including conservative and surgical methods, and risks and benefits of each treatment alternative. It is advisable to ask the patient to come to the visit with family members in an effort to provide a clear understanding of the procedure not only by the patient but also those who may potentially be affected by the surgery or participate in her care during her recovery. Explaining prolapse and the procedure with simplified visuals can make it easier for the patients to differentiate between facts and fallacies in this sensitive era since the warning of the Food and Drug Administration. In our practice, we continue judicious use of grafts for pelvic floor reconstruction in women who present with an isolated stage III proximal posterior compartment prolapse with proximal rectocele and/or enterocele, especially if they have failed a previous native tissue repair. We recommend using a procedurespecific consent form, which lists the potential risks associated with surgery in addition to the one required by the hospital in all surgical cases whether graft material will be introduced or not. Detailed guidelines for the consent can be found on the American Urogynecologic Society Web site using the consent toolkit (www.augs.org).

Bowel Preparation

Although some pelvic surgeons advise a light lunch and clear liquids for dinner followed by a fleet enema, there

is no study to guide us regarding bowel preparation before transvaginal pelvic floor repair. Therefore, surgical preparation for a posterior wall repair can be minimal on the part of the patient. Patients can simply be instructed to discontinue oral intake at midnight the night before surgery. Simple evacuation of the rectum at the time of surgery may be sufficient for posterior vaginal repair.

Anesthesia and Preoperative Preparation

Regional anesthesia with spinal or epidural approach is very suitable and may even be more appropriate for vaginal procedures. Local anesthesia with conscious sedation may also be utilized when general or regional anesthesia is considered too risky. Although there is no strong evidence for guidance, preoperative single-dose intravenous antibiotic has been the standard for all vaginal procedures. Prevention for venous thromboembolism with sequential compression boots or subcutaneous heparin is routine.

Patient Positioning

Posterior compartment repairs are performed with the patient in a dorsal lithotomy position. We prefer stirrups that support the entire lower extremity for these cases, but the surgeon should use the stirrup of his or her choice. During positioning, the minimum angles should be 60 degrees between the thighs and the torso and 90 degrees at the knee in an effort to prevent any tension or pressure on any aspect of the lower extremities. The patient's buttocks should extend slightly over the edge of the table for best access. Although helpful in the anterior compartment procedures, Trendelenburg position may hinder ergonomic dissection during posterior repairs in the distal vagina. The bladder is generally emptied and drained throughout the case as not to obstruct visibility. A self-retaining retractor can be used to improve visualization. We prefer the Lone Star Retractor System (CooperSurgical, Trumbull, CT) for this purpose and generally use at least six retraction hooks during the procedure. We find the rectangular-shaped retractor to be the most helpful, but other shapes may also be adopted. Additional retractors are needed only occasionally when selfretaining retraction systems are in use. Initial retraction can be facilitated by placing the first two hooks at the hymenal ring, which also holds the self-retaining retractor in place.

Instruments

In addition to the self-retaining retractors, several surgical instruments facilitate the identification of tissue layers, dissection, and hemostasis. In addition to at least six to eight medium and at least two long Allis clamps to grasp the epithelium or other tissue layers, we recommend including six to eight Pratt clamps (T-shaped grasping clamps) in the surgical set to hold the edges of epithelial incisions. The blunt rounded tips of curved Mayo scissors are ideal for dissection of vaginal planes. When necessary, Metzenbaum scissors also may be used for delicate dissection. Versatility of ribbon malleable retractors makes them very suitable for vaginal surgery. Deaver and wide Breisky-Navratil retractors also can be used. When an apical suspension procedure such as sacrospinous ligament fixation is also planned, a suture placement device such as Capiro (Boston Scientific, Marlborough, MA) and its special monofilament delayed absorbable sutures should be available. Lighted suction-irrigation devices are very helpful for visualization, irrigation, exposure, and hemostasis. Hemostatic agents such as oxidized regenerated cellulose, topical thrombin, and the other thrombin products in gelatin foam should be present in the operating room particularly for procedures requiring apical repairs.

SURGICAL TECHNIQUES

Site-Specific Repair

In our institution, we have adopted a site-specific approach. This technique requires identification and repair of discrete tears in the rectovaginal wall. Intraoperative examination under anesthesia is essential for confirmation of the findings in the outpatient setting and ascertainment of the specific defects in the posterior compartment. It

also will determine the appropriate plane of dissection during the surgery once the surgeon decides between native tissue and graft-augmented repair in a woman with advanced posterior compartment prolapse who has permitted the use of grafts, if deemed necessary. Full-thickness dissection is imperative if graft use is decided.

After a careful inspection of the rugae and palpation of the rectovaginal wall with rectovaginal examination as described above, the defects may be identified with improved accuracy under anesthesia before any incision is made. If the surgeon decides that apical disruption has resulted in a severe displacement of the most proximal end of the rectovaginal tear from the apical support structures and significant shortening of the

P.873

fibromuscular layer, graft use is considered. Because the possibility of graft utilization is discussed at length during the informed consent process, the surgeon should feel comfortable proceeding with graft application. The other important determinants of graft use include a previous failed attempt, chronic constipation, patient's current sexual activity, and functional expectations from the surgery.

Injection of local anesthetics with epinephrine into the surgical field is commonly recommended in an effort to hydrodissect vaginal tissue planes and provide hemostasis. In our opinion, this is not necessary and may potentially complicate identification of correct tissue planes. If the dissection is performed accurately, there will not be any significant bleeding as the vascular elements reside in the fibromuscular layer. Minor bleeding due to perforators between the layers can easily be controlled with judicious use of cautery.

If intraoperative assessment of the posterior vaginal wall concludes that native tissue repair is to be performed, the surgeon should start the dissection between the epithelial and fibromuscular layers (so-called "rectovaginal septum") of the vagina. The procedure starts with placement of Allis clamps on each side of the hymenal ring at approximately 4 o'clock and 8 o'clock. Approximation of the Allis clamps in the midline will give the surgeon a good estimate of vaginal caliber after the procedure. The reconstructed vagina should be able accommodate three fingers comfortably. These two Allis clamps remain in place for the entire duration of the repair. If these clamps are held by an assistant during dissection and suture placement, the direction and force of the traction applied on these clamps should be equal to maintain symmetry.

FIGURE 38.12 After assessment of targeted introital dimensions by placing Allis clamps on each side of the posterior hymenal ring, a triangular skin incision is made on the posterior fourchette and the skin within this triangle is removed.

Restoration of perineal body anatomy is integral to all posterior vaginal repairs in our practice. As described above, its role in rectal support and normal pelvic function as the level III support is critical. Perineal body repair may also add 2 to 3 cm to the vaginal length. Therefore, our initial incision is made to accommodate a perineorrhaphy as well. With this goal in mind, another Allis clamp is placed at the perineal end of the posterior fourchette. These three clamps represent the corners of a triangular skin incision, which will be made in this location ([Fig. 38.12](#)). These incisions can be made with cautery. This triangular skin portion is then removed with particular attention to preserve the perineal connective tissue and maintain hemostasis. Then, another Allis clamp is placed on the posterior vagina at the midline, approximately 3 to 4 cm proximal from the hymenal ring. After one Allis is placed on each side of the midpoint of the vaginal side of the transverse incision for outward traction, Mayo scissors with their tips up are used to start the dissection of the vaginal epithelium

from the underlying fibromuscular tissue (**Fig. 38.13**). Identification of the correct plane between the vaginal epithelial and fibromuscular layers at the onset is crucial for a complete and hemostatic dissection. The surgeon should be patient as this plane may not be easily entered due to fibrosis caused by previous obstetrical trauma or repair or pelvic floor repairs in the distal posterior vagina. Placing the nondominant index finger on the vaginal epithelium may add tactile feedback at this point (**Fig. 38.14**). Blanching on the vaginal aspect of this dissection plane ensures entry into the accurate plane. Once the commonly fibrotic portion in the distal vagina is passed, the dissection becomes easier. Mayo scissors should never be pushed bluntly when previous repairs or mesh are present in this area. Inadvertent rectal entry can be avoided if the dissecting scissors is maintained parallel to the vaginal wall. Once the correct plane is entered, the dissection is continued toward the proximally placed Allis clamp, which elevates the vaginal midline, and a midline sagittal incision can be made. The cut edges of the midline incision are then grasped with Pratt clamps on each side. The midline Allis clamp is then moved cephalad, and the dissection is continued for another 3 cm. A pair of Pratt clamps is placed on each side. This approximately 6-cm incision is typically sufficient to complete any posterior repair because the rest of the dissection toward the vaginal apex can easily be accomplished without any further midline incision.

FIGURE 38.13 After one Allis clamp is placed on each side of the midpoint of the vaginal side of the transverse

incision, another Allis clamp is placed on the posterior vagina at the midline, approximately 3 to 4 cm proximal from the hymenal ring. Mayo scissors with their tips up are used to start the dissection of the vaginal epithelium from the underlying fibromuscular tissue.

Once the midline incision is complete, the rest of the dissection in the apical and lateral direction is performed with Mayo

P.875

scissors using spread and snip technique with the help of Pratt clamps applying traction on the incision (**Fig. 38.14**). In addition, countertraction provided by an assistant on the fibromuscular layer is helpful. For best results, the concave side of the scissors is pressed against the convex curve of the nondominant index finger lying on the vaginal epithelial surface during this dissection. Starting the dissection at the apex of the midline incision is helpful as tissue planes are easier to identify in this area where scarring is rarely encountered unless the repair is for recurrent prolapse. A white undersurface on the vaginal wall against the pink- and red-colored vascular fibromuscular layer represents the correct dissection plane. Bleeding is often a sign that the fibromuscular layer has been invaded. The dissection is continued laterally to the attachment of the fibromuscular layer to the inner levator fascia and until all the defects are exposed. This dissection leaves an inverted T-shaped incision. Premenopausal women will have abundant venous lakes especially at the perineal body on either side. Energy should be used judiciously to allow for a hemostatic dissection. At this point, the Pratt clamps are replaced with retraction hooks. It is important to maintain symmetry during the placement of these hooks. Typically, there will be no need for a manual retractor once the retraction hooks of the self-retaining system are placed.

FIGURE 38.14 Once the midline incision is complete, the rest of the dissection in the apical and lateral direction is performed with Mayo scissors using spread and snip technique with the help of Pratt clamps applying traction on the incision to facilitate dissection.

After careful evaluation of the entire rectovaginal wall between two opposing index fingers, one in the rectum and the other in the vagina, all the defects are identified and labeled with Allis clamps or sutures ([Fig. 38.15](#)). Torn and retracted perineal fibromuscular structure on both sides distal at the level of the introitus should also be visualized.

FIGURE 38.15 After careful evaluation of the entire rectovaginal wall between two opposing index fingers, one in the rectum and the other in the vagina, all the defects are identified and labeled with Allis clamps or sutures.

For almost all posterior vaginal repairs, we use zero polyglactin 910 sutures, as we noted that monofilament polydioxanone sutures delayed return to comfortable coital activity. This is more because the large knot, created with the six to seven throws required for a secure knot with polydioxanone suture material, takes at least 6 months to absorb.

No vaginal repair will be durable without addressing the apical prolapse. It has been shown that posterior compartment prolapse may be relieved with an effective apical repair per se in 30% of women. If an entirely vaginal repair is planned, bilateral sacrospinous or extraperitoneal uterosacral ligament suspension sutures are placed and turned into pulley stitches at this time; however, these sutures are not tied until all but the most distal transverse defects are corrected. If concomitant vaginal hysterectomy is to be performed, uterosacral ligaments can be accessed with an intraperitoneal approach. Identification of the intermediate segment of ligaments is crucial for prevention of ureteral injury with this intraperitoneal technique. Applying outward traction on the cut end of the uterosacral ligament and the posterior cuff edge with Allis clamps, an index finger placed in the rectum

may help locate the safe zone.

We start with the correction of the most apical defect, which occurs as a result of a transverse tear of the fibromuscular layer from the cervical ring and uterosacral ligaments.

If the uterus is in situ, this edge is attached to the posterior cervix and the uterosacral ligaments with interrupted sutures. In a patient with a history of hysterectomy, the most apical end of the fibromuscular layer of the anterior vaginal wall, so-called pubovesicocervical fascia, is carefully identified and integrity of pericervical ring is restored by suturing the fibromuscular layers of anterior and posterior vaginal walls. Combination of this technique with a vaginal apical repair procedure such as sacrospinous ligament or extraperitoneal

P.877

uterosacral ligament suspension restores the level I defect. In order to correct the level II posterior compartment support, the edges of each defect in the midvagina are reapproximated with the same technique until the distal posterior vagina is reached. Rectal examination is necessary after each defect repair to confirm effective restitution of the posterior vaginal wall support.

Before repairing the most common defect, which is a transverse separation of the fibromuscular layer from the perineal fibromuscular tissue, the perineal body should be restored. It is helpful to label the distal edge of the detached fibromuscular layer first (**Fig. 38.16**). Bulbocavernosus muscles are identified with careful dissection on each side of the vestibule and held with Allis clamps similar to the technique used to locate the torn edges of the external anal sphincter muscle. Of note, deep transverse perineal muscles are not easily identified, but they lie within the dense connective tissue of the perineal body torn and retracted laterally. When placing these sutures, the needle should enter perpendicularly into these structures. No suture is tied until three of these are placed sequentially starting from inside to the outside of the introitus (**Fig. 38.17A**). Attention is paid not to begin too cephalad from the hymenal ring in an effort to prevent inclusion of the pubococcygeus muscles, which are adjacent to these perineal structures. The surgeon should also ensure that sutures, although placed deep into the muscle, are not ending high in the vagina as this will compromise the vaginal caliber. Vaginal caliber should be assessed after these sutures are tied. This is followed by suturing the torn fibromuscular layer to the restored perineal body with approximately four to five sutures (**Fig. 38.17B, C**). Another rectal examination is performed at this time to ensure that the defects have been appropriately addressed and the rectocele has been reduced. Occasionally, a few distal plication sutures are placed on the fibromuscular layer if site-specific repair does not produce the desired vaginal caliber.

Once the repair is complete, the vaginal epithelium can be reapproximated in a running fashion with a 2-0 absorbable suture. Before this closure, the edges of the vaginal epithelium may be slightly trimmed as needed (**Fig. 38.18**). It is not unusual to find excess vaginal epithelium at the most proximal end of the midline incision line; this can be managed by trimming 0.5 to 1 cm further apically. At the distal end of this incision, only rounding up the corners will be sufficient. We place one to two interrupted 3-0 absorbable sutures on each side of the midline at the introitus in a transverse fashion in an effort to prevent introital constriction before completion of the sagittal midline closure.

FIGURE 38.16 Before repairing transverse separation of the fibromuscular layer from the perineal body, torn perineal fibromuscular tissue should be identified.

If the rectum is entered inadvertently during dissection, it is prudent to complete the dissection with the rectum open, providing a good reference. This area should be copiously irrigated

P.878

during this time and after closure. Most teaching texts finish description of a posterior vaginal repair by advising performance of a rectal examination to ensure the rectal lumen is not invaded by any suture. We choose to do this after completion of all reparative sutures before the closure of the vaginal epithelium and perineal skin, as it is the best time to replace any suture that penetrates into the rectal lumen. When the rectum is accidentally entered, graft material should not be used and an alternate native tissue repair should be implemented. Cystoscopy is not necessary for any type of posterior compartment repair as the bladder or ureters are not at risk during this procedure unless any additional procedure such as intraperitoneal uterosacral ligament suspension, anterior compartment repair, or an anti-incontinence procedure is performed.

Site-Specific Repair with Graft

With little data to guide the surgeon regarding use of graft material in the posterior compartment, the decision to augment the repair should be made with careful thought and appropriate patient counseling. Indeed, there are patients that present with large apical defects and severely attenuated posterior vaginal walls where graft use may be appropriate. When pre- and intraoperative assessment suggests displacement of the torn apical edge of fibromuscular layer distally by about 5 to 6 cm, we offer a repair with synthetic graft to well-informed women who have previous failures and chronic constipation and are not sexually active. Patients should be counseled on the lack of data regarding graft use.

FIGURE 38.17 A: After perineal fibromuscular tissue including the bulbocavernosus muscles is reunited.

We begin the procedure with a triangular-shaped incision over the perineal body. Once again, the hymenal ring is grasped with two Allis clamps. The posterior vagina is grasped approximately 3 cm proximal to the hymen with an Allis clamp in the midline. The critical difference in these cases is the plane of dissection. The surgeon must separate the entire vaginal wall including its fibromuscular layer from the rectal wall as opposed to splitting the epithelial and fibromuscular layers as in native tissue techniques. Once the full-thickness vaginal wall is dissected from the rectum, a 5-cm midline sagittal incision is made. It is important to keep the incision short and

away from the vaginal apex, since most graft exposures occur due to infection or dehiscence of incisional wounds.

P.879

P.880

Some surgeons trained to use pelvic floor systems marketed by medical device companies are accustomed to utilizing local anesthetic with epinephrine for hemostasis and hydrodissection. We do not think this approach is necessary. In fact, the tissue planes may be more precisely identified without local infiltration with this local anesthetic solution. If the correct plane is entered, there should be no bleeding. Alternatively, the dissection can be further facilitated with the nondominant finger in the rectum. The initial 3 cm of this dissection is the most difficult in women with previous repair due to dense fibrosis in this area. However, once the correct plane is entered, the rest of the dissection becomes easier. The entire posterior vaginal wall is separated from the rectum. At the apical part of dissection, there is a risk of entering the peritoneal cavity as many patients have an enterocele component. If this occurs, the enterocele is ignored and peritoneum is simply closed with 2-0 absorbable suture. The surgeon must then palpate the ischial spine and sacrospinous ligament/coccygeus complex bilaterally. The ligament is exposed with clearing soft tissue and separation of coccygeal muscle fibers bluntly. A suture is placed through the ligament approximately 1 to 1.5 cm medial to the ischial spine using a suture placement device such as Capio™ and a delayed absorbable suture with the rectum deviated contralaterally. Once the suture is placed, the surgeon should tug on the suture to evaluate the strength of the purchase into the ligament. When performing a posterior repair with graft, we use a 10 × 15 cm sheet of type I macroporous monofilament polypropylene mesh cut into a Y shape and customized for each patient ([Fig. 38.19](#)). The top part of the Y-shaped graft represents its apical part. The graft should be secured apically with one absorbable suture on each side of the midline so that the entire defect is covered and the mesh does not migrate. In a woman who has a uterus, it is attached to the posterior cervix and the uterosacral ligaments. If the patient is posthysterectomy, it is sutured to the most apical end of the fibromuscular layer of the anterior vaginal wall. At this time,

P.881

sacrospinous ligament sutures are passed through the tips of the Y-shaped graft and tied in a pulley fashion. Then, they are tied down without any suture bridging, with an assistant bringing the vaginal apex closer to that side using an instrument. The graft is then sutured laterally to the levator fascia at several locations. Its distal end is trimmed so that it ends about 3 cm cephalad to the introitus, where the perineal body is supposed to start. This procedure not only corrects an apical posterior defect but also repairs an apical prolapse by elevating the vaginal apex toward the sacrospinous ligaments. The surgeon should ensure that the graft lays flat without tension. The procedure ends with a perineorrhaphy as described in the site-specific repair section. These perineal sutures may provide an additional layer of coverage over the distal end of the graft, which has the highest risk of exposure as it is the only part that corresponds to the midline incision line. A Foley catheter is inserted, and the vagina is packed for one night.

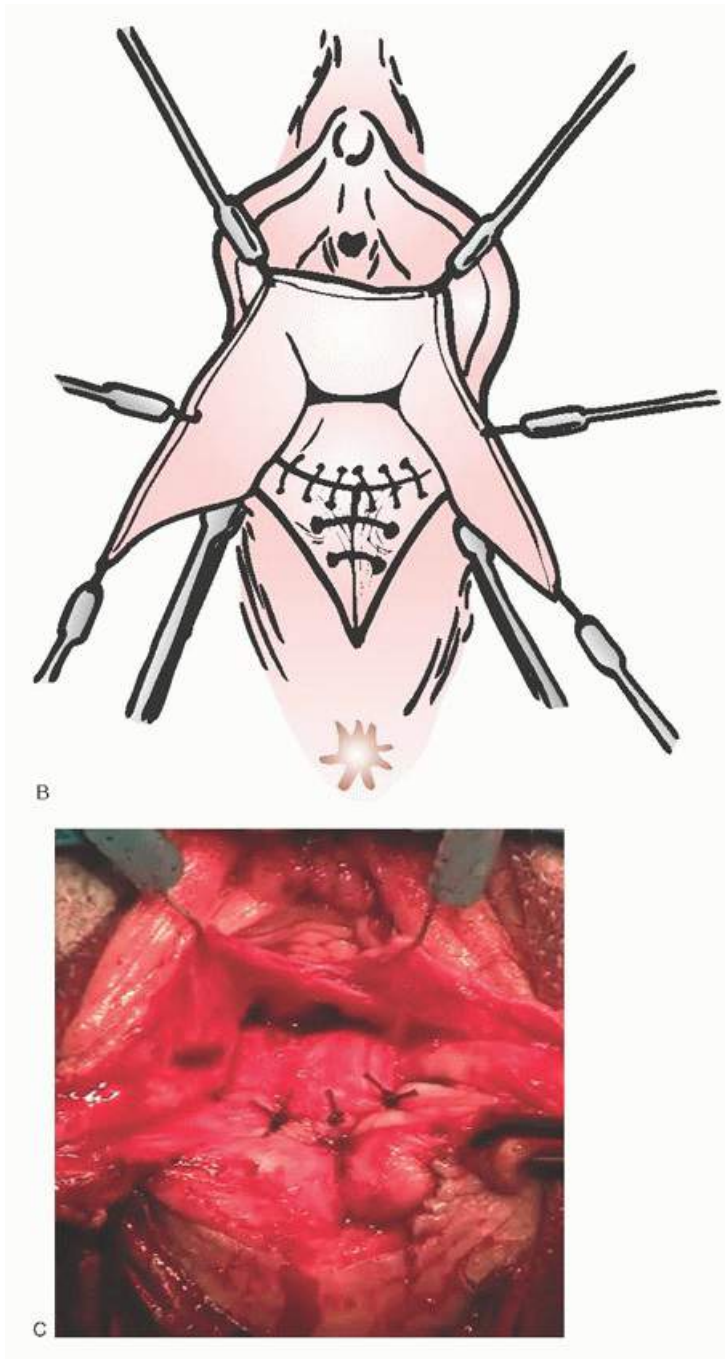

FIGURE 38.17 (*Continued*) **B:** The detached edge of the vaginal fibromuscular layer is sutured to the restored perineal body with approximately four to five sutures. **C:** Shows this technique applied during a surgery.

FIGURE 38.18 Before the closure of the vaginal epithelium, its edges may be trimmed slightly as needed. It is not unusual to find excess vaginal epithelium at the most proximal end of the midline incision line; this can be managed by trimming 0.5 to 1 cm further apically. Sometimes, rounding up the corners of the perineal end of the midline incision may be sufficient.

FIGURE 38.19 When performing a posterior repair with graft, we use a 10 × 15 cm sheet of type I macroporous monofilament polypropylene mesh cut into a Y shape and customized for each patient.

Midline Plication/Traditional Colporrhaphy

An alternate approach to the site-specific repair is the posterior midline plication technique ([Fig. 38.20](#)). This traditional posterior repair method was developed to address obstetric lacerations. It included plication of pubococcygeus and the posterior vaginal fibromuscular layer with perineal body reconstruction.

There is no doubt that traditional posterior colporrhaphy with plication of the fibromuscular layer improves objective and subjective outcomes as shown in case series and comparative studies. However, like many surgical procedures that were developed empirically, it was shown to achieve anatomic and functional goals in most patients. It can be likened to sacrocolpopexy, which is not an anatomic correct procedure but serves as one of the best apical prolapse approaches available.

The incisions and dissection for this technique are similar to that described above for site-specific repair. The fibromuscular layer is then plicated in the midline in one or two layers with 0 absorbable sutures. Care must be taken not to restrict the vaginal caliber. The surgeon should avoid plication of the pubococcygeus muscles and plication in the proximal 5 cm of the posterior vaginal wall because these may cause significant dyspareunia by compromising the vaginal caliber in sexually active women. Perineorrhaphy is also performed by continuation of the plication onto the torn bulbocavernosus and deep transverse perineal muscles and connective tissue in the manner described above. The process of trimming and closure of the vaginal epithelium is also the same. The

surgeon should ensure that the vagina can easily accommodate three fingers at completion of the surgery.

Our reservation for midline plication technique includes the possibility of conversion of the vagina into a tube and tendency to plicate the pubococcygeus muscles overzealously with this approach. As reviewed above, the vagina is not a tube. Turning it into a tube may have functional consequences. Similarly, plication of the levator muscles in the midline between the vagina and the rectum may also cause dyspareunia.

Transanal Repair

According to a recent Cochrane review, transvaginal posterior wall repairs performed better than the transanal repair of rectocele. There was significantly lower recurrence rate of

P.882

rectocele in two trials comparing transvaginal to transanal approach, despite a higher blood loss and greater use of pain medication with the transvaginal approach.

FIGURE 38.20 Midline plication/traditional posterior colporrhaphy.

Sacrocolpoperineopexy

Abdominal or laparoscopic sacroperineopexy is very suitable in women who present with both apical and posterior pelvic organ prolapse. By extending the posterior part of the sacrocolpopexy graft down to the distal

vagina, both level I and II defects of the posterior vaginal wall can be corrected. However, it is not uncommon that the genital hiatus may remain enlarged with this approach as the distal 3 cm of the posterior wall support is provided by the perineal structures described above in detail. Posterior wall support cannot be restored completely without a level III repair, that is, perineorrhaphy.

OUTCOMES

Success Rate

Anatomic success rates have been reported to be 82% to 100% for site-specific repair. Similarly, anatomic cure was achieved in 80% to 96% of the patients with traditional posterior colporrhaphy. In a well-designed randomized study, Paraiso et al. compared these two native tissue methods with graft-augmented repair. At 1 year, they did not find any significant difference between 37 women who underwent traditional posterior colporrhaphy with midline plication (86%) and 37 women who were assigned to site-specific rectocele repair (78%). Abramov et al. retrospectively compared 124 women who underwent site-specific rectocele repair with 183 women who had midline plication with at least 1-year follow-up. They reported a significantly higher recurrence and symptomatic bulge rate in women who underwent site-specific repair (11% vs. 4% for both outcome measures).

Biologic and synthetic graft materials have been used in pelvic floor repairs in conjunction with both traditional and site-specific repairs to enforce the attenuated posterior vaginal wall. Although there have been large randomized trials of graft use in the anterior compartment repairs, there is insufficient evidence for guidance in the posterior compartment. There have been only two randomized trials that addressed graft use to the posterior compartment; however, both utilized porcine graft and did not show any benefit over native tissue repair. In fact, in the trial by Paraiso et al., anatomic outcomes were significantly worse for the graft arm (46%). In a subsequent larger randomized double-blinded trial of 137 women that compared native tissue repair, either midline plication or sitespecific techniques at the discretion of the surgeon, with those undergoing site-specific or traditional repair, augmented with porcine dermis. At 1 year, statistically similar anatomic success (about 90%) was accomplished in both groups. In both of these trials, surgical technique for graft placement such as the size, anchoring sites, and the plane of insertion of the graft was different from the method described in this chapter. Moreover, the outcomes may be different for polypropylene graft, which is a permanent implant, compared to the results from biologic

P.883

grafts, which are usually degraded by the immune system. Undoubtedly, more evidence is needed for guidance regarding graft use in the posterior vaginal compartment.

In the aforementioned randomized study by Paraiso et al., DD, splinting to defecate, straining, and fecal incontinence were significantly improved in all patients regardless of the approach at 1 year after the repair, but new-onset symptoms developed in 11% of the study participants. Of note, anatomic cure was associated with a reduced risk of straining or feeling of incomplete emptying. Sung et al. found that the prevalence of bowel symptoms including splinting, straining, incomplete evacuation, and obstructed defecation were all significantly improved. However, incomplete evacuation (19%), splinting (23%), and straining (37%) symptoms persisted in a considerable group of subjects. Those women who had the longest duration of splinting were found to have over a twofold increased risk for persistent splinting.

Sexual function has been an important concern for the surgeon performing posterior vaginal compartment repair. However, the studies reporting on sexual function have shown conflicting results. Even though traditional midline plication has been associated with postoperative dyspareunia (8% to 26%), especially in the setting of levator plication, a study on 38 women who underwent midline plication for a stage II or greater rectocele and obstructed defecation found dyspareunia significantly improved from 37% at baseline

to 5% postoperatively.

In some studies, postoperative dyspareunia has been associated with native tissue repairs of the posterior compartment regardless of the technique utilized. In the retrospective cohort study by Abramov et al., both site-specific (17%) and midline plication arms (16%) had similar postoperative dyspareunia rates. Of note, levator plication was not used in any arm of this study. In a cohort of 73 women undergoing surgery for urinary incontinence and/or pelvic organ prolapse, 30 women who had posterior repair with either type of native tissue techniques reported higher dyspareunia rates than those who did not. However, sexual function scores based on a validated sexual questionnaire indicated similar improvement in both groups. Graft use has always been associated with dyspareunia; however, in the randomized trial by Paraíso et al. mentioned above, sexual function significantly improved in all groups similarly regardless of the repair technique.

Although the place of perineorrhaphy has always been a subject of heated debate, little evidence exists for guidance in this area. The trial conducted by Paraíso et al. generated some evidence. They performed perineorrhaphy in 82 (78%) women across the study arms. Although it was not independently associated with anatomic success, postoperative dyspareunia, postoperative DD, or “any” postoperative splinting, women who had a perineorrhaphy reported about 12 times (odds ratio, 0.08) less bothersome splinting at 1-year postoperative assessment after controlling for treatment group and baseline symptoms.

Complications

Though uncommon, complications such as bleeding, rectal injury, hematoma, temporary urinary retention, and infection may occur after rectocele repair in the short term. In most studies on the posterior compartment including the randomized trials, the patients had other pelvic floor procedures; therefore, the rates of these complications attributable to posterior wall repairs are not clear. Across the studies, bleeding complications were approximately 1% to 3% and wound-related complications were about 5% to 10%.

In the immediate postoperative period, intractable pain in the posterior aspect of the thighs may be a sign of nerve entrapment of a branch of sacral roots in women who underwent concomitant sacrospinous or uterosacral ligament suspension. De novo dyspareunia is a delayed complication of posterior wall repairs. A detailed review of this is presented in the outcomes section above. Though very rare, complications such as rectovaginal fistula and fecal incontinence may also occur.

There are also complications specific to graft use such as graft exposure. Because biologic grafts were used in the aforementioned randomized trials, graft exposure was not a problem and, therefore, not reported. In one of these trials, wound-related problems were reported with no significant difference between the groups although the study was possibly not powered to analyze this outcome. The studies conducted to evaluate the outcomes of synthetic graft-based kits from medical device companies have not been very helpful to guide us for posterior vaginal wall repairs, as most of the available data come from studies performed on the anterior vaginal compartment.

POSTOPERATIVE CARE

Postoperative management will vary based on training and experience. After our procedures, the vagina is packed with either plain packing or packing lubricated with bacitracin ointment for easy removal the following morning. A Foley catheter is placed for overnight gravity drainage. It may be appropriate to use 1 to 2 g of estrogen cream with packing; however, we feel that using a large amount of estrogen, that is, an entire tube of 42 g of equine estrogen, immediately after pelvic surgery, may potentially increase the risk of thromboembolism in an elderly woman undergoing pelvic reconstructive surgery. The vaginal packing is removed just prior to the removal of the Foley catheter and voiding trial. Patients are discharged with narcotic pain medication, ibuprofen,

docusate, and recommendations to take fiber supplements twice daily in efforts to avoid constipation and straining. All postmenopausal women are advised to use vaginal estrogen starting a few months prior to the procedure and continue this medication postoperatively unless there is a contraindication to estrogen use.

All patients are contacted by phone 2 days after the procedure. Posterior vaginal repair, especially with perineorrhaphy, can be accompanied by significant perineal discomfort. The patient should be counseled extensively to set appropriate expectations about this problem. Often surprised by the degree of discomfort that is “normal” for these procedures, some patients need more reassurance. We advise, if tolerated, the use of ibuprofen every 6 to 8 hours for the first few days after surgery. Sitz baths may be helpful in alleviating some of this perineal discomfort. Since constipation is often an issue, we are very aggressive with the bowel regimen after surgery and in the postoperative period; docusate, fiber, polyethylene glycol, and magnesium-based laxatives can all be utilized in this time period. Patients should be advised to refrain from prolonged narcotic use because it may delay the first bowel movement and complicate postoperative recovery. It is important to prepare the patients for possible buttock pain in the pericoccygeal area when sacrospinous ligament suspension is utilized. Early ambulation is encouraged, but intercourse and any weightbearing activity or exercise should be avoided for 6 weeks.

In women who continue to have severe pain at 2 weeks after the procedure, a gentle rectovaginal exam should be performed to rule out hematoma formation. If this is the case, conservative care with pain medication and close observation will be sufficient. If the hematoma is too large to allow regular bowel movements, vaginal evacuation by separating the

P.884

vaginal incision slightly, followed by placement of a packing to stay overnight, is appropriate. Nerve entrapment should be closely monitored. If further neurologic evaluation confirms this condition, it should be relieved surgically by removing the suture causing the entrapment. For refractory pain, neuroleptics, physical therapy, trigger point injections, and finally suture or graft removal should be considered.

The most common site for graft exposure, though rare, is the distal vagina and likely due to wound separation or infection. It may also occur if the graft is placed too superficially between the epithelial and fibromuscular layers of the posterior vaginal wall. This may cause pain for the patient or her partner, spotting, and discharge. Vaginal estrogen occasionally may help for very small exposures. If the patient is asymptomatic, as may be the case in women who are not sexually active, and there is no recurrent prolapse, no further intervention may be necessary. When the patient requires a procedure for graft removal due to bothersome symptoms and there is no ongoing infection, the exposed graft with 1- to 2-cm margins should be removed after mobilization of the surrounding vaginal tissue. A layered closure over this site may be appropriate.

BEST SURGICAL PRACTICES

- A thorough history and physical examination assessing the patient’s symptoms, anatomic abnormalities, goals, and expectations from the treatment is essential for successful surgical planning in women with posterior compartment defects.
- DD is multifactorial. Not all defecatory problems arise from posterior compartment defects.
- Patients should be well prepared for postoperative perineal discomfort prior to posterior compartment repairs with perineorrhaphy.
- Posterior compartment repairs improve defecatory outcomes in most women; however, at least a third of women may continue to have DD.
- Rectoceles are caused by discrete tears of the fibromuscular layer at various points along the posterior vagina. Best efforts have to be made to identify all anatomic defects of the posterior compartment for a

successful and durable repair.

- Rectal examination prior to, during, and before vaginal closure is critical for identification of the defects and confirmation of restoration of normal anatomy.
- No vaginal reconstruction will be effective without addressing apical support.
- The perineal body constitutes level III support to the vagina. It is the site where most posterior compartment defects occur. Perineal restoration is an integral part of the posterior compartment repair.
- Although traditional plication of the vaginal fibromuscular layer has been shown to provide anatomic success rates similar to site-specific repair, the risk of dyspareunia is increased especially if levator plication is used. There may be functional consequences of turning a naturally conical vagina into a tube.
- Data on graft use in the posterior compartment derive from two randomized trials and are limited to porcine dermis. Though insufficient to make meaningful conclusions, these studies did not show any benefit of porcine graft in the posterior compartment repairs.
- Insufficient evidence exists for guidance regarding polypropylene graft use for posterior compartment defects. In addition, complications due to mesh insertion include, but are not limited to, mesh exposure and dyspareunia. Surgeons must counsel patients extensively with visual tools before surgery if they plan the use of polypropylene mesh in the posterior compartment.
- Selective use of polypropylene grafts may be appropriate in well-informed patients who have a history of previous surgical failure or have infrequent coital activity. Grafts must be inserted beneath full-thickness vagina through a short incision.

Chapter 39

Vaginal Vault Prolapse

Victoria L. Handa

DEFINITIONS

End-to-end anastomosis (EEA) sizer—One of a series of metal instruments that are used primarily to evaluate the size of the end-to-end bowel anastomosis. It is also an excellent instrument for distending and manipulating the vaginal apex from below, allowing the abdominal surgeon to easily feel the vagina and dissect against a firm surface ([Fig. 39.1](#)).

Levels of support defects (according to DeLancey classification)— Level I, apical defects caused by loss of support of the uterosacral ligaments, paracolpium, and parametrium; level II, disruption of the normal lateral attachments of the midvagina; and level III, lower vaginal defects in the perineal body or fusion of the distal urethra to the pubic bone.

Occult urinary stress incontinence—Stress incontinence that becomes apparent after treatment of apical vaginal prolapse. The presumed mechanism is resolution of urinary obstruction with correction of prolapse.

Uterine/cervical prolapse—Descent of the uterus or uterine cervix.

Vaginal vault prolapse—Descent of the vaginal vault (cuff scar after hysterectomy).

As women live longer and healthier lives, pelvic floor disorders continue to become even more prevalent and are an important health and social issue. The prevalence of symptomatic prolapse increases with increasing age. The lifetime risk of surgery for pelvic prolapse has been estimated at 7%. Clark et al. found that 12% of women undergo a second surgery within 6 years of the first procedure due to recurrence, and Denman et al. found the recurrence rate was 17% at 10 years. Thus, prolapse surgery is common, and reoperation is an important concern.

The management of pelvic organ prolapse can be challenging because different support defects often coexist and because of the variable effects on bowel, bladder, and sexual function. The pelvic surgeon must be adept in the thorough evaluation and management of these issues. An understanding of the anatomy and the relationship of the vagina to surrounding structures is imperative.

Our understanding of pelvic prolapse and the treatment thereof has changed in recent years. A number of theories have been proposed to explain the development of pelvic prolapse. It was formerly taught that prolapse resulted from attenuation or stretching of endopelvic fascia. Richardson, Lyon, and Williams challenged this theory by introducing the concept of discrete breaks in endopelvic fascia. However, microscopic studies have failed to identify a distinct histologic “fascia” along the anterior and posterior vaginal wall. Currently, it is now generally accepted that the dense tissue under the vaginal epithelium is muscularis rather than fascia. Also, Richardson's description of an enterocele as a separation of pubocervical fascia from rectovaginal fascia is at odds with microscopic studies of patients with enteroceles, which

P.886

have failed to identify peritoneum in contact with vaginal epithelium ([Fig. 39.2](#)). Work by DeLancey and colleagues has suggested that pelvic muscle weakness may play a critical role in the genesis of prolapse. Specifically, poor function of the levator ani muscle complex or detachment of the levator ani from the pubis may contribute to the development of prolapse for some women. Each of these theories contributes to our overall understanding of vaginal support.

FIGURE 39.1 Instruments useful for the manipulation of the vagina during sacral colpopexy. Shown are a commercially available disposable plastic stent (RUMI handle and Sacrocolpopexy Tip, CooperSurgical, Trumbull CT) and an end-to-end anastomosis (EEA) sizer. (Photo courtesy of Victoria L. Handa.)

FIGURE 39.2 Microscopic hematoxylin and eosin stain of the upper third of the vagina. The vaginal epithelium is at the top, and the rectal mucosa at the bottom.

FIGURE 39.3 Levels of support. DeLancey's biomechanical levels: level I, proximal suspension; level II, lateral attachment; and level III, distal fusion. (Reprinted from DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717, with permission. Copyright © 1992, Elsevier.)

DeLancey divided the support of the vagina into three levels ([Fig. 39.3](#)). This concept is helpful in understanding normal anatomic relationships and appreciating why certain repairs may work in some patients and not in others. Level I support defects are apical defects, which correspond to loss of support of the uterosacral ligaments, paracolpium, and parametrium. Level II support defects may represent loss of normal lateral attachment of the midvagina. Level III support defects correspond to loss in the support of the perineal body or distal urethra.

The goals of surgery for pelvic organ prolapse should be to restore anatomy and minimize symptoms. With respect to restoring anatomy, the main goal should be to suspend the vaginal vault as near as possible to its normal anatomic position. Magnetic resonance imaging ([Figs. 39.4](#) and [39.5](#)) demonstrates that the normal position of the vaginal apex is approximately 5 cm inferior to the second sacral vertebral body and approximately 5 cm medial to the ipsilateral ischial spine. Surgeries that recreate this anatomy will also accomplish the goal of suspending the vaginal apex over the levator plate. Distortion of the position of the vaginal apex, whether in an anterior or posterior direction, can contribute to dyspareunia and could contribute to recurrent prolapse opposite the vaginal vault.

It is extremely important to determine preoperatively whether lower urinary tract dysfunction, sexual dysfunction, and defecatory dysfunction exist. Surgery for pelvic organ prolapse may offer an opportunity to address other pelvic floor problems, including stress urinary incontinence and rectal prolapse. Stress urinary incontinence may be masked in patients with advanced pelvic organ prolapse by obstructing or kinking the urethra. Thus, assessment for “occult” stress incontinence (with reduction maneuvers) has been proposed to identify those patients who would benefit from an anti-incontinence procedure in conjunction with their pelvic reconstructive

surgery. However, the value of testing for “occult” incontinence remains controversial.

FIGURE 39.4 Sagittal MRI illustrating the relationship between the posterior vaginal fornix and the anterior surface of the middle of the second sacral vertebra.

Another controversy is the value of initiating local estrogen therapy preoperatively in patients who have urogenital atrophy. Cytologic and histologic changes in the vaginal epithelium are seen after as little as 3 weeks of therapy, and therefore, 3 to 6 weeks of preoperative vaginal estrogen may be recommended by some surgeons. However, the benefits of preoperative estrogen therapy have not been demonstrated.

FIGURE 39.5 Axial MRI illustrating the relationship between the left cervical vaginal junction (x) and the left ischial spine.

Many operations have been described for suspending the prolapsed vaginal vault. There is no general consensus on what is the best procedure. The choice of procedure is influenced by many factors, including the comfort and skill of the surgeon; whether the prolapse is primary or recurrent; the patient's age, state of health, and sexual activity; anticipated outcome; and overall state of the tissues.

PROCEDURES TO SUSPEND THE VAGINAL APEX

McCall Culdoplasty

Several operations have been described and used by surgeons for vaginal vault suspension with correction of concurrent enterocele. McCall (in 1957) described his technique of surgical correction of enterocele at the time of vaginal hysterectomy. He used several nonabsorbable sutures to obliterate the enterocele (internal McCall sutures) by approximating both uterosacral ligaments and a running suture through the posterior peritoneum (Fig. 39.6). Delayed absorbable sutures are then inserted through the full thickness of the posterior vagina just lateral to the midline and passed through each uterosacral ligament and back out the posterior vaginal wall. Additional external sutures are placed as required by the amount of prolapse. The internal sutures are then tied, and the external sutures are tied after the vaginal cuff is closed. This simple procedure obliterates the cul-de-sac, supports the vaginal apex, and lengthens the posterior vaginal wall. McCall originally reported on 45 cases and stated there was no incidence of enterocele recurrence.

STEPS IN THE PROCEDURE	
McCall Culdoplasty	

- The patient is positioned in high lithotomy position.
- The bladder is drained.
- If the procedure is done in the setting of vaginal hysterectomy, the hysterectomy is completed. If a hysterectomy was previously performed, the apex is grasped with Allis clamps and a colpotomy created.
- The enterocele is obliterated with nonabsorbable sutures, plicating the uterosacral ligaments and inter-vening peritoneum.
- A delayed absorbable suture is inserted through the full thickness of the posterior vagina (just lateral to the midline). The suture is then passed through each uterosacral ligament and back out the posterior vaginal wall.
- The permanent sutures are tied, obliterating the cul-de-sac.
- The delayed absorbable suture is tied, suspending the apex to the uterosacral ligaments.
- Cystoscopy is performed to evaluate ureteral patency and to exclude lower urinary tract injury.

FIGURE 39.7 With the vaginal cuff open, the surgeon palpates the posterior cul-de-sac and enterocele. **Inset:** The redundant wedge of posterior vaginal wall and peritoneum is removed. (Reprinted from Baggish MS, Karram MM. *Atlas of pelvic anatomy and gynecologic surgery*. New York, NY: Saunders, 2001, with permission. Copyright © 2001, Elsevier.)

Several modifications of McCall technique have been described, most notably the modified endopelvic fascia repair, also known as a “Mayo culdoplasty.” The enterocele is delineated, and the sac is then dissected free and excised at the neck (Fig. 39.7). A wedge of vaginal mucosa is removed from the anterior and posterior vaginal wall. This narrows the vault when closed. The ureters are identified by palpation bilaterally. One to three internal McCall sutures are placed as described above, using nonabsorbable suture. After these sutures are placed and tagged, modified external McCall sutures are placed by passing delayed absorbable sutures through the posterior vaginal wall and peritoneum, through remnants of uterosacral and cardinal ligaments on the patient's left. Several bites of peritoneum overlying the rectosigmoid are taken, and then the right perirectal fascia and uterosacral ligament are incorporated into the suture (Fig. 39.8). Last, the suture is passed back out through the posterior vaginal wall. The number of internal and external sutures placed depends on the size of enterocele and redundancy of the upper vagina. After these sutures are tied, the vaginal cuff is closed. There is a risk of ureteral injury or kinking, and therefore, ureteral patency should be confirmed at the conclusion of surgery.

In 1998, Webb reported on 693 women who underwent primary repair of posthysterectomy vaginal vault prolapse at the Mayo Clinic, including 660 who were treated with a Mayo culdoplasty. Among women followed for a mean of 7.4 years, 36/529 (7%) underwent further surgery for prolapse. Of 504 who completed a follow-up questionnaire, 80 (16%) reported symptoms of bulging or protrusion. While these results are encouraging, they are difficult to interpret without information regarding the severity of prolapse before surgery. It is also of note that 42 of 189 sexually active women (22%) reported dyspareunia at the time of follow-up.

FIGURE 39.8 **A:** Placement of internal (nonabsorbable) and external (delayed absorbable) McCall sutures. A wedge of posterior vaginal wall was previously removed. **B:** Cross section of the upper vagina and vaginal vault before tying these sutures. The inset illustrates the final result, after the sutures are tied. (Reprinted from Baggish MS, Karram MM. *Atlas of pelvic anatomy and gynecologic surgery*. Sacrospinous Ligament Fixation

The sacrospinous ligament is a cordlike structure that exists within the body of the coccygeus muscle. The sacrospinous ligament attaches medially to the sacrum and coccyx and attaches laterally to the ischial spine (Fig. 39.9). The complex is collectively called the coccygeus-sacrospinous ligament (CSSL) complex. The CSSL is best identified by palpating the ischial spine and tracing the fingerlike ligamentous structure

P.890

medially and posteriorly toward the sacrum. To perform sacrospinous ligament fixation, it is imperative that the surgeon be familiar with the anatomy of the sacrospinous ligament complex and of the pararectal space (Fig. 39.10). Obtaining adequate exposure is critical, and vascular complications, when encountered, may be life threatening. Superior to the ligament lie the inferior gluteal vessels and the hypogastric venous plexus. The pudendal nerve and vessels pass directly posterior to the ischial spine. The sciatic nerve, derived from the lumbosacral nerve roots, passes superior and lateral to the sacrospinous ligament. To avoid trauma to these structures, it is important to place the fixation sutures two fingers medial to the ischial spine.

FIGURE 39.9 Ligaments of the bony pelvis. The sacrospinous ligament extends from the ischial spine to the sacrum. The ligament is wider medially and narrows as it inserts on the ischial spine. The ligament lies within the coccygeus muscle (not shown).

FIGURE 39.10 The right CSSL complex and ischial spine (IS) are shown with respect to the course and relationships of the internal pudendal artery, inferior gluteal artery (IGA), lumbosacral trunk (LST), and sacral nerves (S1 to S5). Copyright © 2007, Elsevier.)

STEPS IN THE PROCEDURE

Sacrospinous Ligament Suspension

- The patient is positioned in high lithotomy position.
 - The bladder is drained.
 - If the procedure is done in the setting of vaginal hysterectomy, the hysterectomy is completed and the vaginal cuff is closed.
 - The surgeon identifies the intended vaginal apex.
 - The posterior vagina is incised longitudinally. The vaginal epithelium is dissected away to expose the rectovaginal space. If present, an enterocele is identified and repaired.
 - A window is created in the rectal pillar, and the pararectal space is entered.
 - A pair of Breisky-Navratil retractors is used to expose the CSSL complex.
 - Using a Miya hook or similar instrument, a permanent suture is passed through the CSSL, two fingers medial to the ischial spine. The loop of the suture is retrieved with a nerve hook, pulled through, and tagged. A second suture is placed, 1 cm medial to the first.
 - One end of each suspension suture is sewn into the undersurface of the vagina apex and tied by a half hitch.
 - The upper aspect of the posterior vaginal incision is closed.
 - Traction on the free end of each suspension suture pulls the vagina directly onto the ligament. The surgeon then ties a square knot to anchor the apex to the ligament.
 - Cystoscopy is performed to evaluate ureteral patency and to exclude lower urinary tract injury.
 - The vagina may be packed for up to 24 hours after the procedure.
-

Most surgeons prefer to use the sacrospinous ligament opposite their dominant hand; that is, the right-handed surgeon uses the right sacrospinous ligament, although some surgeons prefer to perform a bilateral fixation. The first step of the surgery is to identify the intended vaginal apex by elevating the vagina to the ligament using an Allis clamp. It may be necessary to choose a different fixation point than the original vaginal cuff scar. This is best illustrated in a patient with a foreshortened anterior segment and a large enterocele. In this case, the new fixation point would be moved to an area over the enterocele. After identifying the intended vaginal apex, marking sutures are helpful to identify this site throughout the operation.

A posterior vaginal incision is made and extended to the vaginal apex. The rectovaginal space is developed. Almost always an enterocele sac is present. The enterocele sac should be mobilized off the posterior vaginal wall up to its neck; the sac is then opened and the peritoneum excised. The defect is then closed with purse-string sutures.

The next step is entry into the perirectal space (**Fig. 39.11**). The rectal pillar separates the rectovaginal space from the perirectal space. A window must be created through the rectal pillar, which is best accomplished by blunt dissection just lateral to the enterocele sac over the ischial spine. The window can also be created with the tips of scissors, a tonsil clamp, or a hemostat. The window should be gently enlarged to accommodate the vagina. The sacrospinous ligament can then be palpated by palpating the spine and moving the fingers dorsal and medial. It may be necessary to use blunt dissection to remove excess tissue from the CSSL.

Once the window has been created and the ligament is identified, a Breisky-Navratil retractor is used to displace the rectum medially and to expose the CSSL complex (**Fig. 39.12**). Great care must be taken to avoid raking the retractor over the anterior surface of the sacrum and causing damage to presacral nerves and vessels.

Traditionally, the Deschamps ligature carrier was used to pass the suture through the sacrospinous ligament, but this may be more cumbersome than are other methods. We recommend a Miyazaki hook (Miya hook; [Fig. 39.13](#)) for placement of the suspension sutures. The Miya ligature carrier is easy to operate and facilitates penetration of the sacrospinous ligament under direct visualization.

P.891

FIGURE 39.11 After dissecting the rectovaginal space, the surgeon perforates the rectal pillar to enter the pararectal space. (Reprinted from Cruikshank SH, Cox DW. Sacrospinous ligament fixation at the time of transvaginal hysterectomy. *Am J Obstet Gynecol* 1990;162:1611-1619, with permission. Copyright © 1990, Elsevier.)

FIGURE 39.12 Two Breisky-Navratil retractors are used to expose the CSSL complex. One retractor is placed anteriorly. A second is used to retract the rectum medially. In this figure, a third retractor is placed inferiorly. Alternatively, a notched speculum ([Fig. 39.13](#)) can be used inferiorly. (Reprinted from Baggish MS, Karram MM. *Atlas of pelvic anatomy and gynecologic surgery*. New York, NY: Saunders, 2001, with permission. Copyright © 2001, Elsevier.)

FIGURE 39.13 Instruments for sacrospinous ligament suspension. Miya hook, notched speculum, and suture hook. (Reprinted from Walters MD, Karram MM. *Urogynecology and reconstructive pelvic surgery*, 2nd ed. St. Louis, MO: CV Mosby, 1999, with permission. Copyright © 1999, Elsevier.)

Palpation of the ischial spine identifies the correct location for the placement of the sutures, along the inferior half of the sacrospinous ligament, two fingers medial to the ischial spine. The ligament is exposed using a pair of Breisky-Navratil retractors, and a notched speculum is inserted. The notch can be used to guide placement of the suture. Nonabsorbable suture is used. There should be considerable resistance as the carrier is pushed through the body of the ligament. If no resistance is felt, the surgeon should suspect that the carrier either passed in front of or around the ligament. After the suture has been passed, the loop of the suture is retrieved with a nerve hook, pulled through, and tagged. A second suture is placed in a similar fashion approximately 1 cm medial to the first (Fig. 39.14). If a good purchase of tissue has been taken, the surgeon should be able to gently move the patient with traction of the suture.

Once the surgeon has the two sutures through the sacrospinous ligament, the vaginal vault can be suspended. There are two ways for the surgeon to attach the sutures to the vagina. The first is to use a pulley stitch. Here, one end of the suture is sewn into the full thickness of the fibromuscular layer on the undersurface of the vagina (excluding the epithelium) and then tied by a half hitch. Traction on the free end of the suture will pull the vagina directly onto the ligament. Suture bridging should be avoided, since this could predispose to recurrent prolapse. Once pulled into position, a square knot is used to fix the suture in place. A second technique involves passing each end of the sutures through the full thickness of the vagina. This technique requires the use of absorbable suture, however.

The upper portion of the posterior vaginal wall should be closed with interrupted or running 3-0 absorbable sutures before tying the colpopexy sutures. If the colpopexy sutures are tied before the proximal posterior wall is closed, the visibility of the vault is reduced, and this segment of the posterior vaginal incision is difficult to close.

After the colpopexy sutures are tied, a posterior colporrhaphy and perineorrhaphy are usually performed. If an anterior colporrhaphy is planned, this step is most easily accomplished prior to the sacrospinous suspension. At the conclusion of surgery, the vagina is then packed with moist gauze for 12 to 24 hours.

Injury to the ureter or obstruction due to ureteral kinking has been reported after sacrospinous suspension. Therefore, cystoscopy with assessment of ureteral patency should be performed at the conclusion of surgery.

FIGURE 39.14 Two sutures are passed through the sacrospinous ligament. (Reprinted from Baggish MS, Karram MM. *Atlas of pelvic anatomy and gynecologic surgery*. New York, NY: Saunders, 2001, with permission. Copyright © 2001, Elsevier.)

The overall results from sacrospinous fixation have been good. A 2007 systematic review suggested a low rate of apical prolapse beyond Baden-Walker grade 1 (7.2%, 95% confidence interval: 4.0% to 10.4%). Symptom relief was noted in approximately 90% of women across seven studies. However, recurrent prolapse of the anterior wall remains a long-term challenge after sacrospinous suspension. Specifically, one third of patients may experience recurrent prolapse to or beyond the hymen if all vaginal segments are considered.

Complications can occur, and the more common complications are discussed here. It is important to do a rectal examination during this procedure to make sure that no inadvertent proctotomy has occurred. If there is evidence of suture penetration, the offending suture should be removed and replaced. Lacerations should be closed in a standard two-layer fashion.

Hemorrhage can result from injury to the hypogastric venous plexus, inferior gluteal vessels, and internal pudendal vessels. Barksdale described the rich collateral circulate of these vessels, which also anastomose with the superior gluteal, vertebral, and sacral arteries. Vascular injury can occur from

overzealous dissection, from inappropriate needle passage, or from an improperly placed retractor. If bleeding occurs, pressure should be applied to the bleeding area. Continued bleeding should be addressed with suture

ligation, hemoclips, and possibly embolization. It has been noted that hypogastric artery ligation would likely be ineffective because the anterior division of the internal iliac artery is preferentially ligated during this procedure, and thus, the blood flow could actually increase to the branches of the posterior division (including the inferior gluteal artery). Thus, every effort should be made to control bleeding transvaginally.

Sutures that are placed too close to the ischial spine risk injury to the pudendal nerves and the sciatic nerve (Fig. 39.10). A patient who reports postoperative gluteal pain may have a pudendal nerve injury. Injury to the branches of the sciatic nerve will result in pain that also radiates down the posterior leg. In some cases, symptoms may be self-limiting or may resolve with conservative measures. However, prompt removal of permanent sutures should be considered if pain is severe or is associated with weakness, or if symptoms do not resolve. Improvement in buttock pain after removal of permanent sutures has been reported up to two years after surgery.

According to a 2010 Cochrane review, dyspareunia may be more likely after sacrospinous suspension than other apical suspensions. This may be due to narrowing of the vagina. Vaginal stenosis can occur if too much vaginal tissue is removed before closing the vaginal incision. An aggressive posterior repair can also cause a constriction ring. If a constriction ring is present while the patient is still under anesthesia, it should be addressed at that time. Also, there is some evidence that sacrospinous suspension is associated with a shorter vagina and a change in the vaginal axis. These factors could potentially contribute to dyspareunia.

Uterosacral Ligament Suspension

In 1997, Jenkins published a technique for transvaginal, intraperitoneal suspension of the prolapsed vagina from the uterosacral ligaments. A distinction between this technique and the earlier technique of McCall is that each uterosacral ligament is used to suspend the ipsilateral vaginal cuff and there is no attempt to plicate the ligaments across the midline. A second distinction is that the fixation of the vagina to the uterosacral ligament is at or above the level of the ischial spine. This technique presumes that the ligaments are detached from the vaginal apex but are preserved in their more proximal segments, allowing for a secure attachment of the vaginal apex. This technique is based on Richardson's theory of site-specific defect repair. After Jenkins published results in 1997, a similar technique was described in case series by Shull et al., Barber et al., and Karram et al.

STEPS IN THE PROCEDURE

Uterosacral Ligament Suspension

- The patient is positioned in high lithotomy position.
- The bladder is drained.
- If the procedure is done in the setting of vaginal hysterectomy, the hysterectomy is completed. If a hysterectomy was previously performed, the apex is grasped with Allis clamps and a colpotomy created.
- A Deaver retractor is placed anteriorly, and the abdominal contents are packed up and out of the pelvis with a moist, 4-inch Kerlix sponge.
- The uterosacral ligament is identified and grasped with a long Allis clamp. To identify the ligament, the surgeon may place traction on the vaginal cuff at 5 o'clock or 7 o'clock. Alternatively, the ligament may be palpated, medial and posterior to the ischial spine.
- By palpation, the surgeon confirms that the location grasped with the Allis is at the level of the ischial spine. A nonabsorbable suture is placed through the ligament, and a second suture is placed approximately 1 cm proximally.
- The same steps are repeated on the contralateral side.

- An anterior colporrhaphy is performed if indicated.
 - One arm of each suspensory suture is placed through the anterior cuff and the other arm placed through the posterior cuff, with the superior sutures placed more medially.
 - The sutures are tied down. The vaginal cuff is closed over the permanent suspension sutures.
 - Cystoscopy is performed to evaluate ureteral patency and to exclude lower urinary tract injury.
 - The vagina may be packed for up to 24 hours after the procedure.
-

Uterosacral vaginal vault suspension is performed with the patient in high lithotomy position. It can be performed immediately following a vaginal hysterectomy or in the setting of posthysterectomy prolapse. In the latter setting, two Allis clamps are used to grasp the vaginal apex. With traction on the Allis clamps, the vaginal epithelium overlying the vaginal apex is incised. The cul-de-sac is palpated for adhesions and any unsuspected pathology. If adhesions are present, they should be carefully taken down. The excess peritoneum is excised.

A Heaney retractor or Deaver is then placed anteriorly. The abdominal contents are carefully packed out of the pelvis with a moist, 4-inch Kerlix sponge. The retractor is withdrawn and then replaced so as to elevate the sponge and abdominal contents out of the pelvis, exposing the cul-de-sac (Fig. 39.15). Two Allis clamps are then placed where the remnants of uterosacral ligaments are believed to insert into the vaginal cuff, usually the 5-o'clock and 7-o'clock positions. With tension on the Allis clamp directed outward, the pelvic sidewalls are palpated. The ischial spine is palpated transperitoneally, and an attempt is made to palpate the ureter. If the uterosacral ligament is difficult to find, the Allis clamp can be repositioned. The ureter is usually found 2 to 5 cm ventral and lateral to the ischial spine. The ureter is best found by applying pressure to the pelvic sidewall with the tip of the index or middle finger and sweeping from an anterosuperior to a posteroinferior position.

The uterosacral ligament is identified at the level of the ischial spine. The ligament is grasped with a long Allis clamp and elevated (Fig. 39.15). By palpation, the surgeon confirms that the location grasped with the Allis is medial and posterior to the ischial spine. Then, under direct visualization, sutures are placed through the ligament with a long, straight needle

P.894

driver. The most distal suture is placed at the level of the ischial spine, and a second suture is placed approximately 1 cm proximally. This location is optimal for safety and also approximates the normal position of the vaginal apex. Once placed, these sutures are tagged and set aside. The packing is removed from the pelvis.

FIGURE 39.15 The uterosacral ligament sutures are placed through the vaginal cuff. One end of each suture is placed through the anterior cuff and one through the posterior cuff, including the peritoneum and the entire thickness of the vaginal wall with the exception of the epithelium. The suture that was placed more superiorly on the ligament is passed through the vaginal cuff more medially.

At this point, the surgeon should perform an anterior colporrhaphy if indicated. The tagged uterosacral sutures are then passed through the vaginal wall at the cuff, including the peritoneum and the entire vaginal wall with the exception of the epithelium. The superior sutures are placed through the vaginal cuff more medially, with the inferior suspensory sutures placed more laterally (Fig. 39.15). After one arm of each suspensory suture has been placed through the anterior cuff and the other arm placed through the posterior cuff, the two medial sutures are tied down, bringing the cuff into high apposition with the uterosacral ligament on either side. After the suspension, cystoscopy is performed. Administration of a coloring agent, such as preoperative oral phenazopyridine or intraoperative intravenous methylene blue, is recommended to demonstrate ureteral patency. The final step is closure of the vaginal cuff over the suspensory sutures. A meticulous closure is necessary to minimize the risk of suture exposure.

Some surgeons elect to perform the uterosacral suspension with delayed absorbable suture. A rationale for using delayed absorbable suture is the incidence of exposure or erosion of permanent sutures after uterosacral suspension. Suture exposure may be asymptomatic or may present with bleeding, discharge, dyspareunia, or pain. The incidence of this complication is unknown. Yazdany et al. reported suture erosion in 37 out of 83 patients (44%). In contrast, Kasturi et al. observed suture erosion in 22%, while Chung et al. reported an incidence of 9%. Typically, suture exposure is relatively easy to address in an office setting, with excision of the exposed suture. This complication can be prevented through the use of delayed absorbable suture for the suspension. However, there is controversy regarding whether the effectiveness of the surgery is reduced by the use of delayed absorbable suture. Chung and colleagues reported a higher incidence of prolapse recurrence in the first year if delayed absorbable sutures were used. If delayed absorbable suture is used, the suspension

sutures can be passed through the full thickness of the posterior vaginal wall.

A recent systematic review by Margulies suggested a high success rate for uterosacral suspension of the vaginal vault. Specifically, “optimal” (POP-Q stage 0) or “satisfactory” (POP-Q stage 1) at the apex was observed in 98.3% (95% confidence interval: 95.7% to 100%). Support of the anterior vagina was achieved less often: stages 0 to 1 in 81.2% (95% confidence interval: 67.5% to 94.5%). Also, in the anterior compartment, preoperative prolapse severity was noted to influence postoperative success. Specifically, success for women presenting with preoperative stage II prolapse was 92% versus a success rate of only 66.8% for women presenting with stage III prolapse. Based on these observations, it is our preference to reserve this procedure for women with stage II prolapse.

A potential complication of high uterosacral suspension is ureteral injury or kinking. Karram and colleagues reported a 2.4% risk, Barber and colleagues reported an 11% risk, and Shull and colleagues reported a 1% risk. It is imperative that intraoperative cystoscopy be done to ensure ureteral patency. If ureteral spill is not observed, then the suspension sutures on that side should be cut and removed and the ureter reevaluated. Often, the suture can be replaced using a more medial placement into the uterosacral ligament complex.

Another potential complication of uterosacral suspension is injury to the sacral nerve roots ([Fig. 39.16](#)). This should be suspected in patients presenting with new-onset buttock and/or thigh pain, numbness, or weakness. Chung and colleagues observed this complication in 8 out of 515 patients (1.6%) after uterosacral suspension. A significantly higher incidence was reported by Montoya (19 out of 278 women [6.8%]). Anatomic studies have demonstrated that the sacral nerve roots pass under the uterosacral ligament and are potentially vulnerable to suture entrapment. The risk of nerve injury may be minimized by elevating the ligament with an Allis clamp prior to placing the suspension sutures and by placing sutures within 1 to 2 cm of the ischial spine, rather than more proximally. When recognized, symptoms suggestive of nerve injury may be managed conservatively. However, removal of suspension sutures should be considered if pain is severe or persistent.

Abdominal Sacral Colpopexy

Suspension of the vagina to the sacral promontory or into the hollow of the sacrum with an intervening mesh has been shown to be an effective treatment for vault prolapse. This procedure restores the vaginal apex close to the normal anatomic position, approximately 1 cm anterior and 5 cm inferior to the second sacral vertebra.

P.895

STEPS IN THE PROCEDURE

Sacrocolpopexy

- The patient is positioned in Allen stirrups.
- The bladder is drained.
- A low transverse abdominal incision is created, and the peritoneal cavity is entered. The abdominal contents are packed out of the pelvis. If a uterus is present, a total or supracervical hysterectomy is performed.
- An EEA sizer or similar manipulator is placed in the vagina. The surgeon dissects the bladder and rectum off the vagina.
- A 2- to 3-cm-wide graft of polypropylene is attached to the vagina, with one anterior and one posterior arm. The graft is sewn in place with interrupted sutures of nonabsorbable monofilament.
- The presacral space is entered and the peritoneal incision extended from the cul-de-sac to sacral promontory, keeping the right ureter in view.

- The ventral surfaces of the S1 and S2 vertebral bodies are exposed. Two to three nonabsorbable sutures are placed through the anterior ligament, with care to avoid injury to the middle sacral vessels. The sutures are tagged.
 - Both ends of each suture are passed through the polypropylene graft and tied down. The graft should be in contact with the ligament (without intervening suture bridges). When the sutures are tied down, the vagina should be elevated without tension on the graft.
 - Cystoscopy is performed to evaluate ureteral patency and to exclude lower urinary tract injury.
 - Before the abdomen is closed, the peritoneum is closed over the graft.
-

The patient is placed in Allen stirrups and is prepped and draped. A Foley catheter is placed; a three-way Foley may be useful if the surgeon anticipates distending the bladder to aide in the dissection of the bladder away from the adjacent vagina.

A laparotomy incision is made via a low transverse or vertical midline approach. Moist laparotomy sponges are then used to pack the bowel into the upper abdomen. Any adhesions should be carefully taken down. The course of the ureters and the cul-de-sac should be inspected and palpated. If the patient has a uterus, a hysterectomy should be done first and the cuff closed. It is our practice to perform total hysterectomy, although some surgeons recommend supracervical hysterectomy as a strategy to minimize mesh exposure at the vaginal cuff. Variations of the sacrocolpopexy in which the uterus is retained have been described, but the outcomes of “sacral hysteropexy” are not established.

The vagina is then elevated using an EEA sizer or similar instrument ([Fig. 39.1](#)). The peritoneum is then dissected off the anterior vaginal wall. The peritoneum on the posterior aspect of the vagina is incised in the midline and carried down into the cul-de-sac. The peritoneum is then dissected free laterally. A synthetic polypropylene mesh is then prepared. The mesh is prepared as two separate straps, each 2 to 3 cm wide. Additional width increases the total surface of synthetic material without any proven benefit. Although we prefer two separate straps of mesh, other potential configurations have also been described. For example, some surgeons prefer using a “Y” mesh.

FIGURE 39.16 The sacral nerve roots course under the uterosacral ligament as they pass laterally to exit the greater sciatic foramen. The S4 nerve root passes under the ligament less than 1 cm from the ischial spine, while the S3 root and S2 root pass under the ligament 1.5 cm and 2.6 cm cephalad to the spine, respectively. (Reprinted from Siddique SA, Gutman RE, Schön Ybarra MA, et al. Relationship of the uterosacral ligament to the sacral plexus and to the pudendal nerve. *Int Urogynecol J Pelvic Floor Dysfunct* 2006;17:642, with permission. Copyright © 2006, Springer.)

The sizer is then used to direct the vagina toward the S1 or S2 vertebra. This will allow the surgeon to identify the site along the vaginal wall that will be the new apex. A critical point is that the apex should be selected to provide adequate elevation to both the anterior and posterior vaginal walls without putting excessive tension on either vaginal wall.

A strap of mesh is then sutured to the anterior vagina using interrupted nonabsorbable sutures, placed 1 to 2 cm apart. We prefer monofilament sutures, as these may reduce the risk of graft/suture erosion when compared to braided sutures. We suture the distal aspect of the mesh first. In some cases, it may be easier to place the first (most distal) suture through the vaginal wall, tag the free ends, and then feed both ends of the suture through the mesh. The suture can then be tied. A second mesh strap is fixed to the posterior vagina using a similar technique. The suture should incorporate the full thickness of the vaginal wall without entering the vaginal lumen. The benefit of the EEA sizer is that penetration into the vagina is easily detected by the tactile sensation of the needle on the metal sizer. If two independent straps of mesh are used, the anterior mesh is sewn to the posterior mesh just proximal to the vaginal apex.

FIGURE 39.17 Vascular anatomy of the presacral space. The vessel closest to the sacral promontory (*) is the left common iliac vein (LCIV), which is 2.7 cm from the midline. Also adjacent to the promontory is the middle sacral artery (MSA), middle sacral vein (MSV), and lateral sacral veins (LSV). (Reprinted from Wieslander CK, Rahn DD, McIntire DD, et al. Vascular anatomy of the presacral space in unembalmed female cadavers. *Am J Obstet Gynecol* 2006;195:1736, with permission. Copyright © 2006, Elsevier.)

FIGURE 39.18 The sacral promontory, with permanent sutures placed through the longitudinal ligament of sacrum. (Reprinted from Baggish MS, Karram MM. *Atlas of pelvic anatomy and gynecologic surgery*. New York, NY: Saunders, 2001, with permission. Copyright © 2001, Elsevier.)

The point of attachment for the suspension graft is the anterior longitudinal ligament ([Fig. 39.9](#)). Ideally, the graft is attached at the level of S1 or S2. To expose the ligament, the peritoneum over the sacral promontory is opened and this incision carried down over the anterior surface of the sacrum. The surgeon should be mindful of the position of the bifurcation of the vena cava; the left iliac vein is typically within 2 cm of the sacral promontory and is the structure most vulnerable as the peritoneum is opened at the promontory ([Fig. 39.17](#)). The hypogastric plexus may be present at the sacral promontory, although it is not typically grossly evident. With the peritoneum reflected, the middle sacral artery and vein are identified. The sacral promontory and the anterior longitudinal ligament are then exposed by blunt and delicate dissection.

The peritoneum is opened into the cul-de-sac. Alternatively, a subperitoneal tunnel can be created into the cul-de-sac by blunt and sharp dissection. The goal is to place the graft retroperitoneally.

Two to four sutures of 0 nonabsorbable sutures are placed through the longitudinal ligament over the sacral promontory ([Fig. 39.18](#)). The polypropylene graft is elevated, and the surgeon adjusts tension on the graft to provide adequate elevation of the vagina without excessive tension. The sutures are placed through the graft and tied to bring the graft to the surface of the sacrum without an intervening suture “bridge” ([Fig. 39.19](#)). Excessive graft material is trimmed.

The peritoneum is then closed with a 2-0 or 3-0 absorbable suture, continuing over the anterior vaginal wall (thereby covering the mesh). Cystoscopy is performed to confirm ureteral patency as well as an absence of

FIGURE 39.19 Attachment of the mesh to the sacrum. The peritoneum has been closed over the entire length of the graft. (Preoperative vault prolapse is shown in the inset.) (Illustrated by Samantha Welker.)

The vagina is inspected and evaluated for any remaining support defects. Occasionally, a posterior colporrhaphy and a perineoplasty are also required.

Although the exact indications for abdominal sacral colpopexy are controversial, many surgeons use it as their primary surgery for all cases of posthysterectomy vault prolapse. We typically recommend abdominal sacral colpopexy for patients with stage III support, young patients with advanced prolapse, patients who have previously failed a vaginal approach, patients who have a foreshortened vagina, or patients who have other coexisting conditions that predispose to subsequent failure.

It has been shown by multiple investigators that abdominal sacral colpopexy is a durable and strong surgical correction for vaginal vault prolapse. Excellent results have been reported by many centers. A 2004 review suggested that durable support at the vaginal apex is obtained in more than 90%, although most studies have less than 2 years of follow-up and few have used validated instruments to assess symptoms. Recent long-term data were provided by the Pelvic Floor Disorders Network. Investigators followed 215 women for up to 7 years after sacropexy. Of the 215 women, 149 underwent physical examinations for prolapse assessment. By 7 years, 31 of 149 women (21%) had anatomic prolapse recurrence; 11 women (7%) had apical recurrence. Of 31 with anatomic prolapse recurrence, 16 (52%) were symptomatic. This suggests that the process of deteriorating pelvic support is not completely prevented by sacrocolpopexy and that long-term studies are required to identify the best approaches.

Perioperative complications of sacrocolpopexy include ileus, small bowel obstruction, and wound complications, as would be expected from any procedure addressed via laparotomy. Bladder and ureteral injury are rare (<3%). Hemorrhage, especially from presacral vessels, can be lifethreatening. Hemostasis can be difficult because damaged presacral vessels tend to retract beneath the bony surface. Sutures, hemoclips, and bone wax should be used initially. If these measures fail, then sterile thumbtacks can be employed. These stainless steel thumbtacks should be placed on the retracted bleeding vessel.

The most common long-term complication has been exposure of synthetic mesh in the vagina, which occurs in 3% to 4%. Exposure can present years after sacropexy. Removal of the eroded mesh can be done via an abdominal or vaginal route. We prefer a vaginal approach, because approximately 50% of mesh exposures resolve with excision of the exposed mesh via the vaginal route. With the patient prepped and draped, as much of the mesh as possible is exposed. The mesh is cut as high as possible and

P.898

removed. The vaginal edges are then trimmed and closed in layers. Vaginoscopy (with a zero-degree scope, such as a 5-mm laparoscope) can improve visibility, especially when the vaginal apex is high.

LAPAROSCOPIC AND ROBOTIC APPROACH TO VAGINAL SUSPENSION

The techniques and concepts described for sacral colpopexy can also be approached via laparoscopy, with or without robotic assistance. The laparoscopic approach to the patient for positioning, port placement, and equipment is described elsewhere. The laparoscopic approach to these procedures requires patience, attention to detail, and the realization that there is a steep learning curve. Studies comparing robotic, laparoscopic, and open sacrocolpopexy suggest similar short-term outcomes with respect to pelvic organ support, although costs and short-term complications may differ between these approaches. A critical point is that the route of surgery is not as important to patient outcomes as are the underlying surgical principles. It is our belief that the operation and subsequent outcomes should not be compromised for the purpose of having achieved the operation by this approach. Therefore, the surgical measures taken to achieve the underlying concepts should not be significantly altered or changed.

THE OPTIMAL APPROACH TO PELVIC PROLAPSE

Expert opinion differs as to the most appropriate approach to pelvic organ prolapse. Benson and colleagues randomized patients with prolapse to abdominal sacral colpopexy versus bilateral sacrospinous ligament fixation. They found superior results with abdominal sacral colpopexy. The reoperation rate was 16% in the abdominal group and 33% in the vaginal group. Optimal results were obtained in only 29% of the vaginal group and 58% of the abdominal group. The time of operation was longer for the abdominal group. Lo and Wang also reported higher success rates with abdominal sacral colpopexy than sacrospinous fixation, and Maher and associates reported similar success rates. In summary, these three prospective trials found that sacrocolpopexy has a higher success rate than sacrospinous suspension.

Based on a review of these trials, a recent Cochrane review concluded that recurrent vault prolapse was significantly less common after sacrocolpopexy than sacrospinous suspension (relative risk, 0.23; 95% confidence interval, 0.07 to 0.77). However, this conclusion is based on only three randomized trials, with relatively short-term outcomes and limited information about quality-of-life and subjective patient outcomes. Also, when compared to sacrocolpopexy, the sacrospinous suspension was found to be quicker, cheaper, and associated with an earlier return to activities of daily living. In selected cases, a potential advantage of the sacrospinous suspension is that the procedure does not require entry into the peritoneal cavity. We are not aware of randomized trials comparing sacrocolpopexy versus McCall culdoplasty or uterosacral suspension procedures. However, Denman and colleagues found that an abdominal approach to prolapse repair significantly reduced the odds of reoperation compared with the vaginal approach (hazard ratio, 0.37; 95% confidence

interval, 0.17 to 0.83; $P = 0.02$).

It is our opinion that no one surgical approach is appropriate for all patients. Surgeons must be adept at multiple approaches and procedures to effectively care for all patients. In general, given the available evidence, we prefer to approach most cases of stage II prolapse transvaginally, reserving abdominal sacral colpopexy for patients with stage III support and for those who have failed a previous vaginal approach. Obliterative procedures including partial Le Fort or complete colpocleisis are highly effective options for women who are no longer sexually active.

ROLE OF HYSTERECTOMY IN PROLAPSE REPAIRS

Hysterectomy with repair of pelvic support defects is standard practice for most parts of the world. However, more attention has been placed on uterine preservation when undergoing surgery for prolapse repairs. It is not known whether the surgical modifications required to perform these surgeries with uterine preservation would impact surgical results or complications. Three studies by Maher and associates, Hefni and colleagues, and van Brummen and associates failed to show a decrease in prolapse recurrence if hysterectomy was performed. There are no prospective studies comparing sacrocolpopexy with and without hysterectomy. More research is needed to understand the impact of hysterectomy on anatomic and functional outcomes when performing prolapse surgery.

OBLITERATIVE PROCEDURES

Le Fort Partial Colpocleisis

At times, patients may be sufficiently bothered by uterovaginal or vault prolapse, but they are poor candidates for major reconstructive surgery because of their overall medical condition. An obliterative procedure may then be a good approach for these women. A Le Fort procedure is an option if the patient has her uterus and is no longer sexually active. Because the uterus is retained, it will be difficult to evaluate any future uterine bleeding or cervical pathology. Therefore, evaluation for upper genital tract pathology (potentially including transvaginal ultrasound and/or endometrial biopsy) and Papanicolaou smear must be done before surgery. It is our practice to pursue a different approach for women who require surveillance of upper tract pathology, such as women with a history of preinvasive conditions of the cervix or endometrium.

STEPS IN THE PROCEDURE

Le Fort Colpocleisis

- The patient is positioned in high lithotomy position.
- The bladder is drained.
- The cervix is grasped, and rectangles are marked on the anterior and posterior vagina. The proximal edge of each rectangle should typically be 2 cm distal to the cervix (to allow room for the cervix once the walls are approximated). The distal edge of the anterior rectangle is at the bladder neck, with a corresponding location selected posteriorly. Lateral channels should be left.
- These rectangular areas are injected with a dilute solution of vasopressin, and the marked segments of vaginal epithelium are removed by sharp dissection.
- The edges of the rectangle and denuded vaginal wall are closed in successive rows, using delayed interrupted sutures. As successive rows of sutures are placed and tied, proceeding from proximal to distal vagina, the uterus and vaginal apex are gradually turned inward.
- An aggressive perineorrhaphy should be done to narrow the introitus.

- Cystoscopy is performed to evaluate ureteral patency and to exclude lower urinary tract injury.

P.899

The procedure is started by placing the cervix on traction to evert the vagina. A marking pen or scalpel is used to mark out the areas that are to be denuded both anteriorly and posteriorly (Fig. 39.20). Anteriorly, a rectangle of vaginal epithelium should be marked from approximately 2 cm distal to the cervix to the level of the bladder neck. A mirror image on the posterior vaginal wall should also be marked out. It is critical that these rectangles be selected such that there is sufficient room proximally for the cervix (e.g., after suturing the proximal edges to each other). In addition, a channel should be left on either side of the vagina, with a diameter that is sufficient to allow drainage of blood and cervical secretions but small enough that the cervix cannot prolapse through the channel.

The previously marked areas are injected with a dilute solution of vasopressin (such as 20 units in 30 mL sterile saline). The marked segments of vaginal epithelium are removed by sharp dissection (Fig. 39.21). The surgeon should leave the maximum amount of fibromuscular vaginal wall behind on the bladder and rectum. Hemostasis is an absolute must.

The cut edges of the anterior and posterior vaginal wall are sewn together with rows of interrupted delayed absorbable sutures (Fig. 39.22). The knot should be turned into the epithelium-lined tunnels that were created bilaterally. As successive rows of sutures are placed and tied, the uterus and vaginal apex are gradually turned inward (Fig. 39.23). After the vagina has been inverted, the distal margins of the rectangle can be sutured. In some cases, an anti-incontinence procedure may be indicated to treat stress incontinence or to prevent postoperative stress incontinence. Also, an aggressive perineorrhaphy should be done to narrow the introitus.

FIGURE 39.20 Rectangles of vaginal mucosa are marked on the (A) anterior vagina and (B) posterior vagina. A 2-cm gap is left between the rectangles to allow for the creation of drainage channels. (Reprinted from Bent AE, Cundiff GW, Swift SE. *Ostergard's urogynecology and pelvic floor dysfunction*, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission. Copyright © 2007, Lippincott Williams & Wilkins.)

FIGURE 39.21 The vaginal epithelium is removed. (Reprinted from Bent AE, Cundiff GW, Swift SE. *Ostergard's urogynecology and pelvic floor dysfunction*, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission. Copyright © 2007, Lippincott Williams & Wilkins.)

Due to the potential for ureteral or bladder injury, intraoperative cystoscopy is recommended. Other perioperative

P.900

complications are rare. Because Le Fort colpocleisis is typically reserved for elderly or medically compromised women, the most common perioperative complications are related to their underlying medical and surgical risks. Surgical site infection is rare, although cases of pyometra have been reported months or years after colpocleisis.

FIGURE 39.22 The colpocleisis is closed in rows. **A:** The first row of interrupted delayed absorbable sutures is

placed along the proximal edge of the dissection. **B:** As sutures are tied down, the excised rectangles are brought together. (Reprinted from Bent AE, Cundiff GW, Swift SE. *Ostergard's urogynecology and pelvic floor dysfunction*, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission. Copyright © 2007, Lippincott Williams & Wilkins.)

Long-term results of colpocleisis are excellent. Case series have suggested a cure rate of 90% to 100%. In a recent multicenter study, colpocleisis was associated with high patient satisfaction among 152 women. One year after surgery, 73% had stage 0 to 1 support and an additional 20% had stage 2 support. Ninety-five percent were “satisfied” or “very satisfied.”

FIGURE 39.23 Interrupted absorbable sutures are placed in rows to reapproximate the vaginal muscularis. As each row is placed, the vagina gradually inverts. Laterally, the vaginal drainage channels are preserved. (Reprinted from Bent AE, Cundiff GW, Swift SE. *Ostergard's urogynecology and pelvic floor dysfunction*, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission. Copyright © 2007, Lippincott Williams & Wilkins.)

Colpectomy and Colpocleisis

For patients with posthysterectomy vault prolapse who do not desire coital function and for whom operative time is to be kept at a minimum, a colpectomy and colpocleisis can be done to treat the prolapse.

The distinction between this approach and a Le Fort colpocleisis is that the former technique does not require the creation of lateral drainage channels. Thus, the entire vaginal epithelium is removed ([Fig. 39.24](#)). It is our practice to limit the dissection to the vaginal segment superior to the bladder neck. This allows future suburethral access if needed. After the vaginal mucosa is completely excised from the underlying

P.901

P.902

endopelvic fibromuscular vaginal wall, series of purse-string sutures are used to invert the prolapse ([Fig. 39.24](#)). Once the prolapse is reduced, an aggressive perineorrhaphy is done to narrow the introitus. Cystoscopy should be performed at the conclusion, with verification of ureteral patency.

FIGURE 39.24 Colpectomy and complete colpocleisis. **A and B:** After subcutaneous infiltration with lidocaine or bupivacaine hydrochloride in 1/200,000 epinephrine solution, the vagina is circumscribed by an incision at the site of the hymen and marked into quadrants. Each quadrant is removed by sharp dissection. **C:** Purse-string delayed absorbable sutures are placed. The leading edge of the soft tissue is inverted by the tip of a forceps. Purse-string sutures are tied 1 before 2 and 2 before 3, with progressive inversion of the soft tissue before the tying of each suture. **D:** The final relationship is shown in cross section. A perineorrhaphy is also usually performed. (Reprinted from Baggish MS, Karram MM. *Atlas of pelvic anatomy and gynecologic surgery*. New York, NY: Saunders, 2001, with permission. Copyright © 2001, Elsevier.)

CONCLUSION

Our understanding of the anatomy and concepts of pelvic organ prolapse and its treatments are constantly evolving. This evolution will and must continue to facilitate our understanding of the complex and varied etiologies of pelvic organ prolapse. Surgical treatments must restore both anatomy and address functional derangements. This evolution will also provide insight into preventive measures for women at risk for pelvic

organ prolapse and pelvic floor dysfunction. We, as pelvic surgeons, must continue to evaluate and apply new principles and techniques to established surgical dictums. There must be continued research, education, and a thoughtful, honest comparison of long-term surgical outcomes if we are going to continue to improve our care to a growing number of afflicted but active patients.

BEST SURGICAL PRACTICES

- The ultimate goal of pelvic reconstructive surgery is to restore anatomy, maintain or restore visceral function, and maintain or restore sexual function.
- The McCall culdoplasty and its various modifications are well-established transvaginal techniques to suspend the vaginal apex. Approximately two to three permanent sutures are used to plicate the uterosacral ligaments. The Mayo Clinic technique excises a wedge of vaginal wall, with repair of any enterocele that is present.
- For stage II vaginal prolapse, the sacrospinous ligament fixation is a useful extraperitoneal technique. Surgeons should be very familiar with the anatomy and experienced with the procedure. Injury to the pudendal nerve or vessels can cause serious injury or life-threatening hemorrhage. One third of patients may experience recurrent prolapse, especially pertaining to the anterior vaginal wall.
- An alternative is transvaginal uterosacral suspension of the vagina. The surgeon fixes the vaginal cuff to the uterosacral ligaments at the level of the ischial spine. Long-term outcomes are excellent, although preoperative prolapse severity affects postoperative success.
- Abdominal sacral colpopexy may be preferred by some surgeons for the treatment of severe (stage 3 to 4) prolapse and recurrent prolapse after a prior surgical failure and for women felt to be at high risk for recurrence. The anterior and posterior vaginal walls are supported to the longitudinal ligament of the sacrum using synthetic mesh.

Chapter 40

Nonsurgical Management of Pelvic Organ Prolapse: The Use of Vaginal Pessaries and Pelvic Floor Muscle Training

Chi Chiung Grace Chen

Jaime B. Long

DEFINITIONS

Occult and de novo stress urinary incontinence—Although occult incontinence refers to preexisting incontinence that only becomes symptomatic after prolapse reduction and de novo incontinence refers to new incontinence symptoms that develops after an intervention, these terms are often used interchangeably in the literature.

Pelvic organ prolapse—Descent/herniation of the anterior vaginal compartment (cystocele, urethrocele), apical compartment (uterine or vaginal vault prolapse), and/or posterior compartment (rectocele, sigmoidocele, perineocele, enterocele).

P.904

Pelvic floor muscle training—Exercises aimed to improve the strength and function of the pelvic floor muscles. **Pelvic Organ Prolapse-Quantification (POP-Q) system**—Validated and widely accepted standardized scoring system used to measure the degree and type of pelvic organ prolapse; includes an assessment of vaginal length, genital hiatus, and perineal body; see [Chapter 36](#).

Pessary—Device inserted into the vagina for reduction of pelvic organ prolapse.

Stress urinary incontinence—Involuntary urinary leakage with effort or exertion or with sneezing or coughing as defined by the International Consultation on Incontinence.

Urge urinary incontinence—Involuntary urinary leakage accompanied by or immediately preceded by urgency as defined by the International Consultation on Incontinence.

Vaginal splinting—Digital reduction of prolapse tissue to facilitate urination and/or defecation.

Pelvic floor disorders such as pelvic organ prolapse (POP) are common and costly conditions that will be encountered by any practitioner who cares for women, especially older women. From the 2005 to 2006 National Health and Nutrition Examination Survey of 1961 nonpregnant women, Nygaard et al. reported that the prevalence of symptomatic POP was noted to be 2.87% (3.3 million). Wu et al. in 2009 reported that Due to the aging population, the prevalence of symptomatic prolapse is estimated to increase 46% (4.9 million) by 2050.

According to Olsen et al., in the United States it is currently estimated that by the age of 80, women have an 11% chance of undergoing surgery for POP or urinary incontinence with a reoperation rate of 30%. Subak et al. estimated that over 1 billion dollars are spent and over 300,000 procedures are performed annually to surgically treat prolapse; however, surgery is just one approach, and providers caring for women with this condition should be familiar with conservative options. In comparing the prevalence estimates and the number of surgeries that are performed, it is clear that many women with prolapse either choose conservative strategies or go without treatment. This observation, coupled with the high rates of surgical failure and reoperation, underscores the importance of understanding conservative management options for prolapse and discussing these options with patients. This chapter reviews the available data and recommendations on pessary use and pelvic floor muscle training (PFMT) for POP.

Pessaries have been in use for thousands of years, and although vigorous scientific trials regarding their use are only beginning to emerge, years of expert opinion and experience continue to support and guide clinical decisions. Pessaries are also utilized for urinary incontinence, uterine retroversion, and obstetric indications such as cervical insufficiency; however, this chapter focuses specifically on their use for POP.

PFMT involves exercises aimed to improve the strength and function of the pelvic floor muscles. These exercises are often performed with a physical therapist and may also involve education on lifestyle modifications such as weight loss and avoidance of heavy lifting. Although these interventions are well researched and considered first-line treatment in other pelvic floor disorders such as stress, urge, and mixed urinary incontinence, this chapter focuses specifically on the

HISTORY OF PESSARY

The term “pessary” is derived from the Greek word “pessós,” which is an oval stone used in certain games. This term was originally used to describe oval stones that were inserted into the uteri of camels for contraception and later was used to describe other intrauterine devices.

Throughout history and into modern times, there has been a clear consensus that the ideal conservative treatment for prolapse involves reducing the prolapse with a lubricating substance followed by placement of an object inside the vagina to prevent re prolapse. What has changed are the methods and materials involved in this process. According to Shah and colleagues and Oliver and colleagues, the first reference of uterine/vaginal prolapse and “remedies to allow the womb of a woman to slip into its place” was from the Ebers papyrus, which dates back to as early as 1550 BC. Some of these remedies include the use of honey and petroleum to reduce the prolapse as well as the use of fumes and astringents to penetrate the uterine cavity so that it would revert back into the body.

At the time of Hippocrates (400 BC), many physicians prescribed succussion therapy, which involved hanging the patient upside down from her feet and moving her up and down as to return the prolapsed organ back into the body. Various agents were used to facilitate this process, including hot oil. Earliest pessaries were fashioned from a variety of materials such as an astringent-soaked plug of wool and half a pomegranate soaked in wine. Several methods were described to hold the prolapse and/or pessary in place, including leg binding and bed rest with the foot raised above the level of the head.

In addition to the above methods, Soranus of Ephesus (98 AD) in his treatise *Gynaecology* believed that placing herbs that emit pleasant odors around the patient's head would entice the prolapse to ascend. This was coupled with placing astringents that emit foul odors around the vagina to force the prolapse back into the body. He recommended that surgery not be performed unless the uterus was gangrenous. In the Middle Ages, other methods reported included frightening the prolapse with hot iron so that it would retreat back into the body. Cupping has also been advocated for prolapse reduction.

Until the 16th century, most of the materials used for pessaries were naturally occurring materials or objects that had been repurposed. It was not until the end of the 16th century that devices were purposely made to address prolapse. Notably, Ambrose Pare, a royal surgeon in the French court, made oval-shaped pessaries from materials such as brass or cork covered in wax. These pessaries were often held in place with a belt-like device worn across the waist. Hendrik van Roonhuyse (1625-1672), the Dutch gynecologist who is credited with writing one of the earliest textbooks of operative gynecology, devised a pessary made of cork with a hole in it to allow for passage of discharge. The late 17th century saw a considerable number of medical therapies and pharmaceutical concoctions promoted for the treatment of genital prolapse, which persisted even into the 18th century. Specifically, soft rubber pessaries that resembled contraceptive diaphragms with a perforated gold tip to allow for the escape of discharge were devised to address prolapse and the issue of vaginal wall injuries, which were a common result of metal pessaries. In the mid-19th century, the American Medical Association documented 123 different pessaries. Hugh Lennox Hodge (1796-1873) recommended metal, glass, and porcelain pessaries instead of wood, cork, or sponge due to his belief that the harm attributable to pessaries stems from the material, the form, and the size. Modern pessaries are primarily made of silicone and are rarely made of latex, rubber, or acrylic. These materials have completely replaced the hard plastic and polystyrene used previously. Silicone is advantageous because it is flexible yet sturdy, durable, hypoallergenic, and noncarcinogenic. It is also inert, does not absorb secretions or odors, and can be repeatedly cleaned and autoclaved, if needed for re sterilization.

P.905

INDICATIONS AND THERAPEUTIC BENEFITS OF PESSARY

Pessaries are used to alleviate the symptoms of prolapse and delay or eliminate the need for surgery. As discussed below, there may also be some evidence that pessaries may retard prolapse progression. In recent surveys of gynecologists and female pelvic medicine and reconstructive surgeons/urogynecologists in the United States and United Kingdom, 86% to 98% of respondents prescribe pessaries in their practice. Cundiff et al. reported that specifically, among members of the American Urogynecologic Society (AUGS), 77% of respondents used pessaries as first-line therapy for prolapse, whereas 12% offered them only to women who are not considered good surgical candidates. Ninety-two percent believed that pessaries alleviated prolapse symptoms while 48% believed that pessaries also improved pelvic support.

The 2004 Cochrane Review concluded that there are no published randomized controlled trials addressing pessary use for POP. Although there is still no consensus on the indication for use, the use of different types of pessaries, or the ideal follow-up regimen, as discussed below, there is at least one randomized controlled trial (by Cundiff et al.) comparing the use of two different pessaries for prolapse. It is also important not to discount findings from numerous published series and experience from thousands of years of pessary use.

As most women with prolapse do not tend to experience symptoms until the prolapse extends beyond the vaginal introitus, the primary goal of pessary placement is to prevent the vaginal prolapse from extending beyond the vaginal opening. Although pessary can be offered as a treatment option to most patients with prolapse, managing the patient's expectations regarding the likelihood of successful placement, continued use, alleviation of symptoms, and improvement of quality of life is important and may save both the provider and patient time and frustration. Pessary placement is associated with improvements in vaginal and bladder symptoms. Clemons et al. reported that compared with symptoms at baseline, pessary users were significantly less likely to experience sensation of vaginal bulge (90% to 3%), pressure (49% to 3%), presence of vaginal discharge (12% to 0%), and vaginal splinting (14% to 0%). Pessary placement has also been associated with improvement of bowel symptoms, although this was not a consistent finding in all studies. In addition to overall improvements in quality of life, body image and sexual function are also improved after pessary placement.

Because women with severe prolapse may have voiding dysfunction from the prolapse kinking the urethra leading to bladder neck obstruction, by correcting the vaginal axis, pessaries may improve obstructive and urinary urgency symptoms. In one study by Fernando et al., after pessary placement, fewer women reported difficulty voiding (77% to 48%), urinary urgency (93% to 58%), and urge incontinence (84% to 65%). Similarly, in a small retrospective review of 24 women with prolapse and elevated postvoid residuals (>100 mL) who planned to undergo surgery, Lazarou et al. reported that 75% of women had normal postvoid residuals after pessary placement. Of these women, only 1 had persistence of elevated postvoid residuals after surgery. However, due to the "unkinking" of the urethrovesical angle, pessary placement has also been associated with de novo/occult stress urinary incontinence. One prospective study by Clemons et al. found occult/de novo stress incontinence to occur in 21% of women with symptomatic prolapse fitted with a pessary.

In addition to pessary use for ongoing management of prolapse, pessary placement may also have a diagnostic role in women who desire surgery for prolapse but whose symptoms, such as pelvic or back pain, may not directly result from prolapse. In this group of women, symptom improvement during a trial of pessary may aid the clinician in counseling the patient regarding symptom improvement after surgery.

Although it is beyond the scope of this chapter to discuss pessary placement for obstetric indications such as cervical insufficiency, it is pertinent to mention that pessaries can be used for vaginal prolapse during pregnancy. In this setting, pessary use can result in similar benefits seen in nonpregnant women, such as decreased vaginal bulge symptoms and improved voiding. Although there are no data on the prevalence of prolapse during pregnancy, some experts postulate that pregnant women, may be less likely to experience prolapse later in pregnancy due to the displacement of the gravid uterus outside of the pelvis, while others hypothesize that prolapse may become more severe with pregnancy progression due to the weight of the uterus.

In addition to the symptomatic benefits of pessary use, there are some data by Handa and Jones, Matsubara and Ohki, and Jones et al. to suggest that pessary use may lead to improvement of prolapse stage and decrease in the size of genital hiatus. However, it is unclear if the observed benefit is durable or merely a more transient effect of pessary placement. It is also not evident if the change in anatomy is correlated with a significant change in symptom. These case series were limited by small sample size with short follow-up periods, and most of the observed changes were modest. What is equally or more significant is that pessary use does not appear to be associated with an increase in the severity of prolapse.

Pessary use has also been compared to surgery with mixed results. In one prospective study by Abdool et al. that compared a cohort of women who chose surgery to women who chose pessary, there were similar improvements in urinary, bowel, and sexual function, and quality of life. In a study by Barber et al. addressing the responsiveness of two condition-specific quality-of-life questionnaires (Pelvic Floor Distress Inventory [PFDI] and Pelvic Floor Impact Questionnaire [PFIQ]), women who underwent vaginal reconstructive surgery experienced significantly greater improvement in the above scales than did women enrolled in a pessary trial. Although women in the pessary trial experienced significant improvement in the prolapse and urinary subscales of the PFDI after pessary placement, there were no significant changes in the colorectal subscale of the PFDI or any of the PFIQ subscales (prolapse, urinary, colorectal). As of this publication, there are no randomized controlled

trials comparing pessary and surgery in patients with POP. There is one cost-effective analysis, by Hullfish et al., that demonstrated pessary use may be more cost-effective than vaginal reconstructive surgery or expectant management in women with posthysterectomy POP.

PATIENT CONSIDERATIONS AND SELECTION FOR PESSARY USE

A pessary trial is a low-risk option for women experiencing symptomatic POP and should be considered and offered routinely. According to Pott-Grinstein and Newcomer, a 1998 survey of randomly selected members of the American College of Obstetricians and Gynecologists showed that although 86% of respondents prescribed pessaries, most felt that they underwent minimal to no training during residency. Learning the skills necessary to successfully fit and manage pessaries is fortunately not difficult and improves rapidly with experience.

P.906

Research by Heit et al., Kapoor et al., and Chan et al. shows that 30% to 60% of women diagnosed with POP will initially choose conservative management. Patients who were more likely to choose pessary tended to be older; patients with greater degree of prolapse, impairment in sexual activity, stress urinary incontinence, difficulty with bowel emptying, or previous prolapse surgery were more likely to select surgery. Additionally, those who previously encountered complications related to pessary use were more likely to choose surgery.

Research by Clemons et al., Hanson et al., Maito et al., Cundiff et al., and Komesu et al. shows that most patients (73% to 92%) can be successfully fitted with a pessary with rates of continued pessary use ranging from 16% to 89% at 6 months to 1 year. Patient characteristics that have consistently been associated with unsuccessful fitting include short vaginal length (<6 cm) and wide introitus (>4 fingerbreadths) and previous hysterectomy or reconstructive surgery (Table 40.1). Systemic and local hormone replacement therapy prior to fitting may improve the ability to successfully fit a pessary. Degree or predominant compartment of prolapse was not found to negatively impact the ability to successfully fit a pessary in most studies, but one small study did demonstrate that posterior vaginal wall prolapse was associated with increased fitting failure. Being sexually active also does not impact pessary fitting.

Long-term pessary use is related to the degree that the pessary corrects bothersome symptoms without creating new symptoms. According to Clemons et al., Komesu et al., and Friedman et al., after one year, most women (56% to 77%) will continue pessary use. Older age (>65 years) is the greatest predictor of continued use. Discontinuation of pessary use was associated with preexisting and de novo stress urinary incontinence, previous prolapse surgery, desire for surgery at first visit, and severe posterior vaginal prolapse. Being sexually active does not preclude long-term pessary use.

Pessary use is associated with few complications, and as such, there are few contraindications for usage. The most important contraindication is noncompliance with follow-up, as this can result in severe complications as described below. It is important to consider any medical condition or social situation that may predispose a patient to noncompliance, such as dementia or difficulty accessing health care routinely. Additionally, pessary use should be delayed in women with active pelvic/vaginal infection until these issues are treated and resolved. Patients with latex allergy should not use Inflatoball pessary (CooperSurgical, Inc., Trumbull, CT), but this is the only commonly available pessary made with latex. In the 1997 survey of AUGS members, although 64%, 42%, and 45% of respondents believed hypoestrogenism, prior hysterectomy, or sexual activity, respectively, to be contraindications for pessary placement/use, we do not believe that any of these factors prohibit a trial of pessary based on the existing literature and our experience.

PESSARY SELECTION AND FITTING

Although more than 100 pessaries have been described, 13 styles are most commonly used, each with many different sizes (Fig. 40.1). Pessaries used for prolapse can be broadly classified as support pessaries, such as the ring with or without support or space-filling pessaries such as Gellhorn or Donut (Table 40.2). Support pessaries theoretically use a spring mechanism and are thought to rest between the pubic symphysis and posterior vaginal fornix; however, in actuality, with the patient upright, these pessaries rest just inside the introitus (Fig. 40.2). Space-filling pessaries either occupy the space within the vagina or create suction and adhere to the vaginal tissue. In the standing patient, these pessaries also sit just inside the vaginal introitus (Fig. 40.3).

In the 1997 survey of AUGS members, the most commonly used pessaries were the ring and Gellhorn; 22% of respondents reported using the same pessary, usually a ring pessary, for all vaginal prolapse; 78% tailored the pessary to the prolapse and were more likely to use support pessaries for anterior and apical vaginal prolapse, and space-filling pessaries for posterior vaginal prolapse and total prolapse/complete procidentia. In studies addressing pessaries used to treat prolapse, most analyses examined ring and/or Gellhorn pessaries. In a multicenter, randomized crossover trial comparing Gellhorn with ring to support pessaries, Cundiff et al. reported that both pessaries were found to be similar in decreasing prolapse symptoms as well as associated urinary and bowel symptoms. Pessary fitting is a trial and error process and involves selecting

P.907

the ideal type of pessary as well as the correct size. In our experience, it is reasonable to start with a ring (with or without support) pessary, as this is generally the easiest for the patient to manage herself. If the patient cannot retain a ring pessary, we recommend a Gellhorn pessary followed by the Donut or cube pessary.

FIGURE 40.1 Types of pessaries. *A*: Hodge with knob (silicone); *B*: Risser (silicone); *C*: Smith (silicone); *D*: Hodge with support; *E*: Hodge (silicone); *F*: Tandem-cube (silicone); *G*: Cube (silicone); *H*: Hodge with support plus knob (silicone); *I*: Regula (silicone); *J*: Gehrung (silicone); *K*: Gehrung with knob (silicone); *L*: Gellhorn 95% rigid (silicone); *M*: Gellhorn flexible (silicone); *N*: Gellhorn rigid (silicone); *O*: Ring with support (silicone); *P*: Ring with knob (silicone); *Q*: Ring with support plus knob (silicone); *R*: Shaatz (silicone); *S*: Incontinence dish with support (silicone); *T*: Ring incontinence (silicone); *U*: Ring (silicone); *V*: Incontinence dish (silicone); *W*: Inflatoball (latex); *X*: Donut (silicone).

Both the ring and the Gellhorn, as well as most other pessaries, are available in different sizes. Generally, the smallest size pessary that is retained by the patient and results in alleviation of prolapse symptoms is best. There are pessary fitting kits available, such as the ring pessary sizer; however, it is not clear if these kits are needed to improve pessary fitting success. Most women can be successfully fitted with a pessary after one attempt, with most studies reporting an average of 2 to 3 pessaries tried over 1 to 3 attempts. Not surprisingly, pessary fitting success was highest with the first attempt; however, many women may still benefit from repeat trial of pessary fitting; one study by Clemons et al. reported that 45% of women who initially failed pessary placement were able to be successfully fitted at subsequent visits. After successful fitting, the pessary should be comfortable and relieve prolapse symptoms; it should be retained with Valsalva, ambulation, and urination and defecation.

Women with POP who are contemplating pessary placement should undergo a careful evaluation by history and physical examination as outlined in [Chapter 36](#). As the goal of pessary placement is the alleviation of prolapse symptoms, particular attention should be placed on the assessment of symptoms attributable to prolapse, including sensation of vaginal bulge as well as bowel and urinary symptoms such as voiding/defecatory symptoms and incontinence. The degree of bother resulting from these symptoms as well as the impact on quality of life can also be determined from using validated questionnaires such as the PFDI short form 20 and the PFIQ short form 7. Additionally, it may be important to have the patient self-identify goals of pessary treatment, as attainment of those goals has been shown to be associated with continued pessary use. Although this is not essential, the Pelvic Organ Prolapse-Quantification (POP-Q) system, which is discussed in [Chapter 36](#), can be used to identify and quantify the specific pelvic support defects present in terms of anterior, posterior, and apical vaginal compartments. As patients with severe prolapse may also have incomplete bladder emptying with urinary retention, assessment of postvoid residual before and after pessary placement can be performed. Evaluation of the vaginal epithelium to assess for urogenital atrophy and presence of abnormal lesions or discharge is necessary.

Other evaluations that should be considered include testing the patient for occult/de novo stress urinary incontinence, as one

series by Clemons et al. showed 21% of women without previous incontinence symptoms developing de novo incontinence after pessary placement. This can be demonstrated by having the patient perform provocative maneuvers such as Valsalva and/or coughing while reducing the prolapse at the time of pessary placement or with instruments such as a half speculum or sponge stick. It is important to counsel and manage patients with baseline and de novo stress incontinence, as patients with continued stress incontinence after pessary placement may be more likely to discontinue pessary use. In addition to other conservative measures for stress incontinence as discussed in [Chapter 41](#), prolapse patients with preexisting stress incontinence as well as occult/de novo incontinence may benefit from an incontinence pessary.

If the patient is deemed an appropriate pessary candidate following the above evaluation, the patient is next fitted for a pessary. To accomplish this task, the examiner places two fingers within the vagina as would be done at the time of a bimanual examination to estimate the vaginal depth. The index and middle fingers are spread as wide as comfortably possible to estimate the vagina width, which should approximate the diameter of the pessary ([Fig. 40.4](#)). The vaginal length and width will impact the type and size of pessary the patient may be able to tolerate and retain.

To insert the pessary, apply a small amount of waterbased lubricant to the leading edge of the pessary. Insert the pessary into the vagina by applying pressure gently toward the posterior vagina and placing the pessary at an oblique angle so as to minimize pressure on the base of the urethra. Tips on pessary insertion and removal of a few commonly used pessaries are described in [Table 40.2](#). It is beyond the scope of this chapter to discuss techniques involved in the placement of every pessary. For detailed instructions, consult the pessary company website or the detailed instructions provided with every commercially available pessary.

After the pessary is placed, one finger should easily fit between the pessary and the vagina. The patient should feel no discomfort and may often not feel the pessary at all. Mild vaginal irritation may occur as a result of the fitting process or urogenital atrophy. To increase the success of pessary fitting, patients with urogenital atrophy and other vulvar pathology such as lichen sclerosus may benefit from appropriate treatment before pessary placement. Lidocaine gel may also be placed at the introitus several minutes prior to pessary placement to decrease discomfort. Voiding and/or defecating before pessary placement to optimize room in the vagina may also ease pessary fitting for patients in whom placement is difficult.

TABLE 40.2 Commonly Used Pessaries

PESSARY	TYPE	PROS	CONS	TIPS
<div>Ring</div> <div>  </div>	Support	<ul style="list-style-type: none"> • Easy to insert/remove • Compatible with intercourse 	<ul style="list-style-type: none"> • May not support severe prolapse 	<ul style="list-style-type: none"> • Fold like a taco for insertion/removal or simply insert, unfolded, at an oblique angle
Gellhorn	Space filling	<ul style="list-style-type: none"> • Works well for severe prolapse 	<ul style="list-style-type: none"> • Self-care difficult • Must 	<ul style="list-style-type: none"> • Fold knob against base for insertion

remove for intercourse

- To remove, first break suction separating pessary base from vaginal wall, then use ring forceps or single tooth tenaculum to remove, if needed
- Short knob versions available

Donut

Space filling

- Works well for severe prolapse
- Self-care difficult
- Must remove for intercourse
- Use large-bore needle, and withdraw air to maximally compress pessary for removal and insertion

Cube

Space filling

- Works well for severe prolapse, often used as a last resort
- Foul discharge, erosions common
- Must remove for intercourse
- Must be frequently removed and cleaned (every 1 to 2 night)

FIGURE 40.2 Ring with support pessary shown in the upright patient.

With the patient still in dorsal lithotomy position, the patient should be asked to perform maneuvers that increase the intra-abdominal pressure such as Valsalva or coughing to ensure that the pessary is retained and that there is not significant prolapse beyond the pessary. This process should be repeated with the patient standing and squatting. The patient should also try to void with the pessary in place. While on the toilet, the patient may perform Valsalva maneuvers to mimic defecation to confirm that the pessary will be retained. A plastic urimeter/“nun’s hat” can be placed on the toilet to catch the pessary in case it is not retained. If the patient is not able to successfully retain even large space-filling pessaries, some experts recommend placing two pessaries (e.g., two rings or Donut and Gellhorn).

FIGURE 40.3 Gellhorn pessary shown in the upright patient.

P.910

MANAGEMENT/FOLLOW-UP OF PESSARY

Although most experts would agree that routine follow-up is essential after successful pessary placement, there is no clear evidence or consensus on the optimal interval. According to Cundiff et al., in the 1997 survey of AUGS members, common follow-up schedules included evaluating the patient at 1 week or 1 month after initial pessary placement followed by visits every 1 to 3 months. The follow-up interval is dependent upon whether the patient is able to remove and replace the pessary herself. In general, we recommend a visit 1 week to 1 month after initial fitting to confirm that the patient is comfortable and satisfied with the pessary and, if applicable, able to successfully remove and replace the pessary.

Ideally, pessary removal and replacement should be taught to all patients or their caretakers to maximize patient autonomy. Typically, the ring (with and without support) pessaries are the easiest to self-manage; however, other types of pessaries such as Gellhorn have also been successfully self-managed by patients. For these women who are able to perform selfcare, annual visits are typically sufficient.

For women unable to perform self-care, routine followup is typically every 3 to 4 months. During these visits, questions regarding comfort of use, vaginal bleeding, malodorous discharge, urinary tract infection, and defecation or voiding problems should be elicited and further evaluation performed as needed. The pessary should be removed and cleaned and the vagina thoroughly inspected.

There is no consensus or clear evidence on the optimal frequency of pessary removal. With the exception of the cube and Inflatoball (CooperSurgical, Inc., Trumbull, CT) pessaries, which most experts recommend removal every 1 to 2 nights with pessary replacement the next morning, other types of pessaries can be removed daily, weekly, or monthly and can be tailored to the individual needs of the patient. It is pertinent to consider that the amount of vaginal discharge may be dependent on the duration of continuous pessary use, with less discharge associated with more frequent pessary removal. The more frequent a woman removes her pessary, the less she may also be at risk for development of vaginal erosions. Although a woman can technically engage in vaginal intercourse with certain types of pessaries such as the ring with and without support, typically pessaries should be removed before intercourse.

In terms of concurrent therapies, there is limited evidence recommending the routine use of local or systemic hormone replacement therapy or other vaginal preparations in pessary users. It is important to individualize concurrent therapies based on patient needs and abilities. Vaginal preparations such as estrogen may often be expensive, messy, and difficult to place for some patients. Therefore, mandating their use may unnecessarily deter a patient from using a pessary. The rationale behind estrogen use in postmenopausal women is the improvement of urogenital atrophy by promoting epithelial cell growth and maturation leading to increased vaginal wall thickness and elasticity and decreasing vaginal pH to premenopausal levels (3.5 to 4.5) to promote continued or recolonization with normal flora—lactobacilli. Estrogens used vaginally are more effective than are estrogens taken systemically at correcting urogenital atrophy. In the 1997 survey of AUGS members, Cundiff et al. reported that 94% of respondents recommended estrogen replacement for pessary users. As mentioned above, there is some evidence to suggest that vaginal estrogen use may have a role in the success of initial pessary placement and may decrease vaginal irritation/abrasion. As discussed further in the complications section, vaginal estrogen may also have a role in the treatment of vaginal abrasion.

Some experts also recommend over-the-counter agents such as Trimo-San vaginal jelly (hydroxyquinoline topical) (CooperSurgical, Inc., Trumbull, CT) or vaginal moisturizers that contain polycarbophil (RepHresh, Lil' Drug Store Products, Inc., Cedar Rapids, IA) 2 to 3 times per week for lubrication and to maintain a vaginal pH of 4 to decrease malodorous discharge and patient discomfort. Although there are presently no published efficacy data, there is an ongoing randomized controlled trial addressing the effects of using this gel on the development of bacterial vaginosis and patient satisfaction in pessary users.

Complications

Serious complications of pessary use are rare and can typically be avoided with regular follow-up examinations. A literature review by Arias, Ridgeway, and Barber of major complications from 1950 to 2007 reported 39 published complications that required surgical interventions. These included 8 vesicovaginal fistulae, 5 other urologic complications, 4 rectovaginal fistulae, 3 bowel complications, and 19 impacted pessaries. Only 2 of the 39 patients who developed complications were followed regularly by a health care professional. Therefore, prevention of most major complications can be avoided by educating the patient on the importance of regular follow-up and self-care, if applicable.

More commonly, pessary patients may experience minor, transient complications. These may include, but are not limited to, pessary expulsion, urinary incontinence, rectal pressure, vaginal discharge or bleeding, and mechanical pressure ulcers. A long-term study of ring pessary users (median duration of use was 7 years) by Sarma, Ying, and Moore found that 56% of women experienced bleeding, extrusion, vaginal discharge, pain, or constipation at some point during their pessary use. Although these symptoms are generally not serious, they may limit a woman's ability to tolerate a pessary and desire for continued pessary use, and should be avoided if possible and managed effectively when they occur (Table 40.3).

TABLE 40.3 Management of Common Issues Associated with Pessary Use

ISSUE	MANAGEMENT
Expulsion or rectal pressure	<ul style="list-style-type: none">• Change pessary size or type
Urinary incontinence	<ul style="list-style-type: none">• Use an incontinence pessary with support at urethrovesical junction
Vaginal discharge	<ul style="list-style-type: none">• Inspect the vagina to exclude ulceration• More frequent pessary removal• Acidification gel or douches• Antimicrobial treatment• Vaginal estrogen

Vaginal bleeding	<ul style="list-style-type: none"> • Inspect vagina to exclude ulceration • Consider vaginal or endometrial biopsy or ultrasound if uterus present
Vaginal abrasion/ulceration	<ul style="list-style-type: none"> • Remove the pessary for 2 to 4 weeks. • Vaginal estrogen • Consider biopsy if persistent

P.911

A commonly encountered minor complication with pessary use is vaginal abrasion/ulceration. The patient may be asymptomatic or may experience heavier vaginal discharge or bleeding. Atrophic vaginal epithelium may contribute to a higher rate of vaginal abrasion, and therefore, many practitioners prescribe vaginal estrogen both as a preventative and a treatment measure. Vaginal abrasions may lead to higher pessary discontinuation rates and therefore are important to prevent. Vaginal estrogen therapy is utilized to promote epithelial cell growth and maturation, and increase vaginal wall thickness and elasticity. When abrasions occur, it is generally recommended to remove the pessary and apply topical estrogen for 2 to 4 weeks before reinsertion. If abrasions do not promptly resolve after relief of mechanical pressure, they should be biopsied, as cases of cervical and vaginal cancer have occurred in patients with pessaries.

Another common pessary-related issue is increased vaginal discharge and/or odor. Inspection of the vagina to exclude vaginal ulceration is mandatory. If bleeding is reported, it is important to consider an endometrial biopsy even if vaginal abrasion is found. In one study by Alnaif and Drutz, pessary users were significantly more likely to develop bothersome bacterial vaginosis compared with controls (32% vs. 10%, odds ratio [OR] 4.37, 95% confidence interval [CI]: 2.15 to 9.32). Therefore, appropriate antimicrobial or antifungal treatment should be prescribed based on findings of the wet mount/wet prep. If there are no pathologic organisms on wet mount, vaginal estrogen and/or acidifying products (Trimo-San vaginal jelly [CooperSurgical, Inc., Trumbull, CT] or vinegar douches) can be used as well as recommending more frequent pessary removal.

Pelvic Floor Muscle Training

Women with POP are more likely to have pelvic floor muscle weakness and atrophy, major defects of the levator ani muscles, and/or significantly decreased vaginal closure force when compared to women without prolapse. Greater pelvic floor muscle weakness is associated with larger genital hiatus measurements and more advanced stages of prolapse. Significantly fewer women with prolapse were able to achieve an effective involuntary muscle contraction during cough compared to women without prolapse. These findings are also consistent with the pelvic floor muscle function of women with urinary incontinence.

Pelvic Floor Muscle Training essentially consists of exercises to improve the strength and function of the pelvic floor muscles. Proper identification and contraction of the pelvic floor muscles is essential for women with prolapse. However, with verbal instruction alone, 68% of women with prolapse actually depressed (rather than contracted) their pelvic floor muscles, according to Thompson and O'Sullivan. To ensure proper technique of the pelvic floor muscle contraction, PFMT is ideally performed with guidance from a pelvic floor physical therapist. Besides verifying correct contraction of the pelvic floor muscles, the therapist ensures that a moderate to maximum level of intensity is produced, without contracting accessory muscles including the gluteal, rectus abdominis, or adductor muscles.

Although there are different PFMT regimens and interventions without consensus on the optimal regimen or duration of therapy, the integral components of most programs include assessment of and exercises to improve voluntary muscle strength and endurance, as well as timing of involuntary muscle contraction with increases in intra-abdominal pressure. Patients are prescribed individualized pelvic floor exercise programs to improve any and all of the deficits identified. Functional strategies are also taught, including contraction of the pelvic floor

against anticipated increases in intra-abdominal pressure events (also known as “the Knack”). The goal of pelvic floor muscle exercise and functional training is to ultimately improve support of the pelvic organs, especially during certain activities that may increase intra-abdominal pressure. Although there are limited data regarding increase in efficacy, electrical stimulation and biofeedback are commonly used adjuncts for these programs.

As is the case with other pelvic floor disorders such as urinary incontinence, emerging evidence suggests PFMT may be an

effective conservative management for both anatomic and symptomatic improvements of POP. In a large trial by Braekken et al., 109 women with POP-Q stages 1, 2, and 3 prolapse were randomized to PFMT for 6 months (including both individual sessions with physical therapy and home exercise regimen) versus control (who were only given instruction to avoid straining and to utilize “the Knack”). Compared to women in the control group, those in the PFMT group were significantly more likely to have reduced frequency (74% vs. 31%, relative risk [RR] 0.37, 95% CI: 0.21 to 0.65) and bother (67% vs. 42%, RR 0.56, 95% CI: 0.33 to 0.97) from prolapse symptoms. Additionally, more women from the PFMT groups improved one POP-Q stage on physical examination compared with controls (19% vs. 8%, $P = 0.035$). No adverse events were reported in either group.

Other studies involving women with POP-Q stages 1 and 2 found significant anatomic and symptomatic improvement in women randomized to 14 to 16 weeks of PFMT and lifestyle advice compared with the control group who only received lifestyle advice. A Cochrane Review published in 2011 concluded that there is some evidence to support a beneficial effect of PFMT on prolapse symptom and severity. The improvement in prolapse stage anatomically may be more likely seen in women with less severe prolapse. Given the conclusions of level I evidence supporting the use of PFMT for treatment of POP as well as the lack of harm from this intervention, it should be offered to patients desiring conservative management.

PFMT can also be used in conjunction with pessary placement. Although there are limited data on the effects of pelvic floor muscle exercises in pessary users, in the 1997 survey of AUGS members, Cundiff et al. reported that 61% of respondents recommended pelvic floor muscle exercises for pessary users.

SUMMARY

POP is a common, bothersome, and costly condition and is suspected to become more prevalent as the aging population increases. Most women that present with bothersome prolapse symptoms should be offered conservative management with pessary placement and/or PFMT, especially as these interventions are usually not associated with significant adverse events. Although there are limited level I evidence, the findings from numerous published series and the experiences from years of pessary use suggest pessaries are an effective treatment of prolapse symptoms, and pessary use with routinely scheduled follow-up typically does not result in significant complications. Selection of the ideal type and size of pessary is a trial and error process, which improves with provider experience. Moreover, factors such as patient selection, specific follow-up regimen, and use of concomitant therapies including vaginal agents and pelvic floor muscle exercises should be individualized. Although there is limited data on the optimal duration of physical therapy and the durability of results, there is emerging level I evidence demonstrating the beneficial effects of PFMT on prolapse symptom and possibly anatomic prolapse stage in women with mild to moderate prolapse.

P.912

BEST CLINICAL PRACTICES

- Nonsurgical management of POP including pessary placement and PFMT should be considered in all patients with symptomatic POP.
- Pessary use may improve vaginal, bladder, and possibly bowel symptoms.
- Although pessary use may improve voiding and defecation, it may also exacerbate stress urinary incontinence or result in de novo/occult stress incontinence.
- Patient characteristics that have consistently been associated with unsuccessful fitting include short vaginal length (<6 cm) and wide introitus (>4 fingerbreadths) and previous hysterectomy or reconstructive surgery; sexual activity and the degree or compartment of prolapse do not negatively impact pessary placement.
- Older patients (>65 years) were more likely to continue with pessary use, while preexisting and de novo/occult stress incontinence, previous prolapse surgery, desire for surgery, and severe posterior vaginal prolapse were associated with discontinuation of pessary. Being sexually active does not preclude long-term use of pessary.
- Using vaginal estrogen in patients with urogenital atrophy may improve the success of pessary fitting as well as longterm use.
- Pessary fitting is a trial and error process and should be individualized to the patient.

- Patients should be followed routinely after pessary placement and should be examined with pessary removal at regular intervals.
- Minor complications of long-term pessary use are common and include discharge and mucosal erosion/abrasion, while serious complications including fistulae, cancer, and pessary incarceration are rare, especially with routine follow-up.
- PFMT performed under the supervision of a pelvic floor physical therapist should be offered to prolapse patients, as there has been level I evidence demonstrating this treatment to be effective with no adverse outcomes.
- Although there is limited evidence on efficacy, pessary placement and PFMT can be offered concurrently to women with symptomatic prolapse.

Chapter 41

Stress Urinary Incontinence

Victoria L. Handa

DEFINITIONS

Cotton swab test—Measure of urethral mobility; with the patient in supine lithotomy position, a lubricated cotton swab (or other similar device) is placed into the urethra, allowing a measurement of the rotational descent of the bladder neck with Valsalva; an angle of >30 degrees (with respect to the horizontal) is classically defined as a hypermobile urethra.

Cystometry—Tests of the pressure/volume relationship during bladder filling; “simple” cystometry is a manometric evaluation, while “complex” cystometry involves an electronic measurement and recording of bladder pressure during filling, often with simultaneous measurement of intra-abdominal pressure (and sometimes urethral pressure).

Intrinsic sphincter deficiency (ISD)—Urinary incontinence that is due to dysfunction of the urethral sphincter mechanism, presumably related to loss of smooth muscle tone and/or coaptation of the urethral lumen.

Occult stress incontinence—Stress incontinence only observed after the reduction of coexistent prolapse (e.g., after surgical correction of prolapse).

Stress urinary incontinence—The symptom of involuntary leakage of urine from the urethra at the time of increased intra-abdominal pressure (e.g., coughing, straining).

Urethral hypermobility—Descent of the bladder neck with increased intra-abdominal pressure, typically defined as a cotton swab angle greater than 30 degrees from the horizontal.

Urodynamic stress incontinence—The involuntary leakage of urine during filling cystometry, associated with increased intra-abdominal pressure, in the absence of a detrusor contraction.

Urinary incontinence is a condition that affects 30% to 40% of older American women, with the majority afflicted with stress urinary incontinence (SUI). The management of SUI has changed dramatically over the past two decades, due in part to the introduction of synthetic midurethral slings and due also to the accumulation of evidence from clinical trials to guide therapy. Surgeries that were once the standard of care, such as Pereyra needle suspensions and anterior colporrhaphy with Kelly placcation, are now known to be less effective than are other options and are therefore no longer recommended for treatment of SUI.

P.914

The phrase “stress urinary incontinence” is used to refer to a symptom, a physical finding, and a urodynamic diagnosis. The symptom of SUI is the complaint of involuntary loss of urine on effort or physical exertion (e.g., exercise), or on sneezing or coughing. The sign of SUI is the observation, on physical examination, of incontinence from the urethra synchronous with effort similar provocation, such as coughing. Urodynamic stress incontinence is defined as the involuntary leakage of urine during increased abdominal pressure in the absence of a detrusor contraction.

INITIAL EVALUATION

The history and physical examination are critical in the assessment of SUI. Typically, a thorough history will distinguish SUI from other types of urinary incontinence. The initial assessment should also include an

evaluation of the impact of SUI on quality of life, as treatment is indicated only if the woman considers her symptoms to be bothersome or to interfere with her activities. Other goals for the initial assessment include the identification of other factors that could exacerbate or precipitate symptoms, such as neurologic disease, polyuria, and many medications (especially those with effects on the autonomic nervous system). A voiding diary may be appropriate to assess normal voiding habits. The physical examination should include a measure of postvoid residual. Laboratory studies can be limited to screening for urinalysis to exclude hematuria and pyuria.

Among women planning surgical treatment of SUI, urethral hypermobility should be assessed on physical examination. A variety of methods can be used to assess urethral mobility, although this is traditionally evaluated with a cotton swab test. For this test, a lubricated cotton swab is inserted into the urethra with the patient in the supine lithotomy position (Fig. 41.1). As the patient strains or coughs, the angle formed by the cotton swab with respect to the horizontal is measured. Women with a straining cotton swab angle of at least 30 degrees above the horizontal are said to have a hypermobile urethra. Most women with SUI will have evidence of a hypermobile urethra, but it is important to note that a hypermobile urethra is neither necessary nor sufficient for the diagnosis of SUI. However, this finding has been associated with surgical outcomes, and it is therefore important to assess patients for urethral hypermobility if surgery is planned.

FIGURE 41.1 The cotton swab test demonstrates a resting angle close to 0 degrees and a straining angle of approximately 40 degrees. A straining angle greater than 30 degrees above the horizontal is considered “hypermobile.” (Reprinted from Bent AE, Cundiff GW, Swift SE. *Ostergard, Ostergard's urogynecology and pelvic floor dysfunction*, 6th ed. Philadelphia, PA: Lippincott, Williams & Wilkins, 2007, with permission. Copyright © 2007 Wolters Kluwer Health.)

TABLE 41.1 Criteria for Surgical Management of Stress Urinary Incontinence without Urodynamic Evaluation

- Clear symptoms of SUI in the absence of frequency, urgency, and other significant urge-related symptoms
- Postvoid residual volume less than 150 mL
- Hypermobile urethra
- Positive “stress test” (visual evidence of urine loss with cough or Valsalva)
- No history of anti-incontinence surgery
- No history of radical pelvic surgery or radiation

- No neurologic disease

Urodynamic investigation, including cystometry, has historically played an important role in the preoperative assessment of women with SUI. The goals of urodynamic investigation are to confirm the diagnosis of SUI and to exclude conditions that could either impact the success of therapy or signify an increased risk of adverse outcomes. However, many women with uncomplicated SUI may not benefit from testing. Those unlikely to benefit from testing ([Table 41.1](#)) include women with clear symptoms of SUI in the absence of significant urge-related symptoms, a postvoid residual volume less than 150 mL, a hypermobile urethra, and a positive “stress test” (visual evidence of urine loss with cough or Valsalva). In general practice, most women with SUI probably meet these criteria and can therefore be managed without urodynamic testing. However, in a tertiary setting, Nager and colleagues found that only 1,375 of 4,083 women with SUI (33%) fell into this “low-risk” category. Indications for urodynamic testing or referral to a specialist include those who do not meet the criteria above; those with a history of prior anti-incontinence surgery, prior radical pelvic surgery, or radiation; and those with neurologic disease. Cystoscopy may also be indicated in the evaluation of women with these risk factors.

There is controversy surrounding the value of preoperative assessment for “intrinsic sphincter deficiency (ISD)” in women with SUI. This concept refers to a poorly functioning urethra. The contemporary view is that urethral function is a spectrum and that all women with SUI have at least some component of poor urethral function. In theory, the “intrinsic” sphincter function of the urethra is provided by smooth muscle tone and coaptation of the urethral lumen. Thus, presumably, ISD is related to a deficiency in one or both of these continence mechanisms. Some experts argue that women with SUI who do not have urethral hypermobility must have ISD. Others consider ISD to be a measure of more severe SUI (measured either by symptom severity or with a leak point pressure, an indication of the ease with which SUI is demonstrated on physical examination). Yet a third classification scheme assigns a diagnosis of ISD in cases of low urethral closure pressure or an “open” bladder neck at rest (e.g., during urethroscopy or contrast imaging; [Fig. 41.2](#)). With contemporary treatment of SUI, the distinction between ISD and other types of SUI has become less important. It is not clear that the diagnosis of ISD has an impact on the management of SUI.

P.915

FIGURE 41.2 Photograph from urethroscopy, illustrating a functionless urethra. The bladder neck is passively open at rest. In a woman with stress incontinence, this appearance may signify intrinsic sphincter deficiency. (Reprinted from Bent AE, Cundiff GW, Swift SE. *Ostergard, Ostergard's urogynecology and pelvic floor*

INITIAL MANAGEMENT

Randomized clinical trials have demonstrated the effectiveness of anti-incontinence pessaries and pelvic muscle physical therapy. Conservative therapy helps a large number of these patients. However, a recent multicenter trial by Richter and colleagues suggested that only 50% of women with SUI will be satisfied with the outcome of these nonsurgical approaches. Nevertheless, all women with bothersome SUI should be offered nonsurgical options. Surgery should be reserved for women who decline or fail nonsurgical therapies.

SURGICAL TECHNIQUES FOR THE TREATMENT OF STRESS INCONTINENCE

More than 200 procedures have been described in the literature for the treatment of stress incontinence. This reflects a combination of the evolution of established and effective procedures as well as the introduction of newer technologies and materials. Most of these surgeries, including the anterior colporrhy with Kelly placcation and Pereyra needle suspensions, are now of historical interest only. This chapter focuses on retropubic and transobturator midurethral sling procedures, which have become the mainstays of surgical therapy for SUI. Other options, appropriate for selected populations, include the retropubic urethropexy, rectus fascia suburethral sling procedures, and the injection of bulking agents. These also are addressed.

Retropubic Midurethral Sling Procedures

The retropubic midurethral sling was first described by Ulmsten and colleagues. The appeal of a tension-free midurethral sling is that it is an effective, minimally invasive technique that can be applied to a day-surgery setting. Thus, this approach was an important innovation when it was introduced in the 1990s.

The patient is typically positioned in low lithotomy, with Allen stirrups ([Fig. 41.3](#)). The bladder is emptied with an 18-F catheter. Suprapubic sites are marked approximately 2 to 3 cm lateral to the midline. These sites are selected to be medial to the pubic tubercle; they represent the lateral boundary for safe perforation of the abdominal wall. More lateral sling placement will increase the risk of neurovascular injury.

STEPS IN THE PROCEDURE

Retropubic Midurethral Sling

- The patient is positioned in Allen stirrups.
- The bladder is drained.
- The retropubic space may be injected with saline (or dilute local anesthetic) for hydrodissection.
- An anterior vaginal wall incision (1 to 2 cm) is made over the midurethra.
- A tunnel is created under the vaginal wall, oriented at 45 degrees (toward the descending pubic ramus), for a distance of approximately 2 cm.
- The bladder is deviated away with a catheter guide.
- The insertion trocar is placed through the vaginal incision, under the vaginal wall. The insertion trocar is guided to perforate into the retropubic space, immediately along the bone, entering the space of Retzius at the junction of the descending pubic ramus and pubic bone.
- The trocar is guided along the pubic bone, staying medial to the pubic tubercle and perforating the abdominal wall within 2 to 3 cm of the midline.
- Cystoscopy is performed with the trocar in place.
- The trocar is pulled through the abdominal wall.

- After the same procedure is repeated on the contralateral side, the sling is tensioned with a spacer (such as a 9 Hegar dilator) between the sling and the urethra.
- The plastic sheath is removed, the sling arms are trimmed at the skin, and the incisions are closed.
- The bladder is drained and a voiding trial performed before discharge.

A 1- to 2-cm incision is made under the midurethra ([Fig. 41.4A](#)). Typically, the distal aspect of the incision is 1 to 1.5 cm from the urethral meatus. The midurethral location can be confirmed via palpation of the Foley bulb while gentle traction is placed on the Foley. After the creation of the incision, a 2-cm tunnel is made with Metzenbaum scissors at a 45-degree angle toward the descending pubic ramus on each side ([Fig. 41.4B](#)). Minimal vaginal dissection is recommended to limit bleeding from the paraurethral vascular plexus, to maintain the sling in its position under the midurethra (e.g., minimizing the probability that it will be displaced to the proximal or distal urethra), and to minimize the risk of mesh exposure.

Some surgeons inject the vaginal wall and retropubic space with a dilute solution of local anesthetic (such as a 3:1 dilution of 1% xylocaine or ¼% bupivacaine). A spinal needle is advanced through the abdominal wall, immediately along the pubis, and into the retropubic space. Traditionally, 5 to 10 mL of solution is injected suprapubically on each side. Then, 10 mL

P.916

of the solution is placed in the retropubic space bilaterally by a vaginal approach. The needle is advanced through the vaginal incision and under the vaginal epithelium, injecting small amounts along the intended path of the sling trocar, entering the retropubic space at the junction of the descending pubic ramus and the pubis. Five to ten milliliters is placed on each side. Injection of saline or local anesthetic into the retropubic space ("hydrodissection") is thought to distend the space, facilitating safe placement of the trocars. Some experts prefer injections of saline (for hydrodissection of the retropubic space) rather than a local anesthetic. This is because the benefits of local anesthetic injection are limited to the first few hours after surgery.

FIGURE 41.3 Positioning the patient in Allen universal stirrups to allow vaginal and abdominal access.

FIGURE 41.4 **A:** The vaginal incision for a midurethral sling procedure is approximately 1.5 cm in length and is located at the midurethra, typically 1 to 1.5 cm from the urethral meatus. **B:** For a retropubic midurethral sling, fine scissors are used to dissect a subepithelial tunnel, typically 2 cm in length. The angle of the tunnel is typically at 45 degrees, aimed toward the junction of the descending pubic ramus and the pubis.

Commercially available midurethral slings consist of a polypropylene strap and rigid trocars for insertion ([Fig. 41.5](#)). Prior to placement of the trocar, a rigid catheter guide is placed through the 18-F catheter. Using the rigid guide, the bladder can be directed away from the side on which the surgeon is working, so as to minimize the risk of bladder injury. The retropubic sling is passed into the retropubic space using the curved trocar ([Fig. 41.6](#)). A knowledge of retropubic anatomy is critical to the safe placement of the sling. The trocar should be advanced into the retropubic space at the junction of the descending pubic ramus and the pubis, immediately along the inferior surface of the bone. This is a relatively avascular zone of the retropubic space ([Fig. 41.7](#)). If the trocar perforates in this location, the trocar will be lateral to the retropubic branches of the internal pudendal vessels and medial to the inferior epigastric, obturator, and accessory obturator vessels. If the trocar is directed away from the surface of the bone, a bladder perforation is more likely, as is an injury to branches of the perivesical venous plexus and vesical vessels. The pubic veins, branches of the obturator vessels that course medially along the ventral surface of the pubis, are the only vessels likely to be along the path of the needle placed in this fashion. After initial insertion through vaginal wall, the trocar may also pass close to (or through) the paraurethral vascular plexus, which arise from the internal pudendal and superior vesical arteries. Shobeiri found that injury to

these paraurethral vessels is likely, but the related bleeding is of limited clinical significance and can typically be controlled by pressure or vaginal packing. He recommended minimal vaginal dissection to reduce risk of significant bleeding from the paraurethral vessels.

As the trocar is passed into the retropubic space, it hugs the pubic ramus as the endopelvic fascia is penetrated and then is advanced until the tip appears suprapubically, immediately

P.917

medial to the site previously marked (Fig. 41.8). The needle tip is passed just through the skin. The tape is passed on the opposite side using a similar technique. Cystoscopy is performed after each pass or, alternatively, after both passes have been made (Fig. 41.9). If there is no bladder perforation, the needles are advanced and pulled completely through the abdominal wall. The needles are detached from the sling device. The sling with protective sheath is tightened over a number 9/10 Hegar dilator or other instrument, which is held in place until the sling is secured. The plastic sheaths are pulled free from the mesh, and excess sling material is cut flush to the skin surface. At this point, the Hegar dilator can be removed. The vaginal and skin incisions are closed. The sling is not sutured to any underlying tissue, and the composition of the mesh allows tissue ingrowth to fix the sling in place.

FIGURE 41.5 Vaginal approach for tension-free vaginal tape procedure. Gynecare TVT Obturator System Tension-Free Support for Incontinence. Materials include a catheter guide to retract the bladder away from the working area, the tape material attached to two insertion needles, and the handle to attach to the needles for insertion. FIGURE 41.6 With the rigid catheter guide deviating the bladder to the left, the curved trocar is inserted in the retropubic position. The trocar perforates the retropubic space at the junction of the descending pubic ramus and the pubis, immediately along the surface of the bone.

Anatomic studies have identified several techniques that minimize the risk to obturator and iliac vessels. For example, during passage of the retropubic trocars, the surgeon should not laterally divert the tip of the trocar; rotation of the trocar is a safer technique. Shobeiri demonstrated that if the surgeon rotates the needle without lateral diversion, injury to the external iliac vessels cannot except in cases of extreme rotation (>75 degrees). Injury may be increased if the trocar is both laterally diverted and rotated. The surgeon should also be familiar with the corona mortis, an anastomosis between the obturator and inferior epigastric vessels. This anastomosis is typically greater than 6 cm lateral to the midline and is reliably 3 cm lateral to the midline. Experienced retropubic surgeons are aware that this anastomosis is almost invariably present in a fat pad at the lateral aspect of Cooper ligament. Injury to the corona mortis can easily be avoided if the trocar does not pass more than 3 cm lateral to the midline. Finally, Rahn and colleagues have shown that perforation of the pubococcygeus muscle can occur if the retropubic trocar is deviated laterally ([Fig. 41.10](#)), although perforation of the muscle is of uncertain consequence.

A vaginal pack is not usually placed unless there has been considerable bleeding. A Foley catheter is placed, or, alternatively, the patient may go to recovery without a catheter. A voiding trial is initiated in the recovery room; if the patient cannot void adequately, she performs self-catheterization, or a Foley catheter is placed. In the first week after surgery, voiding dysfunction is common. Patients discharged with an indwelling Foley catheter are scheduled to return to clinic for assessment of voiding function. About half of patients will void adequately by the time of discharge from day surgery. Of those who require catheterization, many are voiding well by the following day, and almost all have recovered normal voiding function within the first week.

FIGURE 41.7 Retropubic trocars in the space of Retzius. The trocars enter the retropubic space approximately 2 to 3 cm from the midline. In this position, they are medial to the inferior epigastric, obturator, and accessory obturator vessels. The pubic branches of the obturator vessels are seen to course medially along the surface of the pubis.

FIGURE 41.8 Insertion of vaginal tension-free tape. **A:** Vaginal guidance of needle under descending pubic ramus along back of symphysis. **B:** Pressure over the skin of the abdomen to allow the needle to penetrate the abdominal skin. **C:** Both needles passed through retropubic space and resting on the abdomen. (Te Linde, Fig. 37.10; With permission: Klutke J, Klutke C. The promise of tension-free vaginal tape for SUI. *Contemporary Urology*®Archive. 2000; October: Figures 4, 6, and 7.)

FIGURE 41.9 Cystoscopy is performed with the retropubic trocar in place. (Reprinted from Zubke W, Gruber IV, Gardanis K, et al. Tension-free vaginal tape (TVT): our modified technique—effective solutions for postoperative TVT correction. *Gynecol Surg* 2004;1:111, with permission. The success rate of the retropubic midurethral sling is approximately 85%. Risk factors for failure include prior incontinence surgery, coexistent urge incontinence, and the absence of preoperative urethral hypermobility. Age also appears to be a risk factor for persistent SUI symptoms. Urodynamic parameters, such as low maximum urethral closure pressure and leak point pressure, may reduce objective success of midurethral slings; however, the predictive value of these parameters is relatively poor.

FIGURE 41.10 Retropubic space illustration showing location a retropubic sling. The sling on the right passes lateral to the arcus tendineus fascia pelvis (ATFP), perforating the levator ani muscle complex. The sling on the left is in the more typical location, medial to the ATFP. (Reprinted from Rahn DD, Marinis SI, Schaffer JI, et al. Anatomical path of the TVT: reassessing current teachings. *Am J Obstet Gynecol* 2006;195:1809, with permission. Copyright © 2006, Elsevier.)

The most serious complications from the retropubic midurethral sling procedure pertain to the percutaneous passage of the trocar (**Table 41.2**). There have been rare deaths from undiagnosed bowel perforation. Major vascular injury is rare and will be minimized by ensuring that the insertion needle does not stray laterally. Smaller venous channels are frequently penetrated and are managed by pressure for 5 minutes or placement of a vaginal pack. Occasionally, a retropubic space hematoma will develop, but it is self-limited, and the usual treatment is observation.

Bladder perforation occurs in 2% to 4%; the incidence decreases with surgeon experience. Once identified, this event is usually managed by withdrawal and reinsertion of the needle (**Table 41.3**). When this occurs, a Foley catheter is recommended for bladder drainage. The optimal duration for bladder drainage in this setting is not known. Assuming that the sling is replaced after a perforation, it is our practice to continue drainage for 1 week, given that the perforation is almost always adjacent to the permanent implant. Bladder perforation may be minimized by hydrodissection of the retropubic space, keeping the bladder empty and directing the bladder away from the operative site with the rigid catheter guide.

There is a 2% to 3% risk of persistent urinary retention requiring sling revision. This is best performed in the first 4 to 6 weeks after surgery (e.g., before advanced scarring around the mesh). Sling revision includes exposure of the sling by sharp dissection, with midline transsection to allow retraction of the mesh away from the underside of the urethra. In some cases of retention, the tape will be found to have migrated somewhat proximally along the urethra. After sling transsection, continence is maintained in most patients, and the release of the sling allows normal voiding in most cases.

De novo urinary urgency occurs in 10% to 12%, although this symptom is typically self-limited. However, a number of patients require medical intervention. Release or loosening of the sling may help resolve severe urgency symptoms.

Exposure of the permanent sling material is a delayed complication, occurring in approximately 4% of patients

within 24 months. Possible symptoms include bleeding, discharge, and dyspareunia. This complication is usually managed by excision of the exposed mesh and resuturing of the vagina.

^bSeven deaths have been reported, six associated with bowel perforation.

Transobturator Midurethral Sling Procedures

Compared to the retropubic sling, the transobturator sling has the advantage of minimizing the risk to the urinary tract (such as bladder perforation) because the procedure is theoretically below the level of the levator muscles. Thus, risk of injury to the bladder or bowel is theoretically avoided. A second argument in favor of transobturator approach is that the procedure is somewhat quicker: Operative times are approximately 10 minutes shorter with this approach. However, this difference is primarily due to exclusion of cystoscopy in many series.

STEPS IN THE PROCEDURE

Transobturator Midurethral Sling (Inside Out)

- The patient is positioned in Allen stirrups.
- The bladder is drained.
- An anterior vaginal wall incision (1 to 2 cm) is made over the midurethra.

- Using Metzenbaum scissors, a tunnel is created under the vaginal wall, oriented at 45 degrees, until the obturator membrane is penetrated with the scissor tips.
- The winged guide is inserted into the incision.
- The helical trocar is placed through the vaginal incision, following the winged guide. The handle is rotated and moved inferiorly to a vertical position such that the trocar exits 1 cm lateral to the groin fold and at the level of the clitoris.
- The sling is tensioned with a spacer (such as a 9 Hegar dilator) between the sling and the urethra.
- Cystoscopy is performed.
- The same procedure is repeated on the contralateral side.
- The bladder is drained and a voiding trial performed before discharge.

There have been several randomized controlled trials comparing outcomes after transobturator and retropubic slings. A recent Cochrane review of published studies concluded that cure rates were higher with the retropubic (vs. transobturator) approach, but with higher rates of complications. Specifically, cure rates were 88% after retropubic midurethral sling versus 84% after transobturator midurethral sling (relative risk 0.96, 95% confidence interval: 0.93 to 0.99). With respect to complications, the transobturator sling was associated with lower rates of bladder perforation (5.5% vs. 0.3%) and voiding dysfunction (7.0% vs. 4.4%). Although some have argued that symptoms of overactive bladder are more likely after the retropubic approach, the Cochrane review concluded that there is no significant difference in de novo urgency or urge incontinence. Thus, the slightly higher probability of cure after the retropubic sling is balanced by a slightly higher risk of bladder perforation and voiding dysfunction. Similar conclusions were drawn by Dyrkorn, Kulseng-Hanssen, and Sandvik, who analyzed data from a registry of 5,942 Swedish women. Thus, weighing the pros and cons, both procedures are reasonable options for the surgical treatment of SUI.

TABLE 41.3 Minor Complications in 1,455 Tension-Free Vaginal Tape Cases^a

The transobturator sling may be placed with either the “inside-out” or the “outside-in” technique. In either case, the manufacturer supplies the sling with a mechanism to attach the sling to a helical insertion trocar. For the inside-out transobturator sling, the vaginal incision is created under the midurethra. Scissor dissection proceeds on one side until the obturator membrane is penetrated with the scissor tips. A metal winged guide is placed into the vaginal incision and advanced to the defect in the obturator membrane. The helical trocar is placed along the direction of the winged guide and then rotated while the handle is moved inferiorly to a vertical position. The trocar exits 1 cm lateral to the groin fold about 2 cm superior to the urethral meatus and parallel to the clitoris (Fig. 41.11). The tape is retrieved, and tightening follows the same pattern as with the retropubic technique.

For the “outside-in” approach, the vaginal incision needs to be larger, such that the surgeon can insert a finger under the vaginal mucosa to reach to the ischiopubic ramus. The thumb of the same hand grasps the outline of the ramus in the genitofemoral fold between labium majus and the thigh. A point in the groin fold level with the clitoris is selected and a 5-mm incision made on each side. The helical trocar is inserted perpendicularly, and the handle of the helical trocar is at a 45-degree angle (from the horizontal) to accomplish the correct passage (Fig. 41.12). The trocar is then rotated under the pubic ramus, and the vaginal index finger guides it into the vaginal incision (Fig. 41.13). The sling is drawn back through the path of the trocar. The identical procedure is performed on the opposite side. The tightening of the sling is the same as the retropubic approach.

FIGURE 41.11 Inside-out transobturator sling. The passage of the helical needle is shown, exiting the skin approximately 1 cm lateral to the groin fold about 2 cm superior to the urethral meatus and parallel to the clitoris. (Reproduced with permission from Cleveland Clinic Foundation.)

FIGURE 41.12 Outside-in transobturator sling. The passage of the helical needle is shown, beginning at a 5-mm skin incision created approximately 1 cm lateral to the groin fold and at the level of the clitoris. The surgeon's finger, inserted via the vaginal incision to the ischiopubic ramus, guides the trocar into the vaginal incision.

FIGURE 41.13 The trocar for the outside-in transobturator sling is guided into the vaginal incision. The end of the sling will be attached to the trocar and then withdrawn to the skin incision. (Reproduced with permission from Cleveland Clinic Foundation.)

FIGURE 41.14 Along the path of the transobturator sling, potentially vulnerable structures include the muscles of the medial thigh, including the gracilis, adductor brevis, adductor longus, and adductor magnus. (Reproduced with permission from Cleveland Clinic Foundation.)

There have been isolated reports of bladder perforation and urethral injury after transobturator sling placement. Therefore, it is appropriate to perform cystoscopy (with urethral inspection) at the end of the procedure, especially in women with significant prolapse. Vaginal perforation can also occur. The surgeon should diligently assess the vaginal fornices at the conclusion of surgery to ensure the mesh is not exposed. Risk factors for failure of the transobturator sling are similar to those for the retropubic sling: prior incontinence surgery, coexistent urge incontinence, age, and the absence of preoperative urethral hypermobility.

Similar to the retropubic sling, urodynamic parameters, such as low maximum urethral closure pressure and leak point pressure, may signify a lower cure rate after transobturator sling. For example, in one recent multicenter randomized comparison of retropubic and transobturator slings, Nager and colleagues found that a low maximum urethral closure pressure or Valsalva leak point pressure almost doubled the odds of surgical failure in each group. Some have argued that women with poor urethral function are better candidates for retropubic than transobturator slings. Schierlitz and colleagues randomized women with low maximum urethral closure pressure or Valsalva leak point pressure to retropubic or transobturator slings and found a superior cure rate in the retropubic sling group. However, Nager and colleagues could not demonstrate a difference between these two approaches for women with poor urethral function.

The transobturator approach minimizes the risk of retroperitoneal vascular injury, bowel injury, and bladder perforation. However, the trade-off is the possibility of damage to the obturator vessels and nerves. Potentially vulnerable structures (some of which are not familiar to the gynecologist) include the anterior and posterior branches of the obturator nerve and several thigh muscles (gracilis, adductor brevis, adductor longus, and

adductor magnus; Fig. 41.14). In fact, the main argument against the transobturator approach is that pelvic surgeons are more comfortable managing complications in the retropubic space than the transobturator space. The transobturator trocars pass within 1 cm of the obturator nerve, especially if the legs are not sufficiently flexed. One study in cadavers by Hubka and colleagues suggested that the distance to the obturator nerve can be increased to greater than 2 cm if the legs are flexed to 90 degrees with 30 degrees of abduction. The transobturator approach can result in the same postoperative complications of bleeding, hematoma, urgency, and bladder infections as with the retropubic approach. Abscess formation in the ischiorectal fossa has been reported, but it is very uncommon.

As previously noted, the transobturator midurethral sling appears to have a slightly lower incidence of postoperative urinary retention than the retropubic sling. For example, in a multicenter randomized trial of these two approaches, Richter and colleagues found that surgical treatment of voiding dysfunction was performed for 2.7% of women who received a retropubic sling and 0% after transobturator sling ($P = 0.004$). Most authors have found no difference in the incidence of de novo urgency symptoms. Leg and groin pain seems to be more common after transobturator sling placement. For example, Cadish and colleagues reported postoperative groin pain in 34 of 219 (15.5%) at a median follow-up of 1.6 months. The incidence of long-term or persistent groin pain is unknown.

Retropubic Urethropexy

Until midurethral slings became the mainstay of therapy for SUI, the gold standard for the surgical treatment of

P.923

SUI was the retropubic urethropexy (either a Burch or Marshall-Marchetti-Krantz [MMK] procedure). In the past decade, these approaches have largely been abandoned, due to evidence suggesting that midurethral sling procedures are equally effective, with less postoperative voiding dysfunction, shorter operative time, and reduced costs. Nevertheless, these procedures remain effective alternatives for selected patients.

STEPS IN THE PROCEDURE

Burch Urethropexy

- The patient is positioned in Allen stirrups.
 - The bladder is drained.
 - A low transverse abdominal incision is created, and the retropubic space is entered.
 - The bladder neck is identified by the surgeon, with one hand in the vagina and using the Foley bulb as a guide.
 - The pubocervical tissue lateral to the bladder neck is elevated with a vaginal finger, and the overlying tissue and bladder are mobilized medially and superiorly.
 - Permanent sutures are placed on either side of the bladder neck, with a second pair of sutures placed at the level of the midurethra.
 - One arm of each suture is placed through the ipsilateral Cooper ligament.
 - Sutures are tied such that the endopelvic fascia is seen to lift slightly.
 - Cystoscopy is performed.
-

FIGURE 41.15 Anatomic landmarks in the space of Retzius.

The traditional approach to the retropubic space has been through a low transverse incision. A Foley catheter keeps the bladder empty and helps identify the bladder neck. Entry into the peritoneal cavity is avoided unless there is a surgical indication. After opening the rectus fascia, the rectus muscles are separated, and then, gentle downward pressure just behind and lateral to the symphysis allows approach to the pelvic sidewall and endopelvic fascia (Fig. 41.15). If there has been prior surgery in this area, sharp dissection is required to separate the rectus muscle from the underlying preperitoneal tissue and bladder. Depending on the incision size, a self-retaining retractor may be used. The bladder is retracted superiorly with the aid of a moist pack, and the inferior part of the incision is retracted to expose the bladder. Following exposure of the retropubic space, the bladder neck is identified by palpation of a Foley catheter bulb, and it may be marked with hemoclips if desired. The anatomic landmarks and points of attachment of endopelvic fascia can then be identified.

When performing a Burch retropubic urethropexy, the paraurethral tissue is exposed either with a “daisy sponge” (three 4 × 4 sponges fanned out on a sponge stick) or by using a moist sponge and narrow retractor. Some surgeons prefer to use a Miyazaki all-purpose lighted retractor. The paraurethral areas may be cleared of fat that overlies the pubocervical fascia (fibromuscular layer of the vagina). The pubocervical tissue is elevated with a vaginal finger, and the overlying tissue and bladder are mobilized medially and superiorly away from the site of suture placement using a small dissecting sponge or “peanut” (Fig. 41.16). The large veins in this area are avoided, if possible, but may require control with suture, hemoclips, or cautery. The most important aspects of the development of the retropubic space dissection are exposure and retraction and identification of the white endopelvic fascia (also called pubocervical fascia or fibromuscular layer of the vagina). Permanent sutures are placed on either side of the bladder neck. The

more proximal pair of sutures are placed 2 cm lateral to the urethra, into the endopelvic fascia (avoiding full thickness). The more distal pair of sutures are placed at the level of the midurethra (Fig. 41.17). For each of these sutures, a figure-of-eight suture is preferred and will provide additional hemostasis.

FIGURE 41.16 Dissection of the bladder medially to expose the endopelvic fascia. The finger of the vaginal hand elevates the vagina while the instrument pushes medially against the finger.

FIGURE 41.17 Permanent sutures on either side of the bladder neck for the Burch urethropexy. The more proximal pair of sutures are lateral to the bladder neck, and the more distal pair of sutures are at the level of the midurethra. The proximal sutures are placed through the more lateral aspect of Cooper ligament with the distal sutures placed more medially. (Adapted from Tanagho EA. Colpocystourethropexy: the way we do it. *J Urol* 1976;116:751. Copyright © 1976, Elsevier.)

One arm of each suture is placed through the ipsilateral Cooper ligament. The proximal sutures are placed through the more lateral aspect of the Cooper ligament with the distal sutures placed more medially. Recommendation for tensioning of the sutures varies. We prefer to tie the sutures such that the endopelvic fascia is seen to lift slightly. Some surgeons tie the sutures with an assistant's fingers in the vagina, tightening the sutures until the assistant feels the vaginal wall lift off the vaginal fingers. Cystoscopy is performed to exclude injury to the bladder and to verify ureteral patency.

An MMK procedure is performed by identifying the urethra with the aid of the Foley catheter (Fig. 41.18). Sutures are placed on either side of the urethra in a paraurethral location quite close to the urethra (Fig. 41.19). Bilateral permanent sutures are placed at the bladder neck, and usually, at least one set is placed more distally. These sutures are attached to the fibrocartilage of the symphysis pubis. Some surgeons open the bladder dome to locate the bladder neck by direct vision for exact suture placement at the bladder neck. Cystoscopy is performed at the conclusion of the procedure.

The aim of both procedures is to reestablish the intraabdominal location of the proximal urethra and urethrovesical junction and to minimize descent of the bladder neck, thus allowing normal pressure transmission to this crucial area during times of increased intra-abdominal pressure. Cure rates for these procedures range from 85% to 90% at 1 to 5 years and greater than 70% at 10 years. Cure rates are lower among women without preoperative urethral hypermobility, those with recurrent incontinence after prior incontinence surgery, and among those with coexistent urge incontinence.

The Burch urethropexy can also be accomplished laparoscopically. The approach could be either intra-abdominal or extraperitoneal. To facilitate the laparoscopic approach, numerous modifications to the original Burch procedure were described (including using only two sutures; substituting mesh; or using tacks, anchors, and other tools to elevate the bladder neck), but these variations significantly lowered

P.925

cure rates as compared with traditional open urethropexy. A laparoscopic approach with placement of four permanent sutures, identical to an open procedure, has yielded similar 1- and 2-year cure rates as an open Burch (93% and 89%, respectively). However, the more recent introduction of tension-free tape procedures made the laparoscopic Burch less popular.

FIGURE 41.18 For the Marshall-Marchetti-Krantz procedure, the surgeon's finger, in the vagina, allows palpation of the Foley catheter and bulb, assisting with the identification of the urethra and bladder neck.

FIGURE 41.19 Suture placement for Marshall-Marchetti-Krantz operation. Sutures are placed into the endopelvic fascia along the urethra and fixed into the periosteum or fibrocartilage along the back of the symphysis pubis.

Suburethral Slings

The concept of placing a material under the urethra and suspending it to the abdominal wall was introduced as early as 1907 when Giordano used gracilis muscle transposed beneath the bladder neck. Goebell in 1910 used

pyramidalis muscles transposed through the space of Retzius, and first Frangenheim in 1914 and then Stoeckel in 1917 described using a strip of anterior abdominal fascia with the pyramidalis muscles. Price in 1933 harvested fascia lata, which he passed beneath the urethra and then retropubically, and attached it to the anterior rectus fascia on either side of the midline. This technique and its modifications became known as the Goebell-Stoeckel-Frangenheim procedure, or fascia lata sling, but the named surgeons never used fascia lata. Aldridge in 1942 used strips of rectus fascia from a transverse abdominal incision, passed them retropubically, and secured them beneath the urethra. McGuire and Lytton in 1978 described a sling procedure using rectus fascia supported by sutures extending through the space of Retzius and attached to the rectus fascia.

STEPS IN THE PROCEDURE

Suburethral Sling

- The patient is positioned high lithotomy. The bladder is drained with a Foley catheter. If rectus fascia is harvested, Allen stirrups may be preferred.
 - A suprapubic transverse abdominal incision is made and continued to the fascia. The surgeon may elect to harvest rectus fascia at this point.
 - Subcutaneous fat is cleared from the surface of the fascia at the location where the sling arms (or sutures) will be passed through the fascia (above the symphysis and 2 cm lateral to the midline).
 - A midline vaginal incision is created, and the vaginal epithelium is dissected off the fibromuscular layer to the descending pubic ramus.
 - The surgeon enters the retropubic space and uses a finger to mobilize the bladder and retropubic fat medially and superiorly.
 - A long pair of packing forceps is inserted via the abdominal incision, perforating the rectus and entering the retropubic space. The surgeon's finger, placed into the retropubic space via the vagina, meets the advancing clamp (minimizing the potential risks of blind passage).
 - Each sling arm is thus passed from the vaginal to the abdominal field. The central portion of the sling is tacked to the bladder neck to prevent movement from the placement site.
 - Tension on the sling arms is adjusted. If the sling is of sufficient length, the sling arms are sutured to the rectus fascia. If the sling is not sufficiently long, permanent sutures, placed through the end of each sling arm, are sutured to the rectus fascia.
 - Cystoscopy is performed.
-

P.926

There are several critical differences between the traditional *suburethral* sling and newer *midurethral* sling procedures. The most obvious difference is that a midurethral sling is positioned at the midurethra, while a suburethral sling is placed at the proximal urethra or bladder neck. Also, suburethral slings are not “tension free,” while the suburethral sling is intended to both elevate the urethrovesical junction into an intra-abdominal location and to provide partial compression of the urethra. Another distinction between the suburethral and midurethral sling is that the ends of the suburethral sling are fixed to the rectus fascia. During periods of increased abdominal pressure, the abdominal wall moves outward and the sling is thus drawn upward. This compresses the urethra and increases intraurethral resistance.

Since the original introduction of the suburethral sling procedure, a variety of materials have been employed, including rectus fascia, fascia lata, grafts of vaginal wall, gracilis muscle, round ligaments, pyramidalis muscle, and rectus muscle. Our preference is to use rectus fascia. However, because of additional operative time and morbidity to harvest autologous materials, a variety of synthetic materials have also been used. Synthetic

materials are now almost completely confined to polypropylene mesh. Other biomaterials, including human allografts and xenografts (such as porcine and bovine tissues), have also been used, but their use has largely been abandoned due to variability in inflammatory response and evidence to suggest poorer treatment outcomes.

Sling length has varied in the many procedures described. Our preference is to harvest an autologous fascial sling of sufficient length to attach directly to the rectus fascia. A full-length sling is greater than 10 cm long; a sling of this length is usually sufficiently long to pass underneath the urethra, through the endopelvic fascia and retropubic space, all the way to the point of fixation at the rectus fascia, where it is secured with sutures. An alternative is a sling that is sufficiently long to extend into the retropubic space (at least 6 cm length) but not to the rectus fascia. This “half-sling” is anchored to the rectus fascia via suspending sutures and secured to the sling arms. Shorter slings (“patch slings”) are similar to the Pereyra procedure and other needle suspension procedures that have been abandoned due to lack of efficacy. Thus, patch slings are not recommended.

The traditional suburethral sling procedure includes both abdominal and vaginal incisions. The retropubic space can be entered from either route, but our preference is to enter this space from the vaginal field. The abdominal incision should be created first if rectus fascia is harvested. The suprapubic incision is typically transverse, approximately 1 to 2 cm above the pubic bone. The goal is to harvest a fascial strip 2 cm wide (Fig. 41.20). After excision, the graft is wrapped in saline-soaked gauze or placed in an antibiotic solution. The fascia is mobilized sharply off the underlying muscle to avoid tension in the closure. The fascial incision is then closed. After the rectus fascia strip is harvested, subcutaneous fat is cleared from the surface of the fascia at sites 2 cm above the symphysis and 2 cm lateral to the midline. This is the location where the sling arms (or sutures) will be passed through the fascia.

The vaginal dissection commences with an inverted T midline incision along the anterior vaginal wall. The epithelium is dissected off the fibromuscular layer laterally until access through the endopelvic fascia is readily available beneath the descending pubic ramus. Sharp dissection to the level of the pubic ramus allows easy access to perforate the endopelvic fascia. The surgeon may perforate into the retropubic space sharply or bluntly, directing the instrument or finger toward the ipsilateral shoulder (Fig. 41.21). Once the endopelvic fascia has been perforated, the surgeon uses a finger to mobilize the bladder and retropubic fat medially and superiorly, clearing the tissue away from the bone.

FIGURE 41.20 Incision for harvest of rectus fascia.

At this point, the fibromuscular layer of the vaginal wall can be plicated if extra thickness is desired under a

synthetic sling or there is a central anterior vaginal wall support defect.

From the abdominal incision, a long pair of packing forceps or similar instrument or a Stamey needle is used to pass the sling from the vaginal to the abdominal incision.

FIGURE 41.21 Perforation of the endopelvic fascia to open the space of Retzius and mobilize the periurethral tissues.

FIGURE 41.22 Passage of sling material through the space of Retzius from vaginal to abdominal site. Rectus fascia partial sling with attached sutures. (Reprinted from Brubaker L. Suburethral sling procedures. *Oper Tech Gynecol Surg* 1997;2:48, with permission. Copyright © 1997, Elsevier.)

The instrument perforates the rectus fascia just superior to the pubis, approximately 2 cm lateral to the midline. A finger placed in the vaginal dissection reaches to the retropubic space to meet the advancing clamp or needle, minimizing the potential risks of blind passage (**Figs. 41.22** and **41.23**). On each side, one arm of the sling is grasped and passed to the abdominal field and held. If the sling is short and the surgeon believes the sling arms cannot reach the abdominal wall fascia, permanent sutures are passed through each sling arm, and these sutures are then passed to the abdominal field.

After the sling arms are passed, the midportion of the sling is sutured under the bladder neck and proximal urethra to prevent movement from the placement site. A Foley catheter bulb is used to identify the bladder neck. Traditionally, the sling was placed at the bladder neck. However, as surgeons have gained experience with slings placed at the midurethra, many have also moved traditional suburethral sling placement more distally, to the proximal urethra or midurethra.

At the abdominal field, the sling arms are sutured to the rectus fascia (**Fig. 41.24**). The arms of the sling or suspending sutures may also be secured to each other, across the midline. Sling tension has been variably described. Some surgeons intentionally leave the sling loose (tension-free). Our practice has been to place a lubricated cotton swab in the urethra and to elevate the sling arms until there is a very slight deflection of the swab (indicating very slight tension on the sling arms). The vaginal and abdominal incisions are closed. A vaginal pack is placed at the discretion of the surgeon.

FIGURE 41.23 Passage of fascia lata strip through space of Retzius. Under guidance from the surgeon's hand in the vaginal incision through the endopelvic fascia into the space of Retzius, a clamp is passed from the abdominal incision to the vaginal incision. The end of the fascia is grasped and retrieved to the abdominal site.

The duration of voiding dysfunction is longer after a suburethral sling procedure than after the retropubic urethra or midurethral sling procedures. Thus, a suprapubic catheter may be preferred in this setting. However, a suprapubic catheter, Foley catheter, and intermittent self-catheterization are acceptable options. In our experience, the duration of hospitalization is one night.

Complications ([Table 41.3](#)) include retropubic bleeding. Large veins under the descending pubic ramus may be avulsed during the vaginal portion of the procedure, and there are often vessels on the medial side of the vaginal dissection into the retropubic space. The latter can be isolated and cauterized or sutured, but bleeding from under the pubis is best controlled by pressure, completion of the procedure, and placement of a vaginal pack. Significant bleeding is rare.

FIGURE 41.24 Sling positioned at proximal urethra, extending through the space of Retzius, and fixed to the rectus fascia.

Bladder perforation can occur during retropubic dissection. Cystoscopy at the completion of the procedure is critical to identify injury to the urinary tract and ureteral compromise; urethroscopy is sometimes used to assess for obstruction due to excessive tension on the sling arms.

Short-term complications include continued voiding difficulty, bladder infection, and overactive bladder symptoms. A wound seroma or infection may occur at either the abdominal incision site or at the fascial harvest site. If a significant hematoma has occurred, abscess formation may follow. Vaginal healing may be compromised by delayed healing of the anterior vaginal wall, oozing or bleeding from the suture sites, and failure of the incision to close properly over the sling.

Long-term complications include voiding dysfunction, overactive bladder symptoms, and procedure failure. If the patient is unable to void at all, the sling may need to be incised. The occurrence of a vaginal exposure of a synthetic sling is usually a delayed event.

The cure rate for sling procedures is more than 80%. Traditionally, suburethral slings were reserved for cases of recurrent incontinence (after prior anti-incontinence surgery) or in cases complicated by ISD. However, suburethral sling procedures may also be considered for the surgical treatment of primary SUI. In a multicenter clinical trial, Albo and colleagues found that the suburethral sling resulted in a higher cure rate compared to retropubic urethropexy (66% vs. 49%, where cure was defined as a negative cough and Valsalva stress test, no self-reported symptoms, and no retreatment for the condition; $P < 0.001$). However, the same investigators found that the suburethral sling was associated with a greater risk of voiding dysfunction at 6 weeks (14% vs. 3%) and a greater incidence of surgical revision due to voiding difficulty (6% vs. 0%). A Cochrane review identified 12 studies comparing traditional suburethral slings with minimally invasive midurethral slings. Effectiveness was

similar, but the traditional slings had longer operative time and more complications. Also, postoperative voiding dysfunction was more likely higher after traditional sling procedures. Thus, suburethral sling procedures are typically reserved for recurrent or complicated SUI.

Periurethral Bulking Procedures

In 1993, the U.S. Food and Drug Administration approved the use of cross-linked bovine collagen (Contigen) for the treatment of SUI complicated by ISD (defined by Medicare as a low Valsalva leak point pressure). Although this product is no longer commercially available, a number of other bulking agents have since been introduced. At this writing, the commercially available urethral bulking products in the United States include carbon-coated zirconium oxide beads (Durasphere [Coloplast; Minneapolis, MN]), calcium hydroxylapatite (Coaptite; Boston Scientific), and polydimethylsiloxane, (Macroplastique [Uroplasty, Inc.; Minnetonka, MN]). Because there is no advantage of any particular bulking agent, selection is usually based on operator experience, ease of injection, cost, and availability of the product.

STEPS IN THE PROCEDURE

Transurethral Injection of Bulking Agent

- This procedure may be done in the office or clinic.
 - The patient empties her bladder and is placed in the lithotomy position.
 - Topical anesthetic gel can be applied to the urethra.
 - Using a cystoscope with a 12-degree or 25-degree lens, the urethra is inspected. The bladder neck is identified, and the scope is withdrawn to visualize the proximal urethra.
 - The desired bulking agent is injected via an appropriate needle (usually gauge), approximately 2 cm distal to the bladder neck.
 - The usual injection sites are 3 and 9 o'clock.
 - Bulking material is injected until visible closure of the urethral lumen.
 - A voiding trial should be performed before the patient leaves the clinic. This can be facilitated by leaving the bladder comfortably full at the conclusion of the procedure.
-

Urethral bulking agents are traditionally a choice for women with limited urethral mobility. Indeed, the initial labeling for Contigen specified that the product was intended for use in the absence of urethral hypermobility. The ideal patient for treatment with a bulking agent is one who has documented SUI with a fixed bladder neck (cotton swab straining angle 30 degrees or less). A bulking agent may also be preferred in women with SUI who are poor surgical candidates and for those who prefer to use a less invasive technique.

FIGURE 41.25 Transurethral needle placement in urethral submucosa. (Reprinted from Bent AE. Periurethral collagen injections. *Oper Tech Gynecol Surg* 1997;2:54, with permission. Copyright © 1997 Elsevier.)

Bulking agents can be injected via either a periurethral or transurethral technique. The ideal setting for injection is the office or clinic. No sedation is required. The injection is performed in a sterilized field by using no-touch technique. We typically prefer the transurethral technique when the procedure is performed in the office setting because of patient comfort. Before the procedure, some surgeons administer a single dose of fluoroquinolone or trimethoprim/sulfamethoxazole, although the benefit of prophylactic antibiotics has not been demonstrated.

Prior to the procedure, the patient empties her bladder and is placed in lithotomy position. Topical anesthetic gel can be applied to the urethra. The transurethral method is best accomplished using a cystoscope with a 12-degree or 25-degree lens. The sheath should have an operating channel that allows the passage of an injection needle, and the tip should not be fenestrated. If a local anesthetic is desired, the needle may be prefilled with lidocaine 1% solution. If no local anesthetic injection is planned, the syringe with bulking material is attached, and the cystoscope with injection needle retracted is placed into the bladder. The bladder neck is identified, and the scope is withdrawn to visualize the proximal urethra. The usual injection sites are 3 and 9 o'clock, but this can be varied, depending on user preference and number of injection sites selected (up to four). The injection needle is advanced into the urethra submucosa approximately 2 cm distal to the bladder neck ([Fig. 41.25](#)), and the bulking material is injected. The goal is to achieve coaptation, with visible closure of the urethral lumen.

For the periurethral technique, local anesthesia using 0.5 to 1.0 mL of lidocaine hydrochloride is injected 0.5 cm on either side of the urethral meatus ([Fig. 41.26](#)). Under endoscopic guidance, lidocaine 1% solution is injected lateral to the urethra, using a spinal needle. The needle is advanced, parallel to the urethra, while endoscopic guidance is used to direct the injection. Lidocaine is injected in small amounts as the needle is advanced until reaching 1 cm distal to the bladder neck ([Fig. 41.27](#)). At this point, the syringe with lidocaine is replaced with a syringe of bulking agent (e.g., without withdrawing the needle), and the material is injected until the entire syringe has been injected or there has been adequate effect noted with urethral bulking. To achieve the desired coaptation, the process may be repeated on the opposite site. The second side may be more difficult to inject because of the distortion caused by the initial injection.

FIGURE 41.26 Periurethral bulking technique. Injection of local anesthetic lateral to Skene duct openings. (Te Linde figure 37.22; Reprinted from Bent AE. Periurethral collagen injections. *Oper Tech Gynecol Surg* 1997;2:52, with permission. Copyright © 1997 Elsevier.)

Injection needles vary in diameter according to the ease of injection of the selected material, and the implant manufacturers typically recommend their own proprietary needles for this purpose. Durasphere and Macroplastique are injected through an 18-gauge needle, while Coaptite can be injected through a 21-gauge needle. Macroplastique injection is accomplished using a proprietary high-pressure administration device that allows the surgeon to deliver the implant by pulling on a trigger-like lever.

A voiding trial should be performed before the patient leaves the clinic. This can be facilitated by leaving the bladder comfortably full at the conclusion of the procedure. If the patient is unable to void adequately, she should be instructed in self-catheterization. After injection, the patient may experience dysuria or urethral burning. This symptom typically lasts for only part of a day and can be controlled with phenazopyridine (Pyridium).

One or two additional injections may be required to obtain a satisfactory result; we typically assess the need for a second injection 4 to 6 weeks after the first. After 1 to 3 initial injections, the success rate is generally quoted to be about 70%. However, there is substantial controversy about the durability of the effect achieved with bulking agents. Chrouser et al. found that the initial success declined by about one half over the first year of observation. In a longitudinal study of women treated with Macroplastique, Ghoniem found that two thirds of those successfully treated remained “dry” at 24 months. Thus, the effectiveness of bulking agents declines over time. Women treated successfully with an injection of bulking agent often experience recurrence; repeat injections can be employed. There is no limit to the number of injections, provided that improvement occurs after each injection and lasts a reasonable period of time.

FIGURE 41.27 A: Periurethral injection at the bladder neck. B: Bulking of bladder neck and proximal urethra.

The success of bulking agents does not appear to depend on the presence of urethral hypermobility. Thus, this option is the most attractive for women with a well-supported urethra (because the success of more invasive methods, such as sling procedures, is relatively low in this setting). However, there have been relatively few clinical trials comparing bulking agents with other surgical treatments for SUI. Corcos and colleagues performed a randomized comparison of Contigen injection versus surgery (a variety of surgical procedures were included). In this study, the majority of participants had urethral hypermobility. The investigators found no significant difference in the proportion of women with a “dry” pad test at 1 year. However, 25% of women did not receive the randomized treatment assignment, thus decreasing the probability that a difference would be detected. In another study, Maher et al. randomized women with SUI and low urethral closure pressure to injection of Macroplastique versus rectus fascia sling. Approximately 10% of the participants had urethral hypermobility. At 6 months, objective but not subjective cure rate was significantly higher in the sling group.

Complications of bulking agents are limited to transient urinary retention (best managed with intermittent self-catheterization) and rare cases of granuloma or erosion of the material into the urethra.

SUMMARY

The surgical management of SUI has developed over almost 100 years. In the past two decades, high-quality randomized controlled trials have been conducted, providing evidencebased options for the surgical treatment of SUI. As a result, less effective surgeries (such as Kelly placcation and needle suspensions) have largely been abandoned. The contemporary approach to treatment of SUI begins with a very careful clinical evaluation and the selective use of urodynamic testing. A positive stress test should be demonstrated before surgery. Referral to a subspecialist is appropriate for women with more complicated incontinence, such as those with mixed incontinence (e.g., significant urge-related symptoms), absent urethral hypermobility, urinary retention (postvoid residual volume >150 mL), prior anti-incontinence surgery, prior radical pelvic surgery or irradiation, and those with neurologic disease. Nonsurgical options,

such as antiincontinence pessaries and supervised physiotherapy programs, result in satisfactory outcomes for 50% of women and should be encouraged. For those who elect surgical treatment, midurethral sling procedures (either retropubic or transobturator) provide high success rates. More invasive options, which might be appropriate in certain clinical situations, include the retropubic urethropexy and suburethral sling procedures.

BEST SURGICAL PRACTICES

- Evaluation before surgery for SUI includes history, physical examination, pelvic examination, voiding diary, symptom questionnaire, residual urine determination, cotton swab test for urethral mobility, and urinalysis. If there is any concern regarding symptoms or prior procedure failure, then cystometry (and often cystoscopy) should be performed. Referral to a subspecialist is appropriate for women with more complicated incontinence, such as those with mixed incontinence (e.g., significant urge-related symptoms), absent urethral hypermobility, urinary retention (postvoid residual volume >150 mL), prior anti-incontinence surgery, prior radical pelvic surgery or irradiation, and those with neurologic disease.
- Women who elect surgical treatment of primary SUI may be offered a tension-free midurethral sling (either retropubic or transobturator). Other effective options include Burch retropubic urethropexy or suburethral sling.
- After an anti-incontinence procedure, cystoscopy is recommended to assure there is no bladder injury.
- Urethral bulking agents may be a good choice in the treatment of women with SUI who are poor surgical candidates and those with minimal mobility of the bladder neck, that is, cotton swab test less than 30 degrees straining.

P.931

TEST QUESTIONS

1. Which of the following women are least likely to benefit from a urodynamic evaluation prior to surgical treatment of stress incontinence?

- A. A 45-year-old with a history of a prior sling procedure
- B. A 55-year-old with a well-supported bladder neck
- C. A 68-year-old who did not experience improvement in symptoms after a course of supervised behavioral therapy
- D. A 44-year-old who has mixed symptoms of stress and urgency incontinence

Answer

(The answer is C.)

2. Which of the following vascular structures are most vulnerable in a retropubic midurethral sling procedure?

- A. The inferior epigastric artery
- B. The internal pudendal artery
- C. The perineal branch of the external pudendal artery
- D. The internal iliac artery

Answer

(The answer is A.)

3. Which of the following is not true?

- A. The incidence of persistent voiding dysfunction requiring surgical revision is approximately 3% after retropubic midurethral sling.
- B. Women with voiding dysfunction can be reassured that continence is usually maintained after sling transection.
- C. Among women with voiding dysfunction after midurethral sling procedure, urinary retention resolves in a majority of cases treated with sling transection.
- D. The incidence of postoperative voiding dysfunction is the same after retropubic versus transobturator midurethral sling.

Answer

(The answer is D.)

Chapter 42

Operative Injuries to the Ureter

E. James Wright

Victoria L. Handa

DEFINITIONS

Cystotomy—Incision into the urinary bladder.

Psoas hitch—A technique to facilitate repair of mid- and distal ureteral injuries. The bladder is mobilized and anchored to the ipsilateral psoas muscle to facilitate tension-free ureteroneocystostomy.

Spatulate—To incise the cut end of a tubular structure longitudinally and splay it open to allow creation of an elliptical anastomosis of greater circumference than would be possible with conventional transverse or oblique end-to-end anastomoses.

Tampon test—A test used to differentiate vesicovaginal from uterovaginal fistula in the setting of postoperative vaginal fluid leak. Saline colored with methylene blue dye is instilled into the bladder and a tampon inserted into the vagina. If the tampon is unstained, a ureteral injury is suspected.

Ureteroileoneocystomy—Restoration of continuity of the urinary tract by anastomosis of the upper segment of the ureter to a segment of ileum, the lower end of which is then implanted into the bladder.

Ureteroneocystostomy—Reimplantation of the ureter into the bladder.

Ureteroureterostomy—Anastomosis between two segments of the ipsilateral ureter. When done between contralateral ureteral segments, this is termed transureteroureterostomy.

Urinoma—A fluid collection containing urine.

Ureteral injuries have been recognized as a potential complication of gynecologic surgery since the inception of our discipline. Over the years, numerous unique surgical modifications of procedures have been offered with the specific intent of decreasing the probability of ureteral injury. Despite these efforts, ureteral injury remains a very real complication of abdominal-pelvic surgery in the female patient.

The incidence of ureteral injury during gynecologic surgery is commonly cited as 1% to 2%, although the incidence varies with the nature of the surgery, the skill of the surgeon, and the complexity of the patient's anatomy. Ibeanu and colleagues reported injury to the ureter in 15 of 839 hysterectomies performed at a teaching hospital in which universal cystoscopy was employed (incidence 1.8%, 95% confidence interval: 1.0%, 2.9%). Therefore, it is important for the gynecologic surgeon to be cognizant of ways to minimize the occurrence of this potentially disastrous complication, and to be facile in the diagnosis and management of such an injury should it occur.

The goals of this chapter are to (a) outline the functional anatomy of the ureter and illustrate how this leads to the ureter being in harm's way during gynecologic surgery, (b) review the unique issues surrounding ureteral injury during the performance of specific groups of gynecologic surgical procedures, and (c) summarize the basic principles of injury avoidance and, should injury occur, recognition and management.

FUNCTIONAL ANATOMY OF THE URETER

When viewed in cross section, the ureter can be divided into distinct layers: the lumen with transitional

epithelium; the mucosa—the muscular layer—which is made up of longitudinal, circular, and spiral smooth muscle fibers; and the adventitia, which contains an intercommunicating network of blood vessels (Fig. 42.1). The peritoneum lies over the ureter, making it a completely retroperitoneal structure.

In normal adults, the ureter is between 25 and 30 cm in length from the renal pelvis to the trigone of the bladder. By convention, the pelvic brim divides the ureter into the abdominal and pelvic segments; each of these components is approximately 12 to 15 cm in length.

The abdominal ureter runs along the ventral surface of the psoas muscle and posterior to the ovarian vessels to the level of the pelvic brim. The right ureter lies slightly lateral to the inferior vena cava and descends into the pelvis over the common iliac artery at approximately the site of the latter's bifurcation. In rare instances, the right ureter can be over the vena cava; therefore, if one is performing a paraaortic node sampling, the ureter must be identified before removing any nodes. The left ureter runs lateral to the aorta and posterior to the inferior mesenteric artery, ovarian vessels, and colon. The left ureter mirrors the right at the pelvic brim, entering the pelvis over the bifurcation of the left common iliac artery (Fig. 42.2). The left ureter is commonly obscured by the sigmoid colon at the pelvic brim.

FIGURE 42.1 Cross-sectional (A) and sagittal (B) views of the longitudinal arteries and veins in the adventitia. These arteries and veins provide the important collateral circulation along the course of the ureter.

FIGURE 42.2 A: Abdominal and pelvic portions of the ureter showing relation to aorta, psoas muscle, vena cava, and common iliac artery and vein. (The original illustration is in the Max Brödel Archives in the Department of Art as Applied to Medicine, the Johns Hopkins University School of Medicine, Baltimore, MD. Used with permission.) B: Pelvic portion of the ureter showing its course along the sidewall of the pelvis and its relation to the common iliac vessels, hypogastric vessels, uterosacral ligaments, uterine vessels, and cervix.

There is little variance between the positions taken by the pelvic ureters. They descend into the posterior lateral pelvis

P.934

lateral to the sacrum and immediately ventral to internal iliac (hypogastric) artery. The ureters then course medial to the internal iliac artery and its anterior branches. The ureters subsequently pass beneath the uterine artery (often referred to as *water under the bridge*). The ureter is approximately 1.5 cm lateral to the cervix where it enters the paracervical tissues. The ureter passes through this paracervical tissue, often referred to as “the tunnel” of the cardinal ligament/anterior bladder pillar (also referred to as the web or the tunnel of Wertheim). Once through this tunnel, the ureter travels medially and anteriorly over the vaginal fornix to enter the trigone of the bladder.

When inflammatory or adhesive changes are not present, the ureters can usually be visualized through the peritoneum from the pelvic brim to this parametrial tissue. Once the ureters have entered this tunnel, they cannot be easily seen or palpated; if identification is required, they must be mobilized out of this tissue. Although the peristaltic activity that occurs in the normal ureter may be helpful in its identification, it is not uncommon that the ureter, following any degree of trauma, will have transient paralysis. Therefore, the skill of accurately identifying the ureter is based on understanding its anatomy, not its motion. The ureter is unique in that it has a “snap” feeling when passed between the fingers during laparotomy. This may be helpful in massively obese women with poor exposure. This “snap” will also permit one to follow the ureter to the tunnel without actually exposing it. This technique is not applicable to laparoscopic or robot-assisted procedures. In these cases, identification of the ureter is enhanced by camera magnification but may require surgical exposure for confirmation of its course. Having defined the general anatomy of the ureter, one must appreciate that there is a significant degree of interpatient variability, even in a pelvis free of inflammatory, infectious, neoplastic, congenital, or postsurgical changes. Direct visualization of the ureter is the only sure way to know its location in any given patient.

FIGURE 42.3 Blood supply of the ureter.

Along its course, the vascular supply of the ureter is derived from a variety of sources. Above the pelvic brim, the blood supply of the ureter is derived from medial vessels; more distally, the blood supply originates laterally ([Fig. 42.3](#)). Thus, cephalad to the pelvic brim, dissection and mobilization of the ureter should be approached from its lateral aspect, and the converse is true distal to the pelvic brim. The ureter is perfused by a rich network, with anastomoses within the adventitial sheath. The ureter is therefore relatively resistant to devascularization. However, such injuries may occur and can be difficult to diagnose, as the sequelae may not be apparent until the

postoperative period.

INJURY TO THE URETER IN GYNECOLOGIC SURGERY

Hysterectomy

The ureter is vulnerable to injury during hysterectomy when the uterine artery is divided (Fig. 42.4). This is because the ureter passes under the uterine artery, lateral to the uterosacral ligaments, as it travels medially and ventrally to terminate in the bladder. The risk of injury to the ureter can be minimized by careful dissection of the bladder off the cervix, by upward traction on the uterus during the placement of clamps, and by clamping the uterine artery immediately along the cervix (rather than more laterally). At the conclusion of hysterectomy, the surgeon should be particularly vigilant when addressing bleeding from pedicles, especially at the vaginal angles. Bleeding from the pedicles or vaginal angle should be controlled by a “superficial” 3-0 suture so as not to incorporate the ureter.

FIGURE 42.4 The ureter may be injured during hysterectomy. The uterine artery is divided adjacent to the cervix, where the ureter is in close proximity to uterine artery. The ureter may also be injured during ligation of the infundibulopelvic ligament, as it passes adjacent to the ovarian vessels.

P.935

Hysterectomy in the setting of cervical or broad ligament fibroids can be particularly challenging. The ureter can be anterior, lateral, or posterior to the fibroid. Clamping pedicles around the fibroid imposes significant risk for ureteral injury. In such cases, it may be prudent to perform a myomectomy by incision adjacent to the uterus or cervix. This can be done without risk of ureteral injury by staying within the myometrial capsule of the fibroid. Bleeding may occur, but once the fibroid is out, such bleeding is easily controlled by clamping adjacent to the uterus. In the rare case when this is impossible, the entire course of the ureter must be identified before clamping or cutting.

Ureteral injury during vaginal hysterectomy is remarkably uncommon. To some extent, this may be because vaginal hysterectomy is not typically performed for conditions most likely to distort ureteral anatomy, such as endometriosis or malignancy. In addition, the risk of ureteral injury is reduced during vaginal hysterectomy (compared to abdominal hysterectomy) because traction on the cervix pulls the uterus farther from the ureter.

Tension on the cervix is therefore critical during the clamping of pedicles.

Ureteral injuries that occur during laparoscopic hysterectomy may be the result of thermal injury. When performing laparoscopic hysterectomy, it is imperative to know the location of the ureter. It can usually be visualized through the peritoneum; when not visible, it should be identified retroperitoneally and followed to the site of operative interest. Extreme caution should be used with cautery near or over the ureter, as thermal spread can cause occult injury that does not become apparent until 2 to 5 days after surgery.

Adnexal Surgery

Ureteral injury at the time of adnexectomy is worthy of specific comment. Especially in cases of an adnexal mass and distortion of the anatomy, the ureter is particularly vulnerable and it is in this setting that the ureter is commonly injured. These injuries can be avoided by using a retroperitoneal approach.

Every pelvic surgeon must be able to quickly and safely enter the retroperitoneum (which continues deep into the pelvis as the pararectal space). This surgical skill is necessary to (a) access the pelvic vessels for the purpose of establishing hemostasis and (b) use the retroperitoneum as an adhesion- and pathology-free “space” in which to operate. Access is obtained most commonly for the latter purpose. Once this retroperitoneal space has been developed, the ureter should be visible on the medial leaf of the broad ligament.

FIGURE 42.5 The ureter is dissected away from the peritoneum to permit resecting of ovarian mass/remnant.

If an adnexal mass is adherent to the peritoneum overlying the ureter, the ureter can safely be dissected from the peritoneum. Distal to the pelvic brim, the dissection should be approached from the medial aspect of the ureter to minimize the risk of devascularizing the ureter. Once the ureter has been mobilized and is out of harm's way, resection of the mass and the inflamed, scarred, or fibrotic peritoneum can be performed safely (Fig. 42.5). There are rare instances when it is impossible to mobilize the ureter from the pathology. In this setting, the surgeon must decide whether to leave residual tissue on the ureter (risking subsequent ureteral obstruction) or to resect a segment of ureter and repair accordingly.

Retropubic Surgery

Injury to the distal ureter may occur with high elevation of Burch colposuspension sutures. The ureter may also be injured by excessive lateral mobilization of the bladder. Mobilization exposes the dorsal surface of the bladder in the vicinity of the trigone and may bring the ureter into the operative field.

There are specific steps that can be taken to avoid such injuries. Dissection into and through the space of Retzius should be done under direct visualization, remaining as close to the symphysis pubis as possible. The amount of dissection that occurs over the lateral paravaginal tissues should be kept to the minimal amount needed to guarantee accurate and appropriate placement of the sutures. Finally, the urethrovesical junction must not be elevated excessively as this can cause kinking not only of the urethra but also the ureters in certain patients.

Surgery for Pelvic Organ Prolapse

The ureter may be ligated or kinked with surgery to correct prolapse. The risk appears to be highest with uterosacral ligament suspensions of the vagina. Barber and colleagues

P.936

reported ureteral obstruction in 11% (5/46) of cases (treated with release of the suspension sutures or ureteral reimplantation). Karram and colleagues reported ureteral injury in 5/202 (2.4%), and Shull and colleagues reported ureteral injury in 3/302(1%).

Anatomic studies by Buller and colleagues demonstrated that the distance from ureter to uterosacral ligament is 4.1 ± 0.6 cm at the sacral origin of the uterosacral ligament, decreasing to 0.9 ± 0.4 as the uterosacral ligament approaches the cervix. Placement of the suspension sutures at or slightly above the level of the ischial spine (in the intermediate portion of the uterosacral ligament) is therefore recommended to minimize the risk of injury. Ureteral injury has also been reported with sacrospinous suspension, midurethral sling, and anterior colporrhaphy. Thus, confirmation of ureteral patency via cystoscopy should be routinely performed at the conclusion of these procedures to verify ureteral integrity.

Radical Pelvic Surgery

Of all the groups of surgical procedures performed, those performed for the treatment of cancers affecting the female reproductive tract are the most likely to involve either intentional ureteral surgery or have the highest risk of an associated ureteral injury. It is important to differentiate between intentional ureteral disruption and unintended or inadvertent injury. The MD Anderson type IV radical hysterectomy, a total or anterior pelvic exenteration, and resection of a fixed pelvic sidewall mass involving the ureter may include ureteral resection and reconstruction by design. As a result of the nature of gynecologic malignancies and the procedures performed to treat those diseases, intentional and sometimes unintentional ureteral injuries occur. Additionally, the need to explore a radiated field, or one in which multiple operations have been performed, compounds cofactors that put the ureter at risk. It is evident that the surgeon must not only be expert in pelvic anatomy but also have the judgment to establish how and when to address a problem while minimizing the probability of injury.

How common are ureteral injuries in association with radical pelvic surgery? Recent data from the National Hospital Discharge Survey suggest that ureteral injury during radical hysterectomy occurs in 7.7 per 1,000 cases. Historically, the average rate of ureteral injury at the time of radical hysterectomy has approximated 1%, with a concomitant similar rate of bladder injury. Interestingly, these rates have been consistent over time and among different surgical groups. In contradistinction to these relatively low rates of ureteral injury, when radical resection is performed following radiation therapy there is an associated risk of ureteral dysfunction of approximately 30%. Ureteral injury associated with lymph node dissection or when performing “radical” oophorectomy is remarkably uncommon when those injuries occurring near the entrance to and through the

tunnel of Wertheim are excluded from the data.

DIAGNOSING URETERAL INJURY

Diagnosis of Ureteral Injury during Surgery

As noted, pelvic surgery risks injury to the ureter at a number of sites along its course ([Table 42.1](#)). A clear understanding of ureteral anatomy and its potential variability is critical to avoiding injury. The surgeon should make a habit of confirming ureteral integrity during and at the conclusion of any pelvic procedure, regardless of whether the surgery is done by the vaginal, open, laparoscopic, or robot-assisted approach. This will require direct visualization of the ureter (or palpation, in the setting of laparotomy). For both open and laparoscopic procedures, opening of the parietal peritoneum may at times be necessary to allow for accurate inspection or to allow for mobilization and separation from the site of operative interest. This is especially important in the setting of inflammatory conditions such as endometriosis, malignancy, or adhesions from prior surgery.

TABLE 42.1 Common Sites of Ureteral Injuries

Cardinal ligament where the ureter crosses under the uterine artery
Tunnel of Wertheim
Intramural portion of the ureter
Dorsal to the infundibulopelvic ligament near or at the pelvic brim
Lateral pelvic sidewall above the uterosacral ligament

If ureteral injury is suspected, visualizing peristalsis is inadequate to exclude occlusion or extravasation. Ureteral integrity can be confirmed during intra-abdominal surgery by intravenous administration of a coloring agent and observation for intrapelvic extravasation. In vaginal surgery, direct visualization of the at-risk ureteral segments is seldom possible. For this reason, we advocate intraoperative cystoscopy for confirmation of urine efflux from the ureteral orifices at the conclusion of transvaginal procedures accessing the anterior or apical vagina. This may be facilitated by an intravenous coloring agent. Following abdominal procedures, cystoscopy may also be performed to confirm ureteral patency. The use of a flexible cystoscope allows this procedure to be done with the patient in supine position if necessary.

To the extent possible, acute ureteral injuries are best recognized and managed intraoperatively. Many of these occurrences may rely on collaborative assistance from colleagues in urology or urogynecology. This would include decisions regarding the nature of the repair and the decision to proceed with intracorporeal repair versus conversion to laparotomy in the setting of laparoscopic and robot-assisted procedures. Successful intraoperative repair of ureteral injuries minimizes the risk of sequelae, including stricture, fistulae, loss of renal function, and need for subsequent reoperation.

With the common and generous use of cautery devices in pelvic surgery, ureteral injury may not be apparent until the postoperative period. Cautery devices must be used with care, as diffusion of thermal energy can cause occult ureteral injury resulting in delayed stricture or urine leak presenting days to weeks postoperatively. A high index of suspicion must be carried through the postoperative period to insure early diagnosis and management if necessary.

It is unclear whether preoperative ureteral stenting helps to prevent ureteral injury. The data generally suggest that presence of a ureteral stent facilitates identification of injury should it occur, rather than prevention of such injuries. Complications related to stent placement (including ureteral perforation, stent malposition, extravasation, hematuria, and stricture) are rare. However, preoperative stent placement is typically considered in complex cases. In this setting, stent placement can be uniquely challenging, with an increase in the probability of complications.

Postoperative Diagnosis of Ureteral Injury

The sequelae of unrecognized ureteral injuries commonly present in the immediate postoperative period, but the related

P.937

complications may develop several weeks following surgery. This is especially true for thermal injuries resulting in intraperitoneal or retroperitoneal urine leak (e.g., urinoma) or ureteral stricture. Common manifestations of urinoma include fever, unexplained leukocytosis, peritonitis, or vaginal fluid leakage. Hematuria may also be seen. Rarely, urinoma may present as a palpable pelvic or abdominal mass. It should be noted that changes in serum creatinine are not a reliable indicator of ureteral injury. Postoperative elevations in serum creatinine should prompt further investigation, but normal values do not adequately exclude ureteral injury.

Accurate diagnosis of a delayed ureteral injury relies primarily on appropriate imaging studies, such as computed tomography with administration of intravenous contrast and delayed image acquisition. This study can delineate ureteral obstruction as well as urine extravasation. In cases presenting with unilateral flank pain postoperatively, a renal ultrasound study may be obtained initially to assess for obstruction (hydroureteronephrosis) as well as urinoma. This study may identify obstruction and urinoma but may fail to detect a urine leak.

Retrograde ureteropyelography is also useful in the diagnosis and initial therapy of a ureteral injury. Contrast injection and opacification of the ureter can define the site and severity of leakage or obstruction and facilitates possible ureteral stenting. This can allow for control and resorption of a urinoma and in many cases may result in spontaneous healing of the ureter. If stenting is not possible, a nephrostomy tube can be placed to facilitate urine drainage and prevent renal injury. If a large urinoma is present, a percutaneous drain can be placed. If surgical intervention is necessary to repair a ureteral injury, this is best done within the first 3 to 5 days postoperatively. Beyond this window, reconstruction is optimal after 6 to 8 weeks to allow resolution of postsurgical inflammation.

In cases presenting with vaginal drainage, it is important to differentiate ureteral injury from bladder injury. Recognition that it is possible for these injuries to occur simultaneously is also important. The bladder can be filled through a catheter with a dilute solution of methylene blue and saline, with a tampon placed in the vagina. Staining of the tampon indicates a vesicovaginal fistula. If this initial test is negative, oral phenazopyridine or an intravenous colorant (methylene blue) can be administered and the test repeated. Staining of the tampon indicates a ureteral vaginal fistula. It is also possible to collect the fluid and analyze its creatinine content. If the value is any greater than the serum level, the fluid contains urine. Urine typically has a creatinine content greater than 10 mg/dL. Imaging studies would follow in order to localize the site of injury.

TECHNIQUES FOR URETERAL REPAIR

Several common elements associated with ureteral injury are listed in [Table 42.2](#). Successful management of surgical ureteral injury requires an understanding of ureteral anatomy as well as the mechanism of injury. The ureter can be divided anatomically into thirds, with the upper segment defined by the ureteropelvic junction and proximal 5 cm. High in the retroperitoneum, this segment is seldom injured during pelvic surgery. The midureter defines the segment from below the ureteropelvic junction to the pelvic brim. The lower ureter includes the segment from the pelvic brim to the ureteral orifice. Selection of repair strategy is based on the location of

ureteral injury.

General principles of ureteral repair include spatulation ≥ 1 cm to create a wide-caliber lumen, judicious ureteral mobilization to allow for tension-free anastomosis, and use of fine absorbable suture (4-0, 5-0) to minimize inflammatory response and subsequent stricture. The ureter is typically stented at the time of reconstruction and a suction drain placed near to but not in contact with the repair. A stent is left in place for at least 14 days. There is little evidence to suggest a longer period of stenting is either necessary or helpful. Strategies for ureteral repair are based on the location of injury and its mechanism ([Table 42.3](#)).

TABLE 42.2 Ureteral Injury Associated with Gynecologic Surgery

Most common site: Pelvic brim near the infundibulopelvic ligament
Most common procedure: Simple abdominal hysterectomy
Most common type of injury: Obstruction
Most common “activity” leading to injury: Attempts to obtain hemostasis
Most common time of diagnosis: None: 50-50 split between intraoperative and postoperative

Acute Ureteral Injury

The ureter may be injured by transection, ligation, or thermal conduction. In cases in which the ureter is partially transected, it can be closed loosely with fine (5-0) absorbable suture and stented. This applies along the entire length. In such cases, placement of the stent can be accomplished over a flexible guidewire using intraoperative cystoscopy (flexible cystoscopy is useful if the patient is supine) or directly through a small anterior cystotomy. The bladder is typically drained for 7 to 10 days following repair.

Ureteroureterostomy

In cases of complete ureteral transection, the level of injury should guide the method of repair. In the midureter, ureteroureterostomy is often the procedure of choice. The proximal and distal ends of the ureter are carefully mobilized with preservation of the adventitia and feeding blood vessels. The exposed ureteral ends should be viable, with a bleeding edge. If thermal injury is suspected, the involved edges should be debrided or resected to healthy tissue. The ends of the ureter are spatulated for at least 1 cm to allow for a wide-caliber tension-free anastomosis ([Fig. 42.6](#)). Fine absorbable suture should be used to minimize risk of stricture. The ureter is stented. A stent of 24 to 26 cm in length is usually sufficient. Stent placement is facilitated by advancing a guidewire into the proximal ureter and renal collecting system and advancing the stent over the wire. The distal end of the stent can be uncoiled, threaded into the ureter with forceps, and advanced into the bladder. Alternatively, the bladder can be opened and a guidewire passed into the ureteral orifice on the side of the injury. The anastomosis may be supported by an omental wrap if available. If transection has occurred in the lower ureter, simple ureteroneocystostomy may be elected.

TABLE 42.3 General Guidelines for Management of Ureteral Injuries Identified at Time of Surgery

Ureteral ligation: Suture release, assessment of viability, stent placement

Partial transection: Primary repair over ureteral stent

Total transection

- Uncomplicated upper and middle thirds: Ureteroureterostomy over ureteral stent
- Complicated upper and middle thirds: Ureteroileal interposition
- Lower third: Ureteroneocystostomy with psoas hitch over ureteral stent

Thermal injury: Resection with management as per a transection

P.938

FIGURE 42.6 Ureteral reanastomosis. **A:** The ends of the ureters are trimmed obliquely and spatulated. **B:** Fine delayed absorbable sutures are used to approximate the ends of the ureter. **C:** The anastomosis is done over a double-J or pigtail stent. A suction catheter is placed retroperitoneally at the site of anastomosis.

If the ureter has been ligated, release of the constricting suture or clip is first undertaken and a judgment made

as to the integrity of the injury site. If the ureter is not deformed, it can be treated conservatively. It may be helpful to wrap the injured area with omentum to facilitate healing. This type of injury can be associated with a delayed ureteral stricture, and one should have a low threshold to place a stent for 10 to 14 days. In the mid ureter, if the site remains blanched or has evidence of crush injury, it should be resected and repaired with ureteroureterostomy over a stent. If injury occurs in the distal ureter, direct ureteroneocystostomy or psoas hitch repair is indicated.

An obvious acute thermal injury poses the greatest challenge, in that the extent of damage can be difficult to assess. We recommend wide resection of the damaged ureter and consideration of ureteroureterostomy only if tension-free anastomosis is possible. Otherwise, thermal injury in the mid ureter should be repaired immediately with neocystostomy and psoas hitch.

Acute injury to the mid or upper ureter may occasionally require complex repair due to a significant gap between the proximal ureter and the bladder. These techniques are reviewed in the sections that follow and may include Boari flap reconstruction, ileal interposition, or possibly renal autotransplantation. Another alternative is transureteroureterostomy, with mobilization of the injured ureter to the contralateral side for end-to-side ureteral anastomosis ([Fig. 42.7](#)). While this technique can be effective, critics highlight the risk of subsequent stricture at the site of repair, putting both kidneys at risk for obstruction and functional compromise.

Transureteroureterostomy is contraindicated in patients with a history of kidney

P.939

stone formation. In cases involving long ureteral defects, it is advisable to ligate the ureter above the site of injury and arrange for postoperative nephrostomy tube placement. This allows for staged repair after adequate patient counseling and additional evaluation.

FIGURE 42.7 Transureteroureterostomy. The injured ureter is mobilized to the contralateral side for end-to-side ureteral anastomosis (A-E). The anastomosis is accomplished with interrupted sutures of fine absorbable suture.

P.940

STEPS IN THE PROCEDURE

Ureteroureterostomy

- The site of ureteral injury is identified. If this is an acute injury in the midportion (below the ureteropelvic junction and above the pelvic brim), ureteroureterostomy is a suitable option.
- The proximal and distal aspects of the ureter are dissected from the surrounding attachments sharply with care taken to preserve the periureteral sheath and periureteral blood supply.
- The exposed ureteral lumen is debrided until a healthy edge is obtained. This is essential in the setting of either a crush injury (from clip, clamp, or suture) or thermal insult, and may require tissue

resection.

- The proximal and distal ends of the ureter are spatulated using fine scissors for 1 cm or more to allow for an overlapping, tension-free anastomosis.
- Ureteroureterostomy is complete using fine (4-0, 5-0) absorbable suture using either a running or interrupted technique.
- Prior to completing the anastomosis, a double-J ureteral stent is placed. A stent of 24 to 26 cm in length is usually sufficient. This is facilitated by advancing a guide wire into the proximal ureter and renal collecting system and advancing the stent over the wire. The distal end of the stent can be uncoiled, threaded into the ureter with forceps, and advanced into the bladder. Alternatively, the bladder can be opened and a guidewire passed into the ureteral orifice on the side of the injury. After the stent is advanced over the wire, the wire is removed and the bladder is subsequently closed with absorbable suture (2-0, 3-0) in one or two layers.
- After the ureteroureterostomy is complete, a portion of the omentum, if available, can be dissected free and wrapped around the ureter to minimize leak and adhesion.
- A suction drain is left in the pelvis for 2 to 3 days following repair. The bladder is drained postoperatively for 7 to 10 days and the stent left in place for at least 14 days.

FIGURE 42.8 Extravesical technique for ureteroneocystostomy. **A:** The distal ureter is freshened and spatulated for 1 cm. The detrusor muscle is incised for 1 to 2 cm on the posterolateral aspect of the bladder to expose the epithelium. **B:** The lateral aspect of the anastomosis is completed before incising the urothelium. **C:** The epithelium is incised and a stent introduced across the anastomosis. **D:** The ureteral anastomosis is completed, and the serosa is closed over the ureter.

Ureteroneocystostomy

Injuries to the distal ureter can be corrected with direct anastomosis to the bladder. The simplest technique is an extravesical, refluxing reimplant (Fig. 42.8). The distal ureter is freshened and spatulated for 1 cm. The bladder is distended with saline through a Foley catheter and the catheter clamped. This allows for selection of a suitable reimplant site on the posterolateral aspect of the bladder and confirmation of adequate ureteral length for tension-free anastomosis. While it may seem suitable, one should avoid reimplantation to the dome of the bladder as this mobile section may allow the ureter to become kinked with filling leading to obstruction. At the reimplant site, the peritoneum and detrusor muscle are incised with cautery for 1 to 2 cm. The detrusor muscle can be dissected free from the bladder epithelium using fine scissors. This is aided by the bladder distension, and the epithelium becomes readily visible. Fine absorbable suture can be used to complete half of the anastomosis, incorporating the epithelium, ureter, and detrusor muscle. The epithelium is then incised, allowing the bladder to decompress. A ureteral stent is placed and the anastomosis completed using the stent as a guide. The bladder can be refilled to insure a watertight connection, and the serosa and peritoneum closed loosely over the ureter with fine absorbable suture to provide additional security (Fig. 42.8).

It is also possible to perform ureteroneocystostomy using an intravesical technique (Fig. 42.9). A midline cystotomy is made and a suitable site for reimplant identified. A hiatus is made in the bladder wall and the ureter transferred to the interior. The ureter can be matured to the full thickness of the bladder using fine absorbable suture (Fig. 42.9).

P.941

STEPS IN THE PROCEDURE

Ureteroneocystostomy with Psoas Hitch

- The peritoneum over the ipsilateral psoas muscle is opened sharply at the level of the pelvic brim.
 - Three 2-0 nonabsorbable sutures are placed in the psoas muscle, parallel to the muscle fibers (to avoid injury to the underlying genitofemoral nerve), and set aside.
 - The bladder is distended with saline through the Foley catheter to near full capacity.
 - An incision is made in the bladder diagonally across the anterior dome. Full-thickness stay sutures are placed at the midpoint of this incision to provide traction.
 - The nonabsorbable sutures are placed through the detrusor muscle. Care should be taken not to perforate the bladder epithelium with the anchoring sutures to avoid bladder stone formation. These are tied in sequence to anchor the bladder.
 - Bladder closure is undertaken perpendicular to the original incision. If desired, the bladder closure can incorporate the site of ureteral reimplantation without the need for separate neocystostomy.
 - Prior to implantation, the proximal ureter is mobilized sharply and spatulated for at least 1 cm. Ureteral vesical anastomosis is completed using fine absorbable suture in a tension-free fashion. The remainder of the bladder wall is closed using 2-0 or 3-0 absorbable suture in one or two layers.
 - The perivesical fat and peritoneum can be closed over the ureterovesical suture line to provide additional coverage.
 - Prior to completion of the bladder closure, a double-J ureteral stent 24 to 26 cm in length is passed into the ureter over a guide wire.
 - Postoperatively, the pelvic is drained for 2 to 3 days, the bladder is drained for 7 to 10 days, and the stent kept in place for at least 14 days.
-

Reimplantation of the ureter high in the pelvis can often be accomplished by incorporation of a psoas hitch to the bladder (Fig. 42.10). This procedure secures the bladder to the ipsilateral psoas muscle allowing for tension-free ureteroneocystostomy. The psoas muscle is exposed by opening the posterior peritoneum and three 2-0 nonabsorbable sutures are placed in the psoas muscle belly. We prefer to place these parallel to the muscle fibers to avoid injury to the underlying genitofemoral nerve. The white band of the psoas minor tendon can often serve as a good anchorage. These sutures are set aside and the bladder distended to confirm adequate capacity and mobility. Peritoneal attachments to the bladder can be extensively divided to improve necessary mobility. The contralateral vascular pedicle can also be divided, but this is not routine. The bladder is then incised diagonally along the anterior dome to allow the posterolateral aspect to reach to the psoas muscle (Fig. 42.10). Full-thickness stay sutures are placed at the midpoint of this incision to provide traction. The previously placed nonabsorbable sutures are fixed to the posterior aspect of the detrusor for anchorage to the psoas muscle, thereby shortening the gap to the distal ureter. The ureteroneocystostomy can be incorporated into the bladder closure, which is undertaken perpendicular to the original incision. Care should be taken not to perforate the bladder epithelium with the anchoring sutures so as to avoid bladder stone formation.

FIGURE 42.9 Intravesical technique for ureteroneocystostomy. After cystotomy, an incision is made in the urothelium and a tunnel created in the bladder wall. The distal ureter is then pulled through this hiatus and fixed to the bladder wall using fine absorbable suture.

Boari Flap

This technique can be used to repair injury to the proximal aspect of the mid ureter. It is best used in a delayed fashion after additional workup and patient counseling. This should include a cystogram and possible cystometrogram to insure adequate bladder capacity and compliance. Functional and anatomic bladder capacity can be reduced following Boari flap reconstruction, and patients should be counseled regarding these outcomes.

The bladder is distended and the gap between ureter and bladder measured. A suitable wide-based flap (4 to 5 cm) originating from the cephalad margin of the bladder is outlined along a diagonal toward the contralateral side. The distal aspect of the flap should not be less than 2 to 3 cm in width. The flap is raised and extended to

the spatulated ureter and sewn into a tube over a 16- to 18-French catheter using absorbable suture (3-0, 4-0). The spatulated ureter can then be fixed end to end to the bladder tube with fine absorbable suture. The repair is stented prior to completion and a pelvic drain placed. The bladder should be drained with a Foley catheter for 7 to 10 days. The stent can be removed after 2 weeks.

Ureteroileal Interposition

Injuries to the upper mid or proximal ureter often require bridging a gap longer than the bladder can extend with psoas hitch or Boari flap construction. In these cases, a segment of ileum can be interposed between the ureter and bladder

P.942

to reestablish continuity (Fig. 42.11). This procedure is best suited for delayed repair following patient counseling regarding the need for bowel anastomosis, extended postoperative recovery, effects on ipsilateral renal function, and the persistence of mucous in the urine.

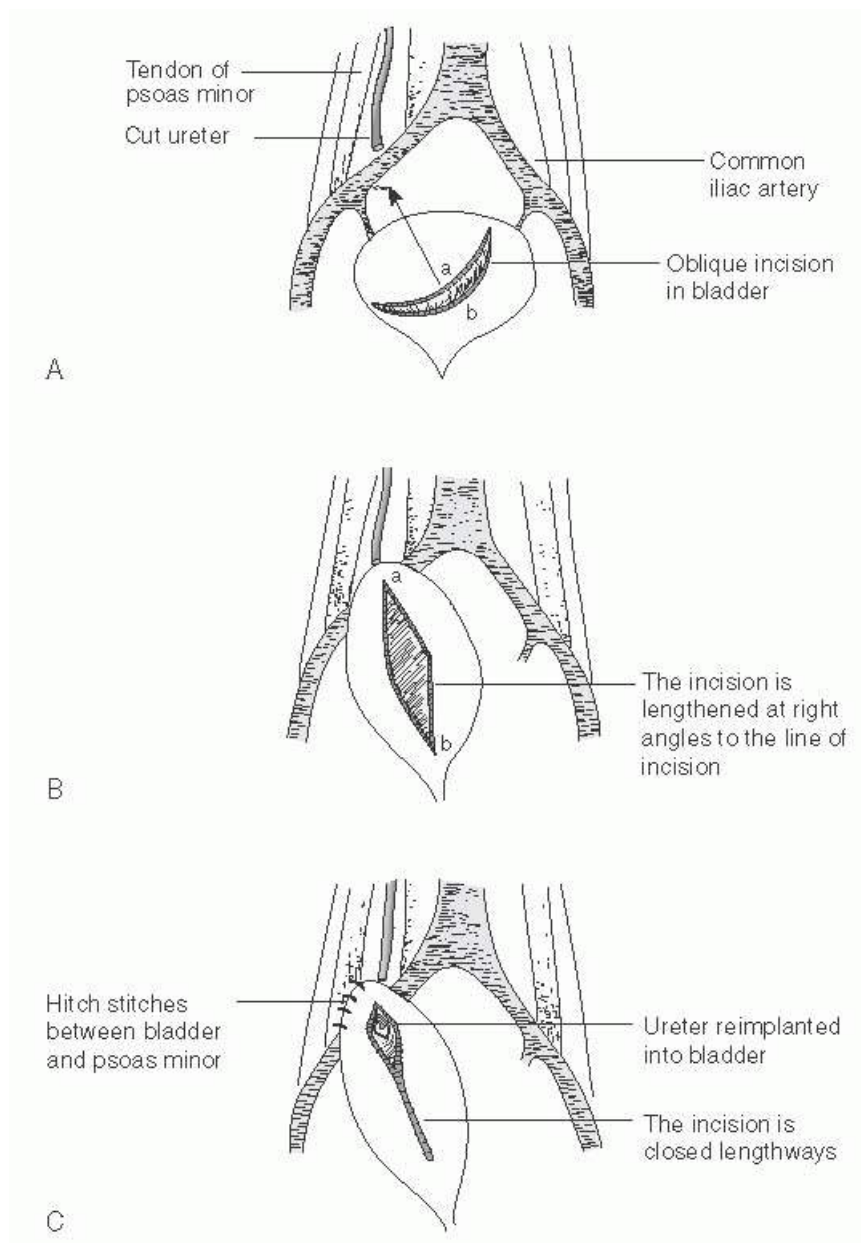

FIGURE 42.10 **A:** An incision is made in the bladder obliquely. **B:** This allows the superior aspect of the bladder (a) to elongate towards the ureter perpendicular to the original cystotomy. **C:** The bladder is anchored to the psoas muscle with permanent suture. Neocystostomy is completed and the bladder closed with absorbable suture. (Reproduced with permission from Hashim H, Reynard J, Cowan NC. Urological Emergencies in Clinical

Following mobilization and spatulation of the distal ureter, the gap from ureter to bladder is measured. A psoas hitch can be incorporated in this procedure to shorten the segment of bowel needed for repair. Use of the shortest ileal segment possible minimizes metabolic derangement from urine resorption as well as mucous discharge with voiding. A segment of ileum adequate to bridge the ureteral defect is identified. This segment should be 12 to 15 cm proximal to the ileocecal valve in order to avoid malabsorption. The mesentery to the ileal segment is preserved and bowel continuity reestablished. It is recommended to place the ileal-ileal anastomosis cephalad to the segment for ureteral replacement. The ureter is brought through the posterior peritoneum and anastomosis to the ileum completed with fine absorbable suture over a stent extending to the bladder. The ileum is typically placed in a properistaltic orientation to facilitate urine drainage and minimize reflux. An end-to-side ileal-vesical anastomosis is completed over the ureteral stent. The pelvis is drained postoperatively. A Foley catheter is kept in place for 7 to 10 days and a cystogram obtained prior to removal to insure absence of extravasation. The ureteral stent can be removed after 2 weeks.

SUMMARY

Sound knowledge of ureteral anatomy is critical to the avoidance of injury. In the event that the ureter is damaged during gynecologic surgery, intraoperative diagnosis allows for immediate repair in most cases. For this reason, intraoperative confirmation of ureteral integrity should be routine, whether the surgical approach is transvaginal or transabdominal through the open, laparoscopic, or robot-assisted approach. The ureter may be assessed visually, by palpation, or cystoscopically. Identification of the mechanism of injury and its location guides immediate or delayed repair. With proper recognition and therapy, ureteral function can be restored and renal function maintained.

P.943

BEST SURGICAL PRACTICES

- Knowledge of ureteral anatomy is critical for avoidance of injury.
- Injury most commonly occurs at the following sites: within the cardinal ligament as it crosses below the uterine arteries, the tunnel of Wertheim, near the infundibulopelvic ligament at or above the pelvic brim, and lateral to the uterosacral ligament in the pelvic sidewall.
- Hysterectomy is the procedure most commonly associated with ureteral injury.
- Intraoperative assessment of ureteral integrity should be a routine part of gynecologic surgery. This may be done by palpation, visually, or cystoscopically.
- Successful ureteral repair relies on careful mobilization, wide spatulation, use of fine absorbable suture (4-0, 5-0), and temporary stenting.
- Transection of the ureter at or below the pelvic brim can often be repaired with simple ureteroneocystostomy.
- Psoas hitch ureteroneocystostomy and Boari flap construction may facilitate ureteral reimplantation.
- Postoperative signs and symptoms of ureteral injury may include unilateral flank pain, fever, prolonged ileus, and abdominal or pelvic fluid collection (urinoma).

Chapter 43

Vesicovaginal and Urethrovaginal Fistulas

Rony A. Adam

DEFINITIONS

Fistula—An abnormal passage or communication that leads from one hollow organ to another.

Interposition graft—Placement of tissue attached to its own blood supply into the space between two viscera to enhance the likelihood of successful repair. Examples include a Martius graft or omental flap.

Retropubic vesicovaginal fistula repair—Access to the fistula and its closure involves dissection in the retropubic space (space of Retzius). This may be accomplished by an open laparotomy, by laparoscopy, or robotically.

Transperitoneal vesicovaginal fistula repair—Access to the fistula and its closure involves entry into the peritoneal cavity. This may be accomplished by an open laparotomy, by laparoscopy, or robotically.

Transvesical vesicovaginal fistula repair—Access to the fistula and its closure involves separate entry into the bladder (excluding entry through the fistula itself). This may be accomplished via a retropubic or a transperitoneal approach.

Urethrovaginal fistula—An abnormal communication between the urethra and the vagina.

Vaginal vesicovaginal fistula repair—Access to the fistula and its closure is accomplished through the vagina.

Vesicovaginal fistula—An abnormal communication between the bladder and the vagina.

INTRODUCTION

It is likely that women have suffered from urogenital fistulas throughout human existence as a consequence of childbirth. From an anthropologic perspective, humans experience difficult birthing requiring assistance primarily due to pelvic adaptations resulting from a trade-off between the evolutionary pressures of large brain size and bipedal biomechanics. Findings of a vesicovaginal fistula (VVF) have been identified in mummified remains from ancient Egypt. Since the mid-19th century, the evolution of surgical management of urogenital fistulas as described by Marion Sims, Thomas Emmet, Howard Kelly, and others has had a lasting influence on the development of our specialty.

It has long been recognized that women with VVF are severely afflicted physically, socially, and emotionally owing to the constant uncontrollable dribbling of urine. In the developing world, VVFs are most commonly noted as a consequence of prolonged labor. Perhaps a hundred years ago the situation was very similar in the (currently) developed world; however, due to dramatically improved access to expert obstetrical care, VVFs are now primarily acquired iatrogenically, mostly following hysterectomy. Providers and patients experience a vastly different set of circumstances in these two settings. In the latter, which is the primary focus of this chapter, patients are often litigious, yet they remain among the most grateful once their condition is explained and cured. Although the published literature regarding urogenital fistulas is extensive, it remains dominated by retrospective case series and expert opinion. The various types of urogenital fistulas are listed in [Table 43.1](#) based upon anatomic involvement. This chapter primarily discusses vesicovaginal and urethrovaginal fistulas encountered in gynecologic and urogynecologic practice with a brief overview of obstetrical fistulas.

Vesicovaginorectal

ETIOLOGY AND EPIDEMIOLOGY

Genitourinary fistulas can be congenital or acquired. Congenital fistulas are exceedingly rare, with only a few case reports in the literature. Most reported cases are associated with other urogenital anomalies. Acquired fistulas may be the result of childbirth, pelvic surgery, malignancy, irradiation, infection, and an assortment of unusual presentations (Table 43.2). This section discusses obstetrical and nonobstetrical urogenital fistulas. The nonobstetrical fistula portion will further discuss the following issues associated with urogenital fistula etiology and epidemiology: hysterectomy-associated cystotomies, urogynecologic and other gynecologic procedures, urethrovaginal fistulas, and an assortment of miscellaneous circumstances that have been reported in the literature.

Obstetrical Urogenital Fistulas

In the developing world, the most common predisposing factor is prolonged, obstructed childbirth, accounting for over 80% of genitourinary fistulas in these regions. These fistulas develop from the resulting necrosis of the vaginal and bladder wall and, therefore, are large and often associated with other related damages. These circumstances have become exceedingly rare in developed countries owing to improvements in access to and delivery of skilled obstetric care. Ibrahim et al. report that the mean age at diagnosis was 15 years, patients were in labor for 4 days on average, and the fetus died in 87% of cases. These findings are similar to another single-institution series from Nigeria, where 79% of fistula patients had labors that lasted over 2 days, and 21% had been in labor for 4 or more days during the index pregnancy associated with the injury. The fetal fatality rate in these cases was 92%. In a rural, population-based study of parturients in Senegal, the incidence rate was 124 per 100,000 deliveries, whereas no fistulas were noted in six major cities in West Africa. It is estimated that over 33,400 new cases of obstetric fistulas occur annually in sub-Saharan Africa, with an incidence of over 120 per

education and socioeconomic levels, and young maternal age. Circumstantial contributing factors include a very high rate of home births attended to by unskilled birth attendants, wherein only 35% of deliveries in Nigeria are attended by trained personnel. Late presentation in northern Nigeria is primarily related to lack of husband's permission followed by transportation difficulties (distance, nonavailability of vehicle, and bad roads). The general lack of hospital resources including surgical supplies and reliable electrical power have been cited as contributing to delayed cesarean section for those who need it.

TABLE 43.2 Conditions Associated with Development of Urogenital Fistulas	
Obstetric conditions or procedures	
Prolonged, obstructed labor	
Placenta percreta	
Cesarean section (especially repeat cesarean section)	
Cesarean hysterectomy

Schistosomiasis

Tuberculosis

Lymphogranuloma venereum

Intrauterine device

Neglected pessary

Retention of other vaginal foreign objects

Accidental trauma

Sexual trauma

Mitomycin C instillation

Hilton reviewed VFs in developing countries and outlined management strategies to include immediate catheter drainage as long as the tract has not yet epithelialized, perhaps even prophylactically following obstructed labor with evident vaginal sloughing. Attention to adequate vulvar skin care, nutrition, lower extremity rehabilitation, and counseling are important adjuncts in the care of obstetrical fistula patients. Arrowsmith et al. similarly remind us of the spectrum of additional trauma sustained by the fistula patient and the need to address more than just the “hole in the bladder.” Additional concurrent injuries may include and result in amenorrhea, total urethral loss, stress incontinence, hydronephrosis, renal failure, anorectal injury, cervical destruction, vaginal stenosis, nerve damage affecting mobility, and other physical maladies. The psychosocial toll is equally devastating with divorce, separation from family and social support structures, worsening economic hardship, isolation, and malnutrition being commonplace.

Surgical correction is curative in the first operation for obstetric VVF in about 80% of cases. Multiple attempts may be necessary to achieve a success rate over 95% for large fistulas. As the reality and complexity of this global tragedy is realized, solutions are suggested for its prevention that include improving the stature of women and access to competent routine and emergency obstetrical care as well as family planning services. Both global and regional economic and political actions will be necessary to effect meaningful and lasting change.

Other obstetric events and procedures have been noted to be associated with urogenital fistula formation worldwide. Cesarean section, especially in patients who have had prolonged, obstructed labor, may result in formation of a vesicouterine fistula (Youssef syndrome). The classic presentation is that of cyclical hematuria (menouria), amenorrhea, and urinary continence, but it may also present with total urinary incontinence with normal menstruation and represents 1% to 4% of all genitourinary fistulas. Vesicovaginal fistulas have also been reported following cesarean section, with or without associated hysterectomy. Even more rarely reported are vesicocervical, urethrovaginal, ureterovaginal, and ureterouterine fistulas following cesarean section. Operative vaginal delivery may rarely result in vesicouterine fistula in a patient undergoing vaginal birth delivery after cesarean section. Similarly, cervical cerclage placed for the treatment of cervical insufficiency has been associated with vesicovaginal and vesicocervical fistulas. A recent case series and pooled analysis suggests that previous cervical procedures (prior cerclage or cervical conization), prior cesarean delivery, and use of the McDonald technique (which does not involve a bladder dissection as with the Shirodkar technique) may play a role in the formation of urogenital fistula in these cases.

Although not an obstetrical practice, the traditional tribal practice of “gishiri cutting” is associated with formation of urogenital fistulas and is common in many parts of northern Nigeria. It involves cutting the anterior vagina with a razor or knife blade and has been noted to be the primary cause of fistula formation in 13% to 15% of cases. In more recently reported series in areas where gishiri cutting was reported, urogenital fistula was noted in 2.3% to 6.2% of cases.

Nonobstetrical Urogenital Fistulas

Nonobstetric urogenital fistulas have been reported as a consequence of gynecologic, urologic, and general surgical procedures and are the most commonly seen in developed countries. Various manifestations of urogenital trauma, certain medical conditions, and even medication instilled into the bladder have also been associated with subsequent development of urogenital fistulas.

Hysterectomy is the most common surgical procedure associated with a VVF. In a retrospective review of the Mayo Clinic experience regarding the treatment of 303 women with genitourinary fistulas, 190 were vesicovaginal. Of these, 156 (82%) were associated with hysterectomy (mostly abdominal), 19 (10%) with cesarean section or forceps delivery, and 6 (3%) each with radiation and with trauma.

Harkki-Siren et al. reviewed the incidence of urinary tract injuries from a Finnish national database of 62,379 hysterectomies with a VVF prevalence of 0.8 per 1,000. In a nationwide registry-based cohort study from Sweden that included all hysterectomies performed for benign indications over 30 years ($n = 182,641$), the prevalence of surgically managed genitourinary fistulas was 1.1 per 1,000. This is the same rate reported in a retrospective study of two institutions in the

P.946

United States but has been reported as high as 3.0 per 1,000 in one of those institutions.

In a retrospective cohort study of 343,771 hysterectomies in the English National Health Service from 2000 until 2008, the overall urogenital fistula (vesicovaginal and urethrovaginal) rate was reported to be 1.3 per 1,000 within the year following surgery. Rates were noted to vary by the procedure type and the indication, with the highest rate in patients undergoing radical hysterectomy due to cervical cancer (11.5 per 1,000) and the lowest for vaginal hysterectomy due to prolapse (0.26 per 1,000). Most interesting was a subanalysis of abdominal

hysterectomy for benign conditions excluding prolapse, where a 46% increase in the risk of fistula rates was noted over the course of the study itself from 1.5 per 1,000 in the first 2 years to 2.2 per 1,000 in the last 2 years of the study. See [Table 43.3](#) for a summary of the various epidemiologic studies discussed.

As previously noted, hysterectomy for cancer is associated with an increased risk of fistula formation. In a retrospective study of 536 patients who underwent a radical hysterectomy due to cervical cancer, a VVF rate of 2.6% and a ureterovaginal fistula rate of 2.4% were reported. Risk factors included cancer stage, intraoperative bladder injury, diabetes, and postoperative surgical site infection. Vaginal cancer shows a high likelihood of fistula development (both vesicovaginal and rectovaginal) with no association to radiation therapy.

Hysterectomy-Associated Cystotomy and Vesicovaginal Fistula Formation

The association of a cystotomy sustained at the time of hysterectomy (recognized or not) and subsequent development of a VVF has long been noted but is nonetheless complex (see further discussion under Pathogenesis). A review of published articles reporting on cystotomies during gynecologic surgery showed that the rate of cystotomy is significantly increased in series that employed routine cystoscopy rather than the traditional intra- or postoperative diagnosis on which the other studies relied. These disparate rates of bladder injury continue with two distinct single-institution studies that employed routine cystoscopy at the time of hysterectomy, reporting a cystotomy rate of 2.6% to 2.9%, while estimates from a US national hospital discharge database-derived study reported bladder injury rates of only 0.7% to 1.4% depending on the type of hysterectomy. Although one cannot conclude that the two- to threefold difference in cystotomy rates is due to detection bias, it is not unreasonable to consider that some bladder injuries may go undetected during hysterectomy, which may contribute to the overall posthysterectomy VVF rate.

TABLE 43.3 Prevalence of Vesicovaginal Fistula by Type of Hysterectomy

TAH, total abdominal hysterectomy; SAH, supracervical abdominal hysterectomy; TVH, total vaginal hysterectomy.

*Vesicovaginal and urethrovaginal fistulas are combined, data are a subset of hysterectomies for benign indications, excluding prolapse.

Even when a cystotomy is immediately recognized and repaired, a subsequent VVF may still occur. In their data on over 43,000 total abdominal hysterectomies, Harkki-Siren et al. report failure of primary bladder repair 18% of the time. In a case-control single-institution study of 1,317 benign hysterectomies, which included routine cystoscopic evaluation, 34 cystotomies were recognized and repaired, but among those, four patients (11.8%) developed a VVF. The degree of bladder injury retrospectively assessed by using the American Association for the Surgery of Trauma (AAST) system was found to be strongly associated with subsequent fistula formation despite cystotomy repair. The AAST grading system is used to describe the degree of injury to the bladder using the location and size of the defect with higher grades denoting worse trauma. Of highest risk are larger extraperitoneal (>2 cm) injuries, any intraperitoneal bladder injuries, and injuries involving the bladder neck or the trigone. Additional associated risk factors for occurrence of a VVF following cystotomy and repair include larger uterus, longer operative time, and longer hospital stay. A trend was noted when the hysterectomy was associated with greater than 1 L blood loss and for tobacco use. The strong association of bladder injury severity with subsequent VVF formation persisted in a subsequent expansion of this original study. There were 5,698 hysterectomies in the combined cohort where 102 cystotomies were diagnosed and repaired. Of these, there were six VVFs (5.9%) identified.

Urogynecologic Procedures

Due to the immediate proximity of the lower urinary tract to the operative field in surgeries for the treatment of urinary incontinence, pelvic organ prolapse, and other pelvic floor disorders, there have been reports of both vesicovaginal and urethrovaginal fistulas with these types of surgery. Surgeries for the treatment of stress urinary incontinence have been implicated, including Burch colposuspension, bone-anchored cystourethropy, Stamey bladder neck suspension, transobturator tape, and retropubic tension-free vaginal tape procedures.

P.947

Surgery for anterior prolapse occurs adjacent to the bladder and may result in immediate or delayed injury to the lower urinary tract. Anterior colporrhaphy has been associated with VVF only in case reports regarding fistula repairs. In a single surgeon case series of 519 anterior colporrhaphy patients (with Kelly-Kennedy urethropey for the treatment of stress incontinence), the authors reported two urethrovaginal fistulas but no VVFs. Mesh kit procedures for the treatment of anterior prolapse have been associated with VVFs by several investigators. The incidence of VVF from trocar-based mesh kit surgery used for the treatment of anterior prolapse has been noted to be 0.3% in a large series. A recent case report noted a ureterovaginal fistula 28 days following a transobturator mesh kit surgery for anterior prolapse. A case report of a VVF following total abdominal hysterectomy with sacrocolpopexy for uterine prolapse noted that the fistula was adjacent to the distal edge of the colpopexy mesh.

Urethrovaginal fistulas have been associated with each of the various forms of midurethral (mesh) slings, vaginal urethropeies, and even periurethral bulking injections. With the increasing popularity of midurethral slings for the treatment of stress incontinence, reports of associated urethral injury and urethrovaginal fistulas have been accumulating. A literature review identified 3 VVFs and 11 urethrovaginal fistulas with retropubic and transobturator approaches implicated in both fistula types. The reviewed literature was insufficient to estimate the rates of urethrovaginal fistulas.

Urethrovaginal fistulas may occur as a consequence of urethral diverticulum repair. Review of available series, ranging from 18 to 85 patients each, reveals that urethrovaginal fistula develops in 1.2% to 7.8% of patients

undergoing vaginal repair of a urethral diverticulum.

Other Gynecologic Procedures

Additional gynecologic procedures associated with urogenital fistulas, although with greater rarity (see [Table 43.2](#)), include myomectomy, loop excision of the cervical transformation zone for cervical intraepithelial neoplasia, and voluntary interruption of pregnancy. Fistulas are noted following radiation therapy for gynecologic cancers and uterine artery embolization for leiomyomatous uteri.

Urethrovaginal Fistula

Urethrovaginal fistulas are less common than are VVFs, with an incidence ratio of 1 per 8.5. In the developed world, the most common predisposing event is surgery for urethral diverticulum, anterior vaginal prolapse and incontinence, radiation therapy, or trauma. Operative vaginal delivery and cesarean section also have been reported to precede urethrovaginal fistula formation. There has been an increase in urethrovaginal fistula formation related to the increased use of suburethral slings in the treatment of stress incontinence (please see subsection on Urogynecologic Procedures).

Miscellaneous Circumstances

An assortment of presentations and conditions can be found in the literature associated with urogenital fistulas mostly in the form of case presentations. These include Behçet syndrome; infections such as schistosomiasis, tuberculosis, lymphogranuloma venereum; endometriosis; accidental trauma; sexual trauma; masturbation; and a variety of retained foreign objects. Bladder calculi are found to be rarely associated with long-standing fistulas but not considered etiologic. Additional gynecologic associations include neglected diaphragm, neglected pessary, intrauterine device, and a ureteral wall stent used to treat a ureteral stricture. Intravesical instillation of mitomycin C has been reported to be associated with urogenital fistula formation.

PATHOGENESIS

The pathophysiologic mechanism of fistula formation is not completely understood. Etiologies have been proposed based on interpretation of the epidemiologic data and risk factors previously discussed. Vascular compromise and subsequent epithelial necrosis of the intervening vaginal walls are indisputable in cases of prolonged obstructed labor where the presenting fetal vertex compresses the vaginal walls against the pubic symphysis. If this pressure is present for a sufficient period of time, even once relieved, the affected vaginal, bladder, and/or urethral walls undergo necrosis and sloughing, thus creating the abnormal (often large) communication between adjoining viscera.

The precise pathophysiology of nonobstetrical urogenital fistulas is somewhat less obvious, but can likely also be understood in terms of abnormal healing associated with microvascular compromise coincident with posterior bladder/anterior vaginal wall injury. From empirical evidence, we know that small-sized bladder perforation in the non-gravity-dependent areas of the bladder rarely if ever results in any fistula formation. Consider suprapubic catheters that are removed with initial formation of a vesicocutaneous tract that almost inevitably heals without further intervention, as well as retropubic tension-free tapes that are found perforating the anterior and anterolateral bladder only to be repositioned with little to no consequence, even without prophylactic catheter drainage. On the other hand, the dependent area of the bladder is more prone to fistula formation due to its closer proximity to the vagina and possibly the effect of gravity and the near-constant presence of urine in this part of the bladder.

Experimental evidence further shows that not all injuries result in VVF formation, even in the dependent portion of the bladder. Meeks et al. demonstrated in a rabbit model that fistula formation did *not* occur when figure-of-eight absorbable sutures were placed incorporating full-thickness bladder wall and vaginal cuff during a hysterectomy.

In a laparoscopic dog model, none developed a fistula after bipolar cautery injury to the bladder base nor when absorbable sutures were placed through the bladder and vaginal cuff during a laparoscopic hysterectomy. Fistula formation, however, was noted in the dogs that had a monopolar cautery-induced bladder base laceration and had repair either with single-layer absorbable suture in the normal fashion or with suture that incorporated the anterior vaginal wall. No differences were found histologically in the specimens that primarily showed inflammation, fibrosis, foreign body giant cell reaction, and recanalization of thrombus. It should be noted that these animal models of hysterectomy, because of anatomic differences, do not require any dissection of the bladder off the uterus and in that respect may be different from humans undergoing total hysterectomy.

From the aforementioned data, vascular or microvascular compromise may be the common pathway to fistula formation, which then leads to localized impairment of healing that allows the formation of an epithelialized tract between the two adjacent organs. Such microvascular compromise may aid in the understanding of urogenital fistulas caused by local infection or even subacute infection when foreign materials (suture, mesh, etc.) or electrocautery are used, as well as aid in the understanding of radiation-associated fistulas. Thus, in posthysterectomy urogenital fistulas, the mechanisms involved may be more complex than the previously assumed “undiagnosed bladder injury” or “inadvertently placed suture” that many have previously suggested. Further research into the pathophysiology is needed to elucidate the mechanisms at work in such circumstances.

P.948

CLINICAL PRESENTATION

The classic presentation of urogenital fistula is continuous urinary leakage from the vagina several days or weeks following pelvic surgery. This may occur in the absence of urinary urgency, Valsalva maneuvers, or changes in body position. The degree to which leakage presents depends primarily on the precise location and size of the fistula, perhaps the pliability and healing of the surrounding tissue, and the condition of the rest of the vagina. Patients have a spectrum of leakage from truly continuous to intermittent primarily at bladder capacity with attendant urinary odor. Although it is generally accepted that the larger the fistula, the worse the leakage, even small fistulas leak significantly. In developed countries, an antecedent gynecologic, urologic, or general surgical procedure involving the pelvis will often be noted. Delivery by the operative vaginal or, more commonly, cesarean section route may precede the onset of symptoms.

The majority of cases will present in 1 to 10 days following surgery and nearly all by 30 days, although the author has seen patients manifest symptoms as much as 3 months postoperatively. The increasing prevalence of multiple procedures undertaken at the same time for complex pelvic floor disorders (often by multiple surgeons) may complicate the diagnosis of subsequent fistula formation, related to multiple potential sites of injury, preexisting symptoms, and added potential postoperative urinary complications. Indeed, subsequent anti-incontinence procedures have been mistakenly done believing the cause of leakage is stress incontinence. Other potential causes of postoperative urinary leakage should be considered and ruled out, as listed in [Table 43.4](#).

Many patients develop coexisting urinary tract infections and symptoms of frequency, urgency, and dysuria. The predominant organism is *Escherichia coli* in most cases. Urinary leakage from any genitourinary fistula may be accompanied by hematuria and rarely may have associated stones.

Vesicouterine fistulas tend to present with cyclic hematuria, and if the fistula is located above the cervix, amenorrhea may occur if all the menstrual blood is redirected into the bladder because of a closed cervical canal. Patients with coexisting mesh erosion into the bladder experience urgency, frequency, voiding dysfunction, and pain. If there is concurrent erosion into the vagina, coital discomfort and a vaginal discharge may occur as well.

Urethrovaginal fistula may present either as continuous vaginal leakage or vaginal voiding either during or just

following micturition. This depends primarily on the location of the fistula whether it affects the continence mechanism or not. Vaginal bleeding and dyspareunia may also present concurrently regardless of the fistula's location and may be exacerbated by foreign material associated with the preceding surgery (mesh, graft, suture, etc.).

Any significant urine leakage for even a short period of time may result in significant irritation of the vagina, the skin of the vulva, or perineum. This often occurs, despite the patient's attempt at frequent cleansing. Among obstetrical fistula patients, dermatitis symptoms were noted in 20% of patients. If urine leakage persists, severe perineal dermatitis may result owing to exposure of the skin to ammonia. Phosphate crystallization may precipitate on the vagina and vulva, further irritating the area.

PREVENTION

Since the occurrence of a cystotomy is considered a risk factor for subsequent fistula formation, prevention is discussed primarily in terms of preventing a cystotomy (primary prevention) or adequately detecting and repairing one if it occurs (secondary prevention). Careful consideration of the bladder, trigone, and ureteral anatomy in relation to the anterior vagina, uterus, and cervix is important to maintain during each step of any hysterectomy, but especially with a total hysterectomy ([Fig. 43.1](#)).

Anatomically, the bladder base overlies the uterine isthmus and the cervix, the bladder trigone is positioned anterior to the upper third of the vagina, and the external cervical os is proximal to the base of the trigone (the interureteric ridge). During a simple hysterectomy, mobilization of the bladder does not involve the upper third of the vagina and therefore rarely puts the trigone at risk. A subtotal (supracervical) hysterectomy requires no bladder mobilization and indeed results in dramatically fewer fistulas even in large series (see [Table 43.3](#)). This is not the case, however, with anterior colporrhaphy or vaginal paravaginal repair, where the anterior vaginal dissection is carried more distally and laterally upon the vagina, indeed involving its middle and upper thirds.

The likelihood of cystotomy is reduced by avoiding blunt dissection at the time of bladder mobilization during hysterectomy (or anterior repair), especially when the vesicovaginal space is scarred from prior cesarean section or other surgery. The precise direction of forces cannot be controlled as accurately when blunt dissection is used, when compared with sharp dissection. Gentle traction and countertraction are helpful in dissecting the correct plane and thereby preventing direct bladder injury, as is utilizing an intrafascial hysterectomy technique. Another cause of bladder injury may be direct trauma by retractors, particularly during vaginal hysterectomy; retractors should always be used with appropriate caution. As previously reviewed (see Pathogenesis section), experimental data suggest a detrimental effect of using monopolar

electrocautery. As such, one should consider electrocautery with monopolar current in the vesicovaginal space only after carefully considering the risks and benefits.

If during the course of a hysterectomy or any pelvic surgery, a bladder injury (cystotomy) occurs, it is critical to diagnose and properly manage it prior to the conclusion of the surgery so as to minimize the likelihood of subsequent fistula formation (secondary prevention). See Steps in the Procedure for the surgical steps of cystotomy repair. In addition to careful inspection of the operative field, cystoscopy is often recommended to assess for bladder and ureteral injury following hysterectomy and routinely recommended after surgery for pelvic prolapse or urinary incontinence. The routine use of cystoscopy at the time of hysterectomy remains controversial by some, yet recommended by others. The alternative to routine cystoscopy is performing it as needed when a suspicion for injury arises as may occur with new-onset gross hematuria, while the bladder is catheterized or visualization of fluid in the operative field. Studies in which routine cystoscopy has been performed report a bladder injury detection rate of only 35% to 50% when relying on visualization alone.

P.949

FIGURE 43.1 Anatomic relations of the bladder, rectum, uterus, and vagina. The right ureteral orifice and interureteric ridge are denoted. Note that the cervix and the anterior cervicovaginal sulcus are at a position higher than the interureteric ridge, which explains why the simple posthysterectomy vesicovaginal fistulas

STEPS IN THE PROCEDURE

Cystotomy Closure

- Recognize that a cystotomy has occurred.
 - Evaluate cystoscopically and vaginally to assess size, location relative to known landmarks (trigone and ureters), and the quality of the injured tissue.
 - If injury deemed needing repair and safe from present or potential ureter injury, simple cystotomy closure is indicated: (1) ureteral catheterization as needed if close to ureter(s); (2) bladder should be catheterized with a transurethral Foley.
 - Carefully and accurately identify the margins of the bladder injury (beware, there often is a hidden invagination). Use fine surgical technique and delicate tissue handling while optimizing visualization, using suction and irrigation as needed. Avoid prolonged clamping of the injured tissue during the repair, and avoid electrocautery near the injury.
 - Sharply dissect the vesicovaginal space sufficiently to allow tension-free closure.
 - Close the urothelial (lamina propria) layer with interrupted or running fine 3-0 delayed absorbable suture.
 - Reapproximate the muscular layer with running or interrupted 2-0 or 3-0 delayed absorbable suture. Ensure hemostasis in the vesicovaginal space.
 - Bring a third layer of peritoneum to further reinforce the repair if available using interrupted 3-0 delayed absorbable suture.
 - Perform cystoscopy to ensure intravesical hemostasis and ensure integrity of the repair by looking vaginally for spillage; assess for injury or obstruction to the ureter using intravenous indigo carmine. Remove any blood clots that may obstruct catheter drainage.
 - If there is an adjacent vaginal injury or opening (e.g., vaginal cuff), ensure it is closed separately by the end of the surgery, making certain that the vaginal closure does not incorporate the bladder in any way.
 - Determine how long bladder catheterization is needed, and ensure orders are written to avoid inadvertent routine catheter removal on the following day.
-

In the event of a cystotomy, the location, extent, and size as categorized in the AAST grading system previously discussed may be an important factor in assessing prognosis of the repair of a posterior bladder injury. Also, as previously discussed in the Pathogenesis section, a small anterior bladder injury does not result in urogenital fistula formation as observed following removal of suprapubic catheters or trocar injuries from retropubic midurethral slings. Since these injuries are approximately 0.5 cm in diameter, any bladder injury greater than that may be considered for primary repair versus longer catheter drainage to allow for spontaneous healing. Owing to the dependent position of the bladder base however, any significant injury in the posterior bladder requires consideration of suture closure and bladder drainage.

Once a cystotomy is recognized, it may be repaired immediately or delayed until the hysterectomy or other surgical procedure is completed. The benefit of immediate repair is that blood and urine do not continually flow into the surgical field; however, with continued surgery and retraction, there may be potential compromise to the fresh suture line, and this should be meticulously avoided. Cystoscopy, when an injury is first suspected, is helpful in delineating the exact location and extent of the injury as well as distance to the

ureters and trigone. Adequate dissection of the bladder off the vagina is usually necessary to ensure tension-free closure and allow sufficient mobilization for a second layer. Careful inspection of the cystotomy is critical to identify the true borders of the defect. Due to the inherent pliability and redundancy of the bladder, repair without careful delineation of the edges may miss a particularly well-hidden portion of the defect, which could lead to nonhealing and subsequent VVF formation. The first layer can be accomplished with 2-0 or 3-0 absorbable suture placed in an interrupted or running fashion (**Fig. 43.2A**). There is controversy regarding whether this first layer can be placed through the mucosa or should remain extramucosal. It is thought that the extramucosal technique may decrease the likelihood of subsequent fistula formation and perhaps prevent bladder stone formation, although this has not been demonstrated, whereas excluding the urothelial edge may result in bleeding from it. Results from an experimental laparoscopic hysterectomy model of electrocautery-induced bladder injury with laparoscopic repair in dogs suggest that double-layer closure is superior to single-layer closure in preventing VVF. The second layer placed to imbricate the first is thought to diminish tension on the suture line. A third layer of closure usually can be achieved with the peritoneum either vaginally or abdominally (**Fig. 43.2B, C**). Cystoscopy is important to evaluate ureteral and bladder integrity following completion

P.951

of the repair and to ensure there is no significant hematuria, which can obstruct catheter drainage with the formation of clots. Cystoscopy should be done with minimal bladder filling to avoid tension on the suture line.

FIGURE 43.2 Closure of cystotomy associated with total abdominal hysterectomy (abdominal view). **A:** Initial layer is closed with a running suture. **B:** An imbricating second layer is being placed using interrupted stitches. **C:** A third layer covering the repair with peritoneum.

Transurethral or suprapubic catheter drainage must prevent bladder filling to avoid exerting tension on the suture line that would otherwise occur when the bladder fills. The lack of reliable postoperative catheter drainage as a significant cause of failure of fistula repair was discussed at length in 1852 by Sims in his

landmark paper regarding urogenital fistulas. Judgment should be exercised regarding duration of drainage, based on the extent of injury, its location, the security of the closure, and any factors that may impact the normal healing process, but generally should be for 7 to 10 days. Some advocate use of a cystogram prior to catheter removal; however, subsequent VVF in the face of a normal cystogram has been noted anecdotally, calling this extra step into question. A retrospective study of bladder injury in the trauma setting concluded that in patients undergoing simple intraperitoneal bladder injury management, routine follow-up cystograms did not affect clinical management, while all extraperitoneal and complex intraperitoneal injuries required follow-up cystograms.

DIAGNOSIS AND EVALUATION

Often, the diagnosis of nonobstetrical urogenital fistula is straightforward based on history and demonstrable pooling of urine in the vaginal vault; occasionally, however, the diagnosis is elusive. In all cases, it is necessary to evaluate the fistula with regard to its size, precise location, degree of epithelialization, whether it is simple or complex, accessibility, and the overall health status and mobility of the surrounding tissues. In the instance of a recurrent fistula, precise knowledge of prior conservative management and review of the surgical description of prior repair attempts are extremely helpful for choosing the most appropriate route, type, and timing of the repair.

In the case of clinical suspicion of a urogenital fistula that cannot be verified on initial speculum examination, the physician can try concurrent Valsalva maneuvers and partial closure of the speculum to reduce the tension on the vaginal walls. If this is not helpful in visualizing vaginal leakage, then a dye test should be tried. Sterile water dyed with indigo carmine or methylene blue is instilled via a transurethral Foley catheter (16 French) with great care taken to avoid spilling the dye externally. Once the vagina and vulva are cleaned, a tampon is placed and the patient is asked to ambulate and wait for one-half hour. The tampon is removed and inspected for the presence of blue dye; if the tampon is wet with urine but not dyed, then a ureterovaginal fistula is suspected and is best diagnosed by appropriate radiologic studies. On rare occasions, these office diagnostic procedures are nondiagnostic despite a compelling history. In this case, the patient is asked to take phenazopyridine (Pyridium) and wear a series of tampons at home over a longer period of time with varying degrees of physical activity. The tampons are placed individually in plastic bags and brought in to be inspected. The patient must be counseled regarding careful use of the tampons to eliminate the possibility of dye contamination during insertion or removal.

Regarding urogenital fistula, radiologic studies are not routinely helpful in the actual diagnosis. However, it is often necessary to evaluate the upper urinary tracts once a fistula is identified. This may be accomplished by an intravenous pyelogram or contrast computed tomography scan. Cystourethrography may be utilized to show a vesicovaginal or urethrovaginal fistula, but it is rarely needed to make an initial diagnosis. It has been occasionally helpful in delineating a complex fistula with multiple channels and openings. The use of Doppler ultrasound has been described to diagnose VVFs, with a sensitivity of 92%. Although this modality may be useful in the follow-up of patients undergoing conservative bladder drainage (one of four such patients demonstrated resolution of the fistula after 6 weeks), it too is rarely necessary to make an initial diagnosis.

All patients suspected of having a nonobstetrical urogenital fistula should undergo cystourethroscopy. This may be done as a separate procedure, allowing for improved surgical planning, discussion, and informed consent prior to the definitive operation, especially in complex or recurrent cases. Alternatively, the evaluation may be done just prior to operative management of the fistula and associated complications, but then surgical consenting must be done assuming all reasonable options.

Information to be sought during cystourethroscopy includes delineating the fistula's precise location and size; noting any surrounding induration, edema, and/or scarring; determining whether it is simple, complex, or multiple; and evaluating ureteral patency, location, and proximity to the fistula. It is preferable to examine the patient under

anesthesia when possible, thus allowing improved determination of fistula accessibility to the vaginal route of repair. If the fistula is large enough to prevent adequate distention of the bladder during fluid-filled cystourethroscopy, placing a vaginal pack is helpful in allowing better visualization. When there is clinical suspicion of a vesicouterine fistula, hysterothorgraphy or hysteroscopy may be helpful in making the diagnosis. If the patient is taken for examination under anesthesia and cystourethroscopy, then diagnostic hysteroscopy may help further delineate the course of such a fistula.

Some have advocated urodynamics testing prior to repair of a urogenital fistula on clinical and medicolegal grounds. Abnormalities on preoperative urodynamics have been reported in most patients. Urodynamic stress incontinence was noted in 75% of patients with urethral or bladder neck fistulas ($n = 12$) and 36% with VVFs ($n = 14$), with detrusor instability, impaired bladder compliance, and voiding dysfunction noted frequently as well. Of the 24 patients who were anatomically cured in this series, 1 (4%) had stress incontinence and 9 (38%) had urgency or urge incontinence. Preoperative urodynamics should be performed only if surgical management will be influenced by the results. Others do not routinely perform urodynamics preoperatively, preferring instead to provide counseling that if bladder symptoms occur and are bothersome to the patient, further diagnostic workup would then be indicated following an appropriate period of healing.

There have been several urogenital fistula classification systems devised in hopes of providing a prognostic indicator prior to intervention. Unfortunately, the prognostic ability of these classification systems has thus far been noted fair to poor. At this time, careful assessment of the type, nature, condition, location, and size of the fistula; condition of the bladder itself (including the trigone); the ureteral orifices and their patency; and the condition of the vagina should be noted and documented.

The classification of fistula is determined by which anatomic structures are found abnormally communicating (see [Table 43.1](#)). The nature of the fistula includes whether it represents a single or multiple channel fistula, while the condition denotes the appearance of the mucosa in the region of the fistula, whether indurated, edematous, necrotic, scarred, etc. The same components of condition should be assessed regarding the bladder in general. Any foreign material or objects in the bladder cavity or exposed through the mucosa should be noted as well, describing its location in the bladder and relative to the fistula.

P.952

Fistula location should be described in terms of distance from known landmarks, such as the (left or right) ureter orifice, interureteric ridge, trigone, bladder neck (or proximal urethra), and/or the urethral meatus as appropriate. Finally, from the cystourethroscopic view, an estimate of the fistula's size (diameter) should be recorded. Similarly, a determination of the size and location of the fistula from the vaginal perspective is useful in the detailed description of a fistula. Specify laterality, distance to the cuff or urethral meatus, condition of the vaginal epithelium (scarring, induration, etc.), and mobility/vaginal accessibility of the fistula.

MANAGEMENT OF UROGENITAL FISTULAS

Nonsurgical Management

Once a urogenital fistula has been diagnosed, a trial of conservative management should be offered, although there is no consensus regarding when this should be offered and for what duration. This is particularly true for small fistulas that present early and have no evidence of epithelialization of the tract. Transurethral bladder drainage may help small (<0.5 cm and certainly <1 cm) and early (<3 weeks) VVFs resolve without further intervention and may be tried for 4 to 6 weeks as long as catheterization resolves the vaginal leakage. Medical management should include optimizing nutrition, correcting anemia, and improving vaginal estrogenization. In a retrospective case series of 558 urogenital fistulas (72% associated with obstructed labor), a trial of conservative treatment was done in 42 patients with successful closure of the fistula in 8 (19%) patients. All patients with successful conservative management had a supratrigonal fistula that was less than 4 mm with healthy

surrounding mucosa as assessed by cystoscopy.

The use of collection devices has been tried with varying success but may be offered for temporary relief of constant urinary leakage until a more permanent solution is performed. Most are based on a Foley catheter or preferably a Malecot drain inserted into the center of a well-fitted contraceptive diaphragm and placed in the upper vagina to temporarily collect urine and avoid the distress of constant leakage.

Conservative Surgical Management

Some success has been reported in small series with cystoscopic laser treatment of VVF, primarily limited to small (2 to 4 mm) supratrigonal fistulas as well as electrocoagulation. Successful occlusion of a large complex postoperative VVF with fibrin was first reported in 1979. Since then, fibrin glue has been used successfully in the treatment of VVFs. Most recently, autologous platelet-rich plasma has been injected transvaginally with interposition of platelet-rich fibrin to successfully treat 11 of 12 iatrogenic VVFs. A small randomized trial comparing interposition of fibrin glue to the use of a Martius flap during complicated obstetrical VVF repair concluded that the outcomes were similar and operative time was decreased with self-made fibrin glue. A recent case report of ureteral obstruction and urinary fistula associated with fibrin glue used at the time of partial nephrectomy is an appropriate general reminder of the potential for risk as well. Experience with all these modalities continues to be sparse but potentially useful pending further long-term data.

Surgical Correction of Urogenital Fistula

When conservative therapy fails or the patient is not a candidate for conservative therapy, surgical repair is the only alternative to relieve the patient of her symptoms. The pelvic surgeon must determine the optimal timing, technique, and route of repair, as well as determine what suturing technique to use, how many layers of closure are sufficient for repair, and whether or not to use an interposition graft. No definitive trials adequately address any of these dilemmas at this time. Several general principles may apply and are discussed, emphasizing the care for iatrogenic rather than obstetrical fistulas. A synopsis of the literature regarding principles related to repair and surgical outcomes is presented, followed by an outline of the technical details of the operations discussed.

Principles of Surgical Repair

Traditionally, delayed repair of VVFs for several months was standard to allow the surrounding tissue to heal from the inciting injury. These recommendations were formulated primarily from what was and still is experienced in cases of obstetrical fistulas where there is often a large amount of tissue necrosis. Since that time, several case series have shown the safety and efficacy of earlier repair as long as there is no evidence of concurrent infection, inflammation, or necrosis in the tissue bed and when the fistula is not associated with radiation. The definition of what constitutes an early repair varies and has not been determined, but the previously referenced series report the interval to be from 1 to 6 weeks after the original insult, with another series specifically reporting excellent results when repair is undertaken 2 weeks or less from the inciting procedure. Obstetric (particularly if the fistula is not supratrigonal) and radiation injuries, however, require more time to heal prior to an attempt at fistula repair. In a large series from England, the first surgical attempt at repair of urogenital fistulas was noted to give the best chance of anatomic cure (98.2% vs. 88.2%) or reduce the chance of repeat surgery.

In Sims' classic article regarding the surgical treatment of VVFs, he emphasized the need to excise all scar tissue within the fistula and create fresh tissue edges for reapproximation. Additional surgical principles include tension-free closure of the wound by widely mobilizing the bladder and atraumatic handling of tissues to preserve the vascular supply needed for subsequent wound healing, including the absolute minimal use of electrocautery. Additional critical elements of success include ensuring excellent hemostasis of the surgical site, fine suture material (silver wire "drawn down to about the size of a horsehair"), avoidance of too much force on the suture

closure, and maintaining good postoperative bladder drainage until healing is established. Of note, since the silver wire had to be subsequently cut and removed, the original operation left the vagina open without any surgical reapproximation.

Despite these original tenets, there is currently no consensus about whether to excise the margins of the fistula. Several series have reported success with preservation of the fistula tract (primarily during vaginal route of repair), with some being concerned about making the fistulous opening larger, as occurs when the fistulous tract is excised. Others have continued to report their experiences with excision of the tract with little concern about the enlargement of the defect in the process. The purported benefit of tract excision is allowing fresh tissue edges to be approximated, thus promoting healing of these surfaces to each other and reducing the likelihood of nonunion of the fistula's epithelialized lining. A randomized trial of 64 obstetrical fistula patients revealed no difference in surgical success with or without trimming of the fibrous fistula edge on the bladder side once the vesicovaginal space was developed. With an average fistula size of 1 to 1.3 cm, the authors voiced concern regarding enlarging the fistula further when the fistula edges were trimmed. It remains unknown how these findings may be interpreted in the management

P.953

of posthysterectomy VVFs, which tend to be significantly smaller.

Another technical dilemma is whether to permit through-and-through suture placement or insist on excluding the mucosal layer from the suture bite. Concern over incorporating the mucosal layer stems from the possibility that it would increase the likelihood of failure and may lead to stone formation given that this region is the most dependent portion of the bladder and is therefore continuously in contact with urine, and how urine solutes would interact with the exposed suture material. The potential benefits of a through-and-through stitch are its ease and better hemostasis at the incision site. It remains for the operating surgeon to decide individually how to balance the pros and cons and how best to close the bladder aspect of the incision.

Similarly, the choice of suture type or caliber in urogenital fistula repair has not been compared in the literature and, therefore, no specific comment regarding the use of braided or nonbraided and absorbable or delayed absorbable suture type can be recommended. However, given the risk of bladder stone formation reported around permanent sutures, these should be avoided in the repair of urogenital fistulas. Many prefer the use of small-caliber fine sutures for repair, particularly on the bladder aspect of the repair, but no data are available regarding this issue. Although rarely noted in the literature since Sims's original description, there are those that only repair the bladder while leaving the vaginal side open.

In Sims's original article, the closure was described as a single-layer closure, which was necessitated by the need to remove the silver sutures postoperatively. In modern surgical practice, many advocate multilayer closure, primarily to reduce the forces that tend to pull the first layer of closure apart but also to add additional tissue bulk between the bladder and vagina. Although data in an animal model have suggested that multilayer closure of a cystotomy is superior to single-layer closure in preventing a subsequent VVF, there are no data comparing the two options in the repair of a VVF once it is established.

Reported techniques also vary concerning whether suturing is interrupted or continuous, with no clear consensus as to which is the better approach in urogenital repair. The reported benefits of a continuous closure are primarily related to convenience, speed, and perhaps use of less suture. The theorized benefit of interrupted suture placement is that it provides a perpendicular orientation of the vector forces, keeping the wound together with the least tension for a given closing force. Increased tension leads to more pressure on the surrounding tissue and may lead to reduced blood flow at the incision where it is most needed for successful healing.

Perhaps the most intense debate has been regarding the route of vesicovaginal repair—transabdominal or transvaginal. There is general agreement that the vaginal repair is more convenient for the patient in terms of

recovery, length of hospital stay, and cosmetic issues, but little agreement regarding which is the better operation. Absolute indications for an abdominal approach include conditions that require bladder augmentation (a small capacity or poorly compliant bladder, as may occur following irradiation), a fistula involving or very close to a ureter that requires ureteral reimplantation, a combination fistula involving other intra-abdominal organs, inability to adequately expose the fistula transvaginally due to positioning, or other access problems (Table 43.5).

The debate over the route of repair is now further complicated by increasing numbers of laparoscopic series both with and without robotic assistance. The scarcity of VFs and the absence of specified centers in developed countries will likely result in the continued absence of large well-designed randomized prospective trials in this setting. Ultimately, this is a decision best made between a patient who is well informed regarding the various options, their advantages, and disadvantages and an experienced pelvic surgeon capable of tailoring the approach to the specific circumstances at hand.

TABLE 43.5 Indications for Abdominal Vesicovaginal Fistula Repair

- Small capacity or poorly compliant bladder requiring bladder augmentation
- Fistula involving or very close to a ureter requiring ureteral reimplantation
- Combination fistula involving other intra-abdominal organs
- Inability to adequately expose the fistula transvaginally

Repair of urethrovaginal fistulas is different from VVF repair given the added issues related to whether the sphincter complex is affected as well as the possibility that urethral stenosis may develop with consequent urinary retention. Reconstruction of the urethra often involves less readily available tissue when compared to VVF repair; thus, some advocate the frequent use of the Martius graft. An added level of complexity is noted in recent increases of fistulas associated with synthetic suburethral slings. The periurethral scarring frequently requires more extensive and difficult urethral repair, which is further complicated by the need to remove the surrounding graft material. Despite these apparent complicating factors, it seems that the overall success rates for both vesicovaginal and urethrovaginal fistula repairs are similar.

When preparing patients for surgical correction of a urogenital fistula, detailed informed consent and discussion are very important. Patients with urogenital fistulas as complications of benign pelvic surgery have already experienced an adverse outcome that they may or may not have been prepared for. They invariably have some degree of frustration, anxiety, and suspicion. All aspects of operative risk should be discussed with the patient prior to fistula repair, including the likelihood of fistula recurrence. Even in the event of successful anatomic repair, the occurrence or persistence of lower urinary tract symptoms such as incontinence, overactive bladder, voiding dysfunction, and bladder pain should be discussed. Discussing the expected recovery course of the various available approaches and potential adverse consequences of associated procedures such as episiotomy or Schuchardt incisions, disfigurement from flaps, and discomfort from suprapubic and transurethral catheters seems to prepare patients for some of the difficulties that may lie ahead. This information should be incorporated into the discussion to decide on the route of repair—a discussion in which the patient should ideally be an active participant. When ureteral reimplantation may be required, the need for stenting and subsequent cystoscopic

stent removal should be discussed, as well as the need for drains, the risk of ureteral stenosis, and the need for subsequent radiologic follow-up. Patients undergoing a vaginal repair should be made aware of the possibility of conversion to an abdominal procedure, although this is a rare occurrence.

Outcomes of Surgical Repair

In a contemporary retrospective cohort study spanning 10 years and derived from the English National Health Service inpatient database, 905 urogenital fistula repairs were noted and 11.9% required a repeat operation. This report did not differentiate the route of the surgical approach.

P.954

Through the abdomen, the physician can utilize the transperitoneal-transvesical approach made popular by O'Connor and Sokol, which involves bivalving of the bladder or avoid entering the peritoneal cavity by a retropubic transvesical repair introduced by Landes, which involves entering the bladder through an anterior cystotomy that does not communicate contiguously with the fistula. Success rates for the transperitoneal-transvesical approach have been between 86% and 100% for benign, nonirradiated fistulas. Furthermore, a technique termed a mini-O'Connor that involves a less extensive bladder incision than originally described reported 100% success in 26 supratrigonal VFs. In data pooled from three studies reporting variations of the retroperitoneal transvesical technique, with a total of 91 fistula patients (primary and recurrent), the success rate is 100%. In a series comparing a center's experience between vaginal and abdominal approaches for the repair of supratrigonal VFs, the rates of successful repair were comparable (94.8% vs. 100%, respectively, $n = 48$).

A number of laparoscopic series have been published since Nezhat et al. first published their case report of laparoscopic repair of a VF in 1994, with reported success rates that are comparable to the open approaches with benefits demonstrated that are inherent to a minimally invasive approach. The vast majority of these reports are transperitoneal-transvesical in the manner of a traditional O'Connor technique, although primarily through smaller cystotomy incisions, thus avoiding bivalving the bladder while maintaining the ability to place an interposition flap when needed. Laparoscopic case series are numerous, mostly consisting of 10 patients or less (some much less) with success rates of 93% to 100%.

In the largest published series thus far, Shah reported on 25 patients with planned laparoscopic transperitoneal-transvesical management of VFs. Of these fistulas, 64% were posthysterectomy with the rest related to various obstetrical circumstances. Of the 22 patients that had undergone laparoscopic management (three required laparotomy due to dense adhesions), the success rate was 86%.

A transperitoneal extravesical laparoscopic technique is also described in which entry into the bladder is made through the fistula itself once the vesicovaginal space has been developed to the area of the fistula. Fistula cure rates of 91% to 100% were reported using this particular approach, including an omental flap.

Even fewer reports are found in the literature regarding laparoendoscopic single-site surgery (LESS) for the repair of VFs. One such report involved 5 patients with a transperitoneal extravesical approach with success. A single case report of LESS using a suprapubic transvesical access similar to the open version reported by Landes has been described as well.

The experience in the literature regarding robotically assisted laparoscopic repair of VFs is again dominated by very small case series (all are seven patients or less, and most had no more than three patients) since the first case report by Melamud et al. in 2005. These case reports and series demonstrate the technique and feasibility of the transperitoneal robotic approach using either a transvesical or extravesical technique, but represent very early experiences utilizing this new technology. A retrospective study compared open versus robotically assisted laparoscopic O'Connor-type repair of recurrent VF. Gupta et al. report 100% success in their 12 robotic cases, which were a result of obstetrical as well as gynecologic etiologies, compared to 90% among their 20 open

cases. This difference was not statistically significant.

Vaginal repairs of VFs have reported success rates of 92% to 97% in the larger series in the literature. These vaginal procedures encompass various techniques with the variations as discussed previously. No comparative studies are available to determine which specific vaginal procedure, if any, is superior. As such, it is clearly advantageous that surgeons who repair these lesions be comfortable with several different approaches and individualize their techniques to the particular case at hand.

Various techniques have been described to augment fistula repairs, both for the transabdominal and transvaginal approaches. This is thought to bring additional tissue to interpose between the bladder and the vagina but more importantly, a healthy blood supply. Occasionally, such grafts also serve to fill in lost tissue space, as with large fistulas where a large amount of tissue is lost. The routine use of interposition grafts has been advanced by some; however, most surgeons use these adjuncts based on individualized clinical judgment. It is generally agreed that tissue interposition is needed in irradiation-induced fistulas or in other instances where there is local vascular compromise, such as recurrent, severely scarred, or previously infected fistulas. Transabdominally, the omentum is most often used with excellent results. In one series, a 100% (10/10) success rate with such interposition grafts compared with 63% (12/19) when grafts were not used in benign VFs repaired transabdominally.

Rangnekar et al. report on Martius bulbocavernosus fat pad grafting to reinforce 21 obstetric urethrovaginal and VF repairs performed transvaginally. Seven patients of 8 (87%) were cured of their urethrovaginal fistula, whereas all 13 patients (100%) with VFs were cured with use of the Martius graft. For extremely large defects, a myocutaneous modification of the Martius bulbocavernosus graft has been described. The island of skin after sublabial transfer was sutured to the defect in the vaginal wall. Such modified repair has been suggested for large obstetric or irradiation-induced fistulas. Eilber et al. report long-term results of transvaginal repair of complex or recurrent VFs with either peritoneal interposition graft for fistulas high in the vault or Martius flap or labial flap for distal defects. Cure rates were 96% of 83 patients with peritoneal graft and 97% of 34 patients with Martius fat pad graft.

Fistulas that form within a previously irradiated field are more prone to recurrence, and most surgeons would agree that additional pedicled flaps are needed in their surgical repair because of the inherent microvascular compromise. In a large series of 210 cases, the primary approach was vaginal (97%). Martius fat pad transposition was used in 41% of the cases. The overall primary repair success rate was 48%, and with multiple interventions the cumulative success rate was 80%.

Alternative vascular flaps have been described in difficult cases. In six patients who failed urethrovaginal fistula closure with Martius transposition, Bruce et al. report 100% successful resolution of the fistula when treated with a pedicled, tubularized rectus abdominis muscle flap interposed suburethrally. In a more recent small series by Svaerdborg et al., such a vascular muscle flap was used to successfully manage postradiation VF without closure of the bladder or vaginal aspects of the fistula. Myocutaneous flaps have also been described, including gracilis and rectus abdominis.

Urethrovaginal fistula repair outcomes are often reported in terms of anatomical and continence cure rates. Anatomic cure rates in surgical series have been reported to be 82% to 92%, while continence cure rate is 80%. Urethral obstruction related to stenosis has been reported in about 10% of cases.

UROGENITAL FISTULA REPAIR—TECHNICAL DETAILS

Vesicovaginal Fistula Repair

See the Steps in the Procedure box for general surgical steps required in the repair of a VF. This is followed by

STEPS IN THE PROCEDURE

Vesicovaginal Fistula Repair

- Evaluate fistula cystoscopically and vaginally to assess size, location relative to known landmarks (urethra, trigone, and ureters), and the quality of the injured tissue.
 - If timing deemed appropriate, proceed with VVF repair as outlined below. Ureteral catheterization is needed if the fistula is close to the ureter(s). Place transurethral Foley catheter.
 - Access the fistula vaginally, intraperitoneally, and/or transvesically (see text for details). Use fine instruments and surgical technique as well as delicate tissue handling while optimizing visualization using gentle suction and copious irrigation. Avoid prolonged clamping of the vagina or bladder during the repair, and avoid electrocautery near the injury.
 - Circumscribe the fistula, and sharply dissect the vesicovaginal space sufficiently to allow tension-free closure, keeping ureteral anatomy and safety constantly in mind.
 - Excise the fistula tract, and send it for histopathologic evaluation. The tract is not excised if a Latzko procedure is performed.
 - Reassess tissue for significant fibrosis and, if appropriate, further excise until healthy, well-vascularized tissue is encountered.
 - Reassess the vesicovaginal dissection to ensure adequate separation of bladder from vagina and a tension-free repair. Approximately 1 cm circumferentially beyond the edges to be reapproximated is needed.
 - The order of closure depends upon the route of VVF repair. Depicted in [Figure 43.3](#) is a transvaginal repair; if transperitoneal or transvesical, the vaginal closure is completed first.
 - Close the urothelial (lamina propria) layer with interrupted or running fine 3-0 delayed absorbable suture.
 - Reapproximate the muscular layer with interrupted 2-0 or 3-0 delayed absorbable suture. Place the sutures in a staggered fashion, thus avoiding overlapping sutures one atop the other. Ensure hemostasis in the vesicovaginal space.
 - A third imbricating layer of bladder muscularis to further reinforce the repair may be possible using interrupted 3-0 delayed absorbable suture.
 - Perform cystoscopy to ensure the following:
 - Intravesical hemostasis. Irrigate with small volumes of fluid, and remove any blood clots that may obstruct catheter drainage.
 - Integrity of the repair by looking vaginally for spillage of cystoscopy fluid.
 - Absence of injury or obstruction to the ureter using intravenous indigo carmine.
 - Determine whether an interposition graft is needed (see text for details), and if performed, ensure adequate vascularity and stable interposition into the vesicovaginal space.
 - Close the vaginal side of the fistula separately with interrupted 2-0 or 0 delayed absorbable suture. It is preferable to perform the bladder and vaginal closures in different orientations, one vertical and the other horizontal. If the same orientation is chosen, place the sutures in a staggered fashion, thus avoiding overlapping sutures.
 - Determine whether a three-way Foley is needed for postoperative bladder irrigation in the face of hematuria.
-

The patient is placed in the dorsal lithotomy position using candy-cane stirrups. Examination under anesthesia is performed with water cystoscopy. The 30 degrees or 70 degrees lens is used to best visualize the fistula intravesically and identify any associated abnormalities. Identify the intravesical and vaginal openings, and assess the tract's angle and rule out multiple tracts. The fistula's proximity to the ureters is assessed, and transvaginal repair is continued if it is not too close. Ureteral stenting may be done to continuously identify the ureters if needed. Dilation of the fistulous tract allows an 8-French Foley catheter to be inserted and the balloon inflated. Appropriate traction allows the fistula to be brought distally for better access and exposure. When the tissue surrounding the fistula is extensively scarred, subepithelial injection of saline may be used to facilitate dissection of the vaginal flap. Some authors advocate the injection of epinephrine or vasopressin to diminish surgical bleeding; some concern may be delayed bleeding into the vesicovaginal space once the vasoconstrictive activity is past, which can undermine the repair.

The vaginal mucosa is incised circumferentially around the fistulous opening; the vaginal mucosa is then carefully dissected off the bladder to a distance that will allow tension-free multiple-layer closure, approximately 1 to 2 cm radially around the incision. All tissue must be handled delicately with fine instruments that are of sufficient length to reach all levels of the fistula and the dissected tissues. Excellent hemostasis is best achieved with liberal use of pressure and subsequent suture closure, avoiding the use of electrocautery if at all possible. The fistula collar is excised and sent for pathologic evaluation. Repeat cystoscopy verifies the location of the ureters in relation to the somewhat larger fistulous opening. A suprapubic catheter is then placed. The bladder mucosa is closed in the direction of least tension (side to side or proximal to distal) with interrupted 3-0 or 4-0 delayed absorbable sutures, placed approximately 0.5 cm apart. Proximal-to-distal orientation is chosen if the ureters are in close proximity to the defect once the fistula is excised. If extramucosal suturing is possible, it is preferred; however, if desired or if mucosal edge bleeding is encountered, through-and-through suturing may be considered. A second layer consisting of bladder muscularis is brought

P.956

together over the first suture line, so it imbricates over it. This is achieved with interrupted suture that is placed staggered in between the underlying stitches on the first layer (**Fig. 43.3**). If the bladder peritoneum can be mobilized over the repair, it is accomplished at this point. If a Martius fat pad transposition is desired, this may be done instead of the peritoneal layer at this time. The vaginal mucosa is then closed with interrupted suture preferably in a different orientation than that of the bladder closure. At all stages of the closure, the absence of tension on each level is paramount to successful repair, as is hemostasis and verification of healthy, well-vascularized tissue for apposition. Cystoscopy may be used to verify watertight closure of the fistula, suture line hemostasis, and integrity of the ureters, but care must be taken to limit retrograde filling to avoid placing the fresh suture line under tension.

FIGURE 43.3 Traditional vesicovaginal fistula repair. **A:** Initial incision of a circumferential collar around the fistulous opening. The vaginal epithelium is sharply dissected radially from the collar. **B:** The fistula is excised sharply, making sure that healthy tissue is left to be reapproximated. Excessive trimming, increasing the loss of tissue, should be avoided. **C:** Interrupted fine, delayed absorbable suture on a small tapered needle is used, extramucosally if possible, to close the first layer. Stitches are placed approximately 0.5 cm apart with sufficient purchase of tissue to securely close the defect. **D:** The second layer imbricates over the first with suture being placed in a staggered fashion into the bladder muscularis so as not to overlap the sutures of these layers. **E:** The vaginal epithelium is closed with interrupted delayed absorbable suture after ensuring proper hemostasis in the vesicovaginal space. (Adapted with permission from Kovac SR, Zimmerman CW. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott, Williams & Wilkins, 2006.)

The Latzko procedure begins in a similar fashion with a circumscribing incision and dissection of the vagina off the

cervicovaginal fascia (**Fig. 43.4**). Instead of excising the fistulous tract, it is imbricated into the bladder cavity with

sequential layers of interrupted 3-0 or 4-0 delayed absorbable suture on a small tapered needle. Care should be taken to stagger the sutures so none lay atop the next layer. Cystoscopy should be used to verify watertight closure of the fistula and integrity of the ureters, but care must be taken to limit retrograde filling to avoid placing the fresh suture line under tension.

FIGURE 43.4 Latzko procedure. **A:** Stay sutures are placed to help stabilize and bring the fistula distally towards the operating surgeon. **B:** Vaginal epithelium is sharply dissected and excised circumferentially about the fistula. **C:** Completed epithelial excision around the fistula. **D:** First extramucosal layer of closure. **E:** Closure of the vaginal epithelial layer. (Adapted with permission from Ostergard DR, Bent AE, Cundiff GW, et al. *Ostergard's urogynecology and pelvic floor dysfunction*, 6th ed. Philadelphia, PA: Lippincott, Williams & Wilkins, 2007.)

Abdominal Approach

Retropubic Transvesical Vesicovaginal Fistula Repair This procedure is indicated for simple posthysterectomy VVF when adequate vaginal exposure cannot be obtained or can be obtained only with a Schuchardt or episiotomy incision and the patient prefers an abdominal approach. A Cherney or midline abdominal wall incision is made, the retropubic space is entered, and a midline vertical incision is made in the anterior bladder. The ureteral orifices are inspected and catheterized if needed. The fistula is identified and dilated to admit an 8-French pediatric Foley catheter after the position of the ureters is verified and the balloon inflated. A pediatric Foley catheter is placed through the fistula and the balloon inflated. Traction on the Foley allows improved access, and a circumscribing incision is made 2 to 3 mm from the fistula and the vesicovaginal space dissected

circumferentially 1 to 2 cm outward. The fistula may be excised or kept in situ (as originally described by Landes) and the defect closed in layers with the vaginal layer first using interrupted delayed absorbable 3-0 suture and the knots placed within the vaginal lumen. The bladder muscularis is closed next with knots placed in the vesicovaginal space. A third row incorporating bladder muscularis and mucosa is closed with 4-0 suture (**Fig. 43.5**). Ureteral integrity is verified. If a suprapubic catheter is used, it is placed through a separate incision. The bladder incision is closed with running delayed absorbable suture in two layers. Cystoscopy is used to verify watertight closure and ureteral integrity prior to wound closure, but care must be taken to limit retrograde filling to avoid placing the fresh suture line under tension.

Transvesical-Transperitoneal Vesicovaginal Repair Intraperitoneal access is obtained by laparotomy, laparoscopy, or robotically, and the bladder is vertically bisected in the midline. Ureteral catheterization is particularly helpful with laparoscopy and robotic access. The original description depicted starting this incision at the retropubic anterior portion of the bladder, but a less extensive bisection is possible and may be used according to the specific circumstance at hand (**Fig. 43.6**). Regardless, the incision is continued to the posterior bladder until it reaches the vesicovaginal space, which is then sharply dissected laterally and distally until the fistula is encountered, using gentle anterior bladder traction with posterior vaginal stabilization. The fistula is identified, and the tract is excised, while ureteral integrity is verified and continually visualized during the surgery. The vagina is closed transversely with interrupted delayed absorbable suture with the knots within the vaginal lumen. A second layer of vagina is used to imbricate the first if sufficient tissue is found. The bladder is closed in two layers side to side with fine absorbable suture to reapproximate the urothelial and muscular layers without tension. Prior to complete closure of the bladder, a suprapubic catheter may be placed through a separate stab incision. If an omental flap is deemed necessary, it is suggested to place the anchoring sutures after vaginal closure but prior to bladder closure to improve accessibility. Once the bladder closure is complete, these sutures are attached to the omental flap and tied into the vesicovaginal space (**Fig. 43.7**). Cystoscopy with small-volume distension is used to verify watertight closure, and care is taken to avoid having any significant blood clots in the bladder that may impede catheter drainage.

FIGURE 43.5 Retropubic intravesical vesicovaginal repair. **A:** The approach is retropubic, with retroperitoneal anterior bladder incision. The fistula is identified and circumscribed, and the vesicovaginal space is dissected radially. **B:** The fistula is shown with vaginal mucosa, bladder muscularis, and urothelial layers depicted. The first layer incorporates the vaginal epithelium in a vertical closure using interrupted suture. **C:** Bladder muscularis is closed with interrupted suture in a horizontal orientation. **D:** The urothelial layer is closed with fine interrupted suture to complete the repair. The anterior bladder incision is closed in layers.

FIGURE 43.6 Transperitoneal-transvesical vesicovaginal fistula repair. **A:** The bladder is incised midline from its anterior portion back posteriorly until the fistula is reached; the fistula is excised, and the ureters are protected. **B:** Dissection is continued in the vesicovaginal space distal to the fistula to allow tension-free closure in layers.

FIGURE 43.6 (Continued) C: The vagina is closed with interrupted delayed absorbable suture with the knots located inside the vagina. A second layer of closure is depicted in the insert. **D:** The dependent portion of the bladder is usually closed with interrupted double-layer closure of the bladder. Depicted in the figure is a single-layer submucosal running suture that was elected due to the very large size of the fistula and its proximity to the ureters. **E:** The rest of the bladder incision is closed with running suture in two layers. (From Lee RA. *Atlas of gynecologic surgery*. Philadelphia, PA: WB Saunders, 1992. By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

FIGURE 43.7 Omental flap. **A:** The omentum is partially detached by severing its vasculature on the left along the greater curvature of the stomach. **B:** This results in extra length so the flap will reach the vesicovaginal space, and is anchored by absorbable suture as depicted.

When the fistula is adjacent to the ureteral orifice, ureteroneocystostomy must be performed at the time of fistula repair (see [Chapter 39](#)). Once the dependent portion of the repair is complete, attention is turned to performing the ureteroneocystostomy. The implantation site should be placed in the posterior aspect of the bladder but sufficiently distant from the repair site. A double-J stent is placed and left for 4 to 6 weeks. The anastomosis site is drained with a Jackson-Pratt drain brought out through a separate stab incision.

Urethrovaginal Fistula Repair

STEPS IN THE PROCEDURE

Repair of a Urethrovaginal Fistula

- Evaluate the fistula cystoscopically and vaginally to assess size, location relative to known landmarks (urethra, trigone, and ureters), and the quality of the injured tissue.
- Place transurethral Foley.
- Circumscribe the urethrovaginal fistula with proximal and distal midline extensions. Then, carefully dissect the urethrovaginal space laterally on both sides avoiding any electrocautery and sufficient to allow for tension-free closure and expose the paraurethral tissue.
- If severe fibrosis noted, carefully excise the fistulous tract until significant scar is removed.
- Close the urethra by placing interrupted fine, 3-0 or 4-0 delayed absorbable suture on a small tapered needle through the muscularis while avoiding intramucosal placement if possible.
- The second layer is closed with interrupted 3-0 delayed absorbable suture utilizing the paraurethral tissue (pubocervical fascia) previously exposed. Place the sutures in a staggered fashion, thus avoiding overlapping sutures.
- Martius fat pad transposition is recommended to further support these repairs, particularly if recurrent, there is significant scarring (such as occurs associated with mesh), or the paraurethral second layer closure is absent or deficient in any way.
- Close the vaginal incision with 3-0 or 2-0 delayed absorbable suture in an interrupted and staggered fashion to avoid overlapping sutures.

The same principles of careful handling of tissues, good hemostasis, and tension-free apposition of tissues must be maintained with surgical correction of urethrovaginal fistulas. A distal fistula may rarely be closed in a proximal-to-distal orientation to limit the possibility of urethral stenosis; otherwise, these defects are closed side to side in layers. Eversion of the fistula edges into the limited space of the urethral lumen is not recommended, and transmucosally placed sutures are to be avoided. If there is adequate substance, the fistula is minimally excised, but often, there is enough loss of urethral wall that this may be impossible without resultant stricture formation (**Fig. 43.8**). A second layer is often created by imbricating paraurethral tissue over the first layer. Liberal use of the Martius flap to support these repairs is advocated by many, particularly if a second layer is not feasible (**Fig. 43.9**).

Postoperative Care Ensuring proper bladder drainage is of utmost importance. If a suprapubic catheter is chosen, then combined transurethral and suprapubic drainage is performed early on. The transurethral catheter is removed once significant gross hematuria has cleared, usually 1 to 2 days. This often takes longer with the transvesical-transperitoneal (especially if done open) than with the vaginal approach. The suprapubic catheter is left for 2 to 3 weeks depending on the complexity of the repair. Some advocate routine evaluation with a cystogram prior to its removal; others do not. The option of having catheter drainage that is exclusively transurethral is also feasible and may be associated with less potential for complications.

FIGURE 43.8 Urethrovaginal fistula repair. **A:** Note the initial circumferential incision with midline extension proximally and distally. **B:** Further lateral dissection exposes paraurethral tissue and allows for tension-free closure. **C:** The first layer is closed by interrupted fine, delayed absorbable suture on a small tapered needle, avoiding intramucosal placement. **D:** The second is an interrupted imbricating layer of paraurethral tissue. Martius fat pad transposition is occasionally needed to further support these repairs. If not, the vaginal epithelium is closed to complete the repair. (Adapted with permission from Kovac SR, Zimmerman CW. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott, Williams & Wilkins, 2006.)

Avoiding bladder spasms is considered important in preventing recurrence, although this has not been well studied. Some patients have severe pain associated with bladder spasms, and these may require belladonna and opioid suppositories. For most patients, standard anticholinergic medication is sufficient to prevent these spasms and detrusor overactivity if needed.

Vaginal packing rarely seems necessary following fistula surgery. Vaginal intercourse is prohibited for 2 to 3 months, to allow complete healing of the suture line. The use of vaginal estrogen cream is encouraged preoperatively to allow for reepithelialization of the incision in patients with vaginal atrophy.

FIGURE 43.9 Martius (bulbocavernosus) fat pad transposition. The labial fat pad is supplied anteriorly by branches of the external pudendal and obturator arteries, and posteriorly by branches of the internal pudendal artery. Although traditionally the posterior blood supply was thought to be of superior quality, the graft may be swung anteriorly or posteriorly depending on the need of the surgeon. **A:** An incision is made over the labial fat pad, and it is dissected bluntly and with electrocautery ensuring adequate hemostasis and a continued adequate blood supply from the chosen pedicle. **B:** Once the labial fat pad is partially detached, a submucosal tunnel is created and enlarged to ensure adequate blood flow to the tip of the graft. **C:** The graft is carefully pulled through the tunnel to the area needed. Once the graft is pulled through the tunnel, it is sutured in place. **D:** Hemostasis of the donor site is verified, the skin and vaginal mucosal incisions are closed. (Adapted with permission from Kovac SR, Zimmerman CW. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott, Williams & Wilkins, 2006.)

Chapter 44

Anal Incontinence and Rectovaginal Fistula

James Unger

DEFINITIONS

Anal incontinence—Involuntary loss through the anus of flatus, liquid stool, or solid stool that is perceived as a social or hygienic problem.

Anal manometry—A diagnostic test that provides information regarding function, sensation, compliance, and the presence of intact reflexes within the anal canal and distal rectum.

Anal ultrasonography—An imaging modality used to define the anatomy of the sphincter complex. It is the simplest, most reliable, least invasive test for definition of anatomic defects in external and internal anal sphincter.

Closing reflex—Exaggerated increase in muscle contraction allowing for anal closure at the end of defecation.

Defecography—A diagnostic test that involves imaging of the rectum with contrast material and observation of the process, rate, and completeness of rectal evacuation using fluoroscopic techniques.

External anal sphincter—Striated muscle sphincter, under voluntary control, that is responsible for much of the squeeze pressure in the anal canal.

Extra-anal incontinence—Involuntary loss through a fistula of flatus, liquid stool, or solid stool.

Fecal incontinence—Involuntary loss through the anus of liquid or solid stool only; excludes flatal incontinence.

Fourth-degree laceration—Complete rupture of the external anal sphincter and laceration of the anorectal mucosa.

Internal anal sphincter—Thickened continuation of the circular smooth muscle layer of the bowel, under autonomic control, that is responsible for much of the resting pressure in the anal canal.

Noble procedure—Transperineal approach to anal sphincteroplasty and perineoplasty in patients with chronic perineal laceration. Since it involves mobilization of the anterior rectal wall outside the anal orifice, it can also be used for analvaginal fistula repair. Major advantage is the lack of sutures in the anorectal canal.

Pelvic floor electromyography—A diagnostic test that evaluates the pelvic floor muscles for evidence of nerve injury. It is performed for three purposes: to identify areas of sphincter injury by mapping the sphincter, to determine whether the muscle contracts or relaxes, and to identify denervation-reinnervation potential indicative of nerve injury.

Puborectalis muscle—Striated muscle medial portion of the levator ani that is responsible for maintaining and increasing the anorectal angle and contributes to the squeeze pressure in the anal canal.

Pudendal nerve terminal motor latency (PNTML)—Operator-dependent technique to measure the response of the external anal sphincter to stimulation of the pudendal nerve. Prolongation of response has been associated with anal sphincter weakness due to pudendal nerve damage, although this is very controversial.

Rectovaginal fistula—Epithelial-lined connection between the rectosigmoid or anal canal and the vagina or perineum.

Rectoanal inhibitory reflex (RAIR)—Complex process in which sampling of rectal contents by the anal

canal occurs every 8 to 10 minutes in response to rectal filling. This reflex primarily occurs through relaxation of the upper internal anal sphincter with continued pressure maintained by the lower internal anal sphincter. Concurrent contraction of the external anal sphincter and puborectalis muscle force the sampled contents back into the rectum.

Resting pressure—Reflects the tonic activity of both internal anal sphincter and external anal sphincter; approximately 75% to 85% of this pressure is derived from the internal anal sphincter.

Sacral neuromodulation—Stimulation of S2-S4 nerve roots via an implanted electrode introduced through selected sacral foramina, which in turn is connected to an implanted electrostimulator in order to cause contraction of levator muscles and external anal sphincter.

Secca procedure—Transanal delivery of temperature-controlled radiofrequency energy to the sphincter complex, which results in tissue remodeling and improved anal sphincter function.

Third-degree laceration—A partial or complete laceration of the external anal sphincter without involvement of the anorectal mucosa.

INTRODUCTION

Obstetricians and gynecologists have an important role to play in the diagnosis, management, and prevention of anal incontinence in women. Women with anal incontinence may bring this problem to the attention of their obstetrician-gynecologist as a

P.967

primary complaint or in many cases discuss it only after close questioning about symptoms. This is because many women are understandably reluctant to mention such problems on their own due to feelings of embarrassment. This discussion may occur with the acute onset of symptoms shortly after a pregnancy or much later in life unrelated to recent childbirth. While in the first case such incontinence may be the direct result of acute childbirth injury, in the latter case, it may be related to chronic injury due to childbirth injury years ago or unrelated to any childbirth event. In either case, the gynecologist is often the first consulted to provide evaluation and management.

In addition, the prevention of obstetric trauma and its adverse effects on pelvic floor function including anal continence has become a major public health question. It seems clear that sphincter injury at the time of vaginal delivery significantly increases the odds of anal incontinence even years later beyond the postpartum period. Pollack and coworkers reported a 53% anal incontinence rate at 5 years in women who had undergone an anal sphincter tear compared to 32% in women without a tear. They calculated an odds ratio of 2.3 (95% CI 1.1 to 5.0) for anal sphincter tear and later incontinence. More recently, Evers and coworkers also calculated an odds ratio of 2.3 (95% CI 1.27 to 4.26) for anal incontinence women 5 to 10 years following an anal sphincter laceration. They also concluded that vaginal delivery in the absence of an anal sphincter laceration was not a risk factor for anal incontinence.

Surgical repair of chronic anal sphincter injury, the major subject of this chapter, is by no means uniformly successful, and results seem to deteriorate with time. Gutierrez and colleagues reported on 191 patients at 10 years after anal sphincter repair and found that only 6% of the 130 patients who returned questionnaires had full continence. In addition, 58% were incontinent of solid stool. Zutshi and coworkers reported on 31 patients with a median age of 44 years at the time of overlapping sphincter repair with a median follow-up of 129 months. No patients were fully continent at 129 months. Patients who were older at the time of surgery and those who had undergone multiple vaginal births had the worse outcomes. Dudding and coworkers in a systematic review of the literature in 2008 determined that only 20% of patients were continent to liquid and/or solid stool at 10 years after overlapping sphincter repair.

Likewise, obstetric lacerations involving the rectum may result in rectal/anal-vaginal fistulae even when expertly repaired. Although childbirth-related fistulae can usually be successfully repaired with surgery, they are physically and emotionally distressing. Sometimes, more than one surgical attempt is required. It is also evident that certain obstetric practices such as midline episiotomy and operative vaginal delivery may contribute to later adverse effects on fecal continence, most likely by increasing the risks of anal sphincter and rectal injury. This has generated considerable discussion and debate regarding the appropriate use of episiotomy, operative vaginal delivery, and even cesarean section on demand for the sole purpose of preventing pelvic floor injury as noted in a recent commentary by Nygaard.

Approximately 1.4% of normal community-dwelling adults are incontinent to liquid or solid stools. Perry and coworkers reported on a total sample of 10,116 adults over age 40 years a major fecal incontinence rate of 1.4%. There was no significant difference between men and women, although incontinence was more prevalent and more severe in older people. Walter and colleagues in a random sample of 2,000 community-dwelling individuals between the ages of 31 and 76 reported a rate of leakage of solid stools of 1.4% in women and 0.4% for men. The prevalence increases with normal aging to 6% to 7% of elderly adults over age 60 years living independently according to a study performed in the Netherlands by Teunissen and colleagues. On the other hand, Tobin and Brocklehurst reported that 10.3% of residents in 30 different residential homes for the elderly had fecal incontinence at least once weekly. Therefore, anal incontinence is a symptom that affects millions of women and has many causes in addition to childbirth trauma ([Table 44.1](#)). In fact,

P.968

Whitehead and coworkers demonstrated that after adjusting for age, neither vaginal delivery nor gender was predictive of anal incontinence. Like Perry, they reported that increasing age is the major determinant of fecal incontinence. However, many cases in women do seem to be strongly associated with pelvic floor injury, especially injury to the anal sphincter sustained either overtly or covertly during childbirth as previously noted. These injuries may result from direct traumatic disruption to some component of the anal sphincter mechanism or functional deterioration over time as a result of occult nerve injury and aging. Identifying the role of childbirth and risk factors associated with delivery that are linked to later incontinence is important since some of these factors may be modifiable by altering certain childbirth practices and thus lowering the risk of subsequent incontinence. Women with either acute or chronic anatomic injury as a cause of their incontinence are the ones most likely to benefit from care of the well-trained surgical gynecologist. The obstetrician-gynecologist not only will be the first one to be involved in the prevention of such injuries but also will be responsible for the surgical repair required in the delivery room. In addition, the obstetrician and gynecologist may be the first one consulted to evaluate women with chronic fecal incontinence and must be able to carefully assess such women with a thorough history, physical examination, and appropriate imaging or testing, in order to arrive at a precise etiology of this condition. At this point, patients may be referred to other specialists such as those in female pelvic medicine and reconstructive surgery, gastroenterologists, colorectal surgeons, physical therapists, and others if treatment of the underlying condition is outside the expertise of the patient's obstetrician-gynecologist.

FUNCTIONAL ANATOMY OF ANAL CONTINENCE

The mechanisms and structures involved in defecation and preservation of anal continence are reviewed in detail in the following section. A summary of the structures and processes involved is illustrated in **Figures 44.1** and **44.2**.

FIGURE 44.1 Location of the anal sphincter in relation to other structures of the female pelvic floor.

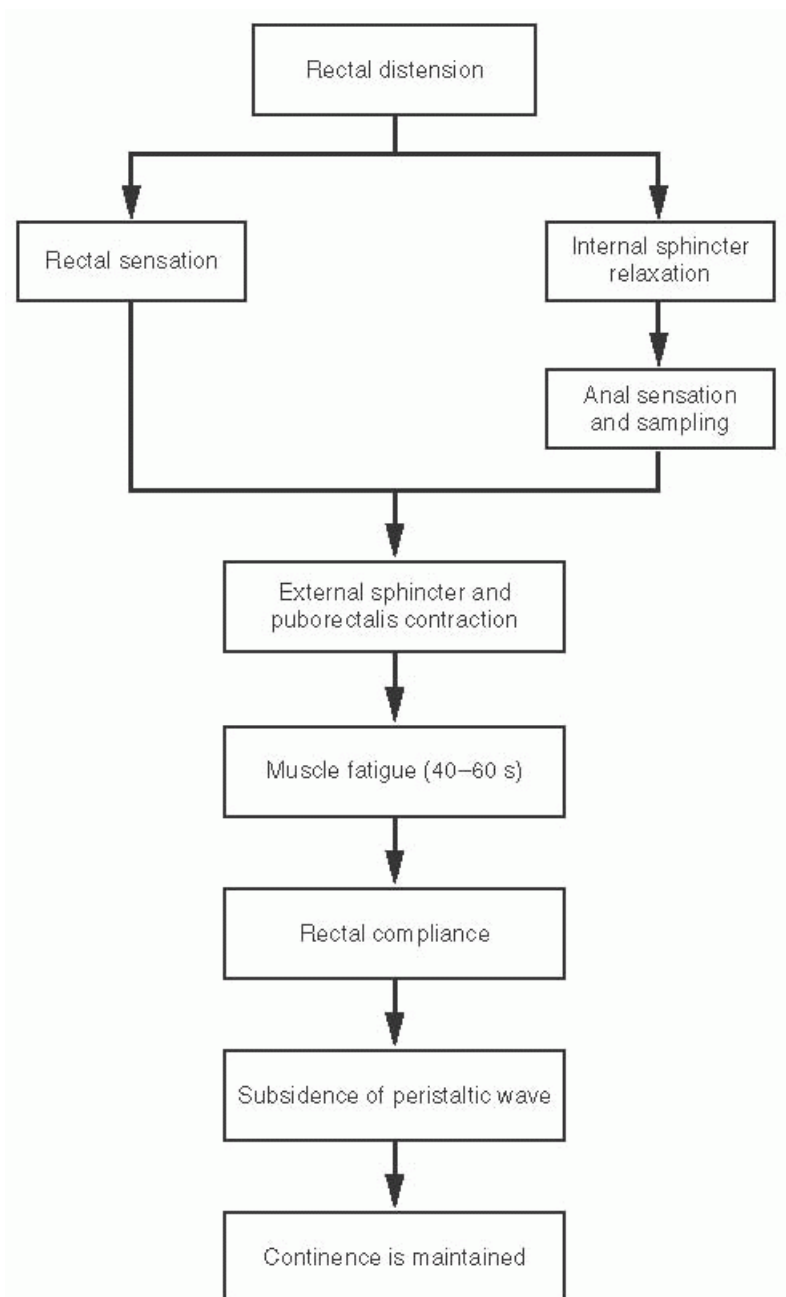

FIGURE 44.2 Algorithm for anal continence mechanism. Diagrammatic illustration of the anal canal and sphincters.

Rectum

Adequate knowledge of the anatomy of the rectum and the anorectal canal and its normal function in defecation is critical to understanding the mechanisms of anal continence ([Table 44.2](#)). The rectum lies posterior to the vagina as it descends below the cul-de-sac peritoneum. Here, it accomplishes one of its major functions contributing to continence, that of a temporary appropriate storage unit when defecation needs to be delayed. The puborectalis muscle, which encircles the rectum and pulls

P.969

it forward toward its own attachment at the symphysis pubis, marks the distal margin of the rectum and the beginning of the anal canal. In addition to the external and internal anal sphincters, it is an important muscular component of the continence mechanism. In addition to its storage role, the rectum functions as a very important sensory unit responsible for the initiation of the continence mechanism. Finally, when the appropriate time arrives, the rectum also has dynamic propulsive activity allowing complete emptying of its contents until it is empty.

Stool volume and consistency

Colonic transit time

Rectal capacity, distensibility, and tone

The process of storage and appropriate evacuation of stool begins when the rectum senses the presence of material within its lumen. Not unlike the bladder, the cerebral cortex is responsible for interpreting this information as regards its precise nature and the problem of what to do about it. Fortunately, also like the bladder, the rectum is a high-volume, low-pressure system when healthy. It can accommodate increasing volumes of material, that is, feces, until a critical volume, and thus ultimately critical pressure is reached. This compliance of the rectum can be compromised due to inflammation of the rectum as in inflammatory bowel disease or with fibrosis as occurs with radiation. Compliance can be measured clinically with anorectal manometry with balloon distention as is discussed later in the section on testing. Patients with urgency, incontinence, and even constipation may have issues with abnormal compliance and/or abnormal sensation. When normal sensation and compliance exists, the sensation of rectal filling allows one to consciously initiate the anal continence mechanism, which is discussed further below. However, without normal rectal compliance, even an otherwise intact continence mechanism will be severely compromised.

FIGURE 44.3 Rectosigmoid colon and anal canal showing collateral arterial circulation from superior hemorrhoidal (inferior mesenteric), middle hemorrhoidal (hypogastric or internal iliac), and inferior hemorrhoidal (internal pudendal) arteries.

Rectal expulsion of its contents when appropriate is the final event in defecation. It seems to be under both voluntary and reflex control. The voluntary nature involves the willful relaxation of the muscular components of the continence mechanism followed by the reflex propulsive contractions of the rectum usually assisted by a voluntary increase in intra-abdominal pressure. This continues until the rectum is completely empty as determined by sensory input from the anal canal.

Anal Canal

The actual structures involved in the anal continence mechanism include the anal canal and its surrounding muscular structures. However, not to be forgotten is the important role of the rectum as it interacts with the continence process as described above. For the obstetrician and gynecologist, it is the anal canal and its related structures such as the anal sphincters that will be most directly linked to the problem of fecal incontinence.

The anal canal in the female is approximately 2.5 to 4 cm in length and normally remains completely collapsed because of the tonic contraction of the sphincters. The lining of the anal canal is nonuniform. The proximal 1 cm is lined by rectal-type columnar mucosa, followed by modified or stratified columnar epithelium for about 1.5 cm. The distal half of the anal canal is lined by squamous epithelium, which is richly supplied by branches of the inferior hemorrhoidal nerves and is exquisitely sensitive. The anal mucosa, like the rectum, is also surrounded by the inner circular layer of smooth muscle, which is in turn surrounded by the outer longitudinal layer. The main

supply to the rectum and the anal canal is from branches of the superior and inferior hemorrhoidal arteries ([Fig. 44.3](#)).

FIGURE 44.4 Anal manometry demonstrating pressures in the anal canal. Rectal pressure reflects intra-abdominal baseline pressure recorded in the rectal reservoir. Resting pressure essentially reflects the effect of the involuntary, smooth muscle internal anal sphincter. Squeeze pressure largely reflects the transient contractile effort of the voluntary, striated external anal sphincter.

The muscular portions of the anal continence mechanism or anal sphincter consist of three separate muscular structures surrounding the anal canal: the internal anal sphincter, the external anal sphincter, and the puborectalis muscle. The internal anal sphincter provides most of the involuntary resting tone to the anal canal, while the external anal sphincter and the puborectalis muscle are under voluntary control and contribute the most when we call upon the need to delay defecation.

The Internal Anal Sphincter

The circular smooth muscle layer of the rectal wall, which is under autonomic control, thickens at the proximal anal canal to form the internal anal sphincter. It triples in thickness and is approximately 3 cm in length and 3 mm wide. It is longer in men and thickens with age. It provides about 85% of the resting anal tone with the remainder supplied by the hemorrhoidal vessels and external sphincter. These pressures can be shown by anal manometry demonstrated in [Figure 44.4](#). The internal sphincter terminates just short of the most caudal portion of the external anal sphincter and is separated from it by the longitudinal smooth muscle layer of the bowel. The internal anal sphincter seems to have two major functions: prevention of passive leakage of anal contents and initiation of the rectoanal inhibitory reflex (RAIR) or anorectal sampling as demonstrated in the anal manometry study illustrated in [Figure 44.5](#).

Injury to the internal anal sphincter may result in passive leakage of anal contents, which may be continuous or intermittent. It should also be suspected when patients complain of loss of stool completely without warning or awareness. Injury to the internal anal sphincter can be diagnosed by endoanal sonography as is discussed in the section on childbirth injury.

FIGURE 44.5 Rectoanal inhibitory reflex. Arrival of stool in the rectum triggers reflex relaxation of the internal anal sphincter, allowing the bolus to enter the proximal anal canal, where discrimination of the solid, liquid, or gaseous nature of the bolus by the sensory-rich upper anal canal occurs.

Anorectal sampling or the RAIR occurs every 8 to 10 minutes in response to rectal filling. The upper internal anal sphincter relaxes in response to rectal filling to allow the sensory epithelium of the anal canal to determine the nature of the rectal contents. The amount of relaxation of the internal sphincter is directly related to the degree of rectal distention. Incontinence does not occur because the lower internal sphincter maintains higher pressure all the while this is occurring. Concurrent contraction of the external anal sphincter and the puborectalis muscle forces the sampled contents back into the rectum. Clearly, damage to the internal anal sphincter, which allows for a larger volume of sampling contents to enter an anal canal that is further compromised by a lack of opposing pressure, may result in leakage. This compromise will be further worsened if there is a lack of voluntary action on the part of the external anal sphincter and puborectalis to force the contents back into the rectum.

The External Anal Sphincter

The external anal sphincter extends approximately 1 cm beyond the internal sphincter. It is generally but somewhat arbitrarily divided into three components: deep, superficial, and subcutaneous ([Fig. 44.1](#)). The deep part blends with the fibers of the puborectalis as its fibers encircle the undersurface of the rectum on its way to the symphysis pubis. The subcutaneous portion is attached to the perianal skin, and the superficial portion forms the bulk of the muscle. Classically, the female anal sphincter complex has been thought of as forming a broad band of tissue posteriorly but narrowing to a small tubular bundle of tissue anteriorly within the perineal body. In the past, the internal sphincter has been most often portrayed as a minor structure. These concepts came from many centuries of anatomic study of cadavers augmented by observations in the delivery room, at the time of third- and fourth-degree laceration repairs, of the transected ends of the anterior portion retracted into round holes in the perineal body. In the recent past, it has become possible to view this anatomy undisturbed in living, continent, nulliparous subjects with magnetic resonance imaging (MRI). In an early MRI study, Aronson and colleagues found the shape of the combined internal and external anal sphincter complex to be nearly cylindrical as it encircles the anal canal. Measured in the midline, the anterior portion of the anal sphincter complex appeared as a broad band of tissue, not a narrow tube. In this study, 54% of the anterior thickness was smooth muscle of the internal anal sphincter. Subsequent studies, including the cadaver studies of DeLancey et al., found a similar shape with a substantial contribution from the internal anal sphincter. This substantial

anterior anal sphincter length and thickness, as well as the contribution from the internal sphincter, is important to keep in mind during primary repair of obstetric lacerations as well as in surgical correction of anal incontinence secondary to chronic perineal laceration. The external anal sphincter is a striated muscle that is under voluntary control via the pudendal nerve. It provides a certain degree of constant tone to the anal canal due to its slow-twitch muscle fibers. However, it can undergo muscle fatigue due to its “fast-twitch” fibers as well. Its primary function is to generate adequate pressure in the anal canal when needed to allow for postponement of defecation. It accomplishes this by allowing the rise in anal pressure to exceed that in the rectum, until rectal accommodation occurs through normal rectal compliance, and rectal pressure falls (**Fig. 44.6**).

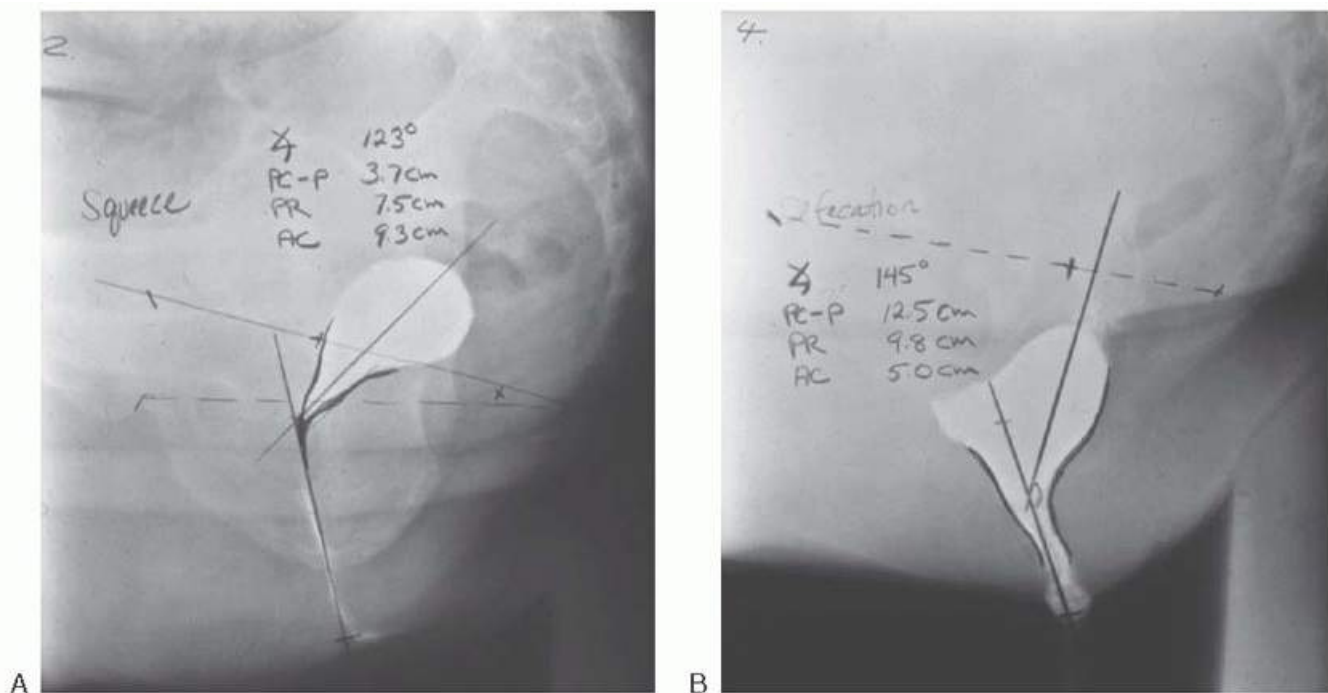

FIGURE 44.6 A: Lateral defecography of normal continent patient deferring defecation by contracting puborectalis sling, increasing anorectal angle, and exerting squeeze pressure in the anal canal. Note how barium bolus is supported over the levator plate and away from the fatigable anal sphincter complex. **B:** Lateral defecography of normal continent patient willfully defecating by relaxing puborectalis sling, decreasing anorectal angle, and decreasing pressure in the anal canal. Note how barium bolus becomes lined up over the anal canal.

As previously mentioned, the external anal sphincter also plays a vital role in the RAIR by helping to generate opposing pressure when the internal anal sphincter relaxes and along with the puborectalis returns the sampled contents into the rectum. This response of the external anal sphincter is critical in preventing passive fecal loss.

FIGURE 44.7 Function of the anal sphincter and puborectalis muscle. **A:** At rest, the constant tone of the puborectalis muscle pulls the anorectal junction anteriorly to create an approximately 90-degree angle between the rectum and anal canal, closing the rectal inlet and maintaining continence of solid stool. At moments of need,

this muscle can be contracted further, increasing the angle and supporting the stool bolus over the levator plate. **B:** During defecation, the puborectalis muscle relaxes, opening the rectal inlet, while intestinal peristalsis and the voluntary increase in intraabdominal pressure move stool into the anal canal. The anorectal angle is decreased, and the stool bolus is lined up over the anal canal.

Finally, the external anal sphincter is important in protecting against postdefecation incontinence. This is demonstrated by the so-called closing reflex. When traction is released on the external anal sphincter as fecal material is evacuated, there is an exaggerated increase in muscle contraction. This allows for anal closure at the end of defecation.

The Puborectalis Muscle

The puborectalis muscle is the most medial portion of the levator ani. The puborectalis muscle encircles the anorectal junction pulling it toward its insertion on the inner surface of the pubis. It thus forms a sling that creates the anorectal angle. The anorectal angle is an approximately 90-degree angle that closes the rectal inlet and maintains the rectum over the levator plate rather than directly over the anal canal (**Fig. 44.7A**). It does this by tonic contraction utilizing its slow-twitch muscle fibers.

P.972

When there is a need to delay defecation, it can contract further under voluntary control and further increase the anorectal angle. When defecation is permitted, the puborectalis relaxes, decreasing the anorectal angle, allowing the rectum to line up directly over the anal canal (**Fig. 44.7B**). The role of puborectalis injury in anal incontinence is unclear.

THE EFFECT OF PREGNANCY AND CHILDBIRTH ON THE PELVIC FLOOR

In this section, we review some of the effects of pregnancy and childbirth on the function of the pelvic floor and also the direct effects of childbirth trauma on the anal sphincter mechanism. This is an area of much conflicting data that are difficult to interpret in terms of developing a clear understanding of the natural history of pregnancy and childbirth and how they relate to anal incontinence. It is hard to tease out the effects of pregnancy itself, vaginal delivery with or without sphincter injury, occult sphincter injury, neurologic injury, efficacy of sphincter repair, and other issues contributing to incontinence. However, it is an area of intense current investigation, and hopefully, many of these questions will be answered in the future. For obstetricians-gynecologists and the women they care for, childbirth-related injuries will be the most common cause of anal incontinence they will have to deal with.

General Effects on the Pelvic Floor and Continence

Signs of pelvic floor dysfunction often develop during pregnancy itself. This adds to the difficulty of trying to differentiate pregnancy-related pelvic floor dysfunction as to its timing— antepartum versus intrapartum. These problems include both urinary incontinence and fecal incontinence. King and coworkers reported that 65% of their nulliparous patients reported anal (flatus and/or fecal) incontinence during the third trimester. Fourteen percent complained of fecal incontinence. By 2 weeks postpartum, the anal incontinence rate had dropped to 47%, while the fecal incontinence rate had risen to 17%, including 10 women who had new-onset fecal incontinence by the 2-week visit. Of these 10 subjects, 3 had spontaneous vaginal delivery, 3 delivered by forceps, and 4 had delivered by cesarean delivery after labor. At 6 months postpartum, 49% still complained of incontinence of flatus and 11% of fecal incontinence. Solans-Domenech reporting for the Catalan Agency for Health Technology Assessment and Research found that 39.1% of previously continent pregnant women developed urinary incontinence at some time during their pregnancy. Ten percent of women in this study developed anal incontinence at some point during the pregnancy. This was incontinence of flatus only in 90%, although during the postpartum period nearly one third of these women noted some loss of liquid or solid stool.

For both urinary incontinence and fecal incontinence during pregnancy, risk factors were related to increased weight and age over 35 years. The major risk factor for the persistence of incontinence at the 7-week postpartum visit was vaginal delivery. However, in the case of anal incontinence, this was true only if anal incontinence was also present during pregnancy. Instrumental delivery and episiotomy were not significant risk factors for postpartum incontinence. Overall, 7.3% of women continued to complain of fecal incontinence at their postpartum visit. This is very similar to the 11.2% prevalence of anal incontinence noted in the vaginal delivery group and the 10.3% prevalence in the cesarean delivery group reported by Borello-France for the Pelvic Floor Disorders Network. At 6 months after delivery, the anal incontinence rate had dropped to 8.2% and 7.6% in the vaginal and cesarean groups, respectively. However, women who had sustained a known sphincter injury reported much higher prevalence of fecal incontinence at both the 6-week postpartum visit and at 6 months, 26.6% and 17%, respectively.

Stretch and compression injury to the pudendal nerve, which innervates the external anal sphincter, and to the S2, S3, and S4 nerve fibers, which directly innervate the levator muscles, may be responsible for incontinence not associated with direct muscle trauma. This may be due to the normal descent of the fetal head or by trauma from forceps. Snooks and coworkers have identified such other risk factors as length of the second stage of labor, multiparity, and high birth weight. Allen and colleagues studied 96 nulliparous women and found electromyography (EMG) evidence of reinnervation in the pelvic floor muscles after vaginal delivery in 80% of those studied. Women with a prolonged second stage and larger babies had the most evidence of nerve damage. Surprisingly, forceps deliveries and perineal tears did not affect nerve damage. None of these studies included neurophysiologic testing during pregnancy itself, and therefore, it is not possible to tease out the role pregnancy itself apart from delivery may have played. However, even though it appears these denervation injuries are common, occurring in up to 80% of women, they seem to be minor and to resolve in most. However, Snooks in a follow-up study in 1990 found evidence of persistent neuropathy in some women even at 5 years.

Another area that may contribute to pelvic floor dysfunction due to childbirth is a direct effect on pelvic muscle strength. This may or may not be due to direct injury to the levator. A recent study by Friedman and coworkers in parous women revealed decreased muscle strength in women with anal incontinence and pelvic organ prolapse 6 to 11 years following vaginal delivery. Vaginal delivery overall was associated with a significant reduction in pelvic muscle strength compared to cesarean delivery. The greatest reduction in strength was in women who had forceps delivery. However, in the study noted above by King, which demonstrated a very high prevalence of anal incontinence in pregnant nulliparous women, they were not able to demonstrate a difference in pelvic muscle strength between those with and without symptoms during the antepartum or postpartum period. Finally, DeLancey and coworkers have reported an association between defects in the levator ani muscle demonstrated by MRI and pelvic organ prolapse. However, the exact role these injuries may play in the etiology of anal incontinence is unknown.

Anal Sphincter Injury and Incontinence

Clinically recognizable anal sphincter injury occurs in from 3.3% to 19% of vaginal deliveries. Handa and coworkers in a large population-based study of over 2 million vaginal deliveries in California reported a frequency of anal sphincter lacerations of 5.85%. Faltin and colleagues reported occult injuries detectable by ultrasound in up to 28% of women without a clinically suspected injury. Direct disruption injury to the external anal sphincter during childbirth has been commonly associated with anal incontinence in women. Farrell and coworkers in a prospective observational study found that incontinence of flatus at 6 months postpartum was higher in women who had sustained a third- or fourth-degree laceration compared to those women without anal sphincter injury. Likewise, earlier, Sultan and coworkers reported higher rates of anal incontinence in women with demonstrable external anal sphincter defects postpartum. Pollack and colleagues reported

a 5-year prospective study where 53% of women with a sphincter injury reported anal incontinence compared to 32% without a sphincter injury. Likewise, as reported above by Borello-France for the Pelvic Floor Disorders Network, there was an 11.2% prevalence of anal incontinence noted in the vaginal delivery group and the 10.3% prevalence in the cesarean delivery group. At 6 months after delivery, the anal incontinence rate had dropped to 8.2% and 7.6% in the vaginal and cesarean groups, respectively, in this study. However, women who had sustained a known sphincter injury reported much higher prevalence of fecal incontinence at both the 6-week postpartum visit and at 6 months, 26.6% and 17%, respectively.

More recently, Evers and coworkers, using anal incontinence and quality-of-life scores to define incontinence, reported on 937 women 5 to 10 years after first delivery, 90 of whom had sustained a clinically diagnosed sphincter injury at the time of delivery. Nineteen percent of women with a sphincter injury had anal incontinence as defined by the score, compared to 10% in the vaginal delivery without injury group and 9% in the cesarean group. Sultan also raised the issue of the effectiveness of primary end-to-end repair of the external anal sphincter performed at the time of delivery by reporting that 82% of women still had a sphincter defect present by ultrasound 7 weeks later. Of note, 33% of women who did not have a recognized anal sphincter injury at delivery were noted to have a defect present at 7 weeks. Subsequently, Sultan and his team reported retrospective case series of 32 women who underwent overlapping sphincter repair in the operating room under anesthesia, of whom only 7% had incontinence of flatus and none had fecal incontinence at 5 months postpartum. However, three subsequent randomized studies (Fitzpatrick et al., 2000; Williams et al., 2006; Fernando et al., 2006) as well as a Cochrane review in 2006 all failed to demonstrate a difference in fecal incontinence between repair types.

In 2010, Farrel and coworkers reported a prospective randomized study on nulliparous women assigned to either end-to-end or overlapping repair after sustaining third- or fourth-degree lacerations. By confining their study to nulliparous women, they hoped to eliminate bias generated by those cases of multiparous women who may have a preexisting injury. They reported a significantly increased rate of incontinence of flatus at 6 months in women undergoing overlapping repair compared to those undergoing end-to-end repair (61% vs. 39%). However, there was not a significant difference in fecal incontinence between the two groups (15% vs. 8%). Ultrasound findings of sphincter defects did not correlate with flatal or fecal incontinence except for those women who demonstrated both internal and external anal sphincter defects. Combined disruption noted on ultrasound was significantly associated with fecal incontinence with an odds ratio of 6.5. There was also no significant difference in rates of isolated internal, external, or combined sphincter defects in either group. Internal anal sphincter defects were present in 46% of the end-to-end repair group versus 38% in the overlapping repair; external anal sphincter defects in 53% versus 62%, respectively; and both sphincters in 32% for each. Rates for incontinence following repair were not statistically different whether there was an intact sphincter on ultrasound or not except as noted above for fecal incontinence in the women with persistent combined defects versus no defect (incontinence of flatus 52% vs. 54%, respectively; fecal incontinence 30% vs. 6%, respectively). Women with a persistent internal anal sphincter defect had a 60% rate of incontinence of flatus versus 50% of those with an intact internal anal sphincter, while fecal incontinence was present in 23% versus 7%, respectively. Finally, women with a persistent external anal sphincter defect had a 51% rate of incontinence of flatus versus 57% with an intact sphincter, while fecal incontinence occurred in 20% versus 7%, respectively. The authors concluded that the primary cause of incontinence following a third- or fourth-degree laceration was denervation injury rather than persistent structural defects following repair. Likewise, it is interesting to note that Frudinger and coworkers failed to demonstrate a link between anal sphincter disruption diagnosed in asymptomatic postpartum women by ultrasound only and anal incontinence 10 years later. The issue of the true relationship between endoscopically defined anal sphincter defects, denervation injury, and symptoms of incontinence later remains unclear.

There are known risk factors for anal sphincter trauma at vaginal delivery. A recent review by Dudding and

colleagues in which 451 articles and abstracts were studied concluded that major risk factors for injury included instrumental delivery, prolonged second stage of labor, birth weight greater than 4 kg, fetal occipitoposterior presentation, and episiotomy. The population-based study of over 2 million vaginal deliveries by Handa and coworkers noted earlier identified primiparity, macrosomia, and operative vaginal delivery as major risk factors. In addition, episiotomy, especially midline episiotomy, is an important risk factor for sphincter lacerations as demonstrated by Angioli and colleagues as well as by FitzGerald and coworkers.

Finally, obstetric lacerations can extend into the rectum resulting in a so-called fourth-degree laceration. Although these usually also involve a complete tear through the anal sphincter, this is not always the case. At times, there may be an isolated laceration through the rectum or anal canal with an intact external anal sphincter. Therefore, these isolated injuries must be looked for and are usually diagnosed by digital rectal exam at the time of delivery. On occasion, the rectal mucosal portion of a repair will break down with or without concomitant disruption of the sphincter and perineum, which can result in rectovaginal fistula. In Hibbard's series of 24 rectovaginal fistulae and 27 chronic perineal lacerations, 47 (92%) were caused by obstetric trauma. Even meticulously repaired lacerations will occasionally completely break down. This leaves the patient with an open cloacal deformity or an isolated rectal/anal-vaginal fistula with an intact perineum and sphincter. Anal incontinence usually is a problem for these patients until the tissues are healed sufficiently to allow secondary repair. Surgical repair will be discussed in detail in the section on fistula repair.

Obviously, the issue of anal incontinence during and following pregnancy and delivery is complex as to its etiology and treatment. Especially confusing is the role of neurologic injury versus structural damage to the anatomic sphincter mechanism. The best surgical method to repair sphincter injury and the effect of the adequacy of the repair on overall continence later is equally unclear. Finally, the overall contribution of childbirth injury to the ultimate development of long-term anal incontinence is uncertain as well, although the significance of intrapartum injury appears to decrease with age. This subject is particularly important when it comes to counseling older patients with anal incontinence and who are also found to have clinical or imaging evidence of sphincter disruption remote from delivery.

Other Causes

A promoter of anal incontinence over time is the fact that the normal process of aging results in decreased efficiency of the anal sphincter complex. Haadem and associates showed a natural decline with aging in resting and squeeze pressures in the anal canal of continent subjects. With increasing age, the

P.974

internal sphincter generates a lower resting pressure, and the proportion of fibrous tissue increases. The squeeze pressure able to be exerted by the external sphincter suffers a natural decline as well. Vaccaro and coworkers found pudendal neuropathy to be an age-related phenomenon as well in patients with anal incontinence and constipation. Because of this, many patients with damaged continence mechanisms may be able to compensate for a period of time, but they go on to decompensate secondary to these age-related changes and become incontinent.

Functional problems of the bowel, such as constipation or diarrhea, can result in incontinence. Chronic constipation with its repeated straining at stool can cause stretch-induced injury to pudendal enervation. Overall, the most common cause of anal incontinence in the elderly, particularly those who are institutionalized, is fecal impaction with overflow incontinence. A diarrheal state can result in anal incontinence even in a patient with normal anorectal function, owing to the presence of large quantities of liquid stool that may overwhelm a normally functional mechanism. Neurologic disorders affecting sphincter control also may result in anal incontinence. Usually, the neurologic defect is widespread, and anal incontinence is but one manifestation.

Traumatic injury, more often a side-straddle injury in young girls, may result in simple or extensive laceration of

the perineum. The extent of the injury may be difficult to determine because of pain, fear, edema, hemorrhage, and hematoma formation. Examination under anesthesia is advisable so that appropriate repair can be made, looking carefully for lacerations of the anal sphincter and rectum as well as other structures. Hematoma dissection above the levator muscles must be ruled out with pelvic ultrasound and with careful rectovaginal examination under anesthesia. Above the levator muscles, there is nothing to impede the progression of a hematoma until the diaphragm is reached.

Rectal trauma from operative procedures can affect rectal capacity and compromise anal continence or perhaps lead to extra-anal incontinence through a rectovaginal fistula. Entry into the rectum may occur during posterior colpoperineorrhaphy, especially when the anterior rectal wall and posterior vaginal skin are closely adherent with little, if any, intervening connective tissue. Such an enterotomy should be repaired transversely if longitudinal closure would compromise rectal capacity. A difficult hysterectomy, either abdominal or vaginal, may result in injury to the rectum, especially when dissection behind the cervix is difficult because of dense adhesions, indurated tissue from infection, or involvement of the cul-de-sac and anterior rectal wall with endometriosis. If the rectal defect does not heal properly or is not closed properly, a high rectovaginal fistula may develop through the newly closed vaginal apex. Partial excision of anal sphincter and other muscles involved in maintaining anal continence may be required in extensive vulvectomy for cancer resulting in anal incontinence, as reported by Berek and others. Injury to the anterior rectal wall may occur during hemorrhoidectomy, excision of a Bartholin gland, or colpotomy for pelvic abscess drainage.

Forty to sixty percent of patients with rectal or rectal mucosal prolapse also have some degree of anal incontinence. Although this was originally thought to be secondary to a dilatation effect on the internal anal sphincter, there is often evidence of associated neurogenic damage to the external sphincter muscles as well. These individuals may present with a patulous anal sphincter, passive stretching of the puborectalis muscles, and a long history of straining with constipation. The tissue prolapse may be related to prolapsing internal hemorrhoidal tissue or rectal mucosa or complete (full-thickness) rectal prolapse. Questions such as the frequency of occurrence of the prolapse, association with activity or defecation, estimated distance of the prolapsed tissue from the anus, spontaneous or manual reducibility, and history of incarceration may be helpful in better defining the type of problem. Patients may have relatively occult prolapse of tissue, which can manifest as mucous or brownish staining in the undergarments with occasional blood.

On physical examination, it is important to note the following: a patulous anus, which may indicate that chronic tissue prolapse has been occurring. The presence of enlarged external hemorrhoidal tissue may suggest the presence of enlarged internal hemorrhoidal complexes; however, they may be found in relative isolation and may be mistaken as prolapsed tissue. Patients should be asked to bear down as if defecating to manifest any prolapsed tissue. Concentric circular folds and a large protruding mass suggest the presence of complete prolapse, which often extends well beyond the anus. Noncircumferential folds may be either mucosal prolapse or hemorrhoidal tissue. If the patient's history suggests the presence of prolapse and it is not visualized with the patient in the left lateral or lithotomy position, it is often helpful to have the patient sit on a commode with subsequent examination in this position. Correction of prolapsing tissue such as hemorrhoids may lead to improvement in anal continence, if this is the primary cause of the problem. In patients with complete rectal prolapse undergoing surgical repair, the rate of some degree of residual incontinence ranges from 40% to 90%, depending on the type of repair used.

Crohn disease is the most important of the variety of inflammatory bowel diseases that may cause extra-anal incontinence through a rectovaginal fistula. Among 138 patients with rectovaginal fistulae seen at Duke University Medical Center, Bandy and associates reported that 15 (11%) were caused by Crohn disease. The diagnosis, perioperative management, and surgical technique chosen for these patients constitute a special challenge for the gynecologic surgeon. Crohn disease must be considered as a possible cause of rectovaginal

fistula in any patient in whom other causes are not clear, particularly if the fistula orifice is tender to palpation. Crohn disease also should be considered in the patient who has failed multiple attempts at fistula repair because the fistula tends to recur at the operative site in these individuals.

The role of diverticulitis as a cause of sigmoidovaginal fistulae has been highlighted by Tancer and Veridiano, who report on 130 such cases. These fistulae usually present with a malodorous vaginal discharge in women older than 50 years of age, some years after a hysterectomy. Such fistulae commonly develop between the inflamed bowel segment and the apical vaginal scar from the previous hysterectomy, although they may infrequently occur through a retained cervix. Often, the diverticular disease is silent and is only discovered with further investigations of the fistula tract. A diverticular abscess may have formed and found drainage through the path of least resistance, which in this case is the thinned out scar of the vaginal cuff.

Malignant tumors may erode through the tissues between the vagina and the rectum. When a patient with tumor involvement of the rectovaginal wall receives radiation, sloughing of the tumor may result in a rectovaginal fistula. Radiation also may cause a rectovaginal fistula without tumor erosion.

Rarely, anal incontinence may be congenital, as seen in one of 5,000 newborn girls who have an imperforate anus with associated fecal incontinence through a congenital rectovaginal or rectoperineal fistula. Total rectal agenesis is rare. Paul and Lloyd reported hindgut duplication with a congenital rectovaginal fistula; however, most anal incontinence is acquired.

P.975

Finally, although anal incontinence may be termed idiopathic in about 10% of women, the mechanism of incontinence in these women is usually secondary to pelvic floor denervation.

In summary, although an intact and functional anal sphincter complex and puborectalis sling are important in the maintenance of anal continence, it must be remembered that a variety of other factors are involved, including intact anorectal sensation and reflexes, rectal capacity and distensibility, reasonable colonic transit time, appropriate stool volume and consistency, and adequate patient mental function and mobility.

EVALUATION OF ANAL INCONTINENCE

The most common cause of anal incontinence that the obstetrician-gynecologist will encounter is that related to obstetric injury. As noted previously, these patients may present shortly after childbirth or many years later. In the latter case, this may be because of failure of compensatory mechanism with time and aging. It is these later cases that require the most extensive diagnostic workup and which are the most resistant to surgical repair of the structural defect.

History and Physical Examination

Most often, history alone provides strong clues as to the etiology of the incontinence. The temporal relationship between a recent traumatic vaginal delivery and the postpartum onset of incontinence, especially urgency, will quickly lead one to suspect an undiagnosed sphincter injury or a failed sphincter repair. This will be quickly confirmed by pelvic examination without the need for additional testing. Likewise, flatal or fecal incontinence without urgency in this context should lead one to carefully search for a rectovaginal or anovaginal fistula. These are usually located in the lower one third of the vagina and are often identified as a red area of what appears to be granulation tissue. This usually represents an isolated small disruption of the previously repaired anal or rectal suture line. Fecal material is usually present near the fistula opening within the vagina. These fresh injuries are usually easy to identify as opposed to some small older fistulae for which patients seek care years later.

Patients who present remote from childbirth with anal incontinence require a more extensive workup both due to the possibility of a cause unrelated to childbirth and to develop a rational plan for repair, if indicated, with

reasonable patient expectations for success. It may be helpful in these cases especially to attempt to quantify the degree of incontinence using one of a number of scoring systems. Scoring systems should include the effect of incontinence on the patient's quality of life and allow for monitoring the response to treatment. There are a variety of these validated questionnaires available. Avery and coworkers have published a very helpful review of these with graded recommendations. Although no questionnaires received an "A" grade for anal incontinence, three were recommended with grades of "B." These were the Fecal Incontinence Quality of Life Scale (Rockwood et al., 2000), Manchester Health Questionnaire (Bug et al., 2001), and Birmingham Bowel and Urinary Symptoms Questionnaire (Hiller et al., 2002).

Pelvic examination should include a careful inspection of the posterior vaginal wall, perineum, anal sphincter, anal canal, and rectum, including assessment of the patient's function as well as anatomy. A patulous anus indicates a major loss of sphincter function and can be associated with rectal prolapse. Most obstetric injuries are associated with an anterior segmental defect in the external anal sphincter and may appear as the loss of the perineal body, loss of the corrugated appearance surrounding the anus, or attenuation of the rectovaginal septum in some instances. In more subtle cases in which the perineal body appears intact but the external sphincter is actually separated, only the dimples of the laterally retracted ends of the anal sphincter muscles may be apparent. This produces a "dovetail" appearance, as described by Toglia and DeLancey, in which the normal radial distribution of the anal creases is absent anteriorly but is present laterally and inferiorly. If there is a question as to the presence of a segmental defect, endoanal or transperineal ultrasound can be useful in delineating the anatomy. Next, a screening evaluation of the perineal reflexes to assess the integrity of the S2-S4 dermatomes should be performed. Perception of pinpoint and light touch over the perineal skin and buttocks can be tested easily with the broken end of a wooden cotton swab or a safety pin. Light stroking of the inferolateral margin of the labia majora should cause a reflex contraction of the bulbocavernosus muscle within the labia. The anal wink reflex can be elicited by lightly stroking the perianal skin or touching it with a pin to cause a reflex contraction of the external anal sphincter. Asking the patient to cough also should elicit the reflex contraction of the external anal sphincter. With both of these maneuvers, the anal canal should constrict concentrically owing to contraction of the external sphincter, and the anus should be pulled inward secondary to the contraction of the puborectalis muscle. In women with separation of the external anal sphincter, voluntary contraction of the pelvic floor muscles can cause an accentuation in the lateral perineal dimpling of the retracted ends. In patients with a denervated sphincter, there is no retraction of the anal skin during voluntary contraction. Patients who demonstrate abnormalities of these pelvic floor reflexes may require more in-depth neurologic evaluation.

Extra-anal incontinence may result from a fistulous tract. A rectovaginal fistula is usually easily diagnosed by careful inspection of the posterior vaginal wall. By spreading the labia, a low fistula can be revealed, usually involving the area of a previous episiotomy or obstetric laceration. A high fistula can be seen using a bivalve speculum and often appears at the vaginal cuff scar. A straight-handled speculum can be useful as it can be rotated to allow full visualization of both the anterior and posterior vaginal walls. The vaginal opening of a fistula may be localized by the presence of feces in the vagina or by the dark red rectal mucosa seen protruding at the fistulous opening contrasting with the lighter pink vaginal mucosa. Colposcopic examination of the vagina sometimes assists in the identification of a small fistula orifice. When the fistula is small, it may be difficult to locate both the vaginal and rectal ends of the fistula, but both orifices must be located for complete care to be given. A small probe can be pushed gently from the vaginal side of the fistula and the tip felt on a rectally placed finger. Instillation of methylene blue through the vaginal orifice of the fistula may aid in the proctoscopic visualization of the rectal orifice. Carey describes the following examination technique to identify a suspected rectovaginal fistula. A Foley catheter with a 10-mL balloon is inserted into the anus, while the posterior vaginal wall is painted with a concentrated solution of soap and water, or, alternatively, the vagina can be filled with water. As the rectum is distended with air by a syringe attached to the Foley catheter, the vaginal orifice of the fistula may be localized by the presence of bubbles forming at the fistula site. A small probe may then be passed

along the fistula tract.

Alternatively, when a rectovaginal fistula is suspected but cannot be identified, radiologic studies such as a vaginogram or fistulogram may identify a fistulous tract. These studies are superior to barium enema for identifying a fistula because they

P.976

use a thin, water-soluble radiopaque medium rather than a thick barium solution. As such, although fistulae occasionally may be identified by barium enema, the intraluminal pressure of the bowel often is inadequate to force the barium solution through a small fistula opening. In addition, the presence of barium in the lower bowel may obscure a fistula tract. Likewise, a tampon test may be performed in which a tampon is placed in the vagina and the patient is given a small enema with methylene blue-colored water, which she is asked to retain for 20 minutes. Blue discoloration of the tampon is noted in the presence of a fistula.

When a rectovaginal fistula is diagnosed, it is important to complete a thorough assessment of the anal sphincter and pelvic floor as well because these patients may have multiple defects. If not properly evaluated preoperatively, the patient may undergo successful repair of her fistula only to become anally incontinent postoperatively. Her compromised sphincter function may have been adequate preoperatively when excess pressure was bypassing the sphincter through the fistula. After her fistula is repaired and the full force of rectal contents is delivered to the sphincter complex, there may not be adequate function to maintain continence. A full treatment of rectovaginal fistula management appears later in this chapter.

A thorough digital rectal examination should be performed. Any rectal mass must be noted and the stool consistency assessed. A gross assessment of the patient's resting and squeeze pressures within the anal canal and her ability to contract her levator ani muscles should be included. Anal sphincter tone should be evaluated with the patient at rest and during sphincter contraction. An anterior sphincter defect may be easily detectable as the loss of the palpable muscular ring within the perineal body. Even in the absence of external anal sphincter muscle anteriorly, a scarified band of tissue can remain that completes the contractile ring and helps the patient maintain continence. Next, the anorectal axis can be assessed. On rectal examination, the puborectalis muscle is palpable posteriorly at the junction between the rectum and the anal canal. By directing the examining finger posteriorly, the angle between the anus and rectum can be estimated and should approximate 90 degrees in a normal woman. More important, when the patient is asked to squeeze the sphincter, the puborectalis muscle should pull the examiner's finger anteriorly toward the pubic bone.

Finally, some patients may complain of passive incontinence, or the loss of stool without their awareness. This may indicate damage to the internal anal sphincter. It cannot be assessed adequately by physical examination alone, but can be determined by radiologic and physiologic tests only. A defect of the internal sphincter can be assumed, however, if there is significant thinning of the rectovaginal septum. In many of these cases, both the internal and external anal sphincters are injured. Certainly, the patient with a chronic perineal laceration or cloacal deformity by definition has a segmental defect in both sphincters. From a practical and technical viewpoint, the internal anal sphincter cannot be repaired unless the external sphincter also is repaired. Surgery is rarely effective for an isolated defect of the internal sphincter. When surgical repair of the external anal sphincter is indicated, however, one should consider repairing defects in the internal sphincter as well.

Testing

Clearly, many patients will have a diagnosis and be ready to proceed to treatment after their history and physical examination. For others, the picture will be less clear. There may be questions about a particular patient that thoughtful use of testing can answer. Is a segmental defect present in the internal or external anal sphincter? What is the functional status within the anal canal? Is rectal sensation normal? Is the innervation to the striated musculature of the continent mechanism intact? How does the patient actually defecate? Judicious use of testing

based on the information needed to arrive at an accurate diagnosis and to plan successful treatment can be important. The American Gastroenterological Association guidelines (March, 1999) for anorectal testing techniques are available through their Web site at www.gastro.org/practice/medical-position-statements. Procedures of value in addition to symptom diary and rectal examination include (a) anal ultrasonography, (b) anorectal manometry, (c) rectal and anal sensory testing, and (d) rectal compliance testing. These are now covered in detail. Endoanal, transvaginal, and transperineal ultrasound techniques have made it simple and relatively inexpensive to identify defects in both the internal and external anal sphincters (**Fig. 44.8**). These defects can go clinically unrecognized, but may be amenable to surgical repair if the patient is symptomatic. Anal endosonography is one radiologic technique for assessing posttraumatic defects of the internal and external anal sphincters. High-resolution images of the separate sphincter muscles are obtained using a rotating Endoprobe, and anatomic defects can be identified as a loss of continuity of the muscle rings. Several studies have found that anal endosonography correlates well with needle EMG mapping of sphincter defects, manometric mapping of sphincter defects, and intraoperative findings. Ultrasound is less timeconsuming than EMG or manometry and much more comfortable for the patient. Other studies have established that transvaginal ultrasound is equally efficacious to endoanal ultrasound in identifying sphincter defects. Peschers and colleagues described normal sphincter and puborectalis anatomy as well as defects in both the internal and external sphincters using exoanal ultrasonography: a conventional 5-MHz convex transducer placed on the perineum. Ultrasound currently is the study of choice for establishing the presence or absence of a segmental anal sphincter defect. The approach chosen—endoanal, transvaginal, or transperineal—may depend on the equipment available and operator expertise.

FIGURE 44.8 Endoanal ultrasound image of an anally incontinent patient with a segmental external anal sphincter defect. *Probe*, endoanal ultrasound probe; *M*, anal mucosa; *IAS*, internal anal sphincter; *EAS*, external anal sphincter; *defect*, segmental defect of external anal sphincter. (Photograph courtesy of Justin A. Maykel, MD.)

Endoanal ultrasound identifies anatomic defects or thinning of the internal anal sphincter, but Heyer and associates showed that interpretation of external sphincter images is much more subjective and confounded by normal anatomic variations in the external anal sphincter. Indeed, the external anal sphincter and perirectal fat are both echogenic and frequently indistinguishable; the external sphincter may be asymmetrical in the upper anal canal, particularly in women. A new imaging modality with better soft tissue definition may be desirable. MRI

may prove to be superior to endoanal ultrasound because of high tissue contrast between the external anal sphincter and the perirectal fat. DeSouza and associates reported 100% concordance between MRI performed with an endoanal coil and surgical findings for presence, size, and location of anal sphincter tears in seven patients with obstetric trauma. Additionally, Lienemann and colleagues and Healy and associates have demonstrated that MRI also can define dynamic pelvic floor motion during defecation and squeeze. Rapid image acquisition is crucial for optimal visualization of dynamic motion, particularly because patients cannot maintain rectal expulsion or puborectalis contraction for more than 15 to 30 seconds.

Anal manometry provides information regarding function, sensation, compliance, and the presence of intact reflexes within the anal canal and distal rectum. It is most useful in defining functional sphincter weakness. Here, it is complementary to endoanal ultrasonography in determining whether this weakness is secondary to an anatomic defect. The first part of this test is essentially a pressure profile of the anal canal, providing information on the functional status of the internal and external anal sphincters. Some computer-based, multichannel manometry equipment can provide graphic cross-sectional analysis of the anal canal to help detect the presence of segmental sphincter defects.

The test usually is performed with the patient in the left lateral decubitus position without any special bowel preparation. There are many different protocols for performing anal manometry. Most commonly, a fluid-filled pressure catheter with radial side ports located 90 degrees apart circumferentially is connected to pressure transducers, and a recording device is used to measure the anal canal pressures during rest and during voluntary contraction of the anal sphincter (**Fig. 44.9**). These pressures may be recorded either as the pressure catheter is slowly pulled through the anal canal—a station pull-through technique—or at static points along the anal canal as the pressure catheter is pulled out in certain increments, usually every 0.5 cm. The average pressure measured at rest in the anal canal is the resting pressure, and the highest pressure recorded along the anal canal with the patient at rest is the maximum resting pressure. The increase in pressure over the basal canal pressure initiated by voluntary contraction of the anal sphincter is the squeeze pressure, and the highest such increment is the maximum squeeze pressure. The resting anal canal length is measured from the point at which the anal sphincter pressure continuously exceeds the average intrarectal pressure by 4 mm Hg. The resting pressure is largely a reflection of the internal anal sphincter function, whereas the squeeze pressure reflects the strength of the external anal sphincter voluntary contraction (**Fig. 44.4**).

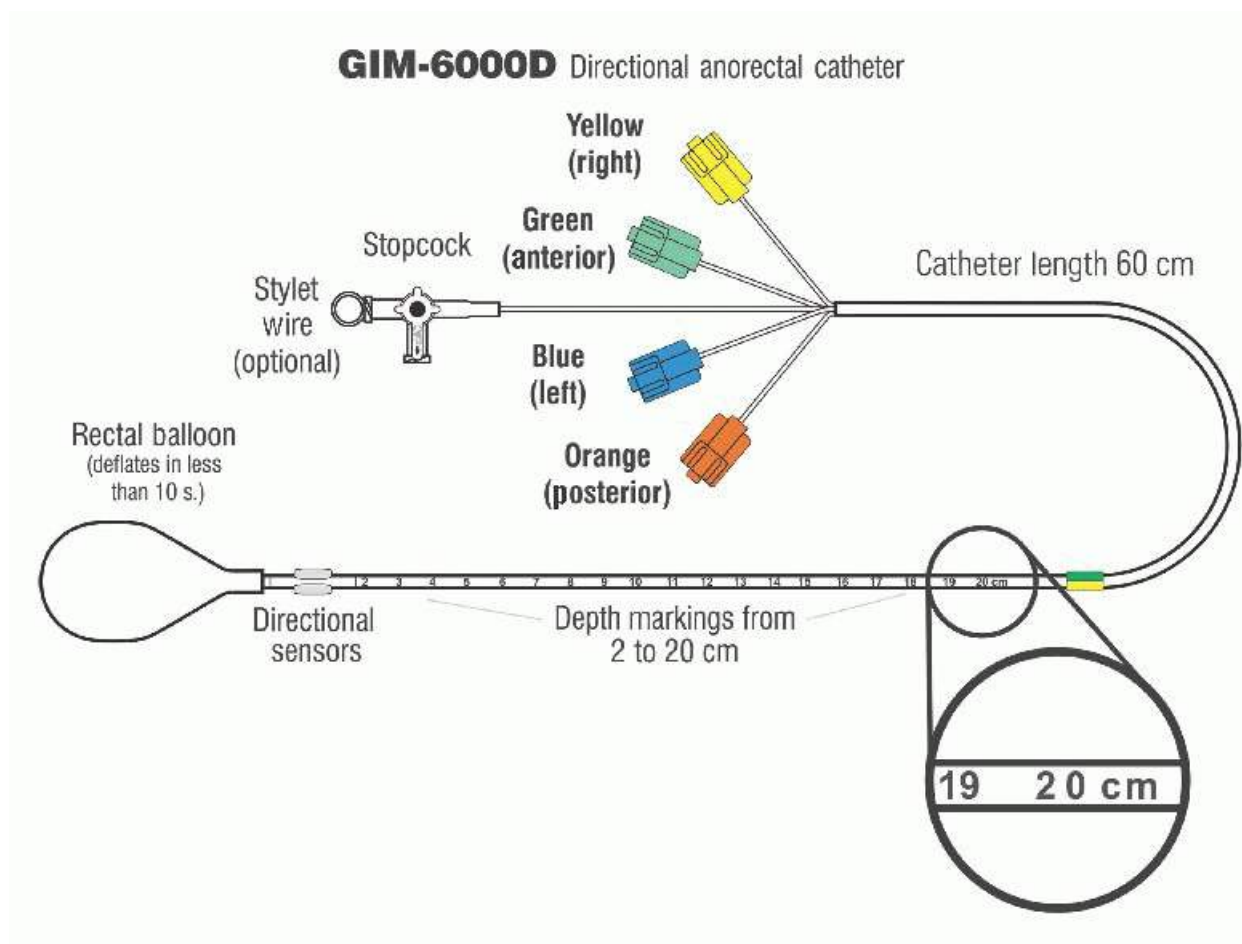

FIGURE 44.9 Drawing of an anorectal manometry catheter. (Courtesy of Sandhill Scientific.)

“Normal” range for maximum resting pressure is 40 to 80 cm H₂O and for maximum squeeze pressure is 100 to 200 cm H₂O; however, there is tremendous overlap in values between patients who are continent and those who are incontinent. As a group, incontinent patients have lower values on anal manometry testing than continent patients, although there is no discriminatory level that can be used to predict incontinence. It has been suggested that patients with a maximum resting pressure of less than 20 cm H₂O and a maximum squeeze pressure of less than 40 cm H₂O are unlikely to be continent. Sentovich and colleagues found decreased resting and squeeze pressures in 90% of patients with a history of anal sphincter injury. Poen and associates also reported significantly decreased maximum squeeze pressures and in addition observed that the first sensation of filling was significantly increased in 40 subjects who had third-degree lacerations primarily repaired compared with controls. They also found that 35 (88%) of these subjects still had sphincter defects present

P.978

on endoanal ultrasound despite apparently successful healing of their repair. Gearhart and colleagues were unable to demonstrate any single preoperative manometric parameter that was predictive of outcome following sphincteroplasty.

A second part of anal manometry testing is the evaluation of rectal sensation. A balloon is placed in the rectum and incrementally distended. The minimum perceived volume, the volume causing the urge to defecate, and the maximum tolerable volume are recorded. Balloon distention is commonly used to detect threshold volumes for three different sensations: (a) the first detectable sensation (rectal sensory threshold), (b) sensation of the urgency to defecate, and (c) sensation of pain (maximum tolerable volume). Most healthy patients have a minimal perceived volume of about 30 mL and a maximum tolerable volume of about 300 to 350 mL, although this can be highly variable. A rectal maximum tolerable volume of less than 100 mL may indicate the presence of

hypersensitivity, poor rectal compliance, or rectal irritability.

Measurements of pressures within the balloon allow the calculation of rectal compliance. The presence of a reflex rectal contraction after a bolus of air is introduced into the balloon, followed by the return to normal baseline pressures as the rectum accommodates, also is noted.

According to the American Gastroenterological Association, EMG of the external anal sphincter and pelvic floor muscles is performed for three purposes: (a) to identify areas of sphincter injury by mapping the sphincter, (b) to determine whether the muscle contracts or relaxes by the number of motor neuron units firing, and (c) to identify denervation-reinnervation potentials indicative of nerve injury. However, anal endosonography has largely replaced EMG in the first instance, defining sphincter trauma. Although neurologic injury may be identified by careful physical examination, information obtained from EMG may be helpful. This is important since patients with neurologic injury are less likely to have a good functional response to operations designed to restore anal incontinence, even when the anatomic result appears completely successful. Knowledge of a patient's pelvic floor neurologic status can be particularly useful for counseling her on prognosis.

The smallest functional neuromuscular unit is the motor unit, and injury to nerves or muscles produces characteristic changes recorded in the motor unit action potential. EMG can be performed using a needle electrode, a surface electrode on the perianal skin, or an anal plug. Concentric needle EMG involves placing a small needle with a recording electrode into the muscle being studied. The firing pattern of the motor units is assessed as the needle is being inserted, during spontaneous muscle activity, and during maximum voluntary contraction of the muscle. The characteristics of the recordings can then be evaluated. Single-fiber EMG allows the recording of action potentials from individual muscle fibers of a motor unit. When nerve injury occurs, there is often reinnervation but with a change in fiber density. The reinnervation is more diffuse and results in less effective muscle contraction than the original active enervation. When these studies indicate nerve reinnervation, therefore, it reflects prior nerve damage that has healed. Osterberg and associates found a correlation between fiber density and clinical and manometric variables in 72 incontinent patients.

Finally, nerve conduction velocities, which are the actual speed of conduction of the action potential along the nerve, are another measure of nerve function. The nerve conduction velocity can be calculated by measuring the nerve latency, which is the delay between the stimulation of the nerve at a specific point and the response in the target muscle supplied by the nerve. Standardized latencies for most peripheral nerves have been established. Evaluation of the pudendal nerve terminal motor latency (PNTML), as developed by Snooks and colleagues, is of interest in patients with anal incontinence. The pudendal nerve is stimulated as it courses behind the ischial spine into Alcock canal, and the time is measured until a response is detected in the external anal sphincter. Prolonged PNTMLs indicate nerve damage; however, this test only reflects the conduction time of the healthiest axon remaining in a nerve. Therefore, normal PNTMLs do not confirm a lack of damage to the whole nerve, only that at least one axon remains intact that can conduct a response normally. Cheong and colleagues found pudendal neuropathy in 36% (21% bilateral and 15% unilateral) of 225 patients (174 women) presenting with anal incontinence. Chen and colleagues found in a small group of patients undergoing sphincteroplasty that, based on continence scores, the one patient with no neuropathy had an excellent result; of seven patients with unilateral pudendal neuropathy, 70% had a good to excellent result and 30% had a fair to poor result; whereas in four patients with bilateral neuropathy, half had a good to excellent result and the other half scored fair to poor. Gilliland and colleagues looked at a large group of patients who had undergone an overlapping sphincteroplasty with a median follow-up of 2.4 years. They found that 62% of 59 patients with normal pudendal function had a successful outcome, compared with only 17% of the 12 patients with unilateral or bilateral prolonged PNTMLs. Although the presence of pudendal neuropathy implies a poorer prognosis for the potential sphincteroplasty patient as noted earlier, it does not mean that some patients may not derive significant improvement in their continence. The American Gastroenterological Association's (AGA) medical position statement on anorectal

testing techniques states that “although interesting from a research point of view, the clinical usefulness of this test is controversial. ... The PNTML cannot be recommended for evaluation of patients with fecal incontinence.”

Defecography is a radiologic evaluation of the lower gastrointestinal tract. It was used initially in the evaluation of patients with defecation disorders; but more recently, it has been used as part of the evaluation of anal incontinence. The rectum of the patient is filled with a barium-oatmeal or barium-potato starch paste mixed to a consistency to approximate semisolid stool. The patient then is seated on a special commode chair and asked to defecate during fluoroscopy. Lateral radiographs usually are taken before, during, and after evacuation of the rectum. Alternatively, cinedefecography can be performed, which is a videotaped dynamic fluoroscopic study.

The anorectal angle can be observed, as can the effect of willful contraction of the puborectalis muscle on this angle. It also provides information about rectal emptying and the mobility of the rectal wall. Indeed, its major value may be in identifying those patients with incomplete evacuation leading the patient's physician to consider overflow incontinence as the cause of the patient's incontinence. Anatomic abnormalities of the gastrointestinal tract not previously identified, such as intussusception, rectal prolapse, and rectal ulcers, can be detected by defecography. Now, it is possible to perform a triple contrast study wherein the rectosigmoid, small bowel, and bladder are all opacified with contrast. These studies often reveal disturbances of dynamic pelvic floor motion and interaction of support defects in more than one compartment, for example, rectoceles, sigmoidoceles, enteroceles, and cystoceles.

In relation to anal incontinence, however, the clinical relevance of many of these findings is questionable because there are no findings that are specific for anal incontinence. Many anatomic abnormalities are also found in asymptomatic controls. Although the anorectal angle may be more obtuse in

P.979

incontinent patients both at rest and during squeezing than in continent patients, recent studies have questioned the significance of the anorectal angle because of the wide overlap in measurements between the two groups. In addition, there is a significant intraobserver variation in the measurement of the anorectal angle from the same set of radiographic films among different radiologists. Last, surgical restoration of the angle with a postanal repair, or retrorectal levatorplasty, is poorly correlated with a return of continence. Therefore, the role of defecography in the evaluation of patients with anal incontinence is unclear.

In summary, because anal continence depends on multiple mechanisms, no one test is ideal for clinical evaluation of the incontinent patient. There is not a standard testing protocol for the anally incontinent patient. Testing should be individualized. Studies should be obtained only to gather specific information needed in the evaluation of an individual patient. As noted above, procedures thought by the American Gastroenterological Association to be of value in selected patients are (a) symptom diary for diagnosis and monitoring of progress, (b) digital examination for basic qualitative assessment of resting and squeeze pressures, (c) anal ultrasound to assess anatomic integrity of the sphincters, (d) anorectal manometry to define sphincter weakness and predict response to biofeedback training, (e) rectal and anal sensory testing, and (f) testing of rectal compliance. Procedures of possible value for an individual patient might include (a) surface EMG for evaluation of sphincter function and evacuation proctography or (b) cinedefecography, when rectal prolapse is suspected. Testing procedures that are controversial for the clinical evaluation of anally incontinent individuals at present include (a) PNTML testing for assessment of pudendal nerve function and (b) MRI, because of its expense.

TREATMENT

Nonsurgical Treatment

Nonsurgical treatment of anal incontinence includes a variety of methods directed at a number of conditions. In some cases, medical treatment may be directed at the primary underlying cause of the

incontinence, such as chronic diarrhea or as an attempt to compensate for functional or structural defects of the continence mechanism by altering the rectal contents into a more suitable solid form for bowel control. Other nonsurgical treatment may be directed at improving actual function of the compromised but intact sphincter mechanism through biofeedback or by augmentation of structural weakness without surgery with injectable bulk-adding agents or radiofrequency tissue remodeling procedures. Perianal electrical stimulation has been used to generate anal contractions in spinal injury patients and as an adjunct to biofeedback in postpartum women. Finally, staged sacral neuromodulation with implantable electrodes has been utilized to provide direct stimulation of the sacral nerves in patients with anal sphincter dysfunction with either intact or structurally damaged anal sphincters.

Patients with chronic diarrhea may suffer from fecal incontinence even with intact and functional sphincter mechanisms. Obviously, if there is an underlying cause of the diarrhea as in irritable bowel syndrome or ulcerative colitis, it should be treated. Otherwise, attempts to improve the consistency of the stool into a more solid form should be undertaken with the use of bulk-adding agents such as fiber or constipating medications such as loperamide. This type of therapy aimed at producing a more solid stool may also be helpful in those patients with mild fecal incontinence due to neurologic injury or those with structural damage who either do not wish attempted surgical repair or who are poor candidates for successful repair. Finally, individuals with overflow fecal incontinence due to chronic fecal impaction may find some degree of relief with the regular use of enemas or scheduled disimpaction.

Both an NIH consensus statement and the American Gastroenterological Association (AGA) have recommended biofeedback therapy in patients with fecal incontinence when it occurs within the first year following childbirth (NIH) or when it is associated with an intact sphincter or decreased rectal sensation due to nerve injury (AGA). Biofeedback is used to train patients to achieve improved striated muscle contraction with their pelvic floor or improve their ability to perceive rectal distention. A variety of techniques have been used. However, the effectiveness of biofeedback especially compared to standard therapy of patient education along with dietary measures and use of medications as needed to improve stool consistency is not settled. A Cochrane review in 2006 of randomized trials of a variety of biofeedback procedures failed to demonstrate an advantage to biofeedback.

A variety of injectable bulking agents and anal submucosal injection techniques have been used since 2001 in an attempt to treat passive fecal incontinence secondary to a damaged or weak internal anal sphincter with variable results. These materials have included silicone-based biomaterials (Malouf et al., 2001; Maeda et al., 2007; Soerensen et al., 2009), hyaluronic acid and dextranomer (Dehli, 2007; Graf et al., 2011; Schwandner et al., 2011), carbon-coated microbeads (Altomare et al., 2008; Aigner et al., 2009), calcium hydroxylapatite (Ganio et al., 2008), and collagen (Ullah et al., 2011). In 2011, the FDA approved Solesta (Salix Pharmaceuticals, Inc., Raleigh, NC), a sterile, injectable dextranomer hyaluronic gel to treat fecal incontinence. This is an office procedure consisting of four submucosal injections just proximal to the dentate line in the anal canal resulting in narrowing of the anal canal ([Fig. 44.10](#)).

P.980

The randomized, double-blind, sham-controlled study by Graf demonstrated a decrease in incontinence episodes by 50% in the Solesta group compared to 31% in the sham treatment group in the short term. However, many questions yet remain about the long-term efficacy and patient selection criteria of this therapy. A Cochrane review done in 2010 examining the effectiveness of perianal injection of a variety of bulking agents up to that point reported that most trials demonstrated a short-term benefit regardless of the material used. No longterm evidence on outcomes is available. It is considered an investigational therapy by most insurance companies.

FIGURE 44.10 FDA approved Solesta, a sterile, injectable dextranomer hyaluronic gel, to treat fecal incontinence. This is an office procedure consisting of four submucosal injections just proximal to the dentate line in the anal canal resulting in narrowing of the anal canal. FIGURE 44.11 The Secca procedure entails the transanal delivery of temperature-controlled radiofrequency energy to the sphincter complex. It is an outpatient procedure usually performed under conscious sedation. An endoscopic device (**left panel**) uses four electrodes to deliver controlled radiofrequency energy to the sphincter muscles (**middle panel**). This results in precise, submucosal burn lesions ultimately resulting in tissue remodeling and improvement in anal sphincter function (**right panel**). (Copyright © Mederi Therapeutics, Inc. 2013. Used with permission.)

The Secca procedure (Mederi Therapeutics, Inc., Greenwich, CT), which received FDA clearance through Investigational Device Exemption in 2002, entails the transanal delivery of temperature-controlled radiofrequency energy to the sphincter complex ([Fig. 44.11](#)). It is an outpatient procedure usually performed under conscious sedation. An endoscopic device uses four electrodes to deliver controlled radiofrequency energy to the sphincter muscles. This results in precise, submucosal burn lesions ultimately resulting in tissue remodeling and improvement in anal sphincter function. Studies mostly consisting of short-term small case series by Takahashi and coworkers and by Efron and colleagues have demonstrated inconsistent

effects on symptoms and quality of life. There have been no demonstrable objective effects such as increased anal canal manometry pressures or sphincter muscle thickness. A follow-up study by Takahashi-Monroy demonstrated sustained improvements in incontinence symptoms and quality-of-life scores at 5 years. However, Kim and associates recently failed to demonstrate either subjective or objective incontinence improvement at 6 months while at the same time reporting significant complications associated with the procedure. Most insurance companies consider the transanal application of radiofrequency energy for the treatment of incontinence to be investigational.

Perianal electrical stimulation has been shown to cause anal contraction in spinal cord injury patients as reported by Riedy and coworkers. A Cochrane review in 2000 of trials attempting to treat fecal incontinence was unable to make any reliable conclusions as to its efficacy. In addition, a randomized controlled trial using electrical stimulation of the anal sphincter as part of a biofeedback program for women with postpartum incontinence failed to demonstrate any benefit in outcome compared to standard biofeedback. There does not seem to be a role for perianal electrical stimulation for fecal incontinence treatment or prevention.

Sacral neuromodulation or sacral nerve stimulation (Inter-Stim, Medtronic, Minneapolis, MN) involves the placement of electrodes under fluoroscopic guidance for stimulation of the S2, S3, and S4 nerve roots via their foramina ([Fig. 44.12](#)). This stimulation results in the contraction of the levator muscles and external anal sphincter. Kenefick and Christensen reported that sacral neuromodulation seems to act by recruiting additional inactive motor units in the sphincter and pelvic floor muscles resulting in improved muscle strength and an increase in resting anal pressure. Originally, it was used only in the presence of intact although weakened sphincters. However, there are now multiple studies documenting improvement in

P.981

fecal incontinence in those with anatomic sphincter defects (Chan et al., 2008; Boyle et al., 2009; Ratto et al., 2010; Brouwer & Duthie, 2010). It is a two-staged procedure involving the placement of a temporary percutaneous electrode attached to an external stimulator. If significant benefits are demonstrated over a 2- to 3-week period, then a permanent stimulator is placed. Wexner and colleagues, in a recent multicenter prospective randomized trial of 120 patients over 36 months, demonstrated a 50% decrease in weekly incontinence episodes in over 75% of individuals. Likewise, a metaanalysis in 2011 by Tan and coworkers of 34 studies involving 944 patients demonstrated significant improvements in objective and subjective outcome measures. Weekly incontinence episodes (weighted mean difference) decreased by 6.83 in the sacral neuromodulation groups compared to conservative management. Likewise, quality-of-life scores were also significantly improved. Both resting anal pressure and squeeze pressure were also significantly improved. Although there was greater improvement seen in sphincter intact patients, there was still significant improvement in the sphincter impaired group. Finally, Hull and colleagues recently reported on 5- to 8-year follow-up on 76 patients who underwent sacral neuromodulation device implantation for severe fecal incontinence. Fecal incontinence episodes per week decreased from a mean of 9.1 at baseline to 1.7 at 5 years, with 89% having a greater than 50% improvement and 36% having complete continence. Improvement in quality-of-life scores was also maintained over this 5-year period. Sacral neuromodulation must be considered in the treatment algorithm in patients with and without an intact sphincter. Its drawbacks are its expense and the need for a two-staged procedure. Matzel has recently published a treatment algorithm for fecal incontinence, which includes sacral nerve stimulation as a therapeutic alternative to surgical repair especially in those patients with a sphincteric defect of ≤ 180 degrees. The InterStim device received FDA approval in April 2011 for the treatment of chronic fecal incontinence.

FIGURE 44.12 Sacral neuromodulation or sacral nerve stimulation involves the placement of electrodes under fluoroscopic guidance for stimulation of the S2, S3, and S4 nerve roots via their foramina. This stimulation results in the contraction of the levator muscles and external anal sphincter. (Copyright of 2011, image provided by Medtronic, Inc.)

Surgical Repair

STEPS IN THE PROCEDURE

Layered Approach to Anal Sphincteroplasty and Perineal Repair for Chronic Perineal Laceration

- Preoperative bowel preparation and antibiotics.
- Use of Lone Star Retractor for adequate perineal exposure.
- Transverse perineal incision at the junction of the posterior vaginal wall and anal mucosa.
- Sharp dissection to create a midline incision of the posterior vagina followed by further sharp dissection to free the distal vagina from the rectum.
- Dissection lateral to anal canal to identify ends of retracted external anal sphincter. Grasp ends of sphincter with Allis clamps.
- After excising scar from margins of anorectal mucosa, repair the defect in the anal mucosa with a continuous 3-0 delayed absorbable monofilament suture. If tissue is friable and won't hold the suture, place sutures full thickness through the mucosa; otherwise, try to stay submucosal.
- Repair the internal anal sphincter in a similar manner. This usually appears as a white layer

of tissue well lateral to the anal mucosa you just repaired. Carry this repair distally for at least 3 to 4 cm all the way to the end of the anal mucosal suture line.

- Repair the external anal sphincter either through simple end-to-end reapproximation or overlapping repair. In the end-to-end repair, use 2-0 delayed absorbable monofilament suture, making sure that all four quadrants of the muscle are repaired. In the overlapping repair, dissect enough sphincter out so that the ends can overlap. Repair with 2-0 delayed absorbable monofilament suture in two rows of two horizontal mattress sutures.
- Narrow the genital hiatus by plicating the most distal ends of the puborectalis muscle together as part of the perineal body reconstruction. Do not allow this placcation to extend above the perineal body and into the vaginal canal. Use 2-0 monofilament absorbable suture.
- Further repair the perineal body by suturing together the disrupted ends of the superficial transverse perineal muscles and the bulbocavernosus muscles using 2-0 delayed absorbable monofilament suture.
- Excise excess vaginal mucosa and repair with 3-0 delayed absorbable monofilament suture including a subcuticular closure of the perineal skin.
- Postoperatively every effort should be made to avoid stool passage through the repair for at least 3 to 4 days. However, avoid constipation. Keep stools soft for the next 6 to 8 weeks.

Patients with a demonstrable external sphincter defect may be considered for a surgical repair with either end-to-end repair or overlapping sphincteroplasty. Overlapping repair of the muscle seems to be preferred although differences in success rate between procedures seem small whether performed at the time of acute injury or delayed repair. The anal sphincter complex is a surgical challenge to repair because both the internal and external sphincters have a constant tone that begins pulling against the healing area almost immediately. Functional results from this surgery are far from perfect. The overlapping repair was proposed for the external anal sphincter in the hopes that the scarified ends of the torn sphincter would bolster support for the reparative sutures and not allow them to pull through, resulting in a better anatomic result and, it is hoped, better functional results. The advantage in terms of outcome seems to favor the overlapping approach over the end-to-end approximation method; however, more data from modern, well-designed, prospective studies clearly are needed in this area.

Many of these patients for delayed repair with a prior obstetrical injury will present with complete disruption of the perineal body along with an injury to the external anal sphincter and require separate repair of the anal canal mucosa and perineal body as well. This is usually performed through the standard layered approach to perineal repair and anterior sphincteroplasty. However, older operations such as the Warren flap or Noble procedure can also be performed.

P.982

The advantage of these two older procedures is the lack of a suture line in the anal mucosa. Regardless of the approach, it is the anterior sphincteroplasty that is most important in determining successful restoration of continence. Oliveira and colleagues demonstrated that in 55 women undergoing anterior sphincteroplasty of whom 39 had a successful outcome, the most important factor correlating with regained continence was the increase in mean and maximal resting and squeeze pressures obtained after surgery.

Blaisdell, in an older report, and Arnaud and associates, more recently, reported success rates of approximately 60% using the end-to-end approach. Using the overlapping technique, Sitzler and Thomson reported a 74% success rate in 27 women, most of whom had obstetric sphincter injuries. The continence rates after anal sphincteroplasty appear to diminish with time from the surgical correction. Rothbarth and colleagues reported on 39 patients who had obstetric injuries and underwent overlapping sphincteroplasty. Their success rates were 77%, 67%, and 62% at 3, 9, and 12 months, respectively. Multiple long-term

follow-up studies of the degree and quality of continence after overlapping sphincteroplasties reflect the difficulty of the task at hand and that success rates diminish with time. Malouf and associates studied patients with a minimum of 5-year follow-up (median 77 months) and reported that 23 of 46 patients (50%) had a successful outcome defined as no further surgery and episodes of urge fecal incontinence occurring once a month or less. Of these, 23 patients were judged to have a successful outcome, 15 had passive soiling, 17 had fecal urgency, 19 were incontinent of solid and liquid stool, and none were fully continent of stool and flatus. In a study of 71 consecutive patients with long-term follow-up treated by overlapping sphincteroplasty, Halverson and Hull found that 54% were incontinent of solid or liquid stool, and only 14% remained totally continent. Median follow-up was 69 months with a range of 48 to 141 months. Gutierrez and colleagues reported on 130 patients with a median follow-up of 10 years. Sixty-one percent continued to have incontinence or required further surgery. Eight patients (6%) were totally continent. Zutshi and coworkers reported on 31 patients with a median age of 44 years at the time of overlapping sphincter repair with a median follow-up of 129 months. No patients were fully continent at 129 months. Patients who were older at the time of surgery and those who had undergone multiple vaginal births had the worst outcomes. Finally, Dudding and coworkers in a systematic review of the literature in 2008 determined that only 20% of patients were continent to liquid and solid stool at 10 years after overlapping sphincter repair. They reviewed 10 studies of secondary overlapping sphincter repair each with greater than 30 subjects with more than 12-month follow-up. The percentage of patients with incontinence to liquid and/or solid stool was significantly greater the longer the duration of the study ($r^2 = 0.71$; $P = 0.0024$).

As previously mentioned, success rates for anal sphincter repair in patients with concurrent pudendal neuropathy are generally worse than for those with intact innervation. Gilliland and colleagues looked at a large group of patients who had undergone an overlapping sphincteroplasty with a median follow-up of 2.4 years. They found that 62% of 59 patients with normal pudendal function had a successful outcome, compared with only 17% of the 12 patients with unilateral or bilateral prolonged PNTMLs.

Karoui and associates also observed that success rates deteriorated with time and that poor results were associated with the presence of an internal sphincter defect. The importance of the internal anal sphincter to continence is a subject of recent interest. It has long been known that this structure contributes most of the resting tone in the anal canal and helps to maintain day-to-day continence. Purposeful lateral disruption of the internal sphincter to aid with anal fissure healing has been shown to be associated with the development of at least transient incontinence. Vaizey and associates have identified primary degeneration of the internal sphincter as an independent cause of passive anal incontinence in some women with normal neurologic function and no obstetric trauma. It follows that repair of a disrupted internal sphincter should contribute to continence.

Little attention has been paid in the past to repair of the internal sphincter either at the time of initial obstetric injury or at the time of reconstruction of a long-standing injury. Repair of the internal anal sphincter should be attempted at the time of anterior sphincteroplasty although this seems to be much more difficult to achieve. A recent report by Farrell and associates on primary repair of obstetrical third- and fourth-degree lacerations demonstrated a persistent defect of the internal anal sphincter in 90% of the 27 women studied. This high incidence of persistent postrepair defect was despite what the author characterized as a heightened emphasis on the identification and repair of the sphincter.

Layered Method of Repair and Anterior Sphincteroplasty

Preoperatively, a mechanical bowel preparation is important. An oral bowel preparation should be given the evening before surgery is scheduled. If such a preparation is given the day of surgery, the patient may still be releasing stool during the operation. Preoperative parenteral prophylactic antibiotics should be given. The optimal postoperative diet for these patients is a matter of much controversy but little scientific study.

Decades ago, these patients were given diverting colostomies to keep the fecal stream away from the repair until healing was complete. Patients would then have another procedure to close their colostomy. Most postoperative feeding regimens are based on the concept of keeping fecal material from the repair site for at least 4 to 5 days until the mucosal suture line has healed adequately and the reparative process is well established. A regimen of clear liquids for 3 to 5 days, with progression to a soft, low-residue diet for the next several weeks, can be given. Constipating agents are sometimes used immediately postoperatively, but should not be used for a prolonged period of time because one wants the first bowel movement to be soft so as not to distend the repair. The use of an elemental liquid diet for 1 week postoperatively can be useful, but is poorly tolerated by many patients and can lead to diarrhea in some. Alternatively, fiber supplementation and adequate hydration can be used to give patients more bulky but deformable stool so as not to traumatize the repair. Stool softeners and a highfiber diet are advisable for 6 weeks postoperatively.

A transverse or crescent perineal incision is used at the junction of the posterior vaginal wall and anal mucosa. The lateral margins of the incision are extended to the region of the perineal dimple created by the retracted external sphincter, and a midline incision is made along the lower half of the posterior vaginal wall (**Fig. 44.13A**).

The edges of the vaginal and rectal mucosa are grasped separately with Allis clamps, and the anterior rectal wall is separated in the midline from the posterior vaginal wall with careful scissors dissection. The dissection is carried laterally by sharp dissection to the region of the external anal sphincter. The internal anal sphincter, which is the thickened distal condensation of the circular smooth muscle layer of the rectum, can be seen between the external anal sphincter and the anorectal

P.983

mucosa as an area of white fibrous tissue (**Fig. 44.13B**). Meticulous hemostasis and wide mobilization to allow closure without tension are crucial to success with this operation.

FIGURE 44.13 Layered closure of a chronic complete perineal laceration with overlapping sphincteroplasty.

A: A transverse incision is made at the junction of the vaginal and rectal mucosa and extended up the midline of the posterior vaginal wall. **B:** The rectal wall has been separated from the posterior vaginal wall with careful sharp dissection. The ends of the external sphincter have been identified and grasped with Allis clamps. The internal anal sphincter can be seen between the external anal sphincter and the anorectal mucosa as an area of white fibrous tissue. **C:** The defect in the anal mucosa has been closed with a continuous 3-0 delayed absorbable suture. The internal anal sphincter then is reapproximated over a length of 3 to 5 cm. This layer also serves to imbricate and isolate the mucosal layer and take tension off of it to help it heal and seal against infection. **D:** The ends of the external anal sphincter are widely mobilized with the scar tissue left on. Care should be taken not to dissect beyond the 3-o'clock and 9-o'clock position as that is where the pudendal enervation to the sphincter enters laterally. The external sphincter then is brought together over the repaired internal sphincter with two rows of two horizontal mattress sutures of delayed absorbable or permanent suture material. **E:** After the external sphincter has been repaired, the genital hiatus is narrowed by bringing the puborectalis muscles closer together with interrupted delayed absorbable sutures placed in the fascia overlying them. **F:** The bulbocavernosus and superficial transverse perineal muscles have been reattached to the perineal body, and the vaginal mucosa was closed with a continuous locking stitch of 3-0 delayed absorbable suture that was continued subcuticularly to approximate the perineal skin.

A fibrous scar that is retracted lateral to the wall of the anal canal often identifies the external sphincter. The exact anatomic margins of the external sphincter frequently are difficult to ascertain. A nerve stimulator can be used to identify contractile skeletal muscle. Alternatively, the Allis clamps containing the ends of the external sphincter can be brought together in the midline and a circumferential sphincter tested for by inserting a double-gloved index finger into the rectum. If necessary, the clamps should be readjusted to incorporate more of the retracted muscle bundles until the constricted effect of the reapproximated sphincter can be demonstrated.

All scar tissue is excised from the margins of the anorectal mucosa, and the defect in the anal mucosa is closed using a

P.984

continuous or interrupted suture of 3-0 delayed absorbable material. A running suture may have the advantage of distributing tension along the entire suture line and helping prevent a gap in the closure that could occur from ischemia if an interrupted suture is tied too tight. A submucosally placed suture is ideal. Sometimes, this tissue is quite friable, and a full-thickness suturing of the mucosa is the safest method.

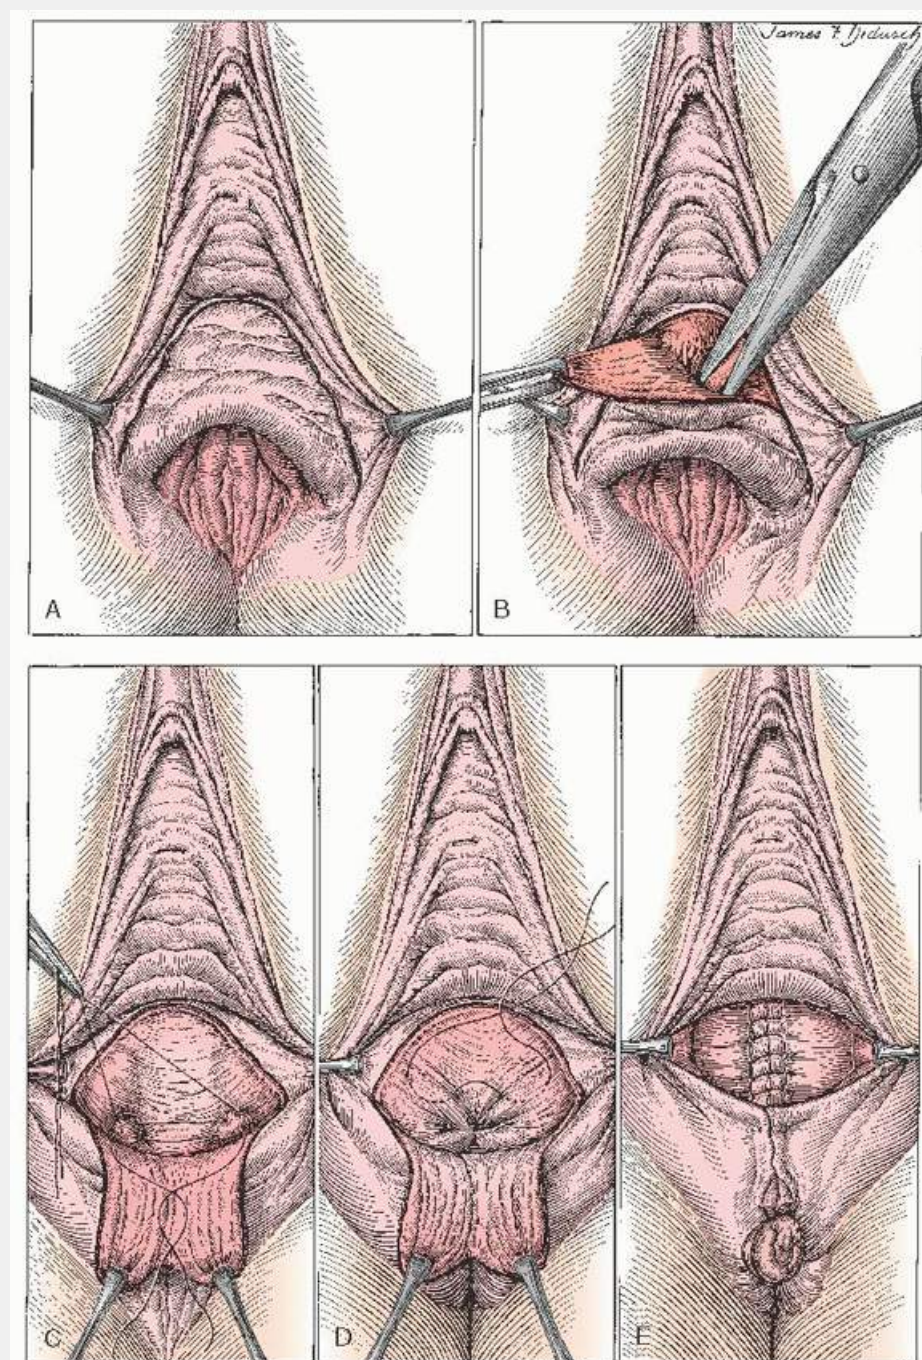

FIGURE 44.14 Warren flap operation for complete perineal laceration. **A:** The line of incision outlines the

flap of vaginal mucosa. **B:** The flap is dissected free and turned back. **C:** The flap is retracted downward. The ends of the sphincter are delivered and are either sutured end to end as pictured or with an overlapping technique as described. **D:** The external sphincter has been repaired, and the puborectalis muscles are then brought closer together taking care to not create a posterior band of tissue. **E:** The vaginal incision is closed with a continuous locking stitch that is continued subcuticularly over the perineum. The margins of the flap are included in the continuous suture, which may temporarily create a peaked appearance in the perineal skin. If the margins of the vaginal mucosal flap are redundant, it may be trimmed.

After the mucosal margins are approximated, a second supporting layer inverts the initial mucosal suture line (**Fig. 44.13C**). This layer often has been thought of in the past as “perirectal fascia,” but in fact, it is the thickened downward continuation of the circular smooth muscle layer of the rectum that is the internal anal sphincter. This appears as a white smooth layer of tissue between the anorectal mucosal closure and the external anal sphincter. Care should be taken in reapproximating this layer over a length of 3 to 5 cm as this muscle is responsible for most of the resting pressure in what is normally a 4-cm high-pressure zone in the anal canal. This layer also serves to imbricate and isolate the mucosal layer and take tension off of it to help it heal and seal against infection.

In an approximation-type external anal sphincteroplasty, the external anal sphincter ends are completely trimmed of scar tissue and united in the midline with interrupted 0 or 2-0 delayed absorbable sutures. Although some surgeons prefer a permanent suture, such as a braided silicone-treated polyester, a delayed absorbable monofilament suture such as polydioxanone has the advantage of maintaining excellent tensile strength for an extended period while avoiding the presence of

P.985

a permanent foreign body. This becomes particularly important in the event of wound infection. Four or five sutures are used to approximate the sphincter muscle. These can be placed 1 cm apart, full thickness, with the nondominant index finger in the anal canal to aid in acquiring excellent purchase on both ends while assuring no penetration of the anal canal itself.

In an overlapping approach to the external anal sphincter, the scarified ends of the sphincter are important to the repair itself and are left in place. The concept of the overlapping sphincteroplasty is to use the scarred ends of the torn sphincter to help hold the sutures that reconstitute the circumferential sphincter. The ends are widely mobilized with the scar tissue left on. Care should be taken to not dissect beyond the 3-o'clock and 9-o'clock position because the pudendal innervation to the sphincter enters laterally. The external sphincter then is brought together over the repaired internal sphincter with two rows of two horizontal mattress sutures of delayed absorbable or permanent suture material (**Fig. 44.13D**).

An important part of the perineal reconstruction is the restoration of a narrower genital hiatus by bringing the puborectalis muscles closer together. One must remember that the arms of the puborectalis muscle do not normally come in contact with each other between the rectum and the vagina. Overzealous plication of the puborectalis muscle can constrict the vaginal introitus and create posterior tissue banding that can lead to dyspareunia. Dissection should be carried out laterally to the fascia overlying the medial border of the puborectalis muscle. This fascia should then be brought together by a series of interrupted, delayed absorbable sutures. Each suture should be held tightly and the vagina tested before tying to assure that posterior banding is not created. If it is, that suture should be removed and another placed (**Fig. 44.13E**).

Further support and elevation of the perineal body are provided by bringing together the disrupted ends of the superficial transverse perineal muscles and the bulbocavernosus muscles. These muscles normally insert on the perineal body and play a part in pelvic floor support. They should be included in perineal reconstruction, including obstetric repair, to reestablish and support the perineal body. After this step, the redundant vaginal mucosa is excised, and the remaining mucosa is approximated in the midline with a

continuous 2-0 or 3-0 delayed absorbable suture. This is followed by a subcuticular closure of the perineal skin (**Fig. 44.13F**).

Warren Flap Operation for Complete Third-Degree Tear

An inverted V-shaped incision is made in the posterior vaginal mucosa, outlining the flap that is to be turned down. The lower ends of the incision should be just lateral to the dimples caused by retracted sphincter ends (**Fig. 44.14A**). The length of the flap should measure a minimum of 3 cm to provide sufficient vaginal mucosa to be incorporated into the anal canal and cover the reconstructed perineal body.

Taking care to avoid injuring the bowel wall, the surgeon dissects the flap of mucosa free from the top downward (**Fig. 44.14B**), stopping short of the margin between the vaginal and anal mucosa. If this margin is perforated, then the blood supply to the mucosal flap is compromised, thereby nullifying the advantage of the flap technique. The properly demarcated flap allows the areas overlying the sphincter ends to be denuded. The flap is grasped with two mucosal Allis clamps and is turned down to hang over the anus. The external anal sphincter ends are then dissected free, using Allis clamps for traction. An approximation- or overlapping-type external anal sphincteroplasty then is performed (**Fig. 44.14C**). Although an approximation-type sphincteroplasty is pictured, an overlapping procedure as described above could be incorporated into this procedure.

The fascia overlying the medial aspect of the puborectalis muscles is identified, and this tissue is brought together with a series of interrupted sutures for reinforcement in the manner described for the layered technique, using 0 or 2-0 delayed absorbable sutures (**Fig. 44.14D**). Each suture should be tested before tying to assure that the caliber of the vagina is not compromised.

Closure of the vaginal mucosa is carried out as in an ordinary perineal repair. Interrupted plication stitches of 2-0 delayed absorbable suture are used to advance the fascia and shorten the muscle fibers of the perineal body, which strengthens the external sphincter as well. The margins of the vaginal mucosa and graft are approximated in the midline by a continuous locking stitch of 3-0 delayed absorbable suture. The tip end of the vaginal mucosal flap should not be trimmed too closely, even though it protrudes somewhat from the repaired perineal body. It retracts as healing occurs (**Fig. 44.14E**).

Noble Procedure for Complete Perineal Laceration

The torn perineal, anal, and rectal tissues in patients with a complete perineal laceration form a “butterfly” appearance across the perineum (**Fig. 44.15A**). The “wings” of the butterfly are the lateral perineal dimples of the retracted ends of the external anal sphincter. The initial incision is outlined around the margins of this area following the margin of the anal mucosa along the anatomic defect in the rectovaginal septum. The perineal skin is left attached and held with Allis clamps to facilitate later dissection of the retracted ends of the external sphincter. A small margin of vaginal mucosa is also left attached to the anal wall for traction because the anal mucosa is so friable.

Atraumatic clamps are placed along the margin of the anal canal, and sharp dissection is used to carefully separate the anal wall from the overlying vaginal mucosa. The external anal sphincter remnants should be sharply mobilized and separated from the underlying anal wall (**Fig. 44.15B**). The vaginal mucosa is widely mobilized from the anal canal and lower rectal wall laterally to the underlying levator muscles and proximally into the middle or upper one third. Adequate mobilization of the anterior anorectal wall allows it to be pulled outside the margin of the anal orifice without difficulty, thus avoiding sutures in the anorectal canal.

Once the ends of the external anal sphincter are mobilized to meet in the midline with traction on the Allis clamps, the overlying skin previously left attached is excised, and the sphincter ends are approximated end to end in the midline (**Fig. 44.15C**). Alternatively, one could perform an overlapping sphincteroplasty as previously described. Several of these sphincteroplasty sutures also should include the muscular layers of the anterior rectal wall to prevent it from retracting inward and to avoid tension on the suture line between

the advanced anterior anorectal wall and the perineal skin. The genital hiatus should be narrowed by bringing the puborectalis muscles closer together as previously described (**Fig. 44.15D**). The transverse perineal muscles and the inferior margins of the bulbocavernosus muscles then are reapproximated, further reconstituting and supporting the perineal body.

The vaginal mucosa is trimmed, if necessary, and the margins of the posterior vaginal wall are approximated with a continuous locking stitch of 3-0 delayed absorbable suture.

P.986

The continuous suture closing the posterior vaginal mucosa is carried over the perineal body as a subcuticular stitch, and the perianal skin then is approximated at the midline. The mobilized anterior wall of the anal canal is drawn outside the reconstructed anal orifice and sutured without tension to the perianal skin (**Fig. 44.15E**). The excess anal mucosa is trimmed. Care should be taken to remove as little of the distal anal canal as possible because this tissue contains the internal anal sphincter. Vertical mattress sutures of 3-0 delayed absorbable suture are used to approximate the broad surface of the anal submucosa to the perianal skin. Any residual separation of the margins of the anal mucosa and perianal skin can be approximated with interrupted sutures.

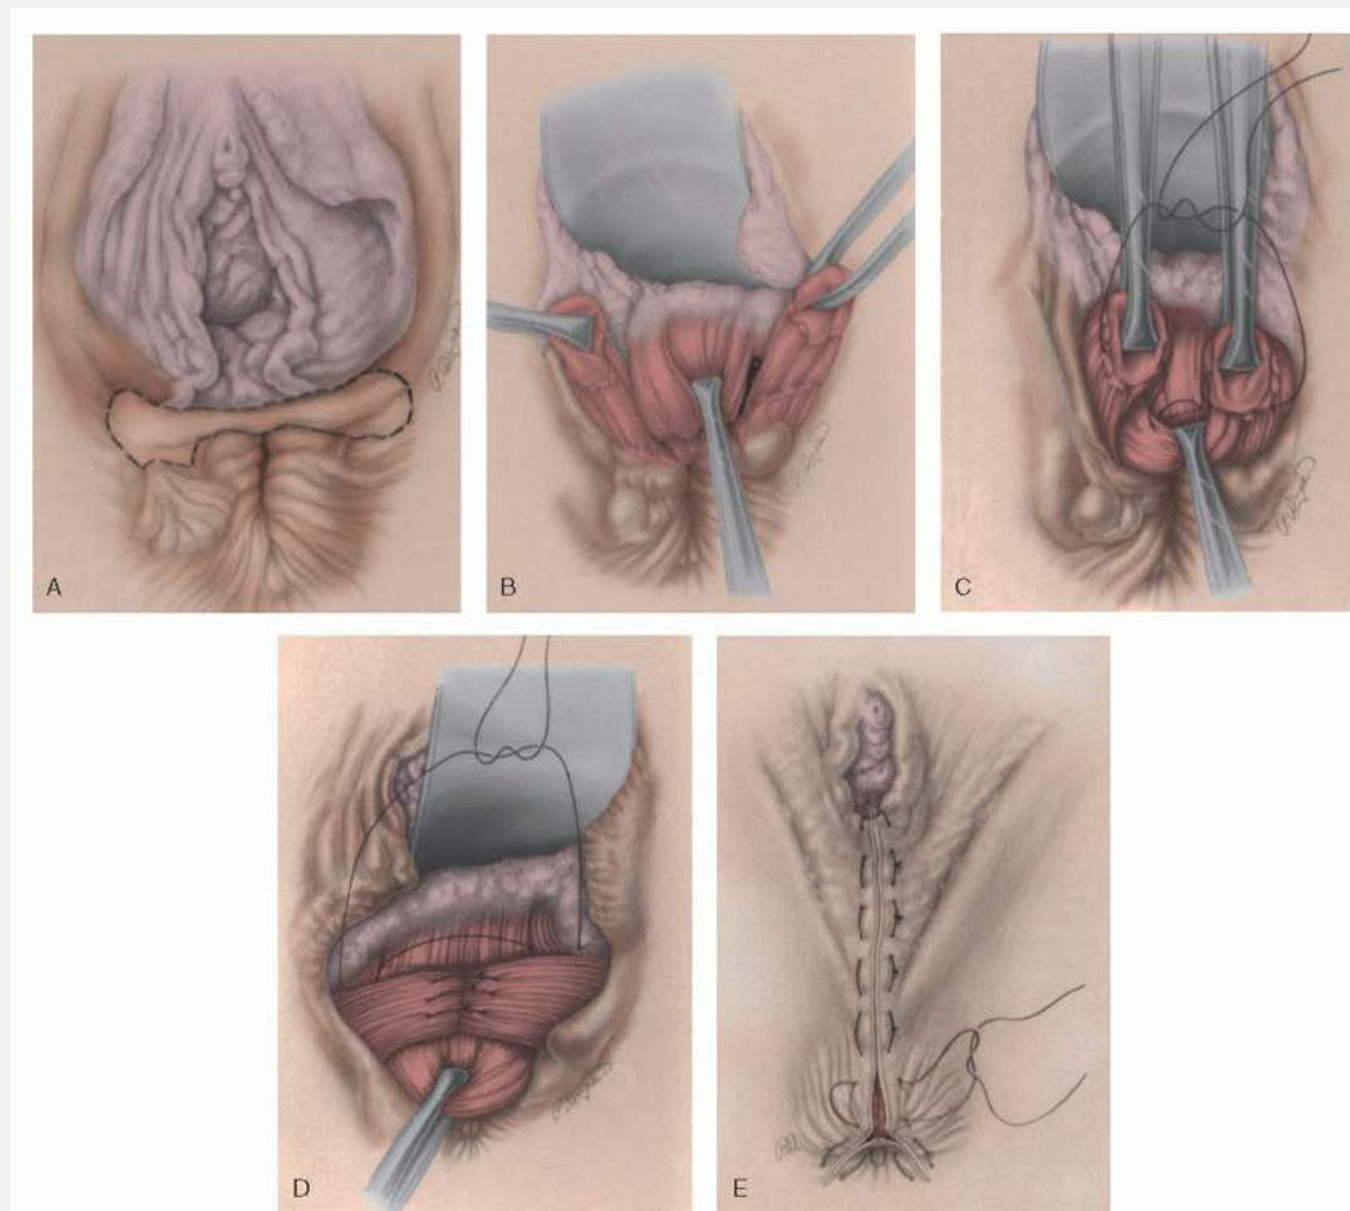

FIGURE 44.15 The Noble operation for complete perineal laceration. **A:** A “butterfly-shaped” scar is noted across the perineum, where there are torn perineal, anal, and rectal tissues. The ends of the external anal sphincter can be recognized by lateral perineal dimpling. **B:** The anterior rectal wall is mobilized extensively

from the posterior vaginal wall to allow it to be pulled down without tension. The wings of the butterfly are left attached to facilitate dissection of the retracted ends of the sphincter. **C:** Ends of the anal sphincter are trimmed and sutured together and to the pararectal fascia of the advanced anterior rectal wall. Several delayed absorbable sutures are used. **D:** The levator muscles and pararectal fascia are brought closer together in the midline. **E:** The transverse perineal muscles and the inferior margins of the bulbocavernosus muscles are brought together to reconstitute the perineal body, and the vaginal mucosa and perineal skin are closed. The mobilized anterior wall of the anal canal is sutured without tension to the perineal skin.

Muscle Transposition, Artificial Sphincters, and Diversion

The following advanced procedures are largely reserved for patients with difficult anal incontinence problems or multiple operative failures. Muscle transposition procedures exist in

P.987

which the gracilis muscle, sartorius muscle, or gluteus muscle is swung a flap to encircle the anal canal. Dynamic muscleplasty procedures involve stimulation of this muscle with an intramuscular neurostimulator to induce it to convert to the characteristics of normal external anal sphincter muscle. The muscle is continuously stimulated at a low frequency for 8 to 10 weeks until the transformation from a fast-twitch to a slow-twitch muscle has been achieved. At this point, the frequency of stimulation is increased so that the muscle contracts around the anal canal and occludes it continuously. When the patient wishes to defecate, the pulse generator can be turned off by a magnet. Once defecation is complete, the stimulator can be turned on again by the magnet. In a series of 20 patients reported by Hallan and associates, 12 have a functioning neoanal sphincter. Madoff and colleagues found a 70% reduction in solid stool incontinence in two thirds of patients undergoing a dynamic graciloplasty. However, one third of these patients experienced a major wound complication with their surgery. Penninckx studied 60 consecutive patients undergoing dynamic graciloplasty. The operation failed in 27, 7 of whom went on to have stoma construction. There were 75 complications that required 61 reoperations in 44 patients.

Some investigators have used an artificial bowel sphincter, ABS (Acticon Neosphincter, American Medical Systems, Minneapolis, MN), around the anal canal in patients with severe anal incontinence (**Fig. 44.16A, B**). It restores physiologic anal canal pressures through the transfer of fluid pressures between components. Although the initial results were good in a small series of patients, cuff erosion into the anal canal and infection have been significant problems that have caused a number of the sphincters to be removed. In a small randomized controlled trial of artificial sphincter versus supportive care, O'Brien and associates found a significant improvement in continence scores in the operative group. Unfortunately, in a review in 2004, Mundy and associates reported revision and removal rates to be between 12.5% to 50% and 16.7% to 41.2%. Revisions seem to be most often due to leaks from the anal cuff from microperforations attributable to repeated cycles of inflation and deflation, while removal is usually due to localized infections around the device components.

FIGURE 44.16 A: Artificial bowel sphincter, ABS (Acticon Neosphincter, American Medical Systems, Minneapolis, MN) illustrating its three major components: pressure-regulating balloon, anal cuff, and pump. It restores physiologic anal canal pressures through the transfer of fluid pressures between components. **B:** Implanted ABS device. (Reprinted with permission of American Medical Systems, Inc.)

More recently, Lehur and coworkers have reported on a magnetic anal sphincter (MAS) device like that used in gastroesophageal reflux disease (Bonavina et al., 2008; Ganz et al., 2008) implanted in a small number of patients with fecal incontinence. This implantable device (FENIX, Torax Medical, Inc., Shoreview, MN) consists of a series of titanium beads with magnetic cores hermetically sealed inside (Fig. 44.17). The beads are interlinked together with independent titanium wires to form a flexible ring around the external anal sphincter in a circular fashion. The purpose of the device is to reinforce the sphincter and prevent episodes of incontinence. Defecation is accomplished by having the patient push as in normal defecation such that a number of beads separate allowing stool to move through the device. Results from an early feasibility study by Lehur and associates involving 14 patients were encouraging with 5 completing at least 6 months of follow-up. There was a mean reduction of weekly incontinence episodes of over 90%, improvement in continence scores, and quality-of-life scores. Wong and coworkers have recently reported comparable results with this device to the ABS noted earlier. This retrospective study involving 10 patients in each group demonstrated improved quality-of-life scores and continence scores in each group. The advantage of the MAS device so far seems to be simpler implantation procedure compared to the artificial sphincter. Obviously, the exact role this device will play in the future will depend on long-term outcomes. For the patient with uncontrollable anal incontinence that cannot be addressed by any other procedure, a permanent

diverting colostomy may be a more manageable and preferable alternative to constant perineal soiling with the hygienic and social problems it brings. Stoma problems, however, occur in as many as one quarter of patients.

FIGURE 44.17 Implanted (FENIX, Torax Medical, Inc., Shoreview, MN) device consists of a series of titanium beads with magnetic cores hermetically sealed inside. The beads are interlinked together with independent titanium wires to form a flexible ring around the external anal sphincter in a circular fashion. Defecation is accomplished by having the patient push as in normal defecation such that a number of beads separate allowing stool to move through the device. RECTOVAGINAL FISTULAE

A rectovaginal fistula resulting in extra-anal fecal incontinence is a distressing condition for the patient and a challenge to her physician. Most fistulae actually arise in the anal canal beginning distal to the pectinate line and should more accurately be considered anovaginal fistulae. The result of this condition often is the uncontrolled passage of flatus or stool from the anorectal canal through the fistulous tract into the vagina. It can be a socially disabling condition. Further, the difficulties of treatment leading to failure (contaminated operative site, high-pressure anal canal, usually without diversion) challenge both the patience of the affected individuals and the surgeon's skill.

Rectovaginal fistulae are usually classified as to their size, location, and cause. A simple system is as follows:

Simple—low or mid vaginal, less than 2.5 cm in diameter, due to trauma or infection

Complex—high vaginal, greater than 2.5 cm in diameter, due to previous inflammatory bowel disease, radiation, or neoplasm, and previous failed repairs

Etiology

Although there are many different causes of rectovaginal fistulae ([Table 44.3](#)), numerous series report that the majority are caused by obstetric trauma. Rectovaginal fistulae usually arise as a complication of a repaired fourth-degree perineal tear. Risk factors for development of a rectovaginal fistula in association with vaginal deliveries include prolonged labor, difficult forceps delivery, shoulder dystocia, and a midline episiotomy.

A rectovaginal fistula may develop as a result of direct surgical injury to the rectum or vagina, ischemia, or

postoperative infection. Other less common causes include blunt instrumentation or penetrating trauma caused by an accident. Occasionally, rectovaginal fistulae follow an infectious process such as a perianal abscess or an infected Bartholin duct cyst abscess. The most common cause of high rectovaginal fistulae is repeated bouts of diverticulitis with abscess formation followed by development of a sigmoidovaginal fistula or a combined sigmoidovesicovaginal fistula. Inflammatory bowel disease such as ulcerative colitis or Crohn disease may result in complex rectovaginal fistulae. Crohn disease is a transmural condition of the bowel that often results in a rectovaginal fistula.

Radiation is a relatively infrequent cause of fistula formation today. These fistulae usually begin as a proctitis with ulceration and fistula formation followed by a stricture. Fistulae may occur several years after completion of radiation therapy. Primary or metastatic disease in surrounding organs (rectum, cervix, uterus, or vagina) may result in rectovaginal fistulae. Because congenital rectovaginal fistula is usually managed at a young age and is associated with other anomalies, it is usually not managed by the gynecologic surgeon.

Clinical Evaluation

The most common symptoms are the passage of flatus and stool into the vagina. The severity of those symptoms may be affected by the size of the fistula. There is usually a foul-smelling vaginal discharge with periodic, uncontrolled escape of gas. Occasionally, the fistula may develop immediately following

P.989

obstetrical trauma. More commonly, it appears 7 to 10 days after delivery. The breakdown of a primary repair, inadequate repair, or infection at the primary site may explain this delayed presentation. Because of antepartum fecal incontinence associated with pregnancy, perineal pain associated with delivery or episiotomy, and/or stool softeners prescribed in pregnancy or postpartum, the patient may not seek medical attention for some time. Diarrhea, rectal bleeding, mucus discharge, and abdominal pain may be caused by the underlying status of the bowel and usually do not result from the fistula per se.

The history frequently suggests the underlying cause of the fistula and may greatly influence the timing and route of repair. On physical examination, the location, size, and number of openings can be identified. On vaginal exam, the granulationlike tissue of the fistula may be noted. The route of the fistula may be outlined by the passage of a thin probe from the vagina through the fistulous tract into the anal or rectal canal. Placing an examining finger in the rectum aids this process. Contraction of the puborectalis and external anal sphincter should be evaluated for competency. Multiple studies have demonstrated that associated sphincter injury is present in nearly 100% of patients where obstetrical trauma is the cause of the fistula. The perineal body is examined, and the tissues about the fistula are delineated to gain more insight into the cause of the underlying fistula. Multiple perianal fistulae should raise the suspicion of Crohn disease. A proctosigmoidoscopic examination usually is done to ensure that the mucosa of the intestinal tract is normal.

In patients with a history compatible with a fistula but in whom no fistula opening can be identified, a simple office examination can be helpful. With the patient in a slight Trendelenburg position with a size 20 Foley urinary catheter, a 5-mL balloon is placed in the anal canal. Air is instilled through the catheter while the water-filled or soap-covered vagina is observed for any escape of air bubbles originating from the anal canal. Likewise, a tampon test may be performed in which a tampon is placed in the vagina and the patient is given a small enema with methylene blue-colored water, which she is asked to retain for 20 minutes. Blue discoloration of the tampon is noted in the presence of a fistula. However, this test may be negative if there is a very low fistula. Contrast studies may be necessary to define the sigmoidovaginal fistula or fistulae associated with primary bowel disease.

Surgical Management

Numerous operative procedures have been described for repair of rectovaginal fistula, including transvaginal, transanal, and abdominal approaches. Gynecologists usually use a transvaginal approach, whereas colon and rectal surgeons prefer the transanal technique. The transvaginal technique allows for a layered closure of the fistula and sphincteroplasty with or without a perineoproctotomy. Also, the vaginal advancement or Noble procedure is an option with the transvaginal approach. Transanal techniques include the layered closure, endorectal flap advancement, and anocutaneous flap advancement. The determining factors to be considered include the cause of the fistula, its location and accessibility, and the status of the anal sphincter. Overall, the success rate for repair seems to be more related to the type of fistula than to the type of repair. Pinto and colleagues in a recent case series of 184 procedures of various types including transanal, transvaginal, gracilis interposition, and transperineal approaches carried out in 125 patients with fistulae of various etiologies from the Cleveland Clinic Florida found that the overall success rate per procedure was 60% with no difference in recurrence rates based on type of repair. Patients with obstetrical injuries had a success rate per procedure of 66.7%. Overall, there was a success rate of 89% with an average of 1.3 procedures per patient for obstetric patients. On the other hand, patients with Crohn disease had more recurrent fistulae with an only 44.2% success per procedure, although eventually 78% of these patients eventually healed with an average of 1.8 procedures.

Early Repair

Hankins and colleagues described early repair of carefully selected rectovaginal fistulae and episiotomy breakdowns using a technique of early return to the operating room for debridement followed by daily cleansing of the wound area. After a 6- to 7-day interval, their patients were returned to the operating room for surgical repair of the fistula. With this approach, successful healing occurred in 90% of their patients. We prefer to wait 8 to 12 weeks to allow the surrounding inflammation to resolve before surgical intervention. Preoperative mechanical bowel preparation should be given. On the morning of operation, tap water enemas can be given until clear.

Appropriate treatment of a rectovaginal fistula requires consideration of the cause and location of the fistula and the condition of the involved tissues. For fistulae located in the lower portion of the anal canal, we prefer to use the lithotomy position to carry out the operative repair. For fistulae at the very apex of the vagina, an abdominal approach generally is required. This may include needed resection of the involved bowel side of the fistula as in the case of a malignant or radiation-induced fistula.

Low Rectovaginal Fistula: Layered Repair

A transvaginal technique for small rectovaginal fistula repair involves a circular incision about the fistulous opening (Fig. 44.18). With traction on the vaginal wall and

P.990

countertraction applied to the edge of the fistulous tract, the vagina is separated from the underlying rectal wall with sharp dissection, and this proceeds circumferentially (Fig. 44.19). This wide mobilization permits later approximation of the fresh injury free of tension. Once the vaginal walls are mobilized from the underlying rectum, the entire fistulous tract is excised to include a small rim of the rectal mucosa (Fig. 44.20), converting the fistula to a fresh injury. With the surgeon's nondominant index finger lifting and supporting the anterior rectal wall, the initial sutures are placed extramucosally, including a portion of the muscularis and submucosa, with 3-0 delayed absorbable sutures (Fig. 44.21). We frequently place all sutures throughout the length of the fistula, after which they are individually tied in the order in which they were placed. The initial suture line begins and is extended a full 5 to 8 mm above and below the site of the fistulous tract to assure complete closure. A second layer (Fig. 44.22) begins 5 mm above the previously closed suture line and extends 5 mm distal to the fistulous closure, inverting the initial suture line into the rectum, and no sutures are located within the rectal lumen.

Once the wall of the rectum is reconstructed, the lower portions of the puborectalis muscle and the external anal sphincter are approximated to add a third layer in the closure (**Fig. 44.23A**), which helps to reconstitute the anterior rectal wall. Care should be taken that approximation is not carried so far superiorly that it results in a transverse bar across the posterior vaginal wall, which may lead to dyspareunia. Once the muscular walls are approximated, the vaginal wall is approximated with 3-0 delayed absorbable sutures, accurately placed so as to promote primary apposition of the fresh edge of the vaginal wall (**Fig. 44.23B**).

FIGURE 44.22 A: Inversion of initial suture line with approximation of the muscularis of the anal canal. This thickened smooth muscle layer is the internal anal sphincter. **B:** Side view representing closure of the first and second layers in the anal canal. (Adapted from Lee RA. *Atlas of gynecologic surgery*. Philadelphia, PA: WB Saunders, 1992. By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Occasionally, the fistulous tract is so close to the external anal sphincter that closure is difficult. In this situation, a perineoproctotomy in which the bridge of skin, sphincter, and perineal body are divided, and the fistula is thus essentially converted to a fourth-degree tear ([Fig. 44.24](#)). The fistulous tract is excised, and the posterior vaginal wall is mobilized from the anterior anal wall ([Fig. 44.25](#)). The anal canal is then reconstructed with interrupted or running fine delayed absorbable sutures approximating the mucosa of the anal canal. This initial suture line then is inverted with a second layer of interrupted fine delayed absorbable sutures approximating the retracted tissues of the internal anal sphincter, resulting in reconstruction of the anal canal ([Fig. 44.26](#)). The retracted ends of the external anal sphincter are approximated

P.992

in the midline in an end-to-end fashion with fine delayed absorbable sutures ([Fig. 44.27](#)). This results in a snug closure that is resistant to the passage of the surgeon's little finger. Alternatively, at this point, one could perform an overlapping sphincteroplasty as described earlier. The perineal body is reconstructed in such a fashion that there is significant support to the reconstructed anal sphincter, and yet entrance to the vagina is not compromised ([Fig. 44.28](#)).

FIGURE 44.25 Mobilization of the posterior vagina off the anterior anal canal with conversion of rectovaginal fistula to fourth-degree injury. (By permission of Mayo Foundation.)

Considerable experience exists with the transanal flap approach to rectovaginal fistulae involving the lower portion of the rectovaginal septum. Rothenberger and colleagues reported on a technique that uses an endorectal flap consisting of mucosa, submucosa, and circular muscle fibers. The flap is twice as wide at the base as it is at the apex. They achieved successful repair in 32 of 35 patients with rectovaginal fistulae. Hoexter and associates reported a similar high rate of fistula healing and improvement in anal continence, emphasizing several points for successful repair via

P.993

endorectal flap: (a) elevating the rectal flap for at least 4 cm to the fistula, (b) excising the fistulous tract, (c) leaving the vaginal wound open for drainage, and (d) using an elliptic flap to avoid devascularization of the flap apex. Others have reported a high degree of efficacy of the endorectal flap for achieving both fistula healing and repair of any associated anal sphincter disruptions.

Tissue Interposition

A variety of techniques have been described to transpose healthy muscle tissue between the vagina and the rectum in order to successfully repair a rectovaginal fistula. Tissue interposition is intended to interpose normal healthy tissue between suture lines and bring well-vascularized tissue into the area. This may be needed in cases of previous failed repairs or radiation injury with resulting fibrosis and poor vascularity of the tissues. Tissue interposition with either the labial fat pad (Martius procedure) or gracilis muscle has been described. However, since successful closure of a radiation fistula requires aggressive excision of the surrounding tissues, the fistula is often best managed with a primary resection and anastomosis of the rectosigmoid through a lower abdominal incision.

Lefevre and coworkers recently reported on eight patients who underwent a gracilis muscle transposition for recurrent fistulae after an average of three prior failed repairs. The etiology was Crohn disease in 5, iatrogenic injury in 2, and obstetrical injury in 1. Six of the eight patients (75%) healed after the gracilis muscle transplant alone.

Boronow has used bulbocavernosus-labial tissue graft (Martius procedure) to successfully treat radiation-induced rectovaginal fistulae. He reported on 25 radiation-induced vaginal fistulae in 22 patients. There were 16 rectovaginal fistulae, 3 vesicovaginal fistulae, and 3 combined vesicovaginal and rectovaginal fistulae. Successful closure was accomplished in 84% of the patients with rectovaginal fistulae.

FIGURE 44.29 Radiation-induced fistula. (By permission of Mayo Foundation.)

A description of the Martius procedure follows. **Figure 44.29** depicts the usual location of a radiation fistula, high in the posterior vaginal wall. The potential sites from which the pedicled bulbocavernosus Martius-type flap are obtained are illustrated in **Figure 44.30**. Initially, an incision is made in the vagina to separate the scarred vagina from the underlying anterior wall of the rectum circumferentially. The edge of the scarred vaginal epithelium adjacent to the edge of the rectal mucosa is excised in anticipation of this being the site of the initial suture line approximating the squamous epithelium from the vulvar flap to the rectum in order to fill the defect in the rectum. With a Mayo scissors, a subcutaneous tunnel is made from the labium majus to the fistula under the labium and vaginal mucosa (**Fig. 44.31**). The free end of the muscle is guided through the subcutaneous tunnel with a single absorbable suture placed along its edge to assist in passage through the tunnel. The rectal defect is such that it cannot be closed primarily. Thus, the edge of the squamous epithelium from the vulvar graft is sutured to the edge of the rectal mucosa with 4-0 delayed absorbable sutures. Occasionally, a Schuchardt incision is required in the vagina to obtain adequate exposure for the dissection.

The pedicled graft is used to close the fistulous defect, beginning at the 3-o'clock position, in a synchronous fashion such that the entire edge of the fistulous tract is in immediate proximity to the edge of the skin from the vulva (**Fig. 44.32**). Once in place, the muscle and subcutaneous tissue of the graft are sutured to the surrounding connective tissue.

FIGURE 44.30 Proposed sites to harvest the skin and subcutaneous tissue in preparation to fill hole of rectovaginal fistula. (Adapted from Lee RA. *Atlas of gynecologic surgery*. Philadelphia, PA: WB Saunders, 1992. By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

FIGURE 44.31 Mobilization of the bulbocavernosus muscle with overlying fat pad. (Adapted from Lee RA. *Atlas of gynecologic surgery*. Philadelphia, PA: WB Saunders, 1992. By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

To provide coverage for the exposed Martius flap, which has been inserted as a plug into the rectum, a similar pedicled graft is developed from the patient's right side; this is placed so that the skin of the vulva is approximated to the skin of the vagina (**Fig. 44.33**). The edges are placed such that there is no exposed source for granulation tissue (**Fig. 44.34**).

A small suction catheter is placed between the two pedicled grafts and brought out through a stab wound lateral to the perineal incision. The vulvar incision is closed in layers and the skin approximated with fine interrupted delayed absorbable suture. In patients requiring a pedicled graft, the repair may result in a narrowing of the vagina and a degree of stenosis. This results not only from the encroachment on the vaginal lumen by the pedicled grafts but also from the associated contracture caused by the underlying cause of the fistula: pelvic radiation. There is a tendency for further contracture and stenosis of the vagina, which may result in significant dyspareunia or apareunia. These potential outcomes should be carefully discussed with the patient and her family prior to attempted surgical correction of a radiation-induced rectovaginal fistula.

Sigmoidovaginal Fistula: Sigmoid Resection with Sigmoidorectostomy

Fistulae between the sigmoid colon and vagina occur infrequently, but the overwhelming majority result from diverticulitis of the sigmoid colon (**Fig. 44.35**) in a patient who has previously had a hysterectomy. Generally, the sequence of events consists of the patient experiencing repeated bouts of acute diverticulitis that finally result in perforation of a diverticulum and abscess formation with a fistulous tract communicating to the vagina. Passage of fecal material or gas through the vagina in the absence of a rectal communication should lead one to suspect

a fistula arising from the sigmoid colon or small intestine. A proctoscopic examination should be done, although often it is impossible to visualize the fistulous orifice because of narrowing or fixation resulting from the inflammatory condition. Surgical intervention is indicated for a sigmoidovaginal fistula that is large enough to permit the passage of fecal material. In a few selected patients, a colostomy may be the only treatment, or the fistula may be divided and the sigmoidal defect closed with or without a temporary colostomy. In the overwhelming majority of patients, we prefer a sigmoid resection with primary anastomosis and closure of the opening into the vagina. The need for a temporary protective colostomy is determined on an individual basis.

Hartmann Procedure

Under some circumstances, the infected, inflammatory process is such that the sigmoid mass may be excised, but a primary anastomosis is ill advised. It may be more appropriate to excise the diseased colon and close the fistula in the vagina, leaving the defunctionalized rectal stump in the pelvis for later reanastomosis ([Fig. 44.36](#)). Omentum and a suction drain are usually placed over the stump. The distal end of the descending colon is brought out as a colostomy, which is matured at the initial surgical procedure. Later, usually after 2 to 3 months, reoperation can be done through the previous incision. Placement of a gauze pack in the vagina and an EEA sizer in the anal stump will help to identify these structures. Once identified, the descending colon is freed from the splenic flexure in a sufficient fashion to permit the primary descending colorectostomy in a noninfected field as a closing step in this two-stage procedure.

oversewn site of sigmoidovaginal fistula. (Adapted from Lee RA. *Atlas of gynecologic surgery*. Philadelphia, PA: WB Saunders, 1992. By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

SUMMARY

The management of the anally incontinent patient is a complex undertaking whether that incontinence is transanal or extraanal through a rectovaginal fistula. Care must be taken in the assessment and diagnosis of these patients with testing judiciously used where it will provide clinically useful information. Because surgical results in anally incontinent patients are less than perfect, consideration should be given to initially trying nonsurgical management. In those who fail conservative therapy, and in those who go directly to surgical therapy, a thoughtful preoperative workup with extensive preoperative counseling regarding expectations and possible outcomes is crucial for the ultimate satisfaction of the patient. Surgery for anal incontinence and rectovaginal fistula repair requires thorough surgical planning, careful attention to detail, and a meticulous operative technique to provide the patient with optimal results.

BEST SURGICAL PRACTICES

- Preoperative evaluation of the anally incontinent patient should include a careful assessment of her symptoms and their impact on her quality of life.
- Success rates of surgical procedures for anal incontinence, especially as they relate to specific diagnoses, should be explained preoperatively to patients. Patients need to understand that results are rarely perfect and even good results may deteriorate with time.
- Consideration should be given to the use of nonsurgical therapy including diet and lifestyle modification before a decision for surgery is made. Physicians must keep up to date regarding newer, nonsurgical options that may be available.
- Judicious use of preoperative testing can aid in the diagnosis of the etiology of incontinence and thus provide assistance when advising patients about prognosis especially as it relates to surgery.
- Mechanical bowel preparation, perioperative antibiotic prophylaxis, and attention to postoperative diet and stool consistency management seem to be important but not well studied or defined.
- The anal sphincteroplasty is the most important part of any perineal reconstruction for the patient with anal incontinence.
- Current data remain unclear as to whether overlapping sphincter repair may yield greater functional improvement than an end-to-end sphincter reapproximation.
- Rectovaginal fistula repair requires careful attention to sharp dissection, gentle tissue handling, wide mobilization, meticulous hemostasis, and a tension-free closure.

ACKNOWLEDGMENTS

The author would like to acknowledge the continued valuable contributions of the previous authors of this chapter, Drs. Raymond Lee and Michael Aronson, and also thank Soumia Brakta, MD, and Teuta Shemshedini, MD, for their assistance with this new edition.

Chapter 45

Diseases of the Breast

Joseph L. Kelley III
Paniti Sukumvanich

DEFINITIONS

Axillary lymph node dissection—Surgical removal of lymph nodes from the pyramidal space in the axilla. The extent of dissection is defined in relationship to the pectoralis minor muscles: level I nodes lateral, level II posterior, and level III medial to this structure. Modern dissection involves the level I and level II nodal groups.

BRCA—One of two tumor suppressor genes (BRCA1 and BRCA2) that, when mutated, are associated with an increased risk of breast and ovarian cancer.

Breast-specific gamma imaging (BSGI)—Imaging modality in which technetium-99m (^{99m}Tc) sestamibi is used to highlight areas of increased metabolic activity in the breast to delineate possible areas of carcinoma from normal tissue.

Computer-aided detection (CAD)—Computer-based algorithms used in the second reading of mammographic films to increase sensitivity and reduce false-negative rates.

Diagnostic mammogram—Imaging utilized when a woman presents with symptoms, which may include multiple views and immediate interpretation by a radiologist. Additional testing, including sonography, tomosynthesis, magnetic resonance imaging (MRI), and percutaneous tissue sampling, may be advised at the radiologist's discretion.

Digital mammogram—An imaging technique that stores an x-ray image as a data file. This technique allows for digital magnification, manipulation of the image contrast, facilitation of storage, and use of telemedicine.

Ductal carcinoma in situ (DCIS)—Carcinoma of the lactiferous ducts that has not spread beyond the basement membrane; several subtypes and histologic grades exist.

Ductogram (galactography)—Contrast-enhanced mammographic imaging of the breast used in the evaluation of nipple discharge. The technique involves cannulation of duct openings in the nipple and injection of contrast dye.

Fibrocystic lesions—Spectrum of benign histopathologic changes in the breast associated with stromal fibrosis and with variable degrees of intraductal epithelial hyperplasia and sclerosing adenosis.

Fine needle aspiration (FNA) biopsy—Percutaneous sampling in which a cytologic specimen is obtained for analysis. This is accomplished through suction applied to a syringe and a fine needle. This can be therapeutic in drainage of a benign cyst and diagnostic in the evaluation of solid masses.

Intraductal papilloma—A benign hyperplastic breast mass within the duct that may present with spontaneous unilateral bloody nipple discharge; can be solitary when in the central ducts and multiple when located in the periphery of the breast.

Lobular carcinoma in situ (LCIS)—Also known as lobular intraepithelial neoplasia (LIN). A benign lesion characterized by distortion of the terminal ductal lobular unit with small cells. This entity is not a malignancy; rather, it is a risk factor for the development of breast cancer in either breast.

Magnetic resonance imaging (MRI)—Noninvasive imaging technique that generates computerized images of internal body tissues and is based on nuclear magnetic resonance of atoms within the body induced by the application of radio waves. A large magnet polarizes hydrogen atoms in the tissues and then monitors the summation of the spinning energies within cells.

Nipple-sparing mastectomy—Surgical removal of the breast, generally through an inframammary incision with preservation of the nipple-areolar complex. Generally reserved for patients undergoing prophylactic surgery but can be used in select circumstances for patients with known malignancy.

Microcalcifications—Calcium deposits visible on the mammogram that may appear alone or in clusters. To judge the likelihood of malignant change, a radiologist uses the shape and appearance of the clusters. Pleomorphism and clustering are concerning findings that warrant additional investigation.

Modified radical mastectomy—Surgical removal of the breast, pectoralis fascia, and axillary lymph nodes (generally levels I and II) with preservation of the pectoralis major muscle.

Paget disease—Changes in the nipple-areolar complex often mistaken for eczema, dermatitis, or mastitis. The condition is associated with an underlying malignancy of the breast, either an invasive or noninvasive cancer.

Partial mastectomy—Also known as "lumpectomy" or "segmental mastectomy." Surgical procedure in which only the portion of the breast in which the cancer is located is removed, along with a margin of normal breast tissue.

Percutaneous core biopsy—Percutaneous sampling using a hollow needle with or without vacuum assistance in which a cylindrical portion(s) of tissue is obtained for histologic analysis.

Positron emission mammography (PEM)—Imaging technique involving a pair of gamma radiation detectors placed above and below the breast to detect high metabolic activity via gamma ray emission after administering 18-fluorodeoxyglucose (¹⁸FDG) and identify probable sites of carcinoma.

Quadrantectomy—A procedure in which a full quadrant of the breast containing the tumor is excised with or without the overlying skin.

Radical mastectomy—En bloc removal of the breast tissue, associated skin, nipple, areola, axillary lymph nodes, and the underlying pectoralis major and minor muscles.

Screening mammogram—Traditional two-view images of each breast in asymptomatic women performed annually beginning between the ages of 40 and 50 years and continued as long as the woman is in good health.

P.1004

Sentinel lymph node biopsy/mapping—Currently considered conventional treatment of the axilla in breast cancer patients without clinical or radiographic evidence of nodal involvement. The surgeon uses a visible blue dye and/or a radioisotope tracer to identify the key lymph node(s). These lymph nodes are used to predict the status of the nodal basin and help direct additional therapy.

Skin-sparing mastectomy—Surgical removal of the breast through a small periareolar incision maintaining the majority of the skin envelope.

Stereotactic needle biopsy—Use of mammogram images taken at two angles to map in three dimensions the location of lesions or microcalcifications. The patient lies prone on a dedicated table, and an automated core needle or vacuumassisted device is used to biopsy the tissue.

Thermography—Imaging technique in which cutaneous temperatures of the breast and infrared radiation from the breast are measured through electronic detectors to aid in the diagnosis of breast disorders.

TNM staging—A system of clinicopathologic evaluation of tumors based on the extent of tumor involvement in the primary site (T), lymph nodes (N), and metastasis (M).

Tomosynthesis—Three-dimensional mammography in which multiple images of the breast are obtained by arcing the x-ray source around the breast. In this manner,

multiplanar images are obtained that can enhance detection of masses within dense breast tissue that can be missed by conventional mammography. Other benefits include more accurate sizing, shape, and location of lesions. The digital nature of the technique may result in less radiation exposure.

Total (simple) mastectomy—Surgical removal of the breast tissue and associated skin, nipple, and areola without removing the underlying muscle.

Transverse rectus abdominis myocutaneous (TRAM) flap— Muscle flap procedure using the transverse rectus abdominus muscle as a method of breast reconstruction. The flap may remain attached to its blood supply (rotational flap) or reanastomosed to regional blood vessels (free flap).

Triple test—Correlation of the results of the breast physical examination, imaging, and tissue sampling technique to determine the malignant potential of a lesion. In instances in which a lesion is believed to be benign, all three results must be concordant or surgical excision must be performed.

Ultrasound (sonography)—Imaging technique for the breast that uses high-frequency soundwave transmission to aid in identification of breast lesions.

INTRODUCTION

Breast cancer is the most common cancer in women and, after lung cancer, is the second leading cause of cancer-related death. Data from the Centers for Disease Control and Prevention estimate 232,670 breast cancer diagnoses and 40,000 related deaths in 2014. The commonly reported statistic is that 1 in 8 women will develop breast cancer in their lifetime.

As providers of primary health care to women in all phases of their life, the obstetrician-gynecologist can be instrumental in the management of breast health concerns. The American Congress of Obstetricians and Gynecologists (ACOG) advocates for the obstetrician-gynecologist to have a working knowledge of the diagnosis of breast disease and cancer, to advise patients to perform self-breast examination, and to refer patients for screening mammography. These recommendations have resulted in increased ability to detect breast diseases and cancer. In the event of a malignant diagnosis, the obstetrician-gynecologist should be able to counsel the patient concerning the general treatment of the disease and facilitate a smooth transition to a breast cancer specialist. The Society of Gynecologic Oncology recently has recognized the expanding role of their specialty in the management of breast cancer. Several fellowship programs now include one additional year of training in the management of breast cancer and allied diseases. The American Board of Obstetrics and Gynecology Guide to Learning in Gynecologic Oncology indicates fellows are expected to have a working knowledge of breast diseases and be able to advise patients with regard to incidence of breast cancer, high-risk lesions, staging of the disease, and the role of multimodal therapy in the management of the disease process.

This chapter discusses basic strategies for the evaluation, diagnosis, and treatment of both benign and malignant breast diseases. The multidisciplinary approach for the evaluation of breast cancer is addressed, including surgical, radiotherapeutic, and adjuvant medical management.

EMBRYOLOGY

The mammary glands are specialized skin derivatives of ectodermal origin. During the 4th week of gestation, a pair of ectodermal thickenings—also known as the mammary ridges or milk line—form on the ventral surface of the embryo and extend in a curvilinear fashion from the axilla to the medial thigh. During the 5th week of gestation, an ingrowth of the ridge in the pectoral region at the fourth intercostal space occurs and forms a primary tissue bud. The remaining milk line regresses. Failure of regression of the milk line can lead to accessory nipples (polythelia) or breasts (polymastia) (Fig. 45.1). Subsequently, over the course of weeks, 15 to 20 secondary buds develop and become the breast lobules.

FIGURE 45.1 Mammary milk line.

TABLE 45.1 Tanner Stages of the Breast		
STAGE	AGE	CLINICAL FINDINGS
I	Prepubescent	Elevation of the nipple without palpable glandular tissue or areolar pigmentation
II	11 ± 1.1 y	Presence of glandular tissue in the subareolar area. Nipple and breast project as single mound. Areola darkens.
III	12.2 ± 1 y	Increased amount of breast tissue. Widening of the areola and single plane between nipple/areola and the breast

IV	13.1 ± 1.2 y	Enlarging of areola, increasing pigmentation. Nipple-areolar complex forms a secondary mound above the breast.
V	15.3 ± 1.7 y	Mature adult breast. Breast covers most of the chest wall. Secondary mound disappears and nipple projects.

From Tanner J. *Wachstum und Reifung des Menschen*. Stuttgart, Germany: Georg Thieme Verlag; 1962; Tanner J. Physical growth and development. In: Forfar JO, Arnell GC, eds. *Textbook of paediatrics*. Edinburgh, Scotland: Churchill Livingstone; 1984:292.

Lactiferous ducts form at approximately the 20th week as a result of luminae that develop within the buds. At term, there are 15 to 20 breast lobes and associated lactiferous ducts. The ducts drain into ampullae located beneath the developing nipple-areolar complex. The nipple forms as a result of mesenchymal proliferation and the formation of circular and longitudinally oriented smooth muscle fibers.

In both the male and female neonates, the breast contains radially arranged breast lobes that drain into the nipple via the lactiferous ducts. The female breast undergoes rapid changes, known as thelarche, during puberty. Exposure to rising levels of estrogen and progesterone induces changes in the ductal epithelium and breast acini. Other circulating agents, including growth hormone, cortisol, insulin, thyroxine, and prolactin, help the breast achieve complete functional status. To gauge pubertal development of the breast, Tanner staging can be assessed. [Table 45.1](#) lists staging criteria. Failure to progress in accordance with established criteria can help identify hormone deficiencies and lead to early evaluation and treatment.

ANATOMY

The mammary gland is a modified sweat gland and is an accessory to reproduction in the female. The breast is located between the second rib and the sixth intercostal space in the vertical axis and extends horizontally from the sternum to beyond the anterior axillary fold. A portion of the breast—the axillary tail of Spence—extends into the axillary basin. It has a dome shape with a conical contour in a nulliparous female and may become pendulous in the mature or parous individual. The gland is composed of skin, subcutaneous tissue, epithelial glandular structures, and supporting stroma ([Fig. 45.2](#)).

FIGURE 45.2 General anatomy of the breast.

P.1006

The breast is composed of 15 to 20 lobes with each lobe being an irregular, flattened pyramid of glandular tissue with the apex directed toward the nipple-areolar complex. From each lobe, a single lactiferous duct extends to the nipple. Within the lobes, these ducts have multiple divisions beginning with branches to 20 to 40 lobules and subsequent branching to 10 to 100 alveoli units. The ducts, referred to as the lactiferous sinuses, are 1 to 2 mm in diameter but dilate to 4 to 5 mm beneath the nipple-areolar complex. The lactiferous sinuses drain to collecting ducts that have openings within the nipple ([Fig. 45.3](#)). Nomenclature for the epithelial system is highlighted in [Table 45.2](#).

The stroma consists of connective tissue, adipose tissue, blood vessels, nerves, and lymphatics. The superficial pectoral fascia envelops the entire gland. The superficial pectoral fascia is in continuity with superficial fascia of the abdominal wall (Camper fascia). The posterior surface of the breast abuts the deep pectoralis fascia.

The nipple and areola are pigmented, covered with keratinized squamous epithelium, and contain smooth muscle fibers, which causes wrinkling of the skin and associated with nipple erection. Within the nipple are two receptor-type nerve endings, Ruffini-like bodies and bulb of Krause, that detect tactile stretch and pressure. The areola has sebaceous and apocrine sweat glands and accessory areolar glands also known as Montgomery glands. In the latter, these glands open onto the areola as small elevations known as Morgagni tubercles.

The major muscles proximate to the breast and axilla include the pectoralis major and minor, serratus anterior, and the latissimus dorsi. The pectoralis major has two parts: the clavicular portion and the sternocostal portion. This muscle forms the fullness of the upper chest and helps flex and adduct the arm. Innervation is from the medial (C8, T1) and lateral pectoral nerves (C5, C6, and C7) that course from the brachial plexus and are named based on their cord of origin rather than anatomic location. The pectoralis minor arises from the third, fourth, and fifth rib and inserts into the coracoid process of the scapula. Motor function is from the medial pectoral nerve (C8, T1). The serratus anterior muscle arises from the first eight ribs and inserts into the vertebral border of the scapula on its costal surface. It is innervated by the long thoracic nerve of Bell

P.1007

that originates from the posterior roots of C5, C6, C7, and C8 of the brachial plexus. This nerve traverses the posterior aspect of the axilla and courses along the superficial aspect of the fascia of the serratus anterior. Injury to the nerve leads to the clinical presentation of a "winged" scapula and impairment of the shoulder.

TABLE 45.2 Nomenclature of the Breast Epithelial System

MAJOR DUCTS	TERMINAL DUCTS
Collecting ducts	Extralobular
Lactiferous sinuses	Intralobular
Segmental ducts	Lobules
Subsegmental ducts	Alveoli
Terminal duct-lobular unit	

From Osborne MP. Breast anatomy and development. In: Harris LM Jr, Morrow M, Osborne CK, eds. *Diseases of the breast*. Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins; 2010:1-11; and Woodburne R. *Essentials of human anatomy*. New York, NY: Oxford University Press; 1979.

FIGURE 45.3 Internal structure of the breast. The breast is a large apocrine gland. The secreting parenchyma is composed of lobules containing acini, fat, and fibrous tissue. The ducts drain centrally toward large lacunae located directly beneath the nipple.

FIGURE 45.4 Lymphatics and blood supply of the breast. Over 97% of lymphatic drainage from the breast is to the axillary nodal basin.

The blood supply to the mammary gland is primarily derived from the internal mammary artery and the lateral thoracic artery. The anterior perforating branches of the internal mammary artery supply the medial and central breast, whereas the lateral thoracic artery supplies the upper outer portion of the gland. Additional vascular supply is derived from branches of the thoracoacromial, intercostal, subscapular, and thoracodorsal arteries ([Fig. 45.4](#)).

Venous drainage follows the course of the superficial and deep arterial supply. The medial quadrants primarily drain to the internal thoracic vein, whereas the lateral quadrants drain via branches of the axillary vein and posterior branches of the intercostal vein.

Over the past decade, the routine use of sentinel lymphatic mapping in the treatment of breast cancer has significantly enhanced the understanding of lymphatic drainage of the mammary gland. The subepithelial lymphatic plexus is confluent with the subepithelial plexus over the surface of the body. These vessels merge with the subdermal lymphatic vessels and drain to Sappey plexus beneath the nipple-areolar complex. Lymph then flows through these valveless ducts in only one direction into lymphatics along the lactiferous ducts to the perilobular and deep subcutaneous plexus. Lymph flow then moves in a centrifugal manner toward the axillary and internal mammary nodes. Approximately 97% of the drainage is to the ipsilateral axilla with the remaining 3% of the effluent to the internal mammary nodes.

Approximately 20 to 30 lymph nodes are located within the axillary basin. They consist of five subgroups denoted by their relationship to the axillary structures. The subgroups include the *apical nodes* located medial to the pectoralis minor muscle, the *axillary vein group* located along the axillary vein extending from the pectoralis minor muscle to the lateral extent of the vein, *interpectoral (Rotter) nodes* located between the pectoralis major and minor muscles, the *scapular group* located along the subscapular vessels, and the *central nodes* located beneath the lateral border of the pectoralis major muscle. An alternative approach to the nodal basin nomenclature is to divide the nodal groups into three levels in relation to the pectoralis minor muscle. Level I nodes are lateral to the lateral border of the pectoralis minor muscle, level II nodes are located beneath this muscle, and level III nodes are located medial to the medial border of the pectoralis minor muscle ([Fig. 45.5](#)).

FIGURE 45.5 Axillary lymph nodes and level designations. Axillary lymph node levels according to the AJCC. 1: low axillary, level I; 2: midaxillary, level II; 3: high axillary, apical, level III; 4: supraclavicular; 5: internal mammary nodes. (Reprinted from Husarik DB, Steinert HC. Single-photon emission computed tomography/computed tomography for sentinel node mapping in breast cancer. *Sem Nucl Med* 2007;37(1):29-33, with permission. BREAST HEALTH ASSESSMENT

An intake history should be obtained in which the patient describes her concerns. Care should be taken to elicit information that can help identify a woman at risk for breast cancer.

Breast cancer cannot be excluded by any single fact within the patient's history; rather, the history can help focus attention on risk factors for the development of breast cancer. The practitioner should obtain detailed information about the patient's symptoms and other pertinent related positive and negative signs or concerns. Age, menstrual status, use of oral contraceptives, and postmenopausal hormone replacement therapy (HRT) (including the regimen and duration) are important parts of risk assessment. A detailed family history spanning three generations on both the maternal side and paternal side may identify an individual with a possible genetic predisposition. It is important to elicit and document the timing and specific nature of the concerns, whether any cyclic changes have occurred, change in site, and the presence of pain.

All previous breast diagnostic and surgical procedures should be documented. Past medical and surgical history, current medications, and social history (including tobacco use, alcohol intake, and educational level) should also be reviewed.

In the past, the traditional approach for early detection of breast cancer used a combination of breast self-examination (BSE), clinical breast examination (CBE), and mammography. For women with average risk of breast cancer, current guidelines from the American Cancer Society (ACS), the American Congress of Obstetricians and Gynecologists (ACOG), and the U.S. Preventive Services Task Force (USPSTF) are shown in [Table 45.3](#). Both ACS and ACOG advise annual mammography beginning at the age of 40, CBE beginning in the 20s, and BSE beginning at age 20. Both groups encourage women to know what their breasts look and feel like and promptly report any changes to their health care providers.

BREAST EXAMINATION

Traditionally, BSE and CBE have been considered important facets of a breast screening program. Controversy surrounds the use of both of these physical examinations.

Breast Self-Examination

Recently, the role of BSE has been called into question, as it has been associated in two major studies with increased rates of radiographic imaging and invasive procedures. Controversy exists regarding the utility of routine BSE for increasing the rate of breast cancer detection. A study from Shanghai involving more than 250,000 women, who were randomly assigned to no instruction or intensive BSE instruction, failed to demonstrate any difference in the number of cancers detected or in the stage or size at which they were found (RR 0.97, 95% CI: 0.88 to 1.06). No reduction in mortality was seen, but more than twice as many benign lesions were found in the BSE group. In breast disease, wherein early detection is so clearly related to improved survival, the value of this relatively simple, economical, and minimally invasive technique cannot be overemphasized. ACOG and the ACS support BSE performed monthly beginning at age 20 as optional approach for early detection.

If BSE is advised, a discussion of the benefits, risks, and limitations for the individual patient should take place. Effective instruction of patients in the technique of BSE incorporates description of the procedure while the patient views the health care provider's performance of the examination. The patient should be encouraged to reiterate her understanding of what has been taught and then demonstrate her mastery of the technique using manufactured breast models to further solidify compliance. The patient should be informed of the significance of breast inspection in various positions and the utility of breast palpation in the standing and supine positions. The circular

P.1009

method of breast palpation using the pads of her fingers is the easiest to master, although for patients with pendulous breasts, positional changes to ensure positioning of the breast tissue on the chest wall must be emphasized. The best time to perform the examination is usually after the week after the end of the menstrual cycle, although menopausal women should pick a convenient time of the month, such as their birth date or the first day of each month. After hysterectomy, patients with continued estrogenic support of the ovaries should observe for breast fullness or tenderness. Breast examination should then be performed 7 to 10 days after cessation of menstrual breast symptoms.

TABLE 45.3 Screening Recommendations for Women at Average Risk

ORGANIZATION	BREAST SELF-EXAMINATION (BSE)	CLINICAL BREAST EXAM (CBE)	MAMMOGRAPHY
American Cancer Society	Women should know how their breasts normally look and feel and report any breast change promptly to their health care provider. BSE is an option for women starting in their 20s.	Annually for women 40 and older Every 2-3 y for women 20-39	Annual mammogram beginning at age 40 and continued as long as in good health
American Congress of Obstetricians and Gynecologists	Breast self-awareness should be encouraged and can include BSE. Women should report any changes in their breasts to their health care providers.	Annually for women 40 and older Every 2-3 y for women aged 20-39	Annual mammogram beginning at age 40 ^{a, b}
U.S. Preventive Services Task Force	Advises against teaching BSE	Insufficient evidence to demonstrate benefits or risks of CBE	Biennial screening mammography between ages 50 and 74 y Insufficient evidence to assess the additional benefits and harms of screening mammography in women 75 y or older Prior to age 50, biennial screening mammography should be an individual one and take patient context into account, including the patient's values regarding specific benefits and harms.

^aWomen should be educated on the predictive value of screening mammography and the potential for false-positive results and false-negative results. Women

should be informed of the potential for additional imaging or biopsies that may be recommended based on screening results.

^bWomen who are estimated to have a lifetime risk of breast cancer of 20% or greater, based on risk models that rely largely on family history (such as BRCAPRO, BODACEA, or Claus), but who are either untested or test negative for *BRCA* gene mutations, can be offered enhanced screening. For women with known *BRCA1/BRCA2* deleterious mutations, enhanced screening should be recommended and risk reduction methods discussed.

Clinical Breast Examination

The CBE is an important part of early detection of breast cancer. The ACS, ACOG, and others recommend CBE beginning in the mid-20s for women at average risk for breast cancer. The USPSTF states that insufficient evidence exists concerning the risk or benefit of this practice. CBE has a sensitivity of 57% to 70% in detecting breast cancer.

Strategies to improve a practitioner's ability to detect a mass include developing a systematic, consistent search mode, increasing the time devoted to the examination, and using a technique with variable degrees of pressure. The more facile and practiced the examiner, the greater the rates of detection of breast lesions.

CBE should be a routine part of the examination of gynecologic and obstetrical patients. Obstetrician-gynecologists should not abdicate their responsibilities by relying on previous examinations performed by other specialists. The practitioner must be mindful of the legal ramifications of errors of omission.

CBE is ideally performed 1 week after the end of the menstrual cycle to diminish the impact of luteal phase breast congestion, which can obscure mass detection. Each portion of the breast examination should be performed with the patient in both the sitting and supine positions because positional changes often expose a lesion that can be masked by the patient's normal anatomy.

The initial part of the examination should focus on breast inspection, viewing for symmetry, skin retraction, rashes, and nipple retraction or deviation (**Fig. 45.6**). Inspection should continue with the patient's arms raised overhead. This allows visualization of the inferior and lateral aspects of the breast. Inspection with the patient placing her hands on her hips while contracting the pectoralis muscles will highlight any changes in the upper quadrants of the breast. In patients with rheumatoid arthritis or other conditions preventing pressure on the hip joint, other more comfortable options may be used. One may have the patient either grasp her fingertips at a level near the waistline while pulling laterally or press her palms together while extended above the head. Because the breast lies on the pectoralis muscle and Cooper ligaments are attached to the muscle and the skin, tension on the muscle accentuates carcinoma invading these structures. An inspection of the breast for nipple retraction or inversion, which can result from either stromal contraction or direct attachment to the tissues beneath

P.1010

P.1011

the nipple, should be performed (**Fig. 45.7**). Nipple inversion can be normal, and if with gentle manipulation eversion occurs, it is considered a normal variant. New onset of nipple inversion is concerning and warrants additional evaluation.

FIGURE 45.6 (1) Examination of the breasts begins with inspection. The patient is disrobed to the waist and comfortably seated facing the examiner. Asymmetry, prominent veins, and skin changes may be signs of disease. (2) The patient raises her arms above her head, thereby altering the position of the breasts. Immobility or abnormal cutaneous attachments may become evident. (3) Inward pressure on the hips tenses the pectoralis major muscle. Abnormal attachments to its overlying fascia and skin can produce retraction or dimpling of the skin. (4) Supraclavicular lymph nodes are examined by palpation. (5) The deltopectoral triangle is palpated for evidence of infraclavicular nodal enlargement. (6) Each axilla is examined for nodal enlargement. Proper placement of the examiner's hands and of the patient's arm is important. (7) Thorough examination of the entire breast for abnormalities is performed with the patient in the supine position. A fine rotational movement of the hands is useful to appreciate the consistency of the underlying tissues. The examiner should check for nipple discharge by compressing the ducts in a clockwise manner toward the nipple. FIGURE 45.7 Nipple inversion due to cancer. (Reprinted from Harris JR, Lippman ME, Morrow M, et al. *Diseases of the breast*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, with permission. Copyright © 2009, Lippincott Williams & Wilkins.)

Inspection of the breast is followed by palpation. The patient should be properly gowned, with only the area being examined exposed. The patient must be positioned (by tilting her hips and torso) to allow the portion of the breast tissue being examined to lie directly upon the chest wall. For patients with pendulous breasts, this may require positional changes for each breast. The pads of the fingers and not the fingertips are the most sensitive and should be used in examination. Three circular motions are made with three levels of pressure (superficial, medium, and firm) on each 1-cm square area of the breast. Not only does this improve mass detection but it also prevents masking a mass through excessive pressure.

The circular pattern is the most frequently used; however, the “vertical-strip” and radial or “wheel and spoke” patterns are acceptable techniques. With the circular method of palpation, the examination proceeds clockwise around the full circumference of the breast at its perimeter and gradually moves inward toward the nipple.

During the vertical-strip search pattern, the provider will begin overlapping circular motions in the axilla extending inferiorly (1 cm at a time) to one to two ribs below the breast tissue. The fingers are then moved inward 1 cm, and the pattern of search is extended superiorly, in a straight line, to the clavicle. This pattern is continued until the sternum is reached. The patient's position may have to be changed several times during this portion of the exam to assure the tissue being examined lies directly upon the chest wall.

The wheel and spoke method requires radially palpating to the clavicle, sternum, and other bony margins and palpating from the nipple or vice versa. Each method should be mastered, as they may be helpful in certain clinical and diagnostic situations, such as patients with large breasts. Regardless of the pattern of breast examination used, the importance of using a consistent and methodical pattern of evaluation and allowing sufficient time for a thorough examination cannot be overemphasized.

Concurrently, the axilla is evaluated for masses. To allow proper assessment of the axilla in the sitting position, the arm should be extended at a 90-degree angle from the chest wall. This maneuver relaxes the area to be examined for a more thorough evaluation. Next, the patient should be placed in a comfortable supine position with her arm—on the same side as the breast being examined—raised above her head to evenly distribute the breast over the chest wall, thereby making its deeper regions of the axillary basin more accessible.

Palpation should extend beyond the actual breast tissue to encompass the supraclavicular and infraclavicular lymph nodes, the area adjacent to the sternum, approximately 1 to 2 cm below the inframammary ridge, and the axillary tail of Spence. In this manner, all the borders of the breast and associated nodal basins are examined. Gentle pressure on the nipple and areolar area can be used to elicit discharge. Excessive breast manipulation can lead to a nipple discharge. Using a milking technique improves the examiner's ability to elicit a nipple discharge. Each quadrant of the breast is “milked” by sliding the fingers from the outer quadrant in a clockwise fashion toward the nipple and documenting the location of any fluid accumulation.

Careful and comprehensive documentation of the history, examination, and disposition of the case should be filed in the patient's record. A clear and legible note should record all findings. The use of a diagram is also helpful ([Fig. 45.8](#)). Although positive or abnormal findings are important, it also is valuable to list negative findings in the medical record.

Radiologic Breast Assessment

Imaging tests of the breast can be considered screening or diagnostic in nature. Screening tests are done in asymptomatic patients, while diagnostic tests are performed in patients with clinical findings such as breast masses, pain, or nipple discharge. Screening tests include mammograms, breast MRI, and tomosynthesis. Screening with breast ultrasounds is not commonly performed and is rarely indicated; however, increasing information suggests benefit from the use of ultrasound when mammography demonstrates dense breast tissue. Diagnostic tests include mammogram, breast ultrasound, breast MRI, tomosynthesis, and breast-specific gamma imaging.

FIGURE 45.8 Breast diagram for documentation.

FIGURE 45.9 Screening mammogram using two views per breast. **A:** Craniocaudal. **B:** Medial lateral oblique views.

Mammography

The most common imaging test used for screening is mammography (**Fig. 45.9A, B**). Albert Salomon published the first study documenting that x-rays can be used to image breast cancer in 1913; however, many decades passed before mammograms were accepted as standard means of imaging the breast. The first randomized controlled trial of breast cancer screening with mammography, the health insurance plan (HIP) study was initiated in the 1960s. The first data were published in 1971; since then, a total of nine major randomized control trials have been completed and reported. A summary is presented in [Table 45.4](#).

It is important to note that these trials have been performed in many countries with varying schedules of screening, study population age, and mammographic technique. The HIP study was one of the few studies in which the control group had no screening mammograms. This study enrolled 62,000 patients aged 40 to 64 years and found that 30% fewer deaths in the study group compared to the control group. A major issue with this study is that the prestudy breast cancer prevalence was unclear in the control group. The screening group underwent examinations at study entry and excluded patients with breast cancer, while the control group did not have equivalent assessment. Whether or not the patient had breast cancer prior to entry into the study was determined retrospectively in the control group; thus, it is possible that the control group had more undiagnosed breast cancer at entry. This bias may favor the screening group with regard to breast cancer mortality rate. Another issue is that the trial used outdated mammographic equipment compared to today's equipment. In Malmö, Sweden, another large randomized controlled trial was initiated in 1976. This trial had two cohorts that were randomized by birth year. This trial enrolled approximately 42,000 patients aged 45 to 69 years who subsequently underwent two-view mammograms every 18 to 24 months for a total of five screening examinations. This study did not find any reduction in deaths between the study and control groups, although a nonsignificant 20% lower breast cancer death rate occurred in the study group for women greater than age 55 years. Lack of a positive finding may have been due to the high number of women in the control group undergoing at least one mammogram (24% for the entire cohort, 35% in women aged 45 to 49 years). Only 70% to 74% of the patients in the study group underwent screening examinations. The Swedish two-county study was a large trial that enrolled patients in two counties in Sweden, Östergötland and Kopparberg. More than 133,000 women between ages 40 and 74 years were enrolled in this study. This trial was different from previous trials in that the four screening intervals were varied by age, every 24 months for women aged 40 to 49 and every 33 months for ages 50 years and older. Data reported after 8, 11, 14, and 20 years of follow-up revealed 30% to 32% fewer breast cancer deaths in the study group compared to the controls. Unlike the HIP and Malmö trials, the Swedish two-county study used a single-view mammogram—a screening test that is not comparable to the current standards of screening mammography in the United States. Another issue with this study is approximately 13% of the control group had mammograms as part of routine care. In Stockholm, Sweden, in 1981, a large trial randomly assigned approximately 40,000 patients aged 40 to 64 years to two rounds of screening every 28 months with a single-view mammogram. The screening group was found to have 29% to 26% fewer breast cancer deaths compared to the controls at 7.4 and 11.4 years of follow-up, respectively. However, these differences were not statistically significant. There were concerns about the randomization methods in this study, and the number of patients in each arm varied significantly. In 1979, a randomized controlled trial was initiated in Edinburgh, United Kingdom, and enrolled approximately 25,000 patients aged 45 to 64 years. The screening strategy consisted

P.1013

P.1014

of a two-view mammogram and clinical breast exam and then annual CBE followed by a single-view mammogram in years 3, 5, and 7. Socioeconomic differences found between the general medical practices were not recognized until the study ended; adjustments were then made for these differences. A nonsignificant 21% reduction in deaths from breast cancer was found between the study and control group. A significant 29% reduction in deaths from breast cancer was noted when breast cancer deaths that occurred 3 years after the end of the study were censored. Only 61% of the screening group underwent screening. A randomized controlled trial performed in Gothenburg, Sweden, in over 51,000 women aged 39 to 59 years randomly assigned participants to five rounds of screening. The screening group underwent a two-view mammogram every 18 months unless a prior screening test indicated that a single-view mammogram was sufficient (this accounted for 30% of the women screened). At 11 years of follow-up, the study group had a 44% statistically significant reduction in breast cancer mortality among women aged 39 to 49 years. Issues with this study included a delay of 3 to 8 months in the end-of-study mammogram in the control group compared to the study group and a complex randomization scheme that resulted in unequal numbers of patients in the study and control groups. Two large Canadian randomized controlled trials, National Breast Screening Study (NBSS) I and II trials, were initiated in 1980. These trials were designed to evaluate the role of screening mammograms in women aged 40 to 49 years and 50 to 59 years, respectively. The NBSS I trial is unique in that it was the first trial designed specifically to test the efficacy of mammographic screening in women younger than 50 years. In this trial, approximately 50,000 patients were randomly assigned to an annual two-view mammogram or CBE for 4 to 5 years. Compliance in the study group was good, with 85.5% of patients undergoing screening mammograms by year 5. In the control group, noncompliance was high: Only 26.4% of patients had at least one mammogram. Surprisingly, this trial revealed more breast cancer-related deaths in the screening group at 7 and 10.5 years of follow-up, 36% breast cancer-related deaths in the study group compared to 14% in the control group. At 11 to 16 years of follow-up, the increase in breast cancer-related mortality persisted, with 7% more breast cancer-related deaths in the study group. The NBSS II study had similar results in the 50-to 59-year-old cohort, with 3% and 2% more breast cancer-related deaths in the study group at 7 and 13 years of follow-up, respectively. There has been much speculation as to why these results have differed from all the other randomized controlled trials. One possible explanation was the statistically significant higher number of advanced cancers in the study group. While this may account for the high death rates, it is not clear why this occurred. Concerns have been expressed with regard to the equipment, technical adequacy of the mammograms, and training of the radiologists. An external independent review found some inadequacy with regard to the mammographic views from 1980 to 1985. The last randomized controlled trial published to date is the UK Age Trial designed to evaluate the role of mammographic screening

starting at the age of 40 years. This trial was unique in that it avoided contamination that can occur by screening episodes after the age of 50 years by starting annual screening at the age of 39 to 41 years and comparing this group to women who were screened beginning at age 50 years. At 10.7 years of follow-up, a statistically nonsignificant reduction occurred in breast cancer mortality in both relative and absolute terms, with a relative risk of 0.83 (95% CI: 0.66 to 1.04) and absolute risk reduction of 0.40 per 1,000 women invited for screening (95% CI: 0.07 to 0.87). The major issue with this trial was that patients underwent a two-view mammogram at entry; subsequent screenings utilized single-view mammograms. The study was stopped early due to funding issues with lower post hoc power analysis than expected (72% vs. 80%).

TABLE 45.4 Randomized Controlled Studies of Screening Mammography

TRIAL	STUDY POPULATION AGE	SIZE OF STUDY GROUP	SIZE OF CONTROL GROUP	INTERVENTION IN STUDY GROUP	CONTROL GROUP	DURATION OF FOLLOW-UP	RELATIVE RISK OF DEATH, SCREENING VERSUS CONTROL (95% CI)
HIP study	40-64	31,092	30,765	Annual two-view MMG and CBE for 3 y	No MMG	18 y	0.71 (0.55-0.93) at 10 y 0.77 (0.61-0.97) at 15 y
Malmö	45-69	21,088	21,195	Two-view MMG every 18-24 mo × 5	Usual care, MMG at the end of the study	12 y	0.81 (0.62-1.07)
Östergötland	40-74	38,405-39,034	37,145-37,936	Single-view MMG every 2 y for women <50 yo × 3 And every 33 mo for women >50 yo	Usual care, MMG at the end of the study	12 y	0.82 (0.64-1.05)
Kopparberg	40-74	38,562-39,051	18,478-18,846	Single-view MMG every 2 y for women <50 yo × 3 And every 33 mo for women >50 yo	Usual care, MMG at the end of the study	12 y	0.68 (0.52-0.89)
Edinburgh	45-64	23,226	21,904	Two-view MMG and CBE, then single-view MMG in years 3, 5, and 7	Usual care	10 y	0.84 (0.63-1.12)
NBSS-1	40-49	25,214	25,216	Annual two-view MMG and CBE for 4-5 y	Usual care	13 y	0.97 (0.74-1.27)
NBSS-2	50-59	19,711	19,694	Annual two-view MMG	Annual CBE	11-16 y (median 13 y)	1.02 (0.78-1.33)
Stockholm	40-64	38,525-40,318	19,943-20,978	Single-view MMG every 28 mo × 2	MMG at year 5	8 y	0.80 (0.53-1.22)
Gothenburg	39-59	21,650	29,961	Initially 2-view MMG then single-view MMG every 18 mo × 4	MMG × 1 3-8 mo after final screen in the study group	12-14 y	0.77 (0.60-1.00)
AGE trial	39-51	53,884	106,956	2-view MMG initially then single MLO view annually	Usual care	10.7 y	0.83 (0.66-1.04)
MMG, mammogram; CBE, clinical breast exam; MLO, medial lateral oblique view.							

Controversies with Regard to Mammographic Screening

There has been much debate over when mammographic screening should be initiated. The main issues with all randomized trials have been the heterogeneity of the type of screening (single-vs. two-view mammograms), length of time between screening exams (range of 12 to 28 months), and variation in the age of the study population. Due to these issues, there have been multiple meta-analyses of the randomized controlled trial data to date, all confirmed that mammographic screening decreased breast cancer mortality rate in patients who were invited for screening. The analysis by Wald and colleagues found a 26% reduction in breast cancer mortality in patients older than 50 years. Hendrick and colleagues found an 18% reduction in mortality rate in patients aged 40 to 49 years. The same authors found a 24% reduction in mortality rate in patients aged 50 to 74 years. The most recent update of the meta-analysis of the Swedish trials found a 21% reduction in breast cancer mortality between the study and control group; however, when various age groups were taken into account, the reduction in breast cancer mortality was not significant in patients younger than 50 years. In a 2004 meta-analysis of all the randomized controlled trials, Smith and colleagues found a 20% reduction in breast cancer mortality in women aged 40 to 74 years, a 15% reduction ($P < 0.05$) in women aged 40 to 49 years, and a 22% reduction ($P < 0.05$) in women aged 50 to 74 years. Given that many women who were invited to have mammographic screening did not have any screening done, the authors went on to analyze the actual effect of having a mammographic screen. When the results were analyzed only for women undergoing screening, the overall effect of mammographic screening was even higher, with a 40% reduction in mortality. Recently, the National Cancer Institute applied mathematical modeling with regard to outcomes of mammographic screening using six models with varying assumptions. All the models found that screening starting at the age of 40 years will lead to reductions in breast cancer mortality from 2% to 10% (median 3%) with annual mammographic screening. This would result in one breast cancer-related death averted per 1,000 women screened and 33 life years gained per 1,000 women. The life years gained per 1,000 women was lower at 25 years if biennial screening was done, but there was a reduction of approximately 50% in false-positive rates and unnecessary biopsies.

Overall, these data suggest that screening starting at the age of 40 years leads to reductions in breast cancer mortality rates but at increased cost. The National Cancer

Institute (NCI) mathematical models suggest there would be approximately 1,250 false-positive results per 1,000 women screened. This has the potential to lead to approximately 88 unnecessary biopsies per 1,000 women. There is also a risk of radiation-induced mortality. It is estimated that that risk of radiation-induced breast cancer death is about 0.22 to 0.50 per 1,000 women screened. With regard to absolute benefit-to-risk ratio, screening starting at age 40 years would still be expected to be of benefit; 1,894 women would need to be screened to prevent one breast cancer-related death, and one radiation-induced breast cancer-related death would likely occur per 6,456 women screened. The recent recommendation from the USPSTF states that screening should start at age 50 years and be conducted biennially. Although starting breast cancer screening at age 40 may result in increase in life years gained, the most efficient means of reducing the breast cancer mortality rate on the analysis of the ratio of benefits to screening exams was to start to screening at

P.1015

age 50 years; hence, this was the basis for the recommendation. Additionally, biennial screening examinations maintained 81% of the benefit compared to annual exams while reducing the number of false-positive exams by nearly 50%. These recommendations are controversial as breast cancers in women younger than age 50 years are thought to be more aggressive and faster growing; thus, a biennial screening schedule may be too long. A recent analysis of the Surveillance, Epidemiology and End Results (SEER) database found that the biennial screening interval was associated with an increased risk of late stage disease (odds ratio 1.35, 95% CI: 1.01 to 1.81). Another study attempted to use the SEER database to evaluate the effect of screening mammogram on breast cancer incidence between 1976 and 2008. The authors found a significant increase in the number of early-stage breast cancer cases (112 to 234 cases per 100,000 women, i.e., absolute increase of 122 cases), while there has been a decrease of 8% in the number of late-stage disease (decrease of 102 to 94 cases per 100,000 women, i.e., absolute decrease of 8 cases). The authors concluded that only 8 of the 122 additional cases were expected to progress to advanced cancer; therefore, screening mammograms may be leading to an overdiagnosis of breast cancer. The main issue with this paper is that the SEER database does not record how the cancers were diagnosed or who within this dataset had screening mammograms. In a different analysis, the authors looked at the utility of mammographic screening in absolute numbers (Fig. 45.10). In this analysis, one life may be extended per 1,700 to 5,000 women screened and followed for 15 years for women aged 50 to 70 years. The same analysis would predict that one or two lives may be extended per 5,000 to 10,000 mammograms in women aged 40 to 49 years. Recommendations from various national organizations are highlighted in Table 45.5. All of these various screening recommendations are reasonable with varying risks and benefits.

FIGURE 45.10 Outcome of screening evaluation in women aged 40 to 49 (A) and 50 to 70 (B).

Breast Magnetic Resonance Imaging for Screening

Breast magnetic resonance imaging (MRI) is typically used for diagnostic evaluation, that is, workup of breast masses or physical findings (Fig. 45.11). The best data for using breast MRI as a screening test come from studies in high-risk populations. In 2004, Kriege and colleagues reported on 1,909 women at high risk for breast cancer (358 of whom were

P.1016

carriers of germline mutations) who were screened with both breast MRI and mammograms. The authors found that the sensitivities of mammography and MRI in detecting breast tumors were 33.3% and 79.5%, respectively. It is important to note that while breast MRI sensitivity is higher than that of mammography, the tests were considered complementary as some breast cancers that were missed by breast MRI were detected by mammography. The overall sensitivity of testing was higher when the results of both tests were used, resulting in a combined sensitivity of 88%. This study demonstrated breast MRI had lower sensitivity for picking up DCIS compared to mammography (17% vs. 83%, respectively). A large study in Canada found that breast MRI was more sensitive than was mammography in the high-risk population. In this study, 236 women underwent screening with breast ultrasound, mammography, and MRI all on the same day. The authors found that breast MRI was the most sensitive test at 77% followed by mammography at 36% and ultrasound at 33%. Again, these tests appeared to be complementary as the sensitivity was improved to 95% when results from all three modalities were combined. Other studies have confirmed these results, and at present, the addition of breast MRI as part of a screening regimen is recommended for patients at high risk for developing breast cancer. The American Cancer Society's most recent guidelines state that women should undergo screening with breast MRI if they have a BRCA1 or BRCA2 mutation or have a first-degree relative (parent, sibling, child) with a BRCA1 or BRCA2 mutation (even if they have yet to be tested themselves), if their lifetime risk of breast cancer has been scored at 20% to 25% or greater based on one of several accepted risk assessment tools for evaluating family history and other factors, if they have received radiation to the chest between the ages of 10 and 30, if they have a male relative with history of breast cancer at any age, or if they have Li-Fraumeni syndrome, Cowden syndrome, or Bannayan-Riley-Ruvalcaba syndrome or may have one of these syndromes based on history in a first-degree relative. The presence of dense breast tissue is not a reason for using breast MRI for screening despite the lower sensitivity of mammography in these patients. It may be reasonable to use breast MRI as a screening test for women with a personal history of lobular carcinoma of the breast as these cancers are difficult to detect via mammography. Another scenario in which screening with breast MRI may be appropriate is in women whose original cancer was not visible on mammography.

TABLE 45.5 Screening Guidelines by Various Organizations

ORGANIZATION	INITIAL AGE FOR MAMMOGRAMS	UPPER AGE LIMIT FOR MAMMOGRAMS	SCHEDULE FOR MAMMOGRAMS	CLINICAL BREAST EXAMS	SELF-BREAST EXAMS
American Congress of Obstetricians and Gynecologists (ACOG)	40 years old	75 years old (older than 75 should be based on patient's life expectancy)	Annually	Aged 20-39 every 1-3 y Aged 40 and older annually	Recommended
American Cancer Society	40 years old	No upper limit (continue as "long as a woman is in good health")	Annually	Optional for women older than 20 years old	Recommended

National Comprehensive Cancer Network	40 years old	No upper limit (patient's "overall health and estimated longevity" should be taken into consideration)	Annually	Recommended	Recommended
National Cancer Institute	40 years old	No statement on upper age limit	1-2 y	Not recommended	No statement
U.S. Preventive Services Task Force	50 years old	74 years old	Biennially	Insufficient evidence	No statement

FIGURE 45.11 Normal MRI of patient at high risk.

Breast Ultrasound

The most common use of breast ultrasound is as an adjunct to mammography. In one analysis of the six studies of screening ultrasounds with a total of 42,838 exams, only 150 (0.35%) additional cancers were only visible via ultrasonography. The largest study to date was performed by the American College of Radiology Imaging Network (ACRIN Protocol 6666). This study enrolled 2,809 women with dense breasts who had elevated risk of breast cancer (i.e., a personal history of breast cancer, lifetime risk >25% by Gail or Claus model, atypical ductal hyperplasia [ADH], atypical lobular hyperplasia [ALH], lobular carcinoma in situ [LCIS], atypical papilloma, presence of BRCA mutation, elevated 5-year Gail model risk, or history of chest radiation). This study found that the addition of screening ultrasound will increase the detection of breast cancer by 4.2 per 1,000 women screened, but will substantially increase the number of false-positive exams. At present, the most common use of breast ultrasound is to further evaluate abnormal findings on mammography and not necessarily as a primary screening tool. It may be of benefit in women with dense breasts; however, the American College of Radiology states that "the addition of ultrasound to screening mammography may be useful for incremental cancer detection." Due to the increase in false-positive rates and decrease in positive predictive value, it is not considered the standard of care for primary screening in women with dense breasts.

Digital Mammography

Digital mammography is a newer technology in which a digital detector is used in place of standard film. The images are then processed by a computer and displayed on a monitor. This results in images with greater resolution that can be easily magnified on a workstation. The contrast can also be adjusted to greater degree than in standard film. The ease in which the images can be manipulated is thought to lead to potential improvements in sensitivity. One of the largest studies to date is the Digital Mammographic Imaging Screening Trial (DMIST). The study compared film with digital mammography in over 49,000 women. Overall, the sensitivities of digital versus film mammography were similar (70% vs. 66%, respectively). Digital mammography was found to be 15% to 30% more sensitive for the detection of breast cancer in premenopausal women and in women with dense breasts (improvement in sensitivity from 51% to 55% to 70% to 78%, respectively). In another study that randomly assigned over 25,000 women aged 45 to 69 years old to either digital mammography or film mammography, a higher prevalence of breast cancer was found with digital mammography (0.59% vs. 0.38%, respectively). Recall rates were higher with digital mammography in comparison to film mammography (4.2% vs. 2.5%, respectively), but no difference in positive predictive value was observed between the two types of mammography. Unlike the DMIST trial, overall sensitivity was higher in the digital mammography arm at 77.4% versus 61.5% seen in the film mammography group. At the present time, digital mammography appears to be useful for breast cancer screening especially in younger patients and patients with dense breasts.

Breast Tomosynthesis

Breast tomosynthesis is a modification of digital mammography that utilizes a moving x-ray source and digital detector. This allows for three-dimensional images to be generated using

P.1017

computer algorithms (similar to CT images of the body) that can overcome the limitation of overlapping tissue that can decrease the sensitivity of traditional film mammography. This technique can avoid additional compression views and recall mammograms. A number of studies have compared breast tomosynthesis to routine two-view mammography with the majority of studies consisting of small case series. At the present time, there is no consensus of whether or not the sensitivity of breast tomosynthesis is higher than that of the traditional two-view mammography as some studies have shown decreased sensitivity while others have shown increased sensitivity. Notably, all of these studies demonstrated the specificity of breast tomosynthesis to be higher than that of two-view mammography. In one study, the use of breast tomosynthesis reduced falsepositive recalls by 40%. The best role for breast tomosynthesis may be to use it in conjunction with two-view mammography. When breast tomosynthesis is performed in combination with two-view mammography, superior accuracy can be achieved.

Breast-Specific Gamma Imaging

Breast-specific gamma imaging (BSGI) is a nuclear medicine technique that measures the mitochondrial density of breast tissue through the use of technetium-99m sestamibi as a tracer. It is expected when there is increased mitochondrial density in breast cancer tissue, and by tagging the mitochondria at a cellular level, breast cancers can be detected. This technology is still relatively new in comparison to the other breast imaging techniques, and as such, there are still limited data on its utility. In general, the majority of the studies have found BSGI to have similar sensitivity to that of breast MRI. In one retrospective review, 159 women with a concerning physical exam and/or mammograms underwent additional testing with BSGI to assess for occult disease; BSGI was able to detect additional suspicious lesions in 29% of the women of whom 3% had occult cancer in the contralateral breast. In a study of 146 women at high risk for breast cancer, BSGI was found to have an overall sensitivity of 96.4% and specificity of 59.5%. A more recent study of 149 women also demonstrated a similar sensitivity rate of 98.0%. In one study that directly compared BSGI to breast MRI, the sensitivities were similar (88.8% vs. 92.3%, respectively), but BSGI appears to have improved the specificity to 90% compared to 39.4% in breast MRI. The main advantage of BSGI is that the study does not require the patient to lie in a prone position and it may be easier to perform in a patient with severe claustrophobia. However, the data are limited given the small cohorts in these studies. More studies are needed to determine the true sensitivity and specificity of BSGI to establish its role in breast imaging.

Positron Emission Mammography

Positron emission mammography (PEM) was designed as a way to use typical whole-body PET technology in breast imaging. Whole-body PET scanning is not particularly useful in imaging the breast due to its low resolution. Resolution with PEM is increased through the use of two detectors that are arranged in similar fashion to conventional mammogram. The dye used is the same as that used in PET scans, a positron-emitting isotope of fluorine, ^{18}F -2-deoxy-2-fluoro-D-glucose (FDG). Early small studies of PEM demonstrated sensitivities of 80% to 86%. One of the larger studies conducted in 94 women found that PEM had a sensitivity of 91% and specificity of 93% when interpreted with mammographic and clinical findings. However, the role of PEM in breast imaging requires further investigation; a recent study found PEM to be inferior to breast MRI in detecting contralateral breast cancers.

FIGURE 45.12 Computer-aided detection. Note the highlighted areas of concern. Additional evaluation was normal.

Thermography

This test is designed to measure the skin temperature over the breast, as it is thought that the presence of breast cancer may cause elevated localized skin temperature. No data exist to support the use of breast thermography, and such testing is not supported by guidelines from any major organizations. The U.S. Food and Drug Administration issued a communication in June of 2011 stating that breast thermography is not a replacement for mammography as a means of breast cancer screening and is not considered to be an effective screening tool.

Computer-Aided Detection

Computer-aided detection (CAD) uses software-based artificial intelligence to function as a “second reader” of mammographic films (Fig. 45.12). Second or double reading of films can improve sensitivity but with some loss of specificity. Improved detection rates upward of 15% have been reported but with an associated increase in false-positive or recall rates up to 45%. It functions as a second reader by identifying areas of concern that the radiologist must then characterize. It is estimated that CAD can correctly identify approximately 80% of cancers. Like double reading, CAD was shown to increase sensitivity but with a decline in specificity.

BENIGN PATHOLOGY

Fibrocystic Change

Fibrocystic change (FCC) of the breast is the most frequently encountered benign breast disorder. It occurs most often in women of reproductive age between 30 and 50 years. FCC does not increase the risk of developing breast cancer, but it can make the physical examination of the patient more difficult.

FIGURE 45.13 Histology of fibrocystic changes with extensive cyst formation, stromal hyperplasia, and apocrine metaplasia (H&E 4×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

In 85% to 90% of cases of significant FCC, breast discomfort is the leading symptom. Women often present with a history of bilateral, menstrual-related, painful, tender, and nodular breasts, most often localized to the upper outer quadrants. Typically, the pain is most severe just before menses as a result of the normal physiologic stromal edema and ductal dilation.

FCC encompasses several histopathologic categories, including microcyst and macrocyst formation, hyperplasia of ductal epithelium, apocrine metaplasia, papillomatosis, duct ectasia, sclerosing adenosis (dense fibrotic tissue surrounds the acini), and stromal fibrosis. In essence, it has no single defining histologic entity (**Fig. 45.13**). Providing no atypia is identified, there is no increased risk of developing breast cancer when FCC is present. **Table 45.6** lists benign pathologic findings and subsequent risk of breast cancer development. An explanation of relative risk is provided in **Table 45.7**.

Fibroadenoma

Fibroadenomas are benign tumors that consist of both fibrous and stromal elements. These are common lesions particularly in adolescents but can be seen in woman of all ages particularly prior to menopause. These lesions are thought to represent an exaggerated response to estrogen. Clinically, the patient presents with a palpable mass that is well circumscribed, rubbery in consistency, and often multilobulated. Lesions are generally 2 to 3 cm. They are commonly found in the upper outer quadrant, and in approximately 25% of cases, there are additional lesions that are present in either breast. Imaging modalities can include ultrasound and, if age appropriate, mammography. On sonography, the lesions are avascular and well circumscribed. Mammogram will often detect a solitary nodule with smooth borders with a halo around the mass. In the adolescent population, mammography should be avoided unless the index of suspicion for malignancy exists. Fine needle aspirate or core needle biopsy can confirm the diagnosis. Observation and reassurance are reasonable options for management. Excision should be considered for enlarging masses or discordant imaging or pathology finding or if the patient desires removal. Histologic evaluation demonstrates a well-circumscribed lesion with both epithelial and stromal elements. One or the other element often dominates. The epithelial component has well-defined, glandlike, and ductlike spaces, whereas the stromal component consists of bands of collagen (**Fig. 45.14**).

TABLE 45.6 Breast Lesions and Risk of Developing Invasive Breast Cancer

PATHOLOGY	RR
Nonproliferative changes (cysts, fibrocystic changes, fibroadenoma, adenosis)	No increased risk
Proliferative changes (hyperplasia, sclerosing adenosis, complex fibroadenoma, papilloma)	1.2-2.0
Hyperplasia with atypia (atypical ductal hyperplasia, atypical lobular hyperplasia)	4.0-5.0
Lobular carcinoma in situ	8.0-10.0

Data from Dupont WD, Page DL. Risk factors for breast cancer in women with proliferative breast disease. *N Engl J Med* 1985;312(3):146-151.

TABLE 45.7 Relative Risk

	DISEASE PRESENT	DISEASE ABSENT
Exposed	A	B
Nonexposed	C	D

Relative risk (RR) is a statistical assessment of developing disease as a result of exposure. It is a ratio comparing those exposed who develop the condition compared to those who were not exposed and developed the condition.
 $RR = a/(a + b)/c/(c + d)$

Phyllodes

These fibroepithelial lesions have diverse biologic behavior. Originally, this entity was termed cystosarcoma phyllodes,

but this terminology was deemed confusing as less than 5% of these lesions actually behave in a malignant fashion. Clinically, they are more common in women in their 30s

and 40s, but presentation can mimic fibroadenomas with the findings of a solitary, well-circumscribed, mobile, multilobulated mass with a rubbery to firm texture. Phyllodes tumors tend to be larger and exhibit more rapid growth. Radiographic imaging with ultrasound and mammography can be similar to fibroadenomas. Determination of the diagnosis on percutaneous sampling can be difficult given similarity to fibroadenomas. On gross examination, the lesions can be gray or tan and tend to be plump and fleshy in texture, and a branching pattern can be seen (Fig. 45.15). On histologic inspection of the lesions, they lack a true capsule. A leaflike pattern involving both the epithelial and stromal components is diagnostic (Fig. 45.16). The stromal component determines the grading of the tumor to include benign, borderline, and malignant entities. Stromal cellularity, atypia, pushing or infiltrative borders, and the presence of stromal overgrowth can be useful in evaluating prognosis and predicting behavior. Surgical excision with a margin of normal breast tissue is recommended. Local recurrence rates of 20% have been reported in instances of inadequate margins with less risk of recurrence for those with benign features.

FIGURE 45.14 Histologic section of fibroadenoma with gland formation and well circumscribed by surrounding stroma (H&E 4×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

FIGURE 45.15 Gross picture of phyllodes tumor. Note leaflike pattern, lack of a capsule, and the fleshy nature of the lesion. (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

FIGURE 45.16 Histology of phyllodes tumor. There is increased stromal cellularity, cleft, and leaflike structures and no true capsule (H&E 4×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

Adenomas

Adenomas are well-circumscribed benign lesions primarily composed of epithelium with rare stroma. This distinguishes them from the diagnosis of fibroadenoma. Radiographic imaging findings with ultrasound and mammography can be similar to fibroadenomas. There are two basic types: tubular adenomas and lactating adenomas. Generally seen in young women, tubular adenomas tend to be ovoid with a pseudocapsule and minimal stroma. An inner epithelial layer and an outer myoepithelial layer line the tubules. Clinical presentation is similar to fibroadenomas with a localized well-defined lesion. Lactating adenomas are seen in pregnancy or postpartum state. In these circumstances, there may be more than one lesion. On gross examination, they are tan in color and softer in texture than a tubular adenoma. Microscopically, cuboidal cells with secretory activity line the tubules. Diagnosis of these entities can be made on percutaneous biopsy. Radiographic imaging in a pregnant woman should be restricted to sonography unless a high suspicion of malignancy exists. Additionally, mammographic imaging of the breast of gravid or lactating women will be compromised due to

increased density. Percutaneous or excisional biopsy during pregnancy or lactation is difficult due to increased vascularity. The presence of milk enhances risk of infection and milk fistula formation.

Papilloma

Papillomas are hyperplastic lesions categorized as central (solitary) or peripheral (multiple). Solitary papillomas are found in the major lactiferous ducts and are most often associated with the bloody nipple discharge. These are commonly seen in women between 30 and 50 years of age. They vary in size from a few millimeters to 1 cm, are attached to the duct walls by a thin stalk, and are prone to infarction. Histologically, they are composed of multiple, branching, and interanastomosing papillae arranged around a fibrovascular core. There can be areas of atypia that will classify them as atypical papilloma; on rare occasions, they are associated with DCIS or invasive cancer. From an epidemiologic point of view, solitary papillomas do not appear to markedly elevate the risk of subsequent breast cancer development.

Peripheral intraductal papillomas tend to be multiple and bilateral. The condition affects younger women and is not usually associated with nipple discharge. The condition itself raises the individual's risk of developing breast cancer, suggesting they are subject to malignant transformation.

Atypical Hyperplasia

Atypical hyperplasia encompasses both ADH and ALH. ADH is often found on percutaneous biopsy where the targeted lesion contains microcalcifications. ALH is often an incidental finding without discrete radiographic changes.

On histologic inspection, ADH has a proliferation of uniform epithelial cells with round nuclei filling part of the duct ([Fig. 45.17](#)). ALH has proliferation of monomorphic, evenly spaced cells filling part but not all of the lobules and sometimes the surrounding ducts. Both ALH and ADH share similar architectural and cytologic features with their in situ counterparts.

P.1020

FIGURE 45.17 Atypical ductal hyperplasia (ADH) note proliferation of uniform epithelial cells with round nuclei filling part of the duct (H&E 10×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

When ADH is found on percutaneous core biopsy, the recommendation is for excisional biopsy. Ideally, the site has been previously marked at the time of biopsy with a titanium clip. Utilizing dye, wire, or radioactive seed localization can help the surgeon identify the site of concern. The basis of excisional biopsy is the concern of upgrading to either DCIS or invasive cancer, which occurs in 10% to 20% of cases. Larger core needles and a larger number of cores are associated with a lower incidence of DCIS and invasive cancer at excisional biopsy.

The presence of ADH increases the individual's personal risk of breast cancer (RR 3.7 to 5.5). This is conferred to either the ipsilateral or contralateral breast. Risk reduction strategies including the use of chemopreventative agents and lifestyle modification can be employed.

For ALH found on percutaneous biopsy, a similar approach to the management for ADH is utilized. Recently, the role of additional excision for areas of ALH has been called into question. For some women with concordant mammogram and pathologic findings, additional excision may be unnecessary.

Lobular Carcinoma In Situ

Originally described in 1941 as a rare form of mammary cancer, LCIS is now considered a benign condition. It is histologically characterized by the involvement of terminal duct lobular unit with small cells with round nuclei that distorts these spaces ([Fig. 45.18](#)). The condition tends to be multifocal in the affected breast and often an incidental finding. At the time of this initial report, recommendation for this condition was at least a total mastectomy. Contralateral breast involvement has been reported to be approximately 30%. The condition is often an incidental finding on percutaneous core needle biopsy and has no mammographic or clinical correlate. At times, mammographic microcalcifications can be an indicator of its presence. Average age of diagnosis is between 40 and 50 years. The lesion is associated with increasing an individual's breast cancer risk estimated to be 1% to 2% per year with a lifetime risk of 30% to 40%. The cancer may be ductal or lobular in nature and involve either breast. The term LCIS is often associated with the diagnosis of carcinoma; hence, there have been efforts to group both ALH and LCIS into the term lobular intraepithelial neoplasia (LIN), which accounts for a spectrum of conditions and is graded LIN1, LIN2, and LIN3 depending on morphology and clinical outcome. This classification system has not been universally accepted. Current clinical management of LCIS is individualized and includes the use of observation, chemopreventative agents, and surgical management of bilateral total mastectomy.

FIGURE 45.18 LCIS and infiltrating lobular cancer. The lobule is filled with small, uniform cells with a high nuclear-to-cytoplasmic ratio. Within the surrounding stroma is infiltrating lobular cancer with its typical pattern of linear infiltration (H&E 10×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

COMMON CLINICAL SCENARIOS

Several clinical scenarios occur in the evaluation of a patient for breast-related issues. Patients may present with complaints of a mass or thickening, abnormal mammogram, nipple discharge, or breast pain. Management and workup of each of these clinical scenarios is described below.

Evaluation of a Breast Mass

Many potential causes of breast mass exist, most of which are not related to a breast malignancy. One should always consider the patient's menopausal status during the evaluation of a breast mass. The likelihood that a mass is malignant is based on the patient's history. A thorough history and physical examination should be performed as part of the initial workup of a breast mass. The main point in the history-taking process is to get a sense of how long the mass has been present and whether it fluctuates with her menstrual cycle (if she is premenopausal) or mass has increased in size or whether any trauma to her breast has occurred. Masses that fluctuate with the patient's menstrual cycle are more likely to be benign. Breast trauma leading to fat necrosis can also lead to a breast mass; a commonly overlooked cause of breast trauma is a shoulder strap/seatbelt injury. Surgeries to the breast can cause scarring and fat necrosis that mimics a carcinoma. Patients with a personal history of breast cancer are at risk for recurrence of breast cancer. It is estimated that the risk of recurrence is approximately 0.7% per year and this risk is considered to be cumulative. Careful attention should be paid to the patient's family history and ethnicity. Ashkenazi Jewish patients have higher risks for harboring a BRCA mutation as it is estimated that the baseline risk in this population can be as high as 1 in 40. This risk can increase markedly depending on what age breast cancer is diagnosed. Strong family history with multiple members with breast and/or ovarian cancer also increases the patient's

P.1021

risk for harboring BRCA mutations. [Table 45.8](#) is a summary of the salient points to consider in the history taking process. Enlarging masses are concerning as are masses in patients with strong family histories of breast cancer.

TABLE 45.8 Key Questions in the Evaluation of a Breast Mass

Features of the Mass

- 1. When did the patient first notice the mass (i.e., length of time the lesion has been present)?
- 2. Does the mass seem to fluctuate in size with her menstrual cycle?
- 3. If the mass does not fluctuate with her menstrual cycle, has the mass grown over this period of time?
- 4. Any other masses that she has noticed, any masses in her axilla?
- 5. Any trauma to her breast?

Surgical History

- 1. Any surgical procedures on either breast?

Medical History

- 1. Any personal history of breast cancer?

Family History

- 1. Any family history of breast, ovarian, or colon cancer?
- 2. What is the patient's ethnicity?

A thorough physical examination should be conducted, identifying the location of the area of concern and documenting the size of the mass, the presence of any skin retraction/changes, nipple discharge, presence or absence of axillary and/or supraclavicular adenopathy, whether the lesion is mobile, whether the mass is firm or rubbery, and whether there is breast symmetry. Physical findings concerning for malignancy include a hard, irregularly shaped mass, presence of axillary and/or supraclavicular adenopathy, retraction or redness of the overlying skin, or an associated bloody nipple discharge. While breast cancer can present as a fixed mass, this is an uncommon finding as most breast tumors, unless very posterior, are not fixed to the pectoralis major until late in their course. At times, especially in a patient with very firm breasts, the tumor can be deceptively difficult to palpate and the only obvious finding is breast asymmetry with the involved breast being either larger or smaller (if there is retraction of the surrounding tissue). See [Table 45.9](#) for the summary of the salient parts of the physical exam. Typically, masses that are concerning for malignancy are firm masses with associated skin retraction, masses in axilla, or masses causing breast asymmetry.

Once the history and physical examination is complete, the next part of the evaluation is to determine the role of imaging tests. This assessment is based on the patient's menopausal status. Imaging tests are appropriate in patients who are postmenopausal even if the mass does not seem to be suspicious. Mammographic evaluation is the initial step, even if the patient has had a mammogram within the past year. Additional testing with breast ultrasound may be helpful especially in patients with dense breasts or if breast cysts are suspected. In a premenopausal patient, a nonsuspicious mass (smooth, mobile, ballotable) can be observed over one menstrual cycle. If the mass persists, imaging tests are recommended. In young patients (<25 years), mammograms are of little use due to the high breast density. In these patients, ultrasound should be the initial test. Regardless of menopausal status, if the mass on ultrasound is a cyst, a fine needle aspiration (FNA) of the cyst is indicated only if it is complex in nature or if the patient

is symptomatic. Repeat imaging with ultrasound should be performed in 6 months to assess for cyst recurrence. If aspiration does not resolve the cyst completely, if it returns in 6 months, or if the aspirated fluid is bloody in nature, then an excisional biopsy should be performed. Simple cysts are not associated with malignancy, and no further workup is required. If the mass is not found to be a cyst, then either a percutaneous core or excisional biopsy (when a core is not possible) of the mass should be performed. In patients younger than 40 years, FNA can be utilized if examination and imaging test indicate a benign process. If the FNA is negative, the risk of the patient for having a breast malignancy is extremely low as the physical examination and imaging tests are concordant with the biopsy results. If the patient is 40 years old or older, then an image-guided core biopsy with either mammographic guidance (stereotactic core biopsy) or ultrasound guidance is recommended. Subsequent treatment is dependent on the results of the core biopsy. In general, most benign lesions do not require additional treatment unless atypical or papillary cells are found. These lesions are hyperplastic and can be associated with underlying malignancy; therefore, an excisional biopsy is required. The other “benign” lesion that requires an excisional biopsy is LCIS. While these lesions are not malignant, concurrent cancer may be found at the time of the excisional biopsy. Additionally, excisional biopsy should be performed if the results of the physical exam, pathology, and imaging results are not concordant; this is called the “triple test.” The radiologist should review all imaging tests after the pathology report is issued to assess for concordance. If the radiologist does not feel that the biopsy explains the radiographic findings, an excisional biopsy is mandated. See [Figure 45.19](#) for algorithm of workup of a breast mass.

TABLE 45.9 Key Physical Examination Points in Evaluating a Breast Mass

PHYSICAL ASSESSMENT

- 1. Location, consistency, and size of the mass
- 2. Presence of associated skin retraction or changes
- 3. Presence of nipple discharge
- 4. Presence of any associated masses in either breast, axilla, or supraclavicular region

Abnormal Screening Evaluation

A common clinical scenario is a patient presenting with an abnormal screening mammogram. Further evaluation and treatment of such abnormal mammographic findings should be based on Breast Imaging Reporting and Data System (BI-RADS) score. This American College of Radiology classification lexicon should be included in all mammogram reports. [Table 45.10](#) details the BI-RADS classification system. Further workup is dependent on the BI-RADS category associated with the mammogram. BI-RADS 0 signifies that further work with spot compression views, breast ultrasound, or other imaging modalities are required to complete the evaluation. BI-RADS 1 indicates that the mammogram looks completely normal without any mammographic findings. BI-RADS 2 indicates a mammographic finding associated with benign disease (e.g., fibroadenoma, simple cyst). An inherent false-negative rate exists, and a negative mammogram (i.e., BI-RADS 1 or BI-RADS 2) does not rule out malignancy if a palpable mass

P.1022

P.1023

is present. (Refer to [Fig. 45.19](#) for evaluation of a palpable mass.) A mammogram interpreted as having findings that do not appear suspicious is classified as BI-RADS 3; by definition, these findings should have a 2% or less risk of malignancy; a repeat mammogram in 6 months is reasonable given the very low risk of malignancy. A BI-RADS 4 report indicates findings that are suspicious for malignancy. This category is further divided into 4A, 4B, and 4C. The risk of malignancy can be as high as 95% based on the subcategory. In these cases, a core biopsy should be considered in order to rule out an underlying malignancy. The same workup should be performed for BI-RADS 5, which indicates the findings are highly suspicious for malignancy ([Fig. 45.20](#)).

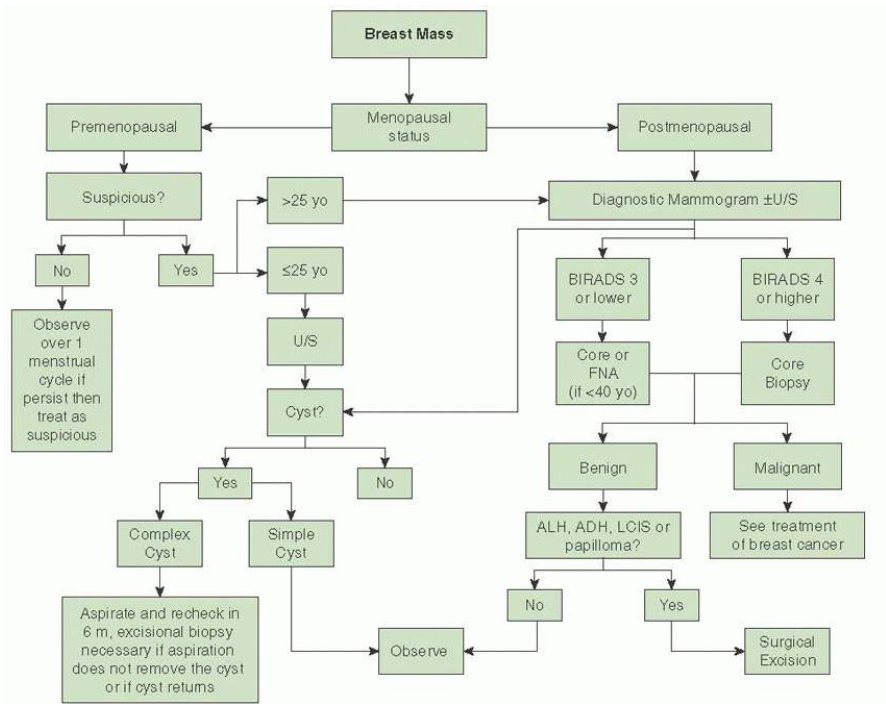

FIGURE 45.19 Algorithm for evaluation of a breast mass.

TABLE 45.10 BIRADS Reporting System

BIRADS CATEGORY	ASSESSMENT	RISK OF MALIGNANCY	RECOMMENDED FOLLOW-UP (MANAGEMENT)
0	Incomplete—need additional imaging evaluation and/or prior mammograms for comparison	N/A	Recall for additional imaging and/or comparison with prior examination(s).
1	Negative	0%	Routine mammography screening
2	Benign	0%	Routine mammography screening
3	Probably benign	≤2%	Short-interval (6-mo) follow-up or continued surveillance mammography
4	Suspicious	>2% to <95% (a) Low suspicion for malignancy (b) Moderate suspicion for malignancy (c) High suspicion for malignancy	Tissue diagnosis
5	Highly suggestive of malignancy	≥95%	Tissue diagnosis
6	Known biopsy-proven breast Malignancy	N/A	Surgical excision when clinically appropriate

Reprinted from Sickles EA, D'Orsi CJ, Bassett LW, et al. ACR BI-RADS® mammography. In: *ACR BI-RADS® Atlas, breast imaging reporting and data system*, 5th ed. Reston, VA: American College of Radiology; 2013, with permission.
(<http://www.acr.org/~/media/ACR/Documents/PDF/QualitySafety/Resources/BIRADS/01%20Mammography/02%20%20BIRADS%20Mammography%20Reporting.pdf>)

In general, when a biopsy is warranted as part of the additional workup, a percutaneous core biopsy should be performed as it provides histopathology. Ideally, the biopsy should be done with the imaging modality in which the mass was discovered. Studies have shown a concordance rate close to 100% between an open excisional biopsy and a core biopsy. Core biopsies have the advantage of being less invasive and resulting in a smaller scar. Even in cases of BI-RAD 5 in which underlying cancer is almost a certainty, a core biopsy allows the surgeon to strategize the operative approach; a diagnosis of DCIS in a patient undergoing breast-conserving surgery does not require sentinel mapping where an invasive cancer would require both partial mastectomy and a sentinel lymph node biopsy (SLNB).

Stereotactic core biopsies may not be possible in some cases (e.g., the breast size is small and compresses to less than 17 mm or if the lesion is superficial or close to the chest wall). Given that the core needle mechanism extends at least 1.5 cm beyond the needle tip, the issue of a through and through injury exists in this circumstance. In these cases, if the lesion is visible on ultrasound, an assessment of feasibility of core biopsy without compression is an option versus a localization and excisional biopsy procedure.

FIGURE 45.20 Mammogram interpreted as BIRADS 5 (highly suspicious for malignancy) based on malignant calcifications that are clustered and pleomorphic.

Further treatment depends on the histologic diagnosis. High-risk proliferative lesions such as atypical lobular/ductal hyperplasia, papillary lesions, and LCIS should be treated with an excisional biopsy. Treatment of breast cancer is discussed elsewhere in this chapter.

Evaluation of Nipple Discharge

One of the most common breast complaints is nipple discharge with up to 80% of women reporting this symptom. Of note, manipulation of the breast and nipple can yield a small amount of clear discharge in most premenopausal women. This section will discuss the management of galactorrhea and pathologic nipple discharge.

An estimated 10% to 15% of patients who present with nipple discharge have an underlying malignancy. Discharge can be classified as related to lactation, physiologic or pathologic (Table 45.11). Nipple discharge that is concerning can present as unilateral, bloody, and/or spontaneous discharge arising from a single duct. Discharges that come from multiple ducts or those that are bilateral tend to be less often associated with malignancy. Discharge from breast can be milky, clear, green, yellow, brown, or bloody. Intraductal papillomas are the most common cause of nipple discharge followed by ductal ectasia and cancer. These anatomic lesions present with unilateral nipple discharge, while physiologic causes such as galactorrhea will present with bilateral nipple discharge. Physiologic causes of galactorrhea include prolactinomas, pharmacologic agents, and any condition that can lead to increased prolactin production. Breast infections can also lead to nipple discharge. The initial workup of nipple discharge entails a thorough history and physical examination. One should get a sense of how long the discharge has been present and whether it was spontaneous, bloody, or unilateral. One also should ask if the discharge was seen coming from one or more ducts. Questions concerning headaches and vision changes should be considered as a

P.1024

means to check for the presence of a symptomatic prolactinoma. A thorough evaluation of the patient's medications is important as common medications such as cimetidine, metoclopramide, and some antipsychotics can also lead to galactorrhea (Table 45.12). In examining the breast, one should pay attention to how many ducts the discharge is coming from, whether or not the discharge is reproducible, and if it is unilateral or bloody. An evaluation should also be made to see if a mass is present and whether or not there are skin changes consistent with Paget disease by the nipple (i.e., scaly rash originating from the center of the nipple spreading outward) or if any signs of infection are present. Guaiac assessment for occult blood (Hemoccult test) may be helpful in the evaluation, but the absence of does not preclude an underlying malignancy. A mammogram and ultrasound should be ordered as part of the workup. A ductogram may help localize the lesion more accurately. Breast MRI may be helpful, but normal imaging cannot rule out an underlying malignancy. If any lesion is found on these imaging tests, an image-guided biopsy should be performed. If no lesions are found, duct excision is still considered standard treatment. If the duct with the discharge can easily be identified, a limited resection of the duct can be done by placing a lacrimal duct probe or fine suture in the affected duct and performing a directed excision. Approximately 2 to 5 cm of tissue distal from the nipple should be removed at the time of surgery.

Figure 45.21 demonstrates an algorithm for evaluation of nipple discharge.

TABLE 45.11 Classification of Nipple Discharge

CLASSIFICATION	DESCRIPTION	ETIOLOGY
Lactation related	Milky Bilateral Multiple ducts Nonspontaneous	Pregnancy
Physiologic	Milky, straw colored, gray, brown, green Bilateral Multiple ducts Nonspontaneous/spontaneous	Prolactinoma Medication related Chronic irritation
Pathologic	Bloody, clear, straw colored, brown, green Unilateral Single duct Spontaneous	Papilloma Duct ectasia Fibrocystic disease Ductal carcinoma in situ Invasive cancer

TABLE 45.12 Medications Associated with Galactorrhea

CATEGORY	EXAMPLES
Antihypertensives	Verapamil, reserpine, methyldopa
Antipsychotics	Phenothiazines, haloperidol, risperdal
Antidepressants	Desipramine, clomipramine
GI medications	Cimetidine, metoclopramide
Analgesics	Opioids-codeine, morphine

Evaluation of Mastalgia

Breast pain or mastalgia is one of the most common breast complaints. In one survey of premenopausal women, 75% of respondents stated that they had this symptom; 30% stated it was moderate to severe in nature. Typically, mastalgia is not considered to be a sign of breast cancer as the frequency of underlying breast cancer in women with breast pain is between 1.2% and 6.7%. Of note, the literature indicates that breast pain is a presenting symptom in 5% to 17% of patients with breast cancer. In one series, mastalgia was the only symptom in 7% of patients. The evaluation of the patient with breast pain should begin with the determination of whether or not the pain is cyclical in nature. Cyclical mastalgia is thought to be due to hormonal stimulation of the breasts. It is not uncommon to have some minor breast discomfort toward the latter half of the menstrual cycle, and this presents as diffuse bilateral breast pain. Cyclical mastalgia is not associated with cancer, and unless there are physical findings of concern, further workup is not necessary. By definition, noncyclical breast pain is not associated with the menstrual cycle. Despite a thorough workup, etiology of the pain often is not found. Noncyclical breast pain may be due to the stretching of the Cooper ligament, mastitis,

P.1025

ductal ectasia, hidradenitis suppurativa, medications (e.g., hormone replacement), increased intake of caffeine, chest musculoskeletal issues, previous surgery to the breast, or in rare circumstances inflammatory breast cancer (IBC).

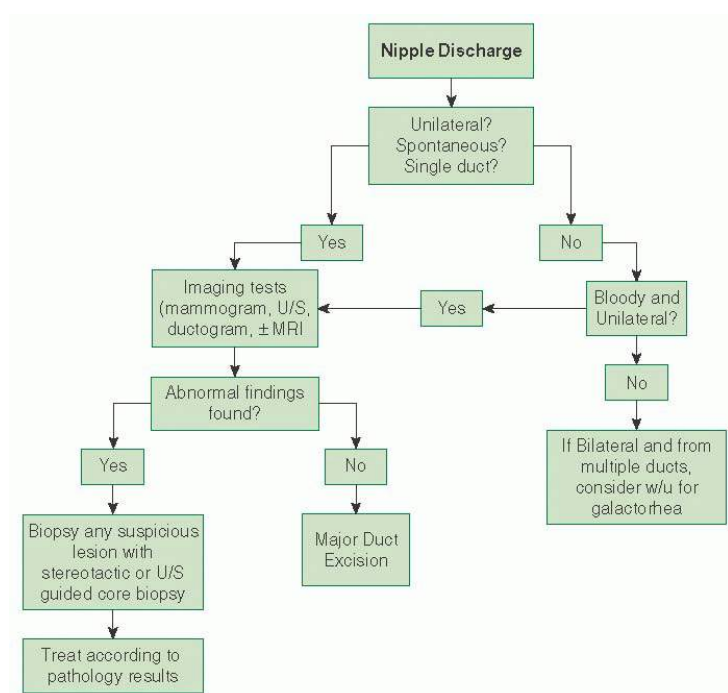

FIGURE 45.21 Algorithm for evaluation of nipple discharge.

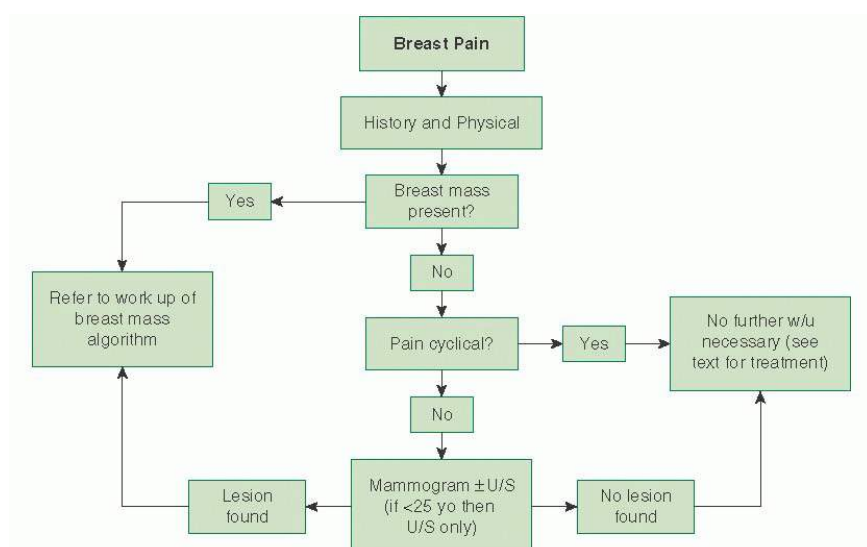

FIGURE 45.22 Algorithm for evaluation of breast pain.

The workup for breast pain begins with a thorough history and physical examination. Assessment should include the location, severity, and duration of the pain, whether it is bilateral, associated skin changes, previous breast surgery and/or other trauma, and if the pain limits her ability to perform daily activities. The patient's medications should be reviewed with particular attention given to oral contraceptive pills or hormone replacement medications, which can cause breast pain. Physical examination should assess the patient for any signs of trauma, skin changes, masses, or nipple discharge. The axillary and supraclavicular area should be examined for signs of adenopathy. [Figure 45.22](#) depicts an algorithm for evaluation of mastalgia.

Patients with IBC can present with a firm, tender, and erythematous breast. Often, the onset is rapid, and the skin may have the typical peau d'orange appearance (dimpling and thickening of the skin) with or without an underlying mass. Mastitis or breast abscess can be associated with mastalgia. This often occurs in lactating women although subareolar abscesses also can occur in nonlactating women. Typically, the abscess will present as a painful mass close to the nipple or with skin changes over the nipple consistent with cellulitis. On occasion, painful masses can be due to hidradenitis suppurativa. This is thought to be due to occlusion of the terminal parts of the follicular acroinfundibulum and can present either on the breast or in the axilla. The lesions can present as solitary painful nodules without an area of central necrosis and can have secondary cellulitis.

Attention to the chest wall during physical examination is essential, as costochondritis can mimic breast pain. Costochondritis pain is parasternal and reproduced by pressing on the costochondral junctions. Most often, the physical exam will be normal with no masses or skin changes found to suggest breast cancer, cellulitis, breast abscess, or hidradenitis suppurativa. It is reasonable to order a breast mammogram and a targeted ultrasound of the tender area, though the yield of such testing is low; one study in 987 women found only four cancers (a prevalence of 0.4%). Breast MRI is not indicated, as no studies suggest any clinical utility at this time.

Treatment of mastalgia will be dependent on the underlying cause. Antibiotics treatment for a breast abscess and cellulitis is generally successful, but refractory cases may require incision and drainage. If possible, a culture of the infected area can be taken and antibiotics regimens adjusted accordingly. In cases in which no underlying cause is found, treatment should be aimed at improving support of the breast through the use of better fitting bras. In patients with large pendulous breasts, a bra with steel underwire may provide relief. Reducing caffeine intake may benefit some patients; however a large case-control study did not find an association between caffeine and breast pain. Several medications have been prescribed for mastalgia. Medical management with nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen should be the first line of treatment. In cases in which medications have not been effective, a topical NSAID such as Aspercreme (Sanofi, Chattanooga, TN) or the Flector Patch (diclofenac epolamine topical patch (13%) Pfizer, Mission, KS) can be tried. Evening primrose oil at 3,000 mg/day or vitamin E at 1,200 IU/day also can be prescribed; however, efficacy may be due to a placebo effect as multiple randomized trials have not proven them to be effective treatment. Randomized trials have demonstrated that tamoxifen 10 mg/day

decreases mastalgia, but this drug can be associated with side effects such as hot flashes, vaginal dryness, leg cramps, increased risk of venous thrombotic events, and development of endometrial cancer. Danazol, a synthetic testosterone (100 to 400 mg/day in two divided doses), also has proved effective for the treatment of mastalgia but can have significant androgenic side effects.

TREATMENT OF BENIGN BREAST DISEASE

Most benign lesions can be treated with observation alone, providing there is concordance between the clinical findings, radiographic imaging, and the cytologic or histologic results. Using these three criteria is referred to as the “triple test.” Cytopathology and histology can be obtained through

P.1026

percutaneous fine needle aspirate and core biopsy, respectively. If all components of the test are concordant with a benign entity, the chance of breast cancer is low (0.7%). Indeterminate or suspicious findings in any one of the components is an indication for further evaluation until confirmation of either a benign or malignant entity is found. Excisional biopsy without percutaneous sampling is a reasonable alternative when the patient desires removal of a mass with benign features.

TABLE 45.13 Advantages of Fine Needle Aspiration

Outpatient procedure
Minimal discomfort
Local anesthetic may or may not be utilized
Negligible complication rate
Rapid diagnosis

Fine Needle Aspiration

Fine needle aspiration (FNA) is an established diagnostic method in the evaluation of palpable breast lesions. In response to the increasing frequency with which women are consulting their obstetrician-gynecologists about concerns related to their breasts, the American Board of Obstetrics and Gynecology (ABOG) has specific educational requirements for resident training in the various aspects of diagnosing and treating breast disease. Technical proficiency in this procedure is recommended. In most areas where dedicated breast imaging centers exist, it is often the radiologist that performs this procedure.

FNA has a sensitivity of 96% and specificity of 98% (similar to core biopsies) as well as a 99% positive predictive value and 94% negative predictive value. It has a false-negative rate as high as 20% most notably in the detection of lobular cancers and carcinoma in situ. Performance of the procedure, preparation of the material for analysis, and the facility of the pathologist can affect these rates.

FNA has multiple advantages (Table 45.13) over excisional biopsy and is helpful in confirming the clinical impression of both benign and malignant breast disease. Nevertheless, a negative cytologic report, as with a negative mammographic report, must not be relied on to rule out malignancy in a clinically suspicious lesion. Any clinically suspicious mass in a patient with negative FNA findings requires additional evaluation, including core or excisional biopsy.

FNA is an easily mastered technique, but the adequacy of specimens is improved with experience and training. Table 45.14 lists suggested equipment for this approach. Procedure risks include infection, bleeding, and bruising at the site. Because the chest wall is immediately beneath the site, pneumothorax is a potential complication. The small size of the needle and assuring the mass is stabilized over a rib during the procedure significantly decreases this complication.

TABLE 45.14 Equipment for Fine Needle Aspiration

Fine needle aspiration gun or 10- to 20-mL syringe
21- to 23-gauge needle
Syringe holder (if desired)
Clear frosted-end glass slides
Alcohol/betadine pads
Fixative
Gauze pads
Adhesive bandage
0.5%-1% lidocaine in separate syringe with 25-gauge needle

After the procedure is explained to the patient and consent has been obtained, the skin is cleansed. The lesion is identified and stabilized, preferably over a rib, between the fingers of the nondominant hand. The area can be anesthetized by injecting and raising a wheal of 0.5% to 1.0% lidocaine in the skin over the mass. A 21- to 23-gauge needle with a clear hub attached to a 5- to 20-mL syringe is then inserted into the central portion of the mass; the smaller the syringe, the greater the pressure that can be generated during aspiration. Increasing the needle gauge does not necessarily increase the sample size as it can raise the risk of bleeding and hematoma formation. Two fingers are placed under the piston of the syringe, and the thumb is used against the body of the syringe to pull the piston toward the examiner, applying negative pressure (Fig. 45.23). A syringe pistol grip holder may be used to facilitate this procedure. With use of the holder, the grips of the holder are pulled together to apply negative pressure. When a breast cyst is encountered, complete drainage of the mass should be attempted. During the aspiration, the fluid will appear in the hub and then fill the syringe. Most

often, the fluid is clear but at times can be cloudy, gray, or green. This fluid can be appropriately discarded. By employing this approach, an immediate diagnosis of cyst can be made and the patient relieved of her concern of over the mass. If the cyst aspirate is bloody, the mass does not disappear, or reoccurs, the patient should be considered a candidate for excisional biopsy. It is important to reinforce to the patient the benefits of following recommended screening guidelines.

After complete sampling along each axis of the mass, suction is released and the needle is removed from the lesion. Releasing the suction *before* removing the needle is a critical aspect of this procedure. Continued negative pressure upon removing the needle (without release of suction) results in aspiration of the specimen into the body of the syringe that can be difficult to retrieve. Once the needle is removed, pressure is applied to the puncture site. A sterile dressing is then applied to the site.

The material should be expelled onto a glass slide with the needle bevel facing down to prevent scatter of the specimen. To release additional sample, the needle is detached, air is drawn into the syringe, the needle is reattached, and further expulsive efforts are accomplished. The "detach, draw air, and reattach" process is repeated until all the cellular material has been expelled. A second slide is placed on top, and the material is smeared between the two slides. Immediate fixation with 95% ethanol or a spray fixative should occur to prevent drying of the cells. The examiner must provide the cytopathologist with an accurate clinical history.

In the instance of a solid mass, the lesion is sampled by moving the needle up and down within the mass several times. Several passes should be made into every portion of the mass to prevent false-negative samples. Valuable cytologic material is harbored within the needle and hub and is then used for evaluation (Fig. 45.24).

Although FNA is cost-effective, several factors have led to diminished use of this technique, including the inability to diagnosis invasive versus in situ disease, the variability in sampling based on the provider's abilities, the limited training of pathologists in cytopathology interpretation, and the rising rates of percutaneous core biopsy. Current preference is for histologic assessment, and this can be obtained through large core needle biopsy.

Core Needle Breast Biopsy

It is estimated that approximately one million breast biopsies are performed yearly to diagnose approximately 200,000 breast cancers. Percutaneous core needle biopsy may spare many of these women the need for more deforming, invasive, and expensive surgical procedures. With this procedure, a

P.1027

P.1028

histopathologic diagnosis is rendered compared with cytologic evaluation with FNA. Studies indicate a high degree of accuracy, with a sensitivity of 89%, specificity of 100%, positive predictive value of 98%, and an 80% negative predictive value in confirming invasive disease. False-negative results may occur, but false-positive results are rare except with radial scars. Increasing the number and the size of core specimens has increased the accuracy of the procedure.

FIGURE 45.23 Technique of fine-needle aspiration. **A:** The mass is stabilized with the nondominant hand (preferably over a rib). After the needle is inserted into the mass, negative pressure is applied. **B:** As a cyst is aspirated, it collapses and the walls adhere and it resolves completely.

FIGURE 45.24 Fine-needle aspiration of a solid mass. **A:** The mass is located and the needle is inserted into the mass without negative pressure. **B:** Negative pressure is applied while the needle is moved in an up-and-down fashion within the mass. **C:** Negative pressure is released. **D:** The needle is removed from the mass.

Core needle biopsy may be performed under tactile, stereotactic, or ultrasound guidance. Less tissue is removed during core needle biopsy compared with excisional biopsy, resulting in no deformity in the breast and minimal to no scarring on subsequent mammograms. Another advantage is the ability to distinguish between invasive and in situ carcinoma. Because special training is not required to interpret the histologic material obtained from core needle biopsy, this obviates the need for skills of a cytopathologist. Given the larger needle size, local anesthesia is required, higher rates of postprocedure bleeding and hematoma formation occur, and there have been instances in which the track of the biopsy has been “seeded” with tumor leading to recurrences at the skin puncture sites. The use of an introducer needle has minimized the latter risk.

At times, core needle biopsy may not be possible due to lesions that are close to the nipple, lesions that are very posterior or superficial, or when the breast compresses to less than 1.7 cm.

This biopsy procedure is often used in the assessment of BI-RADS category 4 and 5 lesions. If core biopsy of a category 4 lesion yields a benign diagnosis concordant with the imaging characteristics, the woman is spared a diagnostic surgical biopsy. Although most often performed for nonpalpable lesions, percutaneous image-guided core biopsy also can be helpful in the evaluation of palpable breast masses, particularly those that are deep, mobile, or vaguely palpable. An advantage of image guidance is the ability to obtain radiographic documentation of the procedure. For select health care providers, this procedure can be performed in their office with or without ultrasound guidance.

Stereotactic core needle biopsy requires dedicated equipment but is helpful in evaluating suspicious mammographic findings that have no palpable or ultrasound correlates. Ultrasound-guided core needle biopsy has several advantages, including real-time visualization of the needle, lack of ionizing radiation, accessibility to all parts of the breast and axilla, multipurpose use of equipment, and lower cost. However, it is limited in detection of lesions less than 1 cm and has decreased sensitivity in detection of microcalcifications. Vacuum-assisted devices (e.g., Mammotome, Cincinnati, OH) may improve tissue sampling by obtaining larger intact samples. The choice of approach depends on several factors, including lesion visibility and accessibility, equipment availability, and preferences of the radiologist.

The area is cleansed and administration of local anesthesia is performed. An introducer needle is placed into the site of interest, and then the coring device is inserted through this conduit (**Fig. 45.25**). This can minimize the risk of seeding

P.1029

the biopsy track with malignant cells and allows for the core needle to be reintroduced multiple times without increasing the risk of further tissue disruption. As the core needle is introduced into the mass, the tissue inside the core of the needle is cut from the surrounding tissue as the outer sheath is advanced. The core needle device is spring loaded allowing for a mechanized capture of the tissue. After removal of the sheath and core needle, a pressure dressing is applied. In some circumstances, the entire lesion can be removed. After the core biopsies are obtained, a titanium clip is deployed into the biopsy site to identify the area for future localization if excisional biopsy is required. A variety of shapes of clips are available, allowing the radiologist to perform multiple biopsies to aid in further identification of these sites. The histopathologic findings then dictate whether observation or further assessment should occur. Discordant histology, that is, the imaging is concerning for malignancy but the biopsy is benign, is an indication for excisional biopsy. The radiologist should provide an addendum to the report when the pathology from the biopsy is available stating what the findings are and whether they confirm a benign entity and observation is acceptable or if further assessment is required. In instances where a cancer has been diagnosed, the core specimen can be assessed to determine the hormone and HER2 receptor status.

FIGURE 45.25 Core needle biopsy technique.

Excisional Biopsy

This procedure is primarily employed when a benign lesion such as a fibroadenoma or papilloma is present. The technique may be used with or without a localization procedure. The lesion in question is removed in its entirety often without additional breast tissue or margin. The surgeon should choose an incision that offers ready access to the site with minimal cosmetic disturbance ([Fig. 45.26](#)). Curvilinear, circumareolar, and radial incisions are chosen depending on location and the size of the lesion. If the incision is made along Langer lines, an improved cosmetic outcome is achieved ([Fig. 45.27A, B](#)).

FIGURE 45.26 Technique of excisional biopsy. **A:** For cosmetic reasons, circumareolar incisions are preferable when the lesion is thought to be within 2 or 3 cm of the areola. Not more than one half of the areolar margin should be incised. A curvilinear incision parallel to the areola along Langer lines is made over lesions further out from the center. **B:** A local anesthetic is given in the proposed incision using 1% lidocaine and a hypodermic (no. 25) needle. From the wheal, deeper injections of anesthetic are made around the circumference of the lesion and beneath it. **C:** The incision is carried down through the dense subcutaneous tissue and into the lobule containing the lesion. Self-retaining retractors are helpful when an assistant is not available. **D:** If the lesion is small or easily mobilized, it should be sharply dissected and excised. **E:** The lobular defect can be sutured with fine absorbable suture material if the closure places no tension on the overlying skin or the cavity can be left open. Bleeding is controlled with absorbable ligatures or electrocoagulation. **F:** The skin is closed within two layers, approximately the deep and superficial subcuticular edges. A pressure dressing for 24 to 48 hours is desirable if a significant amount of dead space has been left behind.

FIGURE 45.27 A: Preferred incision choices. **B:** Incisions to be avoided.

The procedure can be accomplished with sharp dissection, with the aid of an electrosurgical diathermy or high-frequency ultrasound (Harmonic Scalpel, Ethicon Endo-Surgery, New Brunswick, NJ). Meticulous attention to the resultant biopsy cavity is undertaken to assure adequate hemostasis. Most surgeons do not approximate the underlying breast tissue but rather allow a seroma cavity to form to maintain the normal contour of the breast. Subcuticular closure of the skin is then performed using monofilament fine sutures. (See Steps in the Procedure.)

STEPS IN THE PROCEDURE

Excisional Biopsy

- This procedure can be performed under local anesthesia, sedation and local anesthesia, or general anesthesia.
- Identify Langer line proximate to the lesion.
- Infiltrate the incision and surrounding tissue with 1% lidocaine.
- Use a scalpel to make the incision.
- Develop with either sharp dissection or with an electrocoagulation device skin flaps around the incision site.
- Excise the lesion completely.
- Size of excisional biopsy will be dependent on size of the lesion.
- Orient the specimen for pathologist to allow for margin assessment.
- If a radiographic localization was performed, obtain a specimen radiograph to confirm removal of the lesion(s).
- Make the operative bed hemostatic with either sutures or electrocoagulation.
- Leave the operative bed open to allow for seroma formation as this will maintain the normal contour of the breast.
- Skin closure in two layers using both an interrupted and running fine (3-0, 4-0) subcutaneous absorbable suture.

Ablative Techniques

Nonsurgical options currently exist for benign lesions and are being studied for use in known malignancies. Fibroadenomas are responsive to ablative techniques given their indolent nature. Cryoablation has been used successfully for lesions less than 4 cm. A probe is inserted under ultrasound guidance and then activated to achieve -40°C . Two freeze-thaw cycles are required to satisfactorily induce intracellular ice formation and membrane rupture. Over the course of several months, the lesions will resorb. The procedure can be performed in the office, and only local anesthesia to skin site is required.

Other ablative techniques exist including radiofrequency ablation and microwave thermography. Advantages of ablative approaches include minimal scarring, improved cosmesis, and the ability to accomplish the procedure under local anesthesia in the outpatient setting. Lack of complete histologic evaluation, delayed reabsorption of the mass, and incomplete response are some of the concerns surrounding these approaches.

Major Duct Excision

For evaluation of nipple discharge, duct excision can be performed. A technique described by Urban uses a radial or circumareolar skin incision to assess and remove the major ducts of

the breast (**Fig. 45.28**). The overlying areolar skin is separated from the underlying breast parenchyma. As the base of the nipple is approached, the ductal system is visualized. The individual duct can then be isolated either by direct visualization or if previously localized by placing a fine suture or injecting dye into the affected nipple opening. The involved duct is traced for a minimal distance of 2 to 5 cm prior to being truncated. Five centimeters is chosen as the major ducts are present within this distance, and almost 95% of the lesions are located within this region. The ductal attachments to the base of the nipple are severed. In instances of ductal ectasia or where a solitary duct cannot be identified, the surgeon dissects a minimal of 5 cm in a 360-degree manner and in this fashion develops a pyramidal portion of breast tissue, which is then released from the underlying stroma. The operative bed is made hemostatic and skin approximated in two layers. Some surgeons will place a fine (4-0 or 5-0) suture at the base of the nipple to prevent nipple invagination. (See Steps in the Procedure.) A similar approach is used when the patient has nonpuerperal breast abscess formation with or without sinus formation (**Fig. 45.29**). When a draining sinus is present, it is excised with a portion of the nipple. Risks of this surgical approach include denervation of the nipple, nipple necrosis as a result of ischemia, and cosmetic change.

P.1032

FIGURE 45.29 Major duct excision for periductal abscess (A-F). The procedure includes excising the sinus site and a portion of the nipple. (Reprinted from Urban J. Excision of the major duct system of the breast. *Cancer* 1963;16:515, with permission. Published by John Wiley and Sons. Copyright © 1963 American Cancer Society.)

STEPS IN THE PROCEDURE

Duct Excision

- This can be performed under local anesthesia, sedation and local anesthesia, or general anesthesia.
- Identify the duct with the discharge (if there is only one duct with discharge).
- Infiltrate the nipple areolar complex with 1% lidocaine.
- Using a duct probe, cannulate the duct with the discharge.
- Make a circumareolar incision along the edge of the areola that is closest to the duct with the discharge.
- Dissect the breast tissue off the nipple using electrocoagulation device or Metzenbaum scissors.

- If possible, resect the tissue under the nipple around the duct probe, and be sure to take at least 2 to 3 cm of tissue below the nipple.
- Orient the specimen for margin assessment.
- Make the area hemostatic with either sutures or electrocoagulation.
- If all of the tissue below the nipple is removed as part of major duct excision, then a purse-string stitch with a permanent suture such as 3-0 silk can be placed under the nipple in order to prevent the nipple from inverting.
- Skin closure using a running fine (4-0) subcutaneous absorbable suture.

Localization Techniques

In circumstances where the lesion is nonpalpable, localization of the lesion with ultrasound, mammogram, or MRI is warranted. Different techniques can be used to identify and guide the surgeon to the site of interest. Dye injection, wire localization, and seed localization are the current modes utilized. In the instances of dye and wire localization, using imaging guidance, a visual

P.1033

dye (methylene blue) can be injected or a Kopans (hook) wire placed in the area of concern. The dye can be placed up to a day in advance, whereas the wire procedure is performed on the day of the surgical excision. The use of the wire and placement mammograms can guide the surgeon to the site by visualizing in three dimensions the location of the wire tip ([Fig. 45.30](#)). As a matter of convention, the wire tip is placed beyond the lesion to help the surgeon achieve a margin around the mass. The use of the hook wire is the most commonly employed approach. A radiograph of the surgical specimen is then obtained to confirm removal via identification of the lesion or a previously placed clip. The use of radiopaque markers (Margin Map, Beekley Corporation, Boston, MA) can identify the margins of the specimen, and then when two orthogonal radiographs are performed, margin assessment can be obtained.

FIGURE 45.30 Example of wire localization. The patient has known DCIS, and two wires were used to bracket the areas of concern. Refer to [Figure 41.26](#) for original mammogram.

An alternative approach, which we employ at our institution, for high-risk lesions and known cancer is radioactive seed localization. This approach has been shown to be highly effective in localizing nonpalpable breast lesion. An iodine-125 seed is inserted into the lesion of interest via one of three imaging modalities. The surgeon then uses a gamma probe to identify the seed and allows for rapid identification in three dimensions of the site during the surgical event. The seed can be placed up to 5 days in advance of the procedure. Given the inverse square law, radioactivity detection rapidly declines as distance from the seed is increased. This allows the surgeon to assess the margins in all dimensions during the procedure. A specimen radiograph is obtained after the tissue is removed, and the remaining cavity is assessed for residual activity in event the seed has been cut and a portion left within the breast ([Fig. 45.31](#)). We have noted diminished tissue removal and improvement in obtaining clean margins. Special training including radiation safety training and proctoring for the first several procedures is required. Given concerns of radioactive contamination, training of the operating room, radiology, and pathology staff is mandated.

FIGURE 45.31 Specimen radiograph with speculated lesion and use of the Margin Map. (Beekley Corporation, Boston, MA.)

BREAST CANCER

Worldwide, breast cancer is the most commonly diagnosed malignancy in women and a leading cause of cancer-related mortality. In the United States in 2014, it accounts for 29% of all cancer site diagnoses, and it is estimated that there will be in excess of 232,000 women diagnosed with this malignancy. In addition, breast cancer will be the second most common cause of cancer-related deaths accounting for approximately 40,000 deaths, with lung cancer being the leading cause.

Epidemiology

A large body of literature exists examining risk factors associated with the development of breast cancer. The etiology of breast cancer is likely multifactorial. Numerous risk factors have been identified; however, nearly three fourths of women with breast cancer have no known risk factors other than sex and age.

Risk factors for breast cancer include female sex, increasing age, nulliparity, delayed childbearing, personal or family history of breast cancer, atypical proliferative breast disease, obesity in postmenopausal women, a long menstrual history (menarche before age 12 and menopause after age 51), LCIS, prior radiation exposure, and higher education and socioeconomic status.

P.1034

Factors such as fat intake, smoking, and alcohol intake have all been suggested to contribute to breast cancer risks. [Table 45.15](#) lists risk factors for breast cancer development.

TABLE 45.15 Risk Factors for Breast Cancer Development	
RISK FACTOR	RR
Female gender	150
Increasing age > 60	17
Inherited genetic mutation	3-7
Personal history of breast cancer	3-7
≥ 2 first-degree relatives with early onset of breast cancer	2.6
Atypical hyperplasia	3.7
Ionizing radiation to the chest	7
Early menarche ≤ 12	1.5
Late menopause ≥ 55	2.0
Nulliparity	1.4
Delayed childbearing ≥ 30	1.9-3.5
No history of lactation	1.4

Postmenopausal obesity	1.4-1.6
Alcohol consumption (2-5 drinks/d)	1.4
Combination hormone replacement therapy	1.2
Tall stature	1.2
Personal history of ovary, endometrial, or colon cancer	
Jewish heritage	
Data from Costanza ME, Chen W. Factors that modify breast cancer risk in women. In: Dizon DS, ed. <i>UpToDate</i> . Waltham, MA: UpToDate; 2013; Clemons GP. Estrogen and the risk of breast cancer. <i>N Engl J Med</i> 2001;344:276-285; Guibout C, Adjadj E, Rubino C, et al. Malignant breast tumors after radiotherapy for a first cancer during childhood. <i>J Clin Oncol</i> 2005;23(1):197-204; Kelsey JL. Breast cancer epidemiology: summary and future directions. <i>Epidemiol Rev</i> 1993;15(1):256-263.	

Late onset of menarche, early menopause, multiparity, and breast-feeding are associated with risk reduction. Healthy lifestyle with maintenance of ideal body weight, avoidance of alcohol and tobacco, and a well-balanced diet with minimal processed foods and low fat are linked to lower rates of breast cancer.

Gender

Breast cancer is one hundred times more common in women. Male breast cancer is rare with an estimated 2,360 cases in the United States in 2014, accounting for 430 cancer-related deaths. The finding of breast cancer in a male should raise awareness of a possible genetic predisposition. Mutations of BRCA2 are associated with a 100-fold increased risk for the development of male breast cancer.

Age

The risk for developing breast cancer increases with advancing age and reaches its peak in the sixth decade. Between the ages of 20 and 34 years, breast cancer incidence is 2% and rises to 24% between the ages of 55 to 64 years. Subsequently, the risk falls in the elderly population to 6% for women 85 and older.

Ethnicity

Caucasian race has the highest rates of breast cancer, but breast cancer is the most common cancer in women in all ethnic groups. Black women present with more advanced disease and have higher breast cancer-specific mortality. Some factors may be related to lifestyle and access to the health care system, but other risks do exist. Black women have a higher incidence of early-onset breast cancer and rates of “triple-negative” disease. Women with Ashkenazi Jewish ancestry have a higher likelihood of harboring one of the founder mutations of BRCA1 and BRCA2.

Obesity

In and of itself, obesity is associated with increased morbidity and mortality. The Nurses' Health Study reported that a 10-kg weight gain in the postmenopausal period was associated with a relative risk of 1.18 of developing breast cancer. In other studies, elevated body mass index (BMI) has been shown to increase breast cancer risk. The association may be due to peripheral conversion of estrogen precursors within adipose tissue leading to higher levels of circulating estrogens. Women with BMI in excess of 33 kg/m² have an elevated breast cancer risk compared to women of ideal body weight.

Tall Stature

Higher risk of breast cancer is seen with increased height. One study reported a 20% increased risk in women whose heights exceeded 69 inches compared to those with heights less than 63 inches. Underlying association is not yet delineated. A possible explanation may be related to increased bone mineral density in taller women, suggesting exposure to higher levels of endogenous estrogen exposure.

Oral Contraceptives

The use of oral contraceptive pills (OCP) was initially reported to elevate an individual's risk of breast cancer. Subsequent reports fail to demonstrate a relationship between use and breast cancer risk. Three large series, including the Nurses' Health Study, fail to demonstrate an adverse relationship. Use of OCPs in women with a family history of breast cancer is not associated with increased risk. Interaction of OCPs in women who carry a deleterious mutation of BRCA1/BRCA2 is currently unknown.

Reproductive Factors

The longer exposure to endogenous hormonal milieu is associated with greater risk of breast cancer development. Early-onset menarche and later menopause are both associated with increased risk of breast cancer. For each year of delayed menopause, risk increases by approximately 1%. For each 2-year delay in the onset in menarche, the risk is

P.1035

reduced by 10%. Nulliparity, late ages at first pregnancy, and infertility also have been shown to have a relationship to increased risk.

Childbirth before age 18 years portends one third the risk of breast cancer than in a woman delivering at age 35 years. Multiparity is associated with reduced breast cancer risk. Breast-feeding has been demonstrated to have a beneficial effect on cancer risk reduction. An analysis in *Lancet* in 2002 of 47 epidemiologic studies demonstrated 4.3% risk reduction for every 12 months of breast-feeding. The common theme for risk elevation or risk reduction is exposure to ovulatory cycles. Benefits are seen with fewer or delayed onset of ovulatory events, whereas risks are increased with more frequent ovulatory cycles.

Family History

A family history of breast cancer increases the individual's risk. Level of risk depends on the number of relatives, degree of separation, and age at onset of disease in the affected individuals. The presence of breast cancer in a premenopausal relative should raise awareness for genetic predisposition. A collaborative reanalysis published in 2001 in *Lancet* of 52 epidemiologic studies on family history and breast cancer revealed risk of breast cancer is raised twofold when one first-degree relative is affected and threefold if there are two first-degree relatives who are affected by the disease. Identification of patients at increased risk for breast cancer can be obtained through a comprehensive three-generation family history and lead to referral for genetic assessment and modification of screening recommendations.

Personal History of Breast Cancer

A previous history of DCIS or invasive carcinoma increases the risk of developing a contralateral breast cancer. Reported rates are 0.5% to 1% per year after diagnosis. A

woman diagnosed at the age of 40 years would have a 30% chance of contralateral breast cancer by the time she reaches age 70.

Atypical Hyperplasia

The proliferation of the ductal or lobular epithelium with cellular atypia imparts an increased relative risk of developing breast cancer. Dupont and colleagues reported on a retrospective cohort study the risk of estrogen replacement therapy in women with atypical proliferative breast disease and noted an increased risk of breast cancer development in patients who did and did not receive estrogen therapy with relative risks of 2.53 and 2.87, respectively.

If the diagnosis of ADH/ALH is made on percutaneous biopsy, it is advised that formal excisional biopsy is performed given that upstaging to in situ or invasive cancer occurs 10% to 20% of the time. Recently, the role of additional excision for areas of ALH has been called into question by McGhan and others.

Lobular Carcinoma In Situ

Often diagnosed as an incidental finding, LCIS places an individual at a higher than average risk of developing breast cancer. It is considered a marker for the future development of breast cancer. Estimated lifetime risk is between 30% and 40% (up to 1% per year) and depends on the age at diagnosis. This compares to unaffected individuals who have a 12.5% risk (1 in 8 individuals).

Lifestyle

Lack of physical activity, alcohol consumption, smoking, high fat intake, processed foods, and red meat ingestion have been linked to the development of breast cancer. In some circumstances, there is a dose-response relationship.

Night shift work has been correlated with breast cancer risk. A recent study in nurses reported an elevated odds ratio of 1.8 (95% CI: 1.2 to 2.8) working rotating shifts after midnight. In a subset analysis, odds ratio increased to 2.6 (95% CI: 1.8 to 3.8) when nurses worked rotating long-term day and night shifts. A possible hypothesis is the relationship to nocturnal light exposure and its effects on melatonin production as low melatonin levels have been associated with increased breast cancer risk.

Radiation Exposure

Ionizing radiation is directly linked to the development of breast cancer. Data from individuals treated for Hodgkin lymphoma and those who have received exposure as a result of nuclear plant accidents support this finding. An area of current investigation is the risk of exposure to diagnostic levels of radiation during chest radiography, mammography, CT, and others. Patients with BRCA1/BRCA2 deleterious mutations may be more prone to radiation-related risks.

Hereditary Breast Cancer Syndromes

Less than 10% of breast cancers and less than 15% of ovarian cancers are associated with known inherited (germline) genetic mutations. Currently, the majority of hereditary breast cancer syndromes are linked to mutations of breast cancer type 1 and 2 susceptibility genes also known as BRCA1 and BRCA2. Phosphatase and tensin homolog (PTEN) and tumor protein 53 (TP53) mutations identified in Cowden and Li-Fraumeni syndromes also are associated with breast cancer susceptibility.

BRCA1/BRCA2 Mutations

BRCA1 and BRCA2 are tumor suppressor genes. Mutations are linked to hereditary breast and ovarian syndromes. Approximately 5% of breast cancer cases are due to these germline mutations. BRCA1 gene is located on the long arm of chromosome 17, consists of 22 coding exons, and is located in region 2 band 1 (17q21). BRCA2 is located on the long arm of chromosome 13 at position 12.3 (13q12.3).

These tumor suppressor genes encode a protein that combines with other tumor suppressors, DNA damage sensors, and signal transducers to form a large protein complex that assists in the repair of DNA strand breaks. BRCA1 interacts with a number of genes including BARD1, CHK1, and RAD51, whereas BRCA2 interacts with RAD51, which is the strand invasion recombinase. Mutations of BRCA1/BRCA2 can prevent DNA damage repair and increase an individual's risk of cancer.

Mutations of the BRCA1/BRCA2 genes involve either insertion or deletions of DNA base pairs. These genes are inherited in an autosomal dominant manner. Founder mutations are alterations of a gene or genes of one or more individuals who are founders of a distinct population, such as the Ashkenazi Jewish population, which has high penetrance of two specific mutations, 185delAG and 5382insC, seen in 1 in 8 and 1 in 12 individuals, respectively.

Carriers of mutations of BRCA1/BRCA2 gene have a high penetrance of breast cancer up to 85% by the age of 70 years. Risk of ovarian cancer in this group is as high as 40% by the same age. BRCA2 mutation carriers may have a lower ovarian cancer risk. Basal-like or triple-negative tumors are more frequently observed in patients who have mutations of the BRCA1 gene. Luminal A/B lesions are more common in the population with BRCA2 mutations.

P.1036

Prevalence of these genetic alterations varies between ethnic groups and geographic location. As noted, there is higher incidence in the Ashkenazi Jews. Other founder mutations have been seen in populations from French Canada, the Netherlands, Sweden, Hungary, and Iceland.

The diagnosis of early age of onset breast cancer, having multiple family members with either breast or ovarian cancer, and having a personal diagnosis of ovarian cancer and basal-like or triple-negative breast cancer are among the reasons to consider genetic assessment. Ideally, the individual should be referred to a genetic counselor who will obtain a comprehensive family and personal history and estimate the individual's chance of carrying a mutation. Several models to estimate risk exist, including Bayesian probability model BRCAPRO and the Penn II risk model that utilizes logistic regression. An estimated risk of 10% is the threshold for consideration of testing. The National Comprehensive Cancer Network (NCCN) criteria for consideration of testing are listed in Table 45.16. Individuals of Ashkenazi Jewish descent should be assessed for the founder mutations first and if need be full sequencing considered if the original assessment is unrevealing. In addition, an important component of testing is both the pre- and, if appropriate, posttest counseling. The absence of a known mutation in an individual from a family with a known mutation is a true negative and can be used to counsel and reassure the individual that their risk is not greater than that of the general population. However, a negative test in an individual of whom no family member has an identified mutation is considered uninformative. Several possibilities exist, including a deleterious mutation that has not been detected, a gene mutation that is present but not identifiable at present, or the presence of mutation with unknown significance (termed "variant of uncertain significance"). Additionally, a sporadic (as opposed to hereditary) cancer may have developed.

TABLE 45.16 National Comprehensive Cancer Network Criteria for Consideration of BRCA1/BRCA2 Genetic Testing

INDIVIDUAL FROM A FAMILY WITH KNOWN DELETERIOUS MUTATION OF BRCA1/BRCA2 MUTATION

Personal history of breast cancer (invasive or in situ) plus one or more of the following:

- Diagnosed age ≤45
- Diagnosed age ≤50 with ≥1st-, 2nd-, or 3rd-degree blood relative with breast cancer ≤50 y and/or 1st-, 2nd-, or 3rd-degree blood relative with epithelial ovarian/fallopian tube/primary peritoneal cancer at any age
- Two breast primaries (ipsilateral or contralateral) when first breast cancer diagnosis occurred ≤50 y
- Diagnosed ≤60 y with triple-negative breast cancer

Diagnosed ≤50 y with a limited family history
Diagnosed at any age with ≥2 first-, second-, or third-degree blood relatives with breast and/or epithelial ovarian/fallopian tube/primary peritoneal cancer at any age
Diagnosed at any age with ≥2 first-, second-, or third-degree blood relatives with pancreatic cancer at any age
First-, second-, or third-degree male blood relative with breast cancer
For an individual of ethnicity associated with higher mutation frequency (e.g., Ashkenazi Jewish), no additional family history may be required.

Personal history of epithelial ovarian/fallopian tube/primary peritoneal cancer

Personal history of male breast cancer

Personal history of pancreatic cancer at any age with ≥2 first-, second-, or third-degree blood relatives with breast and/or ovarian cancer and/or pancreatic cancer at any age

Family history

First- or second-degree relative meeting any of the above criteria
Third-degree blood relative with ≥ first-, second-, or third-degree blood relatives with breast cancer (at least one breast cancer ≤50 y) and/or ovarian cancer/fallopian tube/primary peritoneal cancer

Phosphatase and Tensin Homolog Mutations

PTEN mutations have been described in multiple rare syndromes collectively referred to as PTEN hamartoma tumor syndromes (PHTS). Cowden syndrome (multiple hamartoma syndrome) is linked to germline mutations of PTEN and is the most well known of the PHTS. It is inherited in an autosomal dominant manner and associated with oral fibromas, palmoplantar keratosis, multiple hamartomas of various tissues, and increased risk of breast, endometrial, thyroid, renal, and colorectal cancers.

Tumor Protein 53 Mutation

Li-Fraumeni syndrome is linked to aberrations in the TP53 gene located on the short arm of chromosome 17 (17p13.1). TP53 is a tumor suppressor gene involved in the management of cells containing damaged DNA. The syndrome is an inherited disorder that manifests itself with a wide range of earlyonset malignancies including breast cancer. This syndrome is also known as the sarcoma, breast, leukemia, and adrenal gland (SBLA) syndrome.

Pathology of Breast Cancer

Breast cancer is most common in the upper outer quadrant of the breast followed by the central, upper inner, lower outer, and lower inner quadrants (Table 45.17). The pattern of distribution correlates with breast tissue distribution in these areas. Regional spread of disease is most common to the ipsilateral axillary basin, and often, the first site of metastases is the nodes most lateral to the pectoralis minor.
Ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS) make up this class of histologic changes. While DCIS is considered a cancer with potential to transform into

an invasive entity, the same is not true for LCIS, which is considered benign but predictive for the future development of breast cancer.

FIGURE 45.32 Ductal carcinoma in situ. The ducts are filled with pleomorphic and atypical cells with central areas of comedo necrosis. In the surrounding stroma, there are nests of infiltrating ductal carcinoma (H&E 10×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

TABLE 45.17 Breast Cancer Site Distribution

QUADRANT	FREQUENCY OF BREAST CANCER
Upper outer	45%
Central	24%
Upper-inner	14%
Lower-outer	9%
Lower-inner	5%

Ductal Carcinoma In Situ

DCIS is a noninvasive histologic variant of breast cancer. The histopathology of DCIS includes the proliferation of malignant cells within the ductal system of the breast but without invasion of the stromal tissue ([Fig. 45.32](#)). DCIS has a broad histologic presentation that includes traditional grading of well, moderate, and poor differentiation and includes subclassifications such as comedo, noncomedo, and micropapillary. These factors and the degrees of differentiation correlate with aggressiveness and likelihood of recurrence.

Widespread use of screening mammography coincides with a shift in the stage at presentation of breast cancer toward earlier-stage disease, particularly for DCIS. Data from the SEER program of the National Cancer Institute show nearly 300% change in incidence of DCIS in women aged 50 years and older and greater than 100% increase in the incidence of stage I disease in the same group. DCIS is considered a nonobligatory precursor to invasive ductal carcinoma (IDC) with variable rates of progression, depending on histology, size, and margin status. Radiographically, the most common finding is pleomorphic, clustered calcifications. Almost diagnostic is the finding of linear calcifications within the duct. DCIS detected based on palpation has up to a 25% incidence of associated invasive carcinoma.

Lobular Carcinoma In Situ

LCIS refers to proliferation of cells within the breast lobules. Typically, they comprise acini filled with small round cells with a thin rim of clear cytoplasm and a high nuclear-to-cytoplasmic ratio ([Fig. 45.18](#)). LCIS is considered a predictive marker of future cancer rather than a cancer precursor. The cancer risk applies to both breasts. It is often found *incidentally* at the time of breast biopsy performed for another indication and does not present characteristic clinical or mammographic findings. LCIS may be associated with clustered microcalcifications on imaging. It is typically multicentric. Studies of women with LCIS managed with biopsy alone demonstrate a risk of cancer development of approximately 1% per year. Management of LCIS is discussed early in this chapter in the section on benign diseases.

TABLE 45.18 Histologic Types of Invasive Breast cancer

HISTOLOGY TYPE	%
Ductal	50-70%
Lobular	5-16%
Medullary	3-6%
Mucinous	1-2%
Tubular	1-2%
Mixed	2-30%

Adapted from Dillon DA, Guidi AJ, Schnitt SJ. In: Harris JA, Lippman ME, Morrow M, et al., eds., *Pathology of invasive breast cancer in diseases of the breast*, 4th ed. Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins; 2010.

Invasive Breast Cancer

Invasive breast cancers are a highly diverse group of tumors. More than 90% of breast cancers arise with the ducts. Infiltrating or invasive ductal carcinoma (IDC) is the most common histologic pattern of breast cancer accounting for greater than 70% of diagnoses. Infiltrating lobular carcinoma (ILC) is the second most frequent cancer with small contributions from the remaining subtypes. See [Table 45.18](#) for breast histology classifications.

IDC accounts for the majority of breast cancers. No clinical or radiographic characteristics distinguish these lesions from the other histologic subtypes. Lesions are hard masses and tend to have stellate borders often with associated reaction of fibrous tissue surrounding the lesion. The histopathology is heterogenous to include cytologic atypia, mitotic activity and stromal desmoplasia. The tumor cells are arranged as glandular structures and exhibit varying degrees of cellular atypia, mitosis and stromal desmoplasia ([Fig. 45.33](#)).

FIGURE 45.33 Infiltrating ductal cancer forming glands with varying degrees of cellular atypia and stromal desmoplasia (H&E 10×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA)

FIGURE 45.34 Histologic section of medullary carcinoma showing smooth margins, primitive malignant cells in syncytial growth surrounded by lymphoplasmacytic infiltrate (H&E 240×). (Courtesy of Taalat Tadros, MD, Emory University, School of Medicine, Atlanta, GA.)

Tubular carcinoma is a variant of ductal carcinoma and has limited metastastic potential and excellent prognosis. It was commonly diagnosed in the early 1960s and was originally described in the literature as a palpable mass. It now accounts for 10% to 20% of cancers detected in a screened population. These tan or white lesions are typically 1.0 cm or smaller and infiltrate the surrounding tissue. Microscopic appearance demonstrates proliferation of well-formed glands or tubules lined by a single layer of epithelial cells. Nuclei are low grade and are pushed toward the lumen of the gland.

Medullary carcinoma has a propensity to be located in the upper outer quadrant of the breast. The tumors tend to be well circumscribed. Imaging echoes the clinical exam findings. The histopathologic appearance exhibits a predominance of syncytial cells, lymphocytic infiltrate, grade 2 and 3 nuclei, and an absence of glandular structure (**Fig. 45.34**). These tumors have a better prognosis than do the other IDC variants.

Mucinous or colloid carcinoma appears as a large, slowgrowing, gelatinous mass usually found in older women. These lesions are associated with improved prognosis and are often diagnosed in the seventh or eighth decade of life. On exam, they are poorly defined or lobulated. On mammographic assessment, a mass lesion with irregular borders is identified; associated microcalcifications are rare. The histologic findings include tumor cells in small clusters, sheets, or papillary configurations with an abundance of extracellular mucin.

ILC often has a more subtle clinical presentation on both clinical and radiographic examinations and often is underestimated based on physical and mammographic examination. The use of **MRI** may be more valuable in patients with this disease process. The cancer tends to be multifocal and have a higher incidence of bilateral disease. Most often, the finding in the contralateral breast is LCIS. Histologically, the cells are small and uniform and infiltrate the surrounding stroma in a linear fashion. Multiple variants of the disease exist (**Fig. 45.35**).

Metastatic Disease to the Breast (Extramammary Malignancies)

Metastatic deposits to the breast from distant sites have been reported. Often, these lesions are multiple, bilateral, and well circumscribed. The sites of origin include the contralateral breast, melanoma, lung, choriocarcinoma, cervix, ovary, and many others. An unusual clinical, radiographic, or pathologic finding should raise the possibility of metastatic disease to the breast, and the clinician should provide adequate historical information to the pathologist to assist in diagnosis.

FIGURE 45.35 Infiltrating lobular carcinoma. The tumor cells are small and uniform and infiltrate the surrounding stroma in a linear fashion (H&E 10×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

Nottingham Score

Histologic grading has been used to correlate with prognosis. The Elston-Ellis modification of the Scarff-Bloom-Richardson system, also known as “Nottingham Score,” is the system most often employed. The current tumor grading system employs nuclear grade, tubule formation, and mitotic rate. Each element is on a scale of 1 to 3. The components are added together and can range from 3 to 9, whereby low is 3 to 5, moderate 6 to 7, and high-grade scores 8 to 9. Nottingham Scoring System is demonstrated in **Table 45.19**.

Molecular Tumor Classification

Gene expression profiling has aided in the identification of subtypes of breast cancer. The four basic subtypes include luminal

A, luminal B, HER2, and basal-like. The subtypes have different patterns of gene expression, behavior, and response to therapy. Identification of subtypes can be beneficial in guiding therapy decisions and lead to individualized or personalized treatment.

TABLE 45.19 Nottingham Scoring System	
Nuclear Pleomorphism	Score

Small regular uniform cells	1
Moderate nuclear size and variation	2
Marked nuclear variation	3
Mitotic Count	Score
0-9 mitoses/10 HPF	1
10-19 mitoses/10 HPF	2
20 or > mitoses/10 HPF	3
Tubule Formation	Score
Majority of tumor (>75%)	1
Moderate degree (10%-75%)	2
Little or none (<10%)	3
Grading	Score
Low grade	3-5
Intermediate grade	6-7
High grade	8-9

Luminal A and B cancers have high rates of hormone receptor expression and improved prognosis. Together, they account for approximately 70% of all breast cancers. Both show high response rates to endocrine therapy, with luminal A demonstrating a slightly higher response. Luminal B has higher rates of response to cytotoxic chemotherapy.

HER2 cancers have higher rates of HER2 expression and are less likely to have estrogen (ER) and progesterone receptors (PR). They account for 15% of all breast cancers. Higher response rates are seen with combination of anthracyclinebased chemotherapy with trastuzumab (Herceptin, Genentech, San Francisco, CA). Basal-like cancers are also known as “triplenegative” cancers and do not express ER, PR, or HER2 genes. They account for 15% of breast cancers and have a poorer prognosis than do the other three subtypes. This phenotype is most often seen in BRCA1 mutation-associated cancers and also is more common in the African American population.

Staging

Staging allows for assessment of extent of disease and correlates with the individual's prognosis. Clinical and pathologic assessment of the tumor (T), regional lymph nodes (N), and the presence of metastatic (M) disease allow for stage assignment. The American Joint Commission on Cancer determines the current TNM staging system. The latest addition was issued in 2009 and takes into account sentinel node evaluation and extent of involvement; it also downstaged the supraclavicular node metastasis from M1 to N3 disease. Stage is assigned after surgery and comprehensive pathologic review. For patients receiving preoperative chemotherapy, clinical staging is assigned until surgery can be accomplished. When surgery is completed, a “y” prefix is used with the TNM assignment. See [Tables 45.20](#) and [45.21](#) for the most recent staging guidelines.

TABLE 45.20 American Joint Committee on Cancer: Breast Cancer Staging

Definition of TNM	
Primary Tumor (T) Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1-cm increment.	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget's)	Paget disease of the nipple NOT associated with invasive carcinoma and/or carcinoma in situ (DCIS and/or LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget disease should still be noted.

T1	Tumor ≤20 mm or less in greatest dimension
T1mi	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to skin (ulceration or skin nodules)
T4a	Extension to chest wall, not including only pectoralis muscle adherence/invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma

Regional Lymph Nodes/Clinical

NX	Regional lymph nodes cannot be assessed (e.g., previously removed).
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral level I, II axillary lymph node(s)
N2	Metastases in ipsilateral level I and II axillary lymph nodes that are clinically fixed or matted, or in clinically detected ^a ipsilateral internal mammary nodes in the absence of clinically evident lymph node metastases
N2a	Metastasis in ipsilateral level I and II axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastasis only in clinically detected ^a ipsilateral internal mammary nodes and in the absence of clinically evident level I and II axillary lymph node metastasis
N3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I and II axillary lymph node involvement, or in clinically detected ^a ipsilateral internal mammary lymph node(s) with clinically evident level I and II axillary lymph node metastases, or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)

Pathologic (PN)^b

pNX	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study).
pN0	No regional lymph node metastasis identified histologically

Note: Isolated tumor cells clusters (ITCs) are defined as small clusters of cells not greater than 0.2 mm, or single tumor cells, or a cluster of fewer than 200 cells in a single histologic cross section. ITCs may be detected by routine histology or by immunohistochemical (IHC) methods. Nodes containing only ITCs are excluded from the total positive node count for purposes of N classification but should be included in the total number of nodes evaluated.

pN0(i-)	No regional lymph node metastasis histologically, negative IHC
pN0(i+)	Malignant cells in regional lymph node(s) not greater than 0.2 mm (detected by H&E or IHC including ITC)
pN0(mol-)	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR)
pN0(mol+)	Positive molecular findings (RT-PCR), but no regional lymph node metastases detected by histology or IHC

pN1	Micrometastases, or metastases in 1-3 axillary lymph nodes, and/or in internal mammary nodes with metastases detected by SLNB but not clinically detected ^c
pN1mi	Micrometastases (>0.2 mm and/or more than 200 cells, but none >2.0 mm)
pN1a	Metastases in 1-3 axillary lymph nodes, at least one metastasis >2.0 mm
pN1b	Metastases in internal mammary nodes with micrometastases or macrometastases detected by SLNB but not clinically detected [†]
pN1c	Metastases in 1-3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected
pN2	Metastases in 4-9 axillary lymph nodes, or in clinically detected [§] internal mammary lymph nodes in the absence of axillary lymph node metastases
pN2a	Metastases in 4-9 axillary lymph nodes (at least one tumor deposit >2.0 mm)
pN2b	Metastases in clinically detected [§] internal mammary lymph nodes in the absence of axillary lymph node metastases
pN3	Metastases in 10 or more axillary lymph nodes, or in infraclavicular (level III axillary) lymph nodes, or in clinically detected [§] ipsilateral internal mammary lymph nodes in the presence of one or more positive level I and II axillary lymph node(s), or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected, ^c or in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in 10 or more axillary lymph nodes (at least one tumor deposit larger than 2.0 mm), or metastases to the infraclavicular (level III axillary) lymph nodes
pN3b	Metastases in clinically detected [§] ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes, or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected ^d
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes

Distant Metastasis (M)

M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven larger than 0.2 mm

RT-PCR, reverse transcriptase polymerase chain reaction.

^aClinically detected is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination. Confirmation of clinically detected metastatic disease by fine needle aspiration without excision biopsy is designated with an (f) suffix, for example, cN3a(f). Excisional biopsy of a lymph node or biopsy of a sentinel node, in the absence of assignment of a pT, is classified as a clinical N, for example, cN1. Information regarding the confirmation of the nodal status will be designated in site-specific factors as clinical, fine needle aspiration, core biopsy, or sentinel lymph node biopsy. Pathologic classification (pN) is used for excision or sentinel lymph node biopsy only in connection with a pathologic T assignment.

^bClassification is based on axillary lymph node dissection with or without sentinel lymph node biopsy. Classification based solely on sentinel lymph node biopsy without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," for example, pN0(sn).

^c"Not clinically detected" is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

^d"Clinically detected" is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination.

IIIC	49%
IV	20.9%

Prognosis

Survival rates after the diagnosis of breast cancer are dependent on a number of factors, including age at diagnosis, stage, molecular subtype of the tumor, medical comorbidities, and performance status. A patient diagnosed with stage 0 (DCIS) has virtually a 100% likelihood of survival from the disease. As the stage of the disease advances, the likelihood of recurrence increases and overall and disease-free survival decreases. Lymph node status (reflected in stage) is the most significant prognostic factor. [Table 45.23](#) lists stage and survival rates. [Figure 45.36](#) demonstrates Kaplan-Meier survival curves by stage.

BREAST CANCER MANAGEMENT

Clinical Presentation

Patients with DCIS are generally without symptoms. The majority of patients are diagnosed with percutaneous biopsy after an abnormal mammogram. If the disease is palpable, there is a high likelihood of associated invasive cancer. Paget disease with its associated nipple areolar erythema and crusting may be an indicator of the presence of this disease process.

Fortunately, the majority of invasive breast cancer is now found on screening mammography without palpable evidence of disease; however, due to mammographic screening failures, rapidly growing disease, or lack of access to the health care system, patients sometimes present with clinical evidence of disease. A patient may present with an irregularly shaped mass with a firm consistency, fixed in position to surrounding tissue, and associated dimpling or retraction of the overlying skin and/or nipple. In advanced disease, peau d'orange skin changes occur due to obstruction of the dermal lymphatics ([Fig. 45.37](#)).

In general, breast cancer is slightly more common in the left breast than in the right. In most women, the left breast is slightly larger than the right. The upper outer quadrant is more frequently involved in malignant changes (this is the site of the highest distribution of breast tissue), with the central and subareolar regions being second ([Table 45.17](#)).

P.1042

FIGURE 45.36 Kaplan-Meier survival curve by stage of breast cancer.

Management of Ductal Carcinoma In Situ

This category represents 20% of all newly diagnosed breast cancers and has a 20-year survival rate of 97%. In at least 90% of patients, the diagnosis is made with mammography. Approximately 10% of patients have a palpable mass. Comprehensive management includes a detailed history and physical examination, bilateral diagnostic mammography, pathology review, and ascertainment of hormone receptor status. A detailed family history can help identify patients who are at high risk for genetic mutations or family cancer syndromes. MRI is recommended for high-grade DCIS and in patients with dense breasts that preclude accurate assessment of disease extent. For patients in whom accelerated partial breast irradiation (APBI) is being considered, MRI is used at our institution to identify individuals with large volume disease and those with multifocal disease who would be ineligible for this treatment.

DCIS is usually identified on mammogram and presents as an area of pleomorphic, clustered calcifications. Linear calcifications tracking toward the nipple are virtually diagnostic for the entity. Percutaneous core biopsy is the most common method to confirm the diagnosis. At the time of surgical excision, associated invasive cancer is found in 25% of specimens and is more common when the DCIS is palpable.

FIGURE 45.37 Inflammatory breast cancer. A 56-year-old who presented with a 2-week history of breast erythema and edema. There is visible nipple inversion from the underlying mass. Marked edema and peau d'orange are visible. (Courtesy of Emilia Diego, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

Surgical management for unifocal disease is surgical excision with a wide margin. Providing free margins are obtained, the patient is eligible for breast-conserving treatment.

Whole breast radiation has been demonstrated to decrease local recurrence rate. In women 50 years of age or younger, a boost to the surgical bed is the traditional approach. No difference in overall survival occurs in patients treated with breast conservation and radiation compared to those treated with mastectomy. In the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-17 study, patients with DCIS were randomly assigned to lumpectomy alone or lumpectomy with radiation therapy. For the radiation-treated cohort, the study demonstrated a 52% reduction in ipsilateral breast tumor recurrence rates. Additionally, the majority of the recurrences were DCIS. In patients treated with lumpectomy alone, recurrences were more common and evenly divided between invasive and in situ disease. The addition of radiation decreases both recurrence rate and invasive disease compared to patients treated with surgery alone.

Retrospective data suggest that radiation therapy is not warranted in all patients treated with breast-conserving surgery. Predictors for recurrence include grade and margin width. Attempts have been made to identify a subset of patients who can avoid postoperative radiotherapy. One such group appears to be those with low- or intermediate-grade lesions smaller than 2 cm with more than 1-cm margins. Margin width appears to be the single most prognostic factor for local recurrence; however, no clear definitions of margin adequacy exist. In reviewing the literature, the range of adequate margins is reported from larger than 1 mm up to 10 mm. Wider margins are associated with poorer cosmetic outcome.

The NSABP B-24 study assessed the role of tamoxifen therapy in patients with DCIS. The use of tamoxifen was associated with a 3.2% absolute reduction in ipsilateral breast tumor recurrence and a decreased incidence of contralateral cancer. The benefit in reducing ipsilateral tumor recurrence was restricted to patients with ER-positive DCIS, but the reduction in contralateral breast cancer was seen regardless of receptor status.

For patients with DCIS that is not amenable to breast conservation, total mastectomy with or without reconstruction is advised. Breast conservation surgery may not be feasible when lesions are multicentric (two or more foci of disease in different quadrants) and multifocal (two or more foci within the same quadrant) and cover a wide expanse such that the margins cannot be achieved or if a poor cosmetic outcome is likely. It is our practice to perform concurrent sentinel lymph node mapping at the time of mastectomy in event invasive cancer is found on final pathology analysis. Given the pathways of lymph

P.1043

drainage are altered by mastectomy, if sentinel lymph node evaluation was not performed, the finding of invasive cancer will obligate the patient to undergo an axillary dissection.

Invasive Breast Cancer Management

As recently as three decades ago, the management of breast cancer relied on local-regional treatments to achieve the best chance for cure. Surgical therapy consisted of radical mastectomy and the use of radiation therapy in a select subset of patients. The notion that radical local regional therapy was the key to preventing systemic failure has been challenged through the use of clinical trials proposing less radical surgery and focusing on the role of adjuvant therapy at diagnosis to treat occult metastatic disease and was a focus of an **NIH** consensus conference.

Today, all patients diagnosed with breast cancer are approached with multimodal therapy. When possible, breast-conserving surgery combined with radiation therapy has achieved equivalent outcomes to mastectomy in terms of local-regional control and overall survival. The use of adjuvant endocrine and chemotherapy has improved both disease-free and overall survival.

In patients with more advanced disease, multimodal therapy has proven beneficial. Again, the traditional approach of using radical local-regional therapy has been altered through clinical trials. The combination of surgery, radiation therapy, and adjuvant therapy has improved outcomes. Altering the traditional order of therapy to allow for upfront endocrine and/or cytotoxic chemotherapy can often allow a patient destined for mastectomy to undergo a breast-conserving surgery instead.

As knowledge has advanced and molecular profiling of tumors has become available, treatment based on subtypes and specific targets has altered recurrence rates. Genomic testing has come of age and allowed for risk stratification and individualization of treatment based on analysis of the tumor genome.

Comprehensive management includes a detailed history, family history, and physical examination. Evaluation should include bilateral diagnostic mammography, pathology review, and ascertainment of hormone receptor and HER2 status. A detailed family history can help identify patients who are at high risk for genetic mutations or family cancer syndromes. Chest radiograph and liver chemistries should be performed to assess for metastatic spread of disease. Patients with abnormal liver function assessment should have directed imaging with either hepatic ultrasound or abdominal CT scan. For patients in whom surgical management is contemplated, preoperative blood tests can be obtained including complete blood count, electrolytes, renal function, and coagulation profile. Patients who present with symptoms suggesting bone involvement should undergo a radionuclide bone scan (bone scintigraphy) or directed plain film radiographs. No role exists for routine use of bone scan, CT scan, PET-CT scan, or tumor markers.

MRI is optional and if performed should be on a machine with a dedicated breast coil. Patients who appear to benefit for MRI assessment are those with dense breasts in whom suspicion for disease extent is not adequately assessed on diagnostic mammography and/or ultrasound, in whom involved axillary nodes and a suspicion of an occult breast primary tumor exists, and in patients with known BRCA1/BRCA2 deleterious mutations for whom breast conservation is being considered. For patients deemed candidates for APBI, MRI can be helpful in assessing multicentric or multifocal disease that would preclude the technique. MRI detects contralateral breast disease in approximately 3% of patients with normal clinical and mammographic examinations. The finding of multicentric/multifocal disease is more common and found in some studies to be 15%. MRI is highly sensitive but not specific; therefore, patients should not be deemed ineligible for breast-conserving surgery without tissue confirmation of multiquadrant involvement.

For patients with locally advanced tumors, preoperative chemotherapy is a reasonable approach. Prior to initiating treatment, the site should be marked with a localization clip in event a complete clinical response is achieved. Radiographic imaging before and after induction therapy should be obtained to document objective response. For patients with ER-, PR-, and HER2-negative (basal-like or "triple-negative") tumors, preoperative therapy regardless of tumor size is a reasonable approach given its aggressive nature.

Axillary assessment with ultrasound is reasonable in patients with clinically negative nodes to identify patients who would not meet the criteria for sentinel lymph node mapping.

SURGICAL MANAGEMENT OF BREAST CANCER

Breast Conservation Surgery

Breast conservation is the favored mode of management of early breast cancer. The march toward breast conservation took almost 100 years. Several sentinel randomized studies demonstrated similar survival outcomes in patients treated with radical mastectomy, total mastectomy, and breast-conserving surgery. A leader in the field of breast cancer care has been Dr. Bernard Fisher and the National Surgical Adjuvant Breast and Bowel Project cooperative group. The NSABP B-4 study randomly assigned over 1,500 patients based on nodal status to radical mastectomy, total mastectomy with postoperative chest wall and axillary radiation, or total mastectomy for patients with clinically negative nodes at diagnosis. For patients with clinically involved lymph nodes, randomization was between radical mastectomy and total mastectomy with postoperative chest wall and axillary radiation. With 72 months of followup, no difference in overall survival or distant recurrence was noted. For patients not treated with axillary dissection, 16% demonstrated subsequent disease in this region and were managed with delayed axillary dissection. This landmark study was first published in 1977 and has had interim reports, the latest in 2002 with 25 years of follow-up demonstrating no difference in overall and disease-free survival. Advancing on this study, NSABP B-6 compared total mastectomy to lumpectomy with or without radiation. Entry criteria were restricted to early-stage disease with tumor size less than 4 cm, free margins in the case of lumpectomy, and patients with involved lymph nodes. All patients underwent an axillary dissection. Patients with node involvement received postoperative

chemotherapy (melphalan and 5-fluorouracil). Overall survival and diseasefree survival were equivalent in all arms of the study, demonstrating equivalency to breast removal. Concurrently, Veronesi and colleagues at the Milan Cancer Institute published their results on quadrantectomy and postoperative radiation therapy, demonstrating similar overall survival to patients treated with radical mastectomy. The procedure involved excision of the overlying skin and the involved quadrant of the breast.

Breast conservation surgery employs the use of wide local excision of the tumor with a margin of normal-appearing breast tissue. Various terms, including "lumpectomy," "tumorectomy," or "segmental mastectomy," have been used to describe the procedure. Multiple studies have demonstrated equivalency to total or radical mastectomy. [Table 45.24](#) lists

P.1044
P.1045

trials that compared breast-conserving surgery and radiation to mastectomy. Interestingly, each trial had a different definition of margins. Many studies specified a 1- to 2-cm minimal margin, whereas the NSABP trials required only "enough normal tissue removed to ensure that the specimen margins were tumor-free."

Breast-conserving surgery relies on the use of radiation therapy to reduce in-breast recurrences. In patients treated with lumpectomy alone, ipsilateral breast tumor recurrence rates were 40% compared to 14% in patients treated with breast conservation and postoperative radiation. Radiotherapeutic approaches are described in the next section of this chapter.

Contraindications to BCS can be classified as absolute and relative. When the concept of breast conservation was first introduced, absolute contraindications were numerous. As an understanding of the pathophysiology of the disease became apparent, and techniques of radiation therapy and neoadjuvant therapy improved, the use of breast-conserving surgery has become feasible in the majority of patients. [Table 45.25](#) lists proposed absolute and relative contraindications.

Partial Mastectomy/Lumpectomy

Partial mastectomy/lumpectomy is the surgical technique employed most often for a known diagnosis of breast cancer. It involves the removal of a portion of the breast containing the known cancer along with additional 1 to 2 cm of normal-appearing breast tissue surrounding the lesion. The terms tumorectomy or segmental mastectomy are often used interchangeably for this procedure. Although varying definitions exist for segmental mastectomy, the description should be reserved for when one or more of the 12 to 16 segments of the breast are excised. Quadrantectomy involves removal of a full quarter of the breast in which the cancer is located (the initial description also included the overlying skin).

Surgical approach in partial mastectomy/lumpectomy is similar to excisional biopsy and is performed with or without a localization procedure. The incision site and size is chosen based on the location of the lesion. Care should be taken to choose existing skin lines (Langer) to achieve the best cosmetic outcome. The surgeon envisions the location by reviewing the radiographs and removes a margin of normal tissue around the cancer. The specimen is then carefully oriented in case additional margins are required. The pectoral fascia should be left intact whenever possible because exposure of the pectoral muscle causes the remaining breast tissue to adhere and cause dimpling of the overlying skin. It is important to assess margins while the surgical site is still open. If a radiographic localization took place, a specimen radiograph in two planes can provide margin information. Additionally, pathologic inspection of the margins should occur. The surgeon should communicate pertinent information to the pathologist, including the clinical size of the tumor, number of tumors, location, whether preoperative therapy was employed, and orientation of the specimen. Orientation is achieved by the use of a Margin Map® (Beekley Corp, Bristol, CT) or placement of sutures following protocol: long suture lateral, short suture superior, medium suture medial, and double sutures for the deep margin. The specimen is then inked with different colors for each margin to aid in microscopic assessment ([Table 45.26](#)). The specimen is divided in 1-cm intervals and the tumor and margins assessed. If any margin appears to be compromised, it is advantageous to excise additional margin at this point, as it will obviate the need for a second surgery. Aesthetic outcome is best if only one procedure is performed. Percutaneous drains should be avoided to prevent cosmetic deformity ([Fig. 45.38](#)).

Total Mastectomy

This procedure is performed in patients with multifocal DCIS, margin involvement after breast-conserving therapy for either DCIS or invasive cancer, or as risk-reducing surgery for genetic predisposition or LCIS. The initial approach can be either an

P.1046

elliptical skin paddle or circumareolar incision. The dissection separates the superficial fascia of the breast from the skin. The surgeon dissects superiorly to the clavicle, laterally to the latissimus dorsi muscle, inferiorly to the inframammary fold, and medially to the sternal border. The pectoralis fascia can be removed at the same time, but no attempt is made to remove the axillary lymph nodes. A single closed suction drain is placed, and the wound is closed using subcuticular sutures. The operation can be combined with immediate reconstruction and sentinel lymph node mapping. If an axillary dissection is performed, the operation is properly termed a modified radical mastectomy. (See Steps in the Procedure.)

FIGURE 45.38 A 52-year-old stage I (T1, N0, M0) invasive ductal cancer status post left breast-conserving surgery and sentinel mapping.

STEPS IN THE PROCEDURE

Mastectomy

- This procedure is done under general anesthesia.
- This can be combined with sentinel lymphatic mapping, axillary dissection, and/or immediate breast reconstruction.
- For a skin-sparing procedure, the preferred incision is made around the nipple-areolar complex (NAC); otherwise, an elliptical incision is made to encompass the (NAC) and the surrounding skin to allow for closure of the skin without having skin tags (incision length should be twice the length of the width).
- Dissection takes place using sharp dissection or an electrocoagulation device. The superficial fascia of the breast is separated from the skin.
- Borders of the dissection include the clavicle, the inframammary fold, the sternal border, and the latissimus dorsi.
- The breast is released by separating the pectoralis fascia from the muscle.

- The specimen is oriented to allow for margin assessment.
- The wound is made hemostatic with either sutures or electrocoagulation.
- A closed suction drain is placed in the operative bed.
- The wound is then closed in two layers with subcuticular sutures.

Modified Radical Mastectomy

Originally described by Patey and Dyson, modified radical mastectomy involved a total mastectomy with preservation of the pectoralis major muscle but removal of the pectoralis minor muscle to allow for access to all three levels of axillary nodes. This modification maintained the contour of the thorax. The current modification of Patey's procedure is dividing the origin of the muscle at the insertion of the coracoid process. The modern modified radical mastectomy was further refined by Madden and colleagues, who reported on the preservation of both the pectoralis major and minor muscles.

The operation involves an elliptical skin incision incorporating the nipple-areolar complex ([Fig. 45.39](#)). To avoid the appearance of excess tissue also known as a "dog ear," the length of the incision should be double the width at the level of the nipple-areolar complex. A flap is developed between the superficial fascia of the breast and the overlying skin. Flaps that are too thin will develop skin necrosis leading to infection and wound separation. Flaps that are too thick will predispose the patient to local recurrence as a result of residual breast tissue. The flaps are developed superiorly to the clavicle, medially to the sternal border, inferiorly to the insertion of the rectus muscle, laterally to the latissimus dorsi muscle, and posteriorly to the pectoralis fascia. The fascia is removed en bloc with the breast. Laterally, the dissection extends to axillary basin. The fat pad located between the pectoralis major and minor muscle and the latissimus dorsi contains the node-bearing tissue. The dissection continues along the latissimus dorsi until the axillary vein is encountered. The axillary vein is the superior border of the node dissection. Located above this vein are the nerves of the brachial plexus; injury to these structures can occur if the operator is too zealous in his or her approach. Care is taken to preserve as many intercostal brachial nerves as possible as they traverse the axillary fat pad. The surgeon must identify and preserve the thoracodorsal neurovascular complex to the latissimus dorsi. The vascular components are best preserved, as they can be utilized during free flap reconstruction. Additionally, the long thoracic nerve to the serratus anterior muscle is identified on the chest wall and preserved. Injury to the nerve leads to the appearance of a winged scapula. Finally, care is taken to identify the medial pectoral nerve as it courses along the lateral border of the pectoralis minor muscle. Injury to the nerve will cause denervation of the lateral portion of the pectoralis major muscle and lead atrophy and the appearance of loss of the muscle along the thorax. During the course of the dissection, the pectoralis muscles are elevated and the level II nodes are excised. Hemostasis is obtained by the use of electrocoagulation, clips, or individual suture ties. This completes the dissection.

FIGURE 45.39 A 61-year-old with stage II (T2, N1, M0) invasive lobular cancer. The disease was multifocal, and she underwent a modified radical mastectomy. Note there is no chest wall deformity and the pectoralis major muscle adds definition to the shoulder.

The specimen is removed and oriented with a long suture for the lateral extent and a short suture for the superior margin. The pathologists then ink the specimen according to a protocol to help assess margin status on histopathologic assessment ([Table 45.26](#)). After obtaining hemostasis, one or two closed suction drains are placed to prevent seroma formation in the mastectomy bed and axillary basin and to allow for the skin to adhere to the underlying tissues. The wound is then closed using

P.1047

a two-layer subcuticular closure, skin staples, or a single-layer barbed suture such as the V-loc (Covidien, Mansfield, MA).

FIGURE 45.40 Patient treated with radical mastectomy and the use of a skin graft. Note the loss of chest wall and shoulder definition. The patient's ribs are also visualized.

Radical Mastectomy

The radical mastectomy was the standard treatment for breast cancer for almost 100 years. Dr. William Halsted theorized that breast cancer spread in an orderly, stepwise manner from the breast via intervening lymphatics to the axillary lymph nodes and then finally to distant sites. His surgical approach was directed toward local-regional control by removing en bloc the breast, the pectoralis muscles, and the regional lymph nodes ([Fig. 45.40](#)). In 1894, he reported his results on 50 patients treated in this manner. Overall, a 6% local recurrence rate occurred, compared to known rates of 50% and no operative mortality. Considered the father of modern surgery, Halsted developed

several tenets of surgery that improved surgical outcome. Halsted's tenets of surgery are listed in [Table 45.27](#). In the same year, Meyer reported his experience with the radical mastectomy at his institution, echoing the findings of Halsted. The operation fell out of favor as a better understanding of the pathophysiology of breast cancer became evident.

In 1895, Röntgen reported on the discovery of x-rays. In addition to aiding in diagnoses, it was discovered that x-rays served a role in the management and treatment of cancer. Over the ensuing decades, less radical or no surgery for breast cancer combined with radiation therapy was investigated and reported. By the mid-1980s, the use of radical mastectomy as primary surgical management for breast cancer was abandoned.

Skin-Sparing Mastectomy

Skin-sparing mastectomy is a modification of the total mastectomy. This technique involves removal of the nipple-areolar complex with preservation of the majority of the skin that serves as an envelope for the underlying reconstruction. This technique can be employed with either prosthetic implantbased or autogenous tissue transfer reconstruction. Long-term follow-up has not demonstrated an increased rate of local-regional recurrence compared to the traditional non-skinsparing mastectomy, hence allowing for an excellent cosmetic outcome without compromising oncologic principles or outcome ([Figs. 45.41, 45.42, and 45.43](#)).

Nipple-Sparing Mastectomy

An extension of the skin-sparing mastectomy is the nipplesparing mastectomy. This procedure allows for preservation of the nipple, the areola, and the skin of the breast with concomitant removal of the underlying parenchyma. The procedure is gaining acceptance as an alternative to skin-sparing or non-skin-sparing mastectomy in the settings of prophylactic/risk-reducing surgery and in selective circumstances for treatment of breast cancer.

Original attempts at a nipple-sparing operation were popularized with the subcutaneous mastectomy; however,

P.1048

the procedure was not optimal given high complication rates, limited reconstructive options, and retention of significant amounts of breast tissue. In 1999, a published report on the efficacy of prophylactic mastectomy in women with a family history of breast cancer reintroduced the concept of this approach. Subsequently, an additional report from the same institution demonstrated benefit in women with known BRCA mutations. Multiple reports have since demonstrated similar results. Varied surgical approaches exist, including the use of a periareolar incision with lateral extension, transareolar incision with medial or lateral extensions, inframammary incision (favored at our institution), and a lateral inframammary incision ([Fig. 45.44](#)).

FIGURE 45.42 Left skin-sparing mastectomy with implant-based reconstruction. (Photo courtesy of Dr. Kenneth Shestak, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

FIGURE 45.43 Bilateral skin-sparing mastectomy with autogenous tissue transfer (TRAM flap) and nipple-areolar reconstruction. (Photo courtesy of Dr. Kenneth Shestak, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

Nipple-sparing mastectomy has been employed in patients as part of therapeutic management of a known breast cancer. General consensus is that the following criteria should be met in order to employ this technique: (a) the lesion should be 3 cm or less in size and at least 2 cm from the nipple-areolar complex, (b) clinically negative axillary nodes, (c) no evidence of skin involvement, and (d) preferably preoperative MRI imaging to rule out occult lesions. During the procedure, consideration should be given to obtaining a biopsy of the subareolar region to rule out occult spread.

If a patient meets oncologic criteria for risk-reducing or therapeutic mastectomy, an assessment should be made by the plastic surgeon with regard to role of nipple-sparing mastectomy. Patients with large and/or ptotic breasts are poor candidates for this operation. Common complications include flap necrosis, nipple-areolar necrosis, and loss of tactile sensation of the nipple.

Oncoplastic Breast Surgery

The use of a variety of techniques to maintain the volume, contour, and symmetry of the breast can be employed as part of breast-conserving surgery. As the name implies, it is used as part of the surgical treatment for breast cancer but also involves plastic surgery techniques to gain the optimum cosmetic outcome.

FIGURE 45.44 Bilateral nipple-sparing mastectomies with inframammary incisions. Acellular dermal matrix-assisted placement of tissue expanders and subsequent silicone gel breast implants with 2-year P.O. appearance. (Photo courtesy of Kenneth Shestak, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

Patients with less than optimal tumor-to-breast ratios or large or ptotic breasts can have improved outcomes through wise choice of incisions, tissue rearrangement, and contouring of the contralateral breast. Partial mastectomy can result in marked volume reduction, dimpling, and nipple-areolar displacement. By employing these techniques,

improved cosmetic results can be achieved. In some cases, muscle or myocutaneous flaps for partial reconstruction of the breast can be employed.

SENTINEL LYMPHATIC MAPPING

Sentinel node identification and lymphatic mapping had its genesis in other disease sites. In 1960, Gould and colleagues originally proposed the concept of a sentinel node for head and neck cancer in their description of the key node being identified at the junction of anterior and posterior veins of the neck. In gynecologic cancer, DiSaia and colleagues utilized the superficial inguinal lymph nodes as the “sentinel nodes” in the treatment of cancer of the vulva, to help identify patients who would not benefit from the more morbid complete lymphadenectomy. In the 1990s, Morton and colleagues described what is now modern lymphatic mapping in the treatment of melanoma in which a colloidal gold was used to identify the primary nodal basin drainage.

The premise of SLNB is that tumor cells from the primary lesion will migrate to one or a few lymph nodes prior to disseminating to others within the region. These key lymph nodes can be identified via the use of a vital blue dye (isosulfan blue/methylene blue) and/or a radiolabeled colloid. Key to the utilization of this technique is validation that identification of the sentinel lymph node accurately predicts the status of the remaining lymph nodes.

The status of the axillary lymph nodes is the strongest prognostic factor for breast cancer recurrence. As tumor size increases, so does the risk of metastatic disease to the lymph nodes. See [Table 45.28](#). For patients with early-stage breast cancer and clinically negative nodes, sentinel lymphatic mapping has replaced axillary dissection as the standard of care. If suspicious nodes are detected on clinical or mammographic exam, ultrasound evaluation with percutaneous core biopsy or FNA can be performed. If an ultrasound reveals that lymph nodes are morphologically normal and/or core needle biopsy

P.1049

or FNA is benign or indeterminate, sentinel lymphatic mapping should be employed.

TABLE 45.28 Tumor Size and Rates of Nodal Metastases

Adapted from Weaver DL, Rosenberg RD, Barlow WE, et al. Pathologic findings from the Breast Cancer Surveillance Consortium: population-based outcomes in women undergoing biopsy after screening mammography. <i>Cancer</i> 2006;106(4): 732-742, with permission. Published by and John Wiley and Sons. Copyright © 1998 American Cancer Society.	

A great benefit of this technique is that patients with uninvolved sentinel lymph nodes can avoid a completion axillary dissection and, hence, have a lower risk of upper extremity lymphedema. Two recent studies demonstrated the rate of lymphedema as a result of SLNB to be approximately 2% to 8% compared to 14% after SLNB and axillary dissection. Historically, rates as high as 40% have been reported.

For the treatment of breast cancer, this technique has been rapidly accepted and is now considered the standard approach for women with invasive or microinvasive breast cancer. It may also have applications in the treatment of DCIS when there is clinical concern for invasion or if the primary treatment will be mastectomy that then precludes a delayed SLNB procedure.

Sentinel lymph node identification is successful in more than 95% of surgical cases. The false-negative rate ranges from 5% to 10% as demonstrated in studies in which a completion axillary dissection was performed following SLNB. NSABP B-32 enrolled 5,611 patients with clinically negative nodes. Patients were randomly assigned to SLNB followed by axillary dissection to SLNB alone with axillary dissection performed in instances of SLNB involvement. SLNB detection rates were 97% with a 9.8% false-negative rate. No significant differences were noted in regard to overall and disease-free survival and importantly no difference in regional control. The later finding suggests that regional control is not achieved by surgical intervention alone, but rather adjuvant therapy is the key component of management. In NSABP B-4, in which one of the randomization arms was total mastectomy with or without postoperative chest wall and axillary radiation, approximately 16% of cancers recurred in the axilla and were managed by a delayed axillary dissection. No difference occurred in survival compared to individuals treated by modified radical mastectomy, suggesting axillary dissection does not improve outcomes in patients with clinically negative nodes.

A learning curve exists with this procedure. Improved detection rates are seen with increased experience of the surgeon. In the initial trials, recommendations were to perform 20 to 30 SLNBs with concurrent axillary dissection. Now that SLNB is considered a standard approach and has been widely adopted, use of backup axillary dissection is not indicated. For surgeons just learning the technique, proctoring with an experienced colleague is advised.

Most institutions use both a visual blue dye and the radiocolloid technetium-99m to identify the sentinel node. More often, radiocolloid is more sensitive in identifying the sentinel node. The site of injection of the tracers has been extensively studied. Peritumoral, intraparenchymal, subdermal, subareolar, and intradermal all seem to have similar success.

Isosulfan blue (Lymphazurin, Covidien, Mansfield, MA) is approved for use in lymphatic mapping. It is a monosodium salt of 2,5-disulfonated triphenyl methane dye. It has a reported 1% incidence of allergic reactions including anaphylaxis. Alternative dyes include Patent Blue V dye (sodium salt of disulfonated triphenyl methane) and methylene blue (methylthioninium chloride). Patent Blue V dye is widely used outside of the United States and has reported allergic reaction rates of 0.2%.

Given a worldwide shortage of isosulfan blue dye in the early 2000s, methylene blue dye was studied and found to be an acceptable alternative. Dilution of methylene blue from full strength of 10 mg/mL to 1.25 mg/mL and giving the injection in the subareolar region was associated with the highest sentinel node detection rate (92%). Hypersensitivity reactions were rare, and the most frequent complication was skin necrosis, which occurred in 1.25% of patients and resolved in 4 of 5 patients without intervention. Allergic reactions to this drug are rare. Methylene blue injection is the drug of choice at our institution unless we are unable to discern radioactivity in the axilla

prior to the surgery, in which circumstance, we use isosulfan blue dye.

At our institution, our preference is to perform the injections for sentinel lymphatic mapping in the operating room. This requires additional training of the surgeon to assure adequate technique and radiation training for patient and operating room personnel safety. After induction of anesthesia, the breast is prepped and 0.3 mL of Tc-99m sulfur colloid (0.45 microns with 0.5 millicuries activity) is injected intradermally at the 12-o'clock position of the breast. Three milliliters of the blue dye is injected into the subareolar region. Care is taken with methylene blue to avoid intradermal injection as this can cause skin necrosis. At the dilution of 1.25 mg/mL (1 mL dye to 7 mL of sterile saline), we have not observed instances of this adverse event.

For patients who have undergone previous breast surgery, particularly when incisions are present in the upper outer quadrant, deep parenchymal injections are preferred in addition to periareolar intradermal/subareolar injections. The normal pathways of drainage can be altered as a result of damage to the main trunks that traverse the upper outer quadrant.

Lymphoscintigraphy was used on a regular basis during the early phases of this technique (Fig. 45.45). As sentinel node detection rates exceed 95%, the role of this added procedure is diminished. Lymphoscintigraphy may have a role in the initial learning phase to assist the surgeon in identifying the number of sentinel nodes to be removed. At our institution, we no longer employ this nuclear medicine evaluation.

Sentinel lymph nodes receive a more intense evaluation using step sectioning to assess for metastatic disease. The lymph node is sectioned at 2-mm intervals along its long axis. If a previous frozen section was obtained (routine approach is to divide the node in half along its long axis), the two pieces of the lymph node are sectioned in a similar manner. A 4-micron section is cut from each block, and hematoxylin and eosin (H&E) staining is performed. Cytokeratin staining is not routinely performed unless the cancer is of the lobular cell type

P.1050

that can be difficult to identify on routine H&E staining. We have utilized this approach at our institution for many years, and it is a well-accepted approach.

FIGURE 45.45 Lymphoscintigram for sentinel node mapping demonstrating one lymph node with marked radioisotope uptake.

More intense evaluation of the sentinel node has led to more frequent findings of occult metastatic disease within the lymph nodes, but the prognostic significance is uncertain. Isolated tumor cells are small clusters not greater than 0.2 mm or nonconfluent or nearly confluent clusters of cells not exceeding 200 cells in single histologic node cross section. Although the current staging system takes this into account, in this situation, prognosis is considered similar to that of patients with nodenegative cancers and no additional axillary surgery is advised. Micrometastases are defined as a cluster of tumor cells greater than 0.2 mm but not greater than 2.0 mm. Separate designation in staging is pN1mi. The finding of micrometastatic disease impacts prognosis, but whether there is a benefit from further axillary surgery is debatable. At present, NCCN guidelines recommend completion axillary dissection in this setting.

Occult micrometastases are not seen on traditional H&E staining but rather detected by the additional use of immunohistochemistry (IHC) or by reverse transcriptase polymerase chain reaction (RT-PCR). Initially employed in the evaluation of the sentinel node, a prospective study by the American College of Surgeons Oncology Group (ACOSOG) demonstrated no impact of IHC-detected metastases on overall survival. In a substudy of NSABPB-32, in patients treated with SLNB alone, initial pathologically negative sentinel lymph nodes were reevaluated. Paraffin-embedded tissue blocks were assessed using routine staining and immunohistochemical staining for cytokeratin. Occult metastases were detected in 15.9% of patients. A slight calculated overall 5-year survival difference of 1.2% (94.6% vs. 95.8%) was noted between those with and those without occult metastases. They concluded no clinical benefit derived from IHC staining of initially negative sentinel nodes. Current guidelines from the American Society of Clinical Oncology and NCCN do not support the routine use of IHC or RT-PCR in the evaluation of sentinel lymph nodes. The exception to this rule is in the setting of lobular cancer in order to discern metastatic cells by cytokeratin staining.

As a rule of thumb, if a sentinel lymph node harbors metastases, the risk of additional lymph node involvement is approximately 40%. Various nomograms exist to help predict possible involvement of the remaining axillary lymph nodes. At our institution, the commonly used site is the Memorial Sloan Kettering Cancer Center nomogram (www.mskcc.org/cancer-care/adult/breast/prediction-tools). The nomogram takes into account the size of the primary tumor, presence of lymph vascular space invasion, grade, nodal involvement, extranodal spread, number of sentinel nodes (SN) removed, and the number of involved SNs. The Z0011 study by ACOSOG examined the role of completion axillary dissection in patients with early-stage breast cancer in whom SN metastases were detected. Entrance criteria included T1 or T2 lesions, clinically negative nodes, and 3 or fewer involved sentinel nodes. Randomization was to observation or completion of axillary dissection. Overall 5-year survival was the same between the groups, and no difference was noted with regard to local-regional recurrence. Criticism of the study includes premature closure due to low accrual rates. These findings add to the growing body of literature demonstrating an advantage to adjuvant therapy. Clinical judgment and an informed discussion with the patient should guide the clinician in determining the role of axillary dissection.

For patients receiving preoperative endocrine/chemotherapy who have clinically negative nodes, controversy exists as to whether to perform sentinel mapping prior to initiating therapy to determine the role of axillary dissection at the time of local therapy. Alternatively, sentinel mapping can be performed at the time of postoperative local therapy. At our institution, if the nodes are clinically and radiographically normal, we delay the sentinel lymphatic mapping procedure until the time of definitive breast surgery.

Technique of SNLB

The site is marked in advance of surgery. After induction of anesthesia, the affected breast is cleansed with an alcohol wipe. At the 12-o'clock position, a dermal injection of the radioisotope is performed. Subsequently, 3 mL of the blue dye is injected into the subareolar area at the lateral extent of the nipple-areolar complex. The patient is then prepped and draped for surgical intervention. Using the gamma probe, an area of increased radioactivity is identified; the majority of the time, this is in the ipsilateral axilla.

Using an indelible marker, the area is demarcated. An incision line is drawn between the anterior and posterior axillary lines 1 to 2 cm beneath the axillary hairline. We routinely infiltrate the incision line with 0.5% bupivacaine hydrochloride as preemptive analgesia. Incision length can vary depending on the comfort of the surgeon. Dissection takes place through the subcutaneous tissue until the clavipectoral fascia is encountered and incised. This exposes the axillary fat pad. At this point, the surgeon attempts to identify afferent lymphatics bearing blue dye and begins to trace them to the lymph node. Concurrently, the surgeon should employ the gamma probe to direct the surgical dissection and identify the area of highest activity. Once this lymph node is identified, care is taken to remove the lymph node without removing any additional tissue. Approximately 95% of the time, the sentinel lymph node is both blue and radioactive. An ex vivo count is performed and recorded, and the hunt begins anew to identify additional SNs. Any lymph node that has an afferent lymphatic with blue dye or has a radioactivity count of 10% or more of the highest count is considered sentinel. Any node that is clinically suspicious regardless of the presence of radioactivity or blue dye should be removed. Intraoperative assessment of the lymph

P.1051

node(s) is left to the discretion of the surgeon. We advise assessment only if this alters operative events. If the node is clinically suspicious, it is our practice to obtain intraoperative assessment and if the node is involved to perform an immediate axillary dissection to avoid a second operative event. The operative bed is made hemostatic and closed in subcuticular manner without the use of a closed suction drain. (See Steps in the Procedure.)

STEPS IN THE PROCEDURE

Sentinel Lymphatic Mapping

- This procedure is performed under general anesthesia.
- Inject the radioactive tracer (technetium-99m-human colloid albumin) in the subdermis at the 12-o'clock position of the areola.
- Inject the isosulfan blue/methylene blue dye in a subdermal manner by the areola.
- Wait several minutes, and then use a gamma probe to identify in the axilla the highest radiation activity. Also assess the internal mammary nodes for activity.
- Make a mark over the area.
- Infiltrate the skin with 1% lidocaine.
- Incise the skin over the area; the incision site should allow for conversion of the sentinel node biopsy into an axillary dissection if gross disease is found. This incision site is typically by the axillary fold just beneath the hair line.
- Using the gamma probe, identify the hot nodes and remove them. These nodes are often found below the clavipectoral fascia. Visual inspection and removal of any blue nodes should be done at this point as well.
- Take note of the radioactivity of the hottest sentinel node as the background count after removal of all of the sentinel nodes should not be greater than 10% of the hottest node.
- Once all the hot and blue nodes have been removed, the axilla should be palpated in order to inspect for any firm nodes. These nodes should be removed as well.
- The fat tissue can be closed under the skin using a fine (3-0) absorbable suture.
- Skin closure using a running subcutaneous absorbable suture. A drain is not necessary.

The role of SLNB in patients undergoing neoadjuvant therapy is evolving. NCCN guidelines advise SLNB prior to induction chemotherapy as this can provide prognostic information to aid in determination of local-regional therapy. This is an area of active investigation with some institutions performing SNLB at the time of definitive surgical intervention if the patient has a clinically and radiographically negative axillary node at the onset of therapy. A recent trial by ACOSOG Z1071 was designed to define the accuracy of SNLB after neoadjuvant therapy. Women with prechemotherapy clinical T0-4, N1-2, M0 breast cancer were enrolled. At time of surgery, all patients underwent sentinel lymph node surgery followed by axillary dissection. Primary endpoint was false-negative rate. Majority of women underwent dual tracer identification of the sentinel node. Over a 2-year period, 756 women were enrolled. Sentinel node was identified in 84% of patients; false-negative rate was 12.8%, with 40% of the patients having a complete pathologic response in the lymph nodes. These findings demonstrate that SLNB is feasible after neoadjuvant therapy and may help identify a subset of patients who do not require completion axillary dissection.

Axillary reverse sentinel mapping (ARM) may have some feasibility in preventing the development of upper extremity lymphedema. In this technique, the tracers are injected intradermally into the upper extremity and identification of the nodes responsible for the drainage of the extremity can be identified and preserved. The inherent risk is in leaving metastatic disease behind in the basin.

In patients previously treated with breast-conserving surgery and SLNB who have a subsequent in-breast recurrence, the current recommendation is to perform an axillary dissection. Emerging studies are demonstrating the feasibility of a second mapping procedure. In our own experience, aberrant drainage to the contralateral axillary basin has been identified.

Axillary Dissection

In circumstances of known axillary lymph node involvement based on preoperative assessment, disease detected in the course of sentinel lymph node mapping, or on postoperative analysis and in the setting of IBC, an axillary dissection is employed. For patients with early-stage breast cancer and clinically negative nodes, axillary dissection is contraindicated and the correct management is the use of sentinel lymphatic mapping. If on clinical or radiographic exam, suspicious nodes are detected, cytologic or histopathologic confirmation should be obtained. If the ultrasound, pathology, or cytology is normal, sentinel lymphatic mapping should be employed.

The patient should be positioned to allow adequate visualization of the axillae. The upper extremity should be at no more than a 90-degree angle from the chest wall. Abduction beyond 90 degrees will introduce the potential for stretching the nerves of the brachial plexus and resultant injury.

In cases in which the axillary dissection is performed in concert with a partial mastectomy, a separate 2- to 3-cm incision is made in the axilla between the anterior and posterior axillary fold along Langer lines, 1 to 2 cm below the axillary hairline. When a skin-sparing or nipple-sparing mastectomy operation is performed and inadequate visualization of the axilla is anticipated, a separate incision can be made. Often, a lateral extension of the existing incisions can improve visualization. Dissection takes place through the subcutaneous tissue until the clavipectoral fascia is encountered. It is then divided to expose the underlying axillary fat pad. The borders of the axilla are defined by identifying the pectoralis major and minor muscle medially, the latissimus dorsi laterally, and the axillary vein at the superior aspect of the dissection. In the course of the operation, both sharp and blunt dissections are utilized to aid in identification and preservation of the sensory (intercostobrachial) and motor nerves. The three major motor nerves are the medial pectoral, the thoracodorsal, and the long thoracic nerves. The medial pectoral nerve is bundled with both a venous and arterial blood supply that supplies the pectoralis minor and lateral aspect of the pectoralis major muscles. Approximately 60% of the time, this complex passes through the pectoralis muscle; 40% of the time, it courses along the lateral border of the pectoralis minor muscle. Injuring this complex will lead to atrophy of these muscles and subsequent loss of chest wall definition. The long thoracic nerve can be found beneath the medial aspect of the axillary vein and passes along the chest wall. This nerve provides motor function to the

P.1052

serratus anterior muscle, and injury leads to the clinical finding of a winged scapula. Finally, the thoracodorsal neurovascular complex is identified in the midaxilla. Anterior to this complex is a superficial vein, the thoracoepigastric vein, which can be divided once confirmation of the integrity of the neurovascular complex is confirmed. Once the major nerve bundles are identified and secured, the fat pad can be removed en bloc.

The extent of the nodal dissection is defined by levels I to III in relationship to the anatomic location of the pectoralis minor muscle. The more comprehensive the dissection, the higher the rates are of postoperative morbidity.

A closed suction drain is then placed in the axillary basin and remains in place until the amount is less than 30 mL in 24 hours to prevent seroma formation. This allows for adherence of the surrounding structures. Some surgeons opt against placing a drain and will aspirate any seroma that forms. (See Steps in the Procedure.)

STEPS IN THE PROCEDURE

Axillary Dissection

- This procedure is performed under general anesthesia. Paralysis should be avoided to alert the surgeon of proximity to the major motor nerves.
- The procedure can be combined with either a segmental resection or mastectomy.
- Local anesthesia can be injected into the proposed incision site to reduce postoperative pain.
- When performed with a segmental resection, a separate incision is made between the anterior and posterior axillary fold just distal to the axillary hairline. If the operation is performed with a mastectomy, the operation is accomplished through the existing incision.
- Dissection takes place to identify the clavipectoral fascia.
- The borders of the axilla are identified—the medial border is the pectoralis major muscle, the lateral border is the latissimus dorsi, and the superior border is the axillary vein.
- Care is taken to preserve the intercostal brachial sensory nerves. The major motor nerves include the long thoracic nerve, which is located medially along the chest wall; the thoracodorsal neurovascular complex, which is identified medially to the latissimus dorsi; and the medial pectoral nerve, which either courses along the lateral border of the pectoralis major muscle or is located beneath the pectoralis minor muscle and traverses through both the minor and major muscles.
- The nodal tissue is gently dissected free to accomplish a level I and II dissection (removing nodal tissue lateral to and beneath the pectoralis minor muscle).
- Hemostasis is obtained with clips, ties, or electrocoagulation.
- Palpation of the basin should be performed to assess for any concerning lymph nodes.
- A closed suction drain is placed and secured to the skin.
- The wound is then closed in two layers with subcuticular sutures.

Postoperative complications include wound infection, hematoma and seroma formation, lymphedema, sensory loss, and motor injury. Rates of these complications vary from 1% to 10%. The most disturbing long-term complication is the development of lymphedema that can be seen in varying degrees depending on the extent of dissection.

Lymphedema

The most morbid outcome from breast cancer-related surgery is lymphedema. This is most often encountered as a result of breast-conserving surgery with axillary dissection, SLNB followed by completion axillary dissection, or modified radical mastectomy. Lymphedema is the result of disruption of the drainage pathways and manifests by swelling of the affected extremity. The degree of swelling is directly related to the extent of the axillary surgery, but similar to sentinel surgery, “key” lymph nodes or lymphatics, when disrupted, trigger this condition. Reported incidences range from 10% to 20% but can be as high as 40% if postoperative axillary radiation is employed.

Whenever possible, SLNB should be the procedure of choice, as multiple studies have demonstrated a low incidence (2%) of lymphedema when employed. If an axillary dissection has been performed, secondary prevention of lymphedema is the best defense. Meticulous skin and nail hygiene is recommended with prompt intervention if any signs of infection are noted. The patient should be taught to monitor for lymphedema and promptly report any changes in diameter, color, or temperature changes of their extremity. Avoiding tight-fitting garments that can impede lymph flow and not allowing the affected extremity to be maintained in a gravity-dependent position can help prevent the development of this condition. The patient should be instructed to avoid needle punctures and intravenous catheter placement in their upper extremity. Finally, maintaining an ideal body weight can prevent the development of lymphedema.

If lymphedema develops, early intervention has higher rates of success. The most commonly employed approach is complex decongestive therapy that has multiple components and involves physiotherapeutic techniques. The initial phase of treatment includes meticulous skin and nail care coupled with treatment of any signs of infection. Subsequently, manual lymphatic drainage coupled with compression garments is utilized on a frequent basis until the desired effect is reached. The patient is then placed on a maintenance program with use of compression garments to prevent recurrence.

BREAST RECONSTRUCTION

For patients not amenable to breast conservation surgery, breast reconstruction offers an option. Mastectomy not only carries physical changes but also has been associated in survivors with poor body image, depression, feelings of diminished self-worth, and alterations in occupational and social functioning. Breast reconstruction has been demonstrated to minimize these effects. Legislation introduced in 1998, in the Women's Health and Cancer Rights Act, mandated health care payer coverage for breast and nipple reconstruction, contralateral breast surgery to achieve symmetry, and surgical treatments for the sequelae of mastectomy.

Breast reconstructive techniques can use autogenous tissue, prosthetic placement, or a combination of both. The reconstruction can take place at the time of mastectomy or delayed to a later time.

It is preferred to offer the reconstruction at the same time as mastectomy. An advantage to this approach is the combination

P.1053

of both procedures into one setting, thereby minimizing the number of operative interventions, anesthetic risk, and cost. Additionally, a skin-sparing approach and the retention of the inframammary fold provide enhanced cosmetic outcome. Data exist to suggest psychosocial benefits. Potential disadvantages include prolonged operative time that may affect rates of infection and skin necrosis. Immediate reconstruction also carries the risk of identifying postoperatively the patient who should undergo postmastectomy chest wall radiation (tumor size 5 cm or larger, skin or chest wall involvement, or involvement of four or more lymph nodes). Fortunately, with the use of preoperative MRI, the incidence of this entity is low. Patients with locally advanced disease and multiple medical comorbidities (i.e., insulin-dependent diabetes, chronic obstructive pulmonary disease, smoking, obesity) are not ideal candidates for immediate reconstruction. Higher rates of skin necrosis, infection, donor site complications, and flap necrosis are seen when these medical issues exist.

In the past, delayed reconstruction was the usual approach. The basis of this was the belief that this allowed time for psychological adjustment to the loss of the breast. Advantages of delayed reconstruction include assessment of margins and nodal involvement, management of comorbidities to optimize the patient for surgery, and, in instances of advanced disease, allowance for neoadjuvant chemotherapy and postmastectomy radiation. Disadvantages include a second surgical procedure and less than optimal cosmetic result.

Options for reconstruction include prosthetic devices and autogenous tissue transfer utilizing skin, muscle, and fat. Determination of reconstruction is dependent on the patient's body habitus, type of therapy received or to be administered, and ability to achieve an optimal aesthetic outcome. Extensive counseling and discussion between the plastic surgeon and the patient is required.

Implant Reconstruction

Implant-based reconstruction utilizes a two-phase technique. In the first phase, a tissue expander, which is a silicone shell, is inserted at the initial operative event and incrementally expanded over several months with saline via an integrated port. In the second phase, after the desired breast size has been achieved from skin distention, the tissue expander is removed and a silicone or saline-based implant is placed. In women with an A cup sized breast, it may be feasible to avoid tissue expansion and immediately place the implant. To achieve symmetry, contralateral breast contouring may be required.

Autogenous Tissue Transfer

For patients who have large and/or ptotic breasts, have a large tissue deficit, or have undergone previous radiation therapy, myocutaneous flaps are often the best option. Aesthetically, the use of the patient's own tissue to develop the breast mound provides a more nature feel and appearance to the reconstructed site.

Flap placement can either utilize a pedicle-based transfer (moving the flap while keeping the vascular supply intact) or be completely mobilized and freed from the blood supply (free flap) and a microsurgical anastomosis performed to the internal mammary or thoracodorsal vessels.

The most common approach is the transverse rectus abdominis myocutaneous (TRAM) flap. It may be either pedicle based or developed as a free flap. Other techniques include the latissimus dorsi reconstruction, deep inferior epigastric pedicle flap (DIEP), and superficial inferior epigastric flap (SIEP). The DIEP and SIEP flaps use the same skin and fat island as a TRAM flap without the underlying rectus muscle. For patients who do not have sufficient abdominal fat, options include use of the superior gluteal artery (SGAP), inferior gluteal artery flap (IGAP), and a transverse upper gracilis (TUG) flap. These three types of flaps also place the scars in the less visible locations of the buttock or thigh.

RADIATION THERAPY

Breast conservation therapy relies on the use of postoperative radiation to achieve local control within the breast. For invasive cancer, NSABP B-6 demonstrated recurrence rates approaching 20% in patients treated with lumpectomy alone compared to 14% when treated with lumpectomy and radiation. For DCIS, postlumpectomy radiation therapy decreased ipsilateral breast tumor recurrence rates from 19.4% to 8.9%. Traditional radiation is delivered via two tangential planes to the breast in 1.8 to 2 gray (Gy) fractions daily, 5 days per week for 5 to 6 weeks for a total of 50 Gy. This amount has been shown to treat microscopic disease.

Newer techniques of delivering radiation therapy include intensity modulated radiation therapy (IMRT) and accelerated partial breast irradiation (APBI). Studies are ongoing to improve outcomes in an efficient manner and to decrease damage to surrounding tissues.

IMRT uses high-precision radiotherapy utilizing computercontrolled linear accelerators to treat the breast and minimize treatment of the surrounding tissues. IMRT allows for the radiation beams to conform to the breast and minimize treatment of the underlying lung and heart. Treatment involves 3D CT or MRI coupled with computerized dose calculations to modulate the dosing to the tumor bed and breast.

APBI can be given by external beam irradiation to a portion of the breast or by a directed, localized form of brachytherapy that involves the afterloading of radioactive sources (iridium-192) into catheters placed into the surgical bed. Interest in this technique was generated based on the findings that most in-breast cancer recurrences are near the prior lumpectomy site, thus calling into question the value of whole breast radiation. This technique delivers effective dosing and reduces treatment time. Treatment is usually twice a day for a period of 5 to 10 days. Prior to the advent of single-insertion site devices, multiple catheters were threaded through the lumpectomy bed at the time of surgical intervention. Newer devices are utilized via a single site and conform to the bed by either encasing catheters into a balloon or deploying the catheters to encompass the lumpectomy site. They can be placed either at the time of surgery or 1 to 4 weeks postsurgery. The advantages of postsurgical placement include the adequate assessment of the margins and sufficient time for regression of the surgical site to allow for a more adequate fit.

Several devices exist, including MammoSite or MammoSite ML (Hologic, Inc., Marlborough, MA) balloon apparatus with either a central single lumen or 4 lumens for afterloading radioactive sources, the Strut Assisted Volume Implant (SAVI) (Cianna Medical, Aliso Viejo, CA) device with 7 to 11 struts or catheters that conform to the cavity, and the Contura (Bard, Tempe, AZ) balloon device that contains 5 catheters.

Criteria for use include patient age older than 50 years, tumor size less than 3 cm, clear margins, and no evidence of lymph node metastases. Patients not meeting these criteria have a higher incidence of recurrence. The device must conform to the cavity, and adequate skin thickness is necessary to limit dosing to the skin to prevent necrosis.

P.1054

Overlying skin thickness should be approximately 0.7 cm to avoid skin necrosis.

This treatment is not universally accepted, and ongoing randomized trials are comparing its effectiveness to standard whole breast irradiation. A recent retrospective population cohort review of 92,735 women aged 67 years or older demonstrated higher rates of subsequent mastectomy in patients treated with APBI compared to traditional whole breast irradiation. Additionally, patients treated with breast brachytherapy had high rates of complications, including breast infection, breast pain, fat necrosis, and rib fracture. Notably, overall survival was the same in both cohorts.

Alternative techniques to both whole and APBI are being investigated including intraoperative radiation therapy (IORT), permanent seed implantation, and electronic brachytherapy.

Intraoperative radiation therapy is attractive in that it is a one-time treatment, delivers the radiation directly to the tumor bed, and minimizes toxicity to the skin, chest wall, muscles, and ribs as it utilizes electron beam or low-energy x-ray. Criteria for treatment include unifocal disease, negative nodes, intraoperative assessment, and confirmation of clean margins. This approach requires retooling of the operating room suite and close coordination with the radiation oncologist. In addition, these changes require significant increases in treatment costs. Several studies evaluating this approach show promising results but, at present, should not be accepted as standard of care.

SYSTEMIC THERAPY

The use of both chemotherapy and hormone management has improved outcomes in individuals afflicted by breast cancer. These therapies can be engaged in different settings to include adjuvant therapy for early-stage disease, neoadjuvant therapy as opposed to immediate surgical intervention, and in the management of late-stage and metastatic breast cancer.

Adjuvant therapy is given after primary surgical therapy for breast cancer with the goal of preventing recurrence of disease and improving overall survival. Adjuvant therapy includes chemotherapy, endocrine therapy, targeted therapy, and radiation therapy.

The use of oophorectomy as adjuvant therapy for breast cancer was reported in the late 1880s. An initial observation of the effect of ovarian function on breast cancer was noted by Thomas Nunn who reported on perimenopausal women whose breast cancer began to regress within months of menopause. Others suggested oophorectomy would be of benefit for patients with advanced disease and to protect against local recurrence. In 1895, Beatson performed a bilateral oophorectomy on a woman with extensive soft tissue recurrence. This patient experienced a complete remission and survived 4 years after surgery.

As success in the treatment of patients with advanced breast cancer with endocrine and/or chemotherapy became apparent, these agents were introduced in early-stage disease. Adjuvant chemotherapy for breast cancer came of age in the late 1970s with the use of tamoxifen as single- and multiagent chemotherapy. The NIH had multiple consensus conferences to develop guidelines for care of pre- and postmenopausal women with or without nodal spread of disease. In May 1988, the National Cancer Institute issued a clinical alert advising adjuvant therapy for both pre- and postmenopausal women with stage I or stage II node-negative disease.

Initially, the decision-making process was based on the patient's age, menopausal status, presence of either estrogen receptor (ER) or progesterone receptor (PR) on the

tumor, and the status of the axillary nodes. As understanding of the pathophysiology of the disease has increased, further stratification became possible based on subset analyses. Genomic testing has come of age and as a result is now being employed to identify patients who may receive the most benefit from additional therapy.

Adjuvant Therapy

Multiple randomized trials have demonstrated that use of adjuvant chemotherapy and/or endocrine therapy improves outcomes in patients with breast cancer. Several resources exist to help the clinician determine the therapeutic approach that will provide the most benefit to the individual patient. NCCN guidelines (www.nccn.org) and Adjuvant!online (a benefit/risk calculator) (www.adjuvantonline.com) are excellent guides for making therapy decisions. Regardless of recommendations from these guidelines, clinical judgment with regard to the benefits and risks should direct therapy.

Factors to consider when determining adjuvant therapy include tumor histology, tumor size, nodal status, presence or absence of estrogen and/or progesterone receptors, and human epidermal growth factor receptor 2 (HER2). The use of a risk to benefit calculator and genomic profiling may be of benefit in selecting appropriate candidates for the type of adjuvant therapy. Patients with favorable histology (tubular, colloid) and small tumors (≤ 2 cm) that are ER and/or PR positive and HER2 negative without nodal involvement may not receive great benefit from additional cytotoxic or endocrine therapy.

Patients with early-stage, hormone receptor-positive/HER2-negative, node-negative (or microscopic nodal disease pN1mi ≤ 2 mm) are excellent candidates for endocrine therapy. The use of chemotherapy should be individualized based on patient and tumor characteristics. The NCCN guidelines suggest for tumors greater than 5 mm to utilize 21-gene RT-PCR assay (Oncotype DX, Redwood City, CA) to stratify risk of recurrence and consider adjuvant chemotherapy for scores greater than 18. For individuals with hormone receptor-positive, node-positive (> 2 mm disease) HER2-negative disease, adjuvant chemotherapy and endocrine therapy should be offered. A subset of these patients may benefit from genomic analysis to determine the role of adjuvant cytotoxic therapy; however, this group is yet to be defined.

Patients with early-stage, ER-, PR-, HER2-negative node-negative disease should be stratified for treatment based on tumor size. For patients with lesions ≤ 5 mm, no adjuvant therapy is recommended; patients with lesions greater than 5 mm or with pN1mi disease should be offered adjuvant cytotoxic therapy.

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meets every 5 years to review data from global breast cancer trials. The most recent publication occurred in 2012. Chemotherapy commonly employed included doxorubicin (or related anthracycline) and cyclophosphamide with or without 5-fluorouracil (AC/FAC) or cyclophosphamide, methotrexate, and 5-fluorouracil (CMF). These regimens have demonstrated improvements in the risk of recurrence and reductions in breast cancer mortality and overall mortality. Patients who received the greatest benefit from cytotoxic therapy were those with estrogen receptor-negative disease. Furthermore, at standard dosing of doxorubicin-based regimens, AC and CMF were equivalent, but dose-dense AC (higher dose

P.1055

with shorter treatment interval) had an advantage over CMF. The most recent edition also reported that adjuvant taxanes (paclitaxel, docetaxel) were considered the most effective single agents in the treatment of early breast cancer.

General recommendation is for adjuvant cytotoxic therapy utilizing an anthracycline-based regimen for patients with node-negative disease with tumors that are greater than 0.5 cm and are ER, PR, and HER2 negative. Regardless of tumor size, if there is nodal involvement, the same regimen is recommended. For patients with ER-positive and/or PR-positive tumors, the use of genomic assessment should be applied for node-negative or microscopic nodal spread. In patients with hormone receptor-positive, HER2-negative tumors, large tumor size, high-grade, presence of lymph vascular space invasion, and macroscopic nodal involvement, chemotherapy in addition to endocrine therapy should be employed. For the same patient profile without nodal involvement and a high recurrence score (> 31) on the 21-gene recurrence assay, adjuvant cytotoxic chemotherapy should be considered in addition to endocrine therapy.

Patients with HER2-positive breast cancers will benefit from the use of trastuzumab (Herceptin, Genentech, San Francisco, CA). In approximately 30% of patients, HER2 is overexpressed. Only patients who overexpress HER2 will benefit from this drug. HER2 expression is detected by immunohistochemical assays and is considered to be present if 3+, equivocal if 2+, and negative if 1+ or 0. In instances of equivocal findings, the gold standard is fluorescent in situ hybridization (FISH) to identify HER2 amplification. Trastuzumab is a monoclonal antibody that interferes with the HER2 receptor, blocks intracellular signaling, and interferes with cell proliferation. Several prospective adjuvant trials have demonstrated consistent benefit from the use of trastuzumab. For individuals with tumors greater than 5 mm that express hormone receptors, the use of endocrine therapy and trastuzumab should be considered. For individuals with tumors that do not express hormone receptors, adjuvant chemotherapy and trastuzumab should be considered for all tumors greater than 5 mm. In addition, adjuvant chemotherapy should be considered for if there is nodal involvement, if the tumor size is greater than 1.0 cm, or both. Ventricular dysfunction occurs in up to 7% of patients and may be exacerbated by left chest or breast irradiation. Lapatinib (Tykerb, GlaxoSmithKline, Brentford, United Kingdom) is a dual tyrosine kinase inhibitor that interrupts the HER2 and epidermal growth factor receptor (EGFR) pathways. This agent is used in patients whose tumors overexpress HER2 that are either chemotherapy naïve or previously failed other agents including anthracyclines, taxanes, or trastuzumab.

Molecular Profiling Tests

The knowledge of the genomic makeup of tumors has advanced and is now being employed in decision making for adjuvant therapy. Previously, factors such as age, ER/PR receptor status, tumor size, tumor grade, and nodal involvement were key components to determine therapy choices. The three distinct breast cancer subtypes of basal-like (also known as triple-negative), luminal A/luminal B, and ERBB2 type have different molecular footprints and have distinctly different prognostic and therapy response profiles. To help the health care provider make clinical decisions, a variety of molecular assays exist. The most commonly employed tests include Oncotype DX, MammaPrint, and Mammostrat. The test results, when combined with an assessment of traditional risk factors for recurrence, can help the clinician and the patient make a more informed decision regarding adjuvant therapy.

Oncotype DX (Genomic Health, Redwood City, CA) is used to calculate the risk of recurrence and the benefits of cytotoxic chemotherapy for early-stage, ER-positive breast cancer. It utilizes a 21-gene set assay and an algorithm to assign a recurrence score. The testing is done on paraffin-embedded tissue. Scoring is as follows: less than 18 low risk, 18 to 30 intermediate risk, and greater than 30 high risk. The test is considered prognostic in the ability to estimate recurrence and predictive as it assesses likely benefit from chemotherapy. It is included in three clinical guidelines: the NCCN, ASCO, and St. Gallen Consensus Guidelines.

Recently, a new assay has been developed for patients with DCIS that utilizes a subset of the gene assay and a different algorithm to assess risk of recurrence of either DCIS or invasive cancer and the benefit of tamoxifen in hormone receptor-positive disease.

MammaPrint (Agendia, Irvine, CA) analyzes 70 genes involved in the molecular pathways of the metastatic cascade and provides a prediction of 10-year recurrence of either low or high. It is utilized in early-stage (I, II) ER-positive or ER-negative tumors that are less than 5 cm and do not have involved nodes. Fresh/frozen or paraffin-embedded tissue is required, and the 70 genes are analyzed to give a risk recurrence prediction in the absence of either hormone or cytotoxic chemotherapy. The results are dichotomous, whereby low risk signifies a 10% or less chance of recurrence within 10 years and high risk signifies at least a 29% chance of recurrence without adjuvant therapy during the same time period. There is no intermediate result. Another product, Symphony (Agendia, Irvine, CA), includes MammaPrint assay along with Blueprint (molecular subtyping assay), TargetPrint (ER/PR and HER2 status), and TheraPrint (56 gene assay) to provide a comprehensive molecular profile of the individual's tumor.

Mammostrat (Clariant Diagnostic Services, Aliso Viejo, CA) assesses the level of five biomarkers for early-stage (I, II), hormone receptor-positive breast cancer. This test can help identify patients at high risk who may benefit from cytotoxic chemotherapy in addition to hormonal therapy. The test was validated against NSABP B-20, which identified a subset of patients with ER-positive disease who benefited from cytotoxic chemotherapy. The test is additive to ER, PR, HER2, and Ki-67 testing. Paraffin-embedded tissue is used in the assay assessment. Biomarkers evaluated include p53 and HTF9C, CEACAM5, NDRG1, and SLC7A5, which assess cell cycle regulation, differentiation, hypoxia, and nutrient supply. The biomarker levels are assessed in a mathematical algorithm and a risk level assigned. Patient stratification is as follows: low risk 7.6%,

moderate risk 16.3%, and high risk 20.9%. Utilizing the risk assignment along with the age of the patient, grade of the tumor, hormone receptor levels, and nodal involvement can help the patient and provider make an informed decision.

Neoadjuvant Therapy

For patients with locally advanced disease, multimodal systemic and local-regional therapy is utilized. Neoadjuvant therapy can be employed for locally advanced disease to induce tumor regression and may allow a patient to convert to breast conservation surgery. Regardless of tumor size or nodal involvement, neoadjuvant chemotherapy can be used in patients with triple-negative breast cancer. Most often, chemotherapy is utilized, even in patients with hormone receptor-positive disease. In patients in whom HER2 is overexpressed, there is a role for

P.1056

trastuzumab. Once a maximal or complete clinical response has been achieved, surgical intervention should occur. Indications for breast conservation surgery have been discussed elsewhere in this chapter. NSABP B-18 randomly assigned patients to either upfront AC chemotherapy or postoperative AC chemotherapy and demonstrated feasibility of this approach and noted 80% of patients experiencing regression of their primary tumors and decreased incidence of nodal metastases. Thirty-six percent of patients had a complete clinical response, and of those patients, approximately one fourth had a complete pathologic response. Upfront therapy increased the rate of lumpectomies by 175% in patients with tumors larger than 5 cm. As such, preoperative therapy should be considered for patients with tumors too large to be considered for primary breast-conserving surgery. Subsequently, NSABP B-27 evaluated the addition of docetaxel. Randomization was between upfront AC, upfront AC followed by four cycles of docetaxel, and upfront AC followed by surgery then postoperative docetaxel. By utilizing all three drugs prior to surgery, the complete pathologic response rate was doubled compared to those treated with AC alone. Despite improvements in breast conservation, no statistical improvement occurred in overall survival or disease-free survival. Patients receiving the additional taxane therapy had a trend toward increased disease-free and overall survival.

Treatment of Recurrent Disease

Treatment of recurrent disease varies depending on the location and extent of the disease. A local or regional recurrence can be managed by either surgical intervention or, when appropriate, radiation therapy. Careful history taking and comprehensive physical examination combined with radiographic assessment with a bone scan and CT of the chest/abdomen/pelvis should ensue in this circumstance. The use of fluorodeoxyglucose (^{18}F) (FDG) PET-CT is approved when looking for metastatic foci in patients with recurrent breast cancer. This test has decreased sensitivity for bone metastases; hence, plain radiographs, a bone scan, or a sodium fluoride PET-CT should be considered.

For individuals who have an in-breast recurrence after undergoing breast-conserving surgery, the recommendation is total mastectomy with or without reconstruction. Management of the axilla for individuals who have sentinel mapping is to perform a level I or II axillary dissection. Isolated nodal recurrences can be treated with resection of the involved node or, in cases of previous SLNB, a completion axillary dissection. The role of postoperative chemotherapy in the absence of known metastases is not clear at this time.

Treatment of Metastatic Disease

Patients with metastatic disease are unlikely to be cured of their disease. Hence, the goals of therapy are palliation of symptoms with minimal toxicity from treatment. In patients with hormone receptor-positive disease, endocrine therapy should be the first line of therapy. In patients who are premenopausal, ovarian ablation or suppression should be considered. Metastatic disease to the bone places patients at increased risk for debilitating fractures. Drugs that help maintain bone integrity, denosumab, zoledronic acid, or pamidronate (given with calcium and vitamin D supplementation), should be added to the regimen. In the absence of hormone receptor-positive disease, chemotherapy is employed. If visceral metastases within the liver, lung, or other organs are encountered, cytotoxic chemotherapy is considered front-line treatment. When chemotherapy is employed, a risk-to-benefit assessment should take place and single-agent therapy given in a sequential fashion should be considered over combination therapy.

Endocrine Therapy

Endocrine therapy can be achieved through either ovarian ablation or the use of pharmacologic agents. Either selective estrogen receptor modifiers (SERMs) or aromatase inhibitors (AIs) are the current class of agent used to achieve endocrine suppression.

Ovarian Ablation

The role of ovarian ablation was first reported in 1896 by Beatson who demonstrated regression of recurrent breast cancer in premenopausal women whom he treated with bilateral oophorectomy. Until the advent of estrogen receptor modifiers, either surgical removal or radiation therapy was used to suppress ovarian function. For patients who are perimenopausal, the use of luteinizing hormone-releasing hormone (LHRH) analogs such as leuprolide and goserelin can bridge the patient to menopause and avoid the morbidity of surgery. LHRH analogs down-regulate receptors for LHRH and lead to decreased FSH and LH production and a resultant decrease in ovarian production of estrogen and progesterone. Data suggest that these agonists also may exert a direct effect on tumor cells.

In 1996, the EBCTCG reported a meta-analysis of 12 studies in which ovarian ablation was utilized. In women younger than 50 years, an improvement was seen in patients treated with ovarian ablation, with the most profound effect noted in patients with positive nodes. The same group published an analysis of 55 studies employing tamoxifen as adjuvant therapy. The analysis found tamoxifen to be efficacious for the reduction of recurrence in patients with ER-positive tumors. Survival benefit was greater in node-positive versus node-negative disease, with almost doubling of the reduction of recurrence risk in node-positive disease. Tamoxifen benefit was greater in the postmenopausal patients but was present in the pre- and perimenopausal group as well. An almost 50% reduction in contralateral breast cancer was observed in the tamoxifen-treated patients. Compared to historical controls, tamoxifen and ovarian ablation were equally efficacious. Patients with familial or genetic predisposition to ovarian cancer also benefit from surgical bilateral salpingo-oophorectomy.

Selective Estrogen Receptor Modulators

SERMs have a unique role in the management of breast cancer. The two most well-known drugs are tamoxifen and raloxifene.

Tamoxifen is a nonsteroidal triphenylethylene derivative that binds the ER. It has both estrogenic and antiestrogenic actions depending on the target tissue. In the breast, it has strong antiestrogenic effects but exerts estrogenic effects on the endometrium, as evidenced by the development of hyperplasia and on rare occasions carcinoma, and on the bone where it improves both osteoporosis and osteopenia. The mechanism of action is not completely delineated, but one pathway is the blockage of the ER in mammary epithelium and estrogen-driven proliferation of breast epithelium. This drug has a role in both advanced and early breast cancer. In the initial trials, a decreased risk of contralateral breast cancer was noted leading to a chemoprevention trial in which the drug was found to have significant activity in preventing both invasive and in situ diseases. Side effects include hot flashes,

P.1057

vaginal dryness, non-vision-threatening cataracts, venous thromboembolic events, and, as noted, endometrial hyperplasia and carcinoma. The Adjuvant Tamoxifen: Longer Against Shorter (ATLAS) trial demonstrated that 10 years of tamoxifen use for women with ER-positive disease was associated with decreased reduction in recurrence in mortality compared to 5 years of use.

Unlike tamoxifen, raloxifene is a benzothiophene. One mechanism of action is the binding of the estrogen receptor of breast epithelium that prevents estrogen stimulation and proliferation. Other pathways are still being elucidated. Unlike tamoxifen, it does not exert an estrogenic effect on uterine epithelium and, as such, does not increase risk of endometrial hyperplasia or cancer. Like tamoxifen, the drug helps to maintain bone density. When the drug was initially introduced, its primary focus was for treatment of

osteoporosis in postmenopausal women. During the Multiple Outcomes of Raloxifene Effects (MORE) trial, usage was noted to decrease the incidence of breast cancer. Subsequently, a randomized trial demonstrated raloxifene to be of benefit in breast cancer risk reduction. Side effects are similar to those of tamoxifen with the exception of uterine cancer risk. It is not currently used as adjuvant therapy for breast cancer.

Aromatase Inhibitors

Als inhibit the action of the enzyme aromatase that converts androgens to estrogens and thereby lowers levels of circulating estrogen. There are two basic types of Als, steroidal (anastrozole, letrozole) and nonsteroidal (exemestane). Both types are equally efficacious with no clear advantage with regard to adverse events. The drugs are indicated for use in the treatment of hormone receptor-positive postmenopausal breast cancer. Most frequent side effects are musculoskeletal (myalgias and arthralgias), increased risk of hypercholesteremia, cardiovascular disease, and osteoporosis. This class of drugs is not used in premenopausal women as it can stimulate ovulation and increase endogenous estrogen levels due to ovarian stimulation. At present, no role exists for these drugs in the chemoprevention setting.

Anastrozole has proven superior to tamoxifen in the Arimidex, tamoxifen, alone, or in combination (ATAC) trial of treatment of 9,366 postmenopausal women with localized breast cancer with respect to disease-free survival, time to recurrence, incidence of contralateral breast primary tumors as first events, and a number of important tolerability parameters. Fewer patient withdrawals from the study occurred with anastrozole than with tamoxifen. Anastrozole was associated with fewer vascular and gynecologic side effects, including thromboembolism, hot flashes, vaginal bleeding, endometrial cancer, and vaginal discharge.

Letrozole also has shown effectiveness in ovulation induction and is one of the only safe options for breast cancer patients wishing to undergo in vitro fertilization and ovarian stimulation to assist in cryopreservation of embryos before their cancer therapy. Although the product's label states there is a contraindication in premenopausal women because of "the potential for maternal and fetal toxicity," many intrauterine insemination programs have replaced the standard clomiphene citrate with letrozole because of its superior pregnancy success rates and ability to decrease gonadotropin requirements.

Exemestane is an irreversible, steroidal aromatase inactivator. It is structurally related to androstenedione. It acts as false substrate for the enzyme and binds irreversibly to the active site of the enzyme. It has not been demonstrated to be superior to anastrozole. A recent study was completed comparing the steroidal AI exemestane to the nonsteroidal AI anastrozole. A total of 7,576 women were enrolled and randomly assigned to one of the two drugs. At 4 years of follow-up, event-free, distant disease-free, and disease-specific survival were the same with both drugs. Exemestane was associated with lower rates of osteoporosis, osteopenia, vaginal bleeding, hypertriglyceridemia, and hypercholesterolemia compared to anastrozole.

The Early Breast Cancer Trialists' Collaborative Group reported a meta-analysis comparing Als to tamoxifen and noted an absolute 3% decrease in recurrence in the AI-treated patients. The report concluded that either monotherapy or introduction of Als after 2 to 3 years of tamoxifen is beneficial. In 2003, the National Cancer Institute (NCI) issued a clinical alert recommending patients with ER-positive disease receive letrozole 2.5 mg daily for 5 years after concluding 5 years of tamoxifen therapy. The recommendation was based on the outcome of the NCI of Canada Clinical Trial MA27 that demonstrated an increase in both disease-free and overall survival when treated in this manner.

Cytotoxic Chemotherapy

Common cytotoxic multiagent chemotherapy regimens are listed in Table 45.29. Table 45.30 lists chemotherapy agents, mechanisms of action, dosages, and common adverse effects.

TABLE 45.29 Adjuvant Chemotherapy Regimens

REGIMEN		DOSING
AC-T	Doxorubicin, cyclophosphamide followed by taxol	60/600 mg/m ² × 4 followed by 175 mg/m ² × 4
TAC	Doxorubicin, docetaxel, and cyclophosphamide	50/75/500 mg/m ² × 6
CMF	Cyclophosphamide, methotrexate, and 5-fluorouracil	600/40/600 mg/m ² × 6
FEC	5-Fluorouracil, epirubicin, cyclophosphamide	500/100/500 mg/m ² × 6
FEC-T	5-Fluorouracil, epirubicin, cyclophosphamide followed by paclitaxel	500/100/500 mg/m ² × 3 followed by 100 mg/m ² × 3
TC	Docetaxel, cyclophosphamide or carboplatin	75 mg/m ² /600 mg/m ² or AUC 5-6

TABLE 45.30 Chemotherapy Agents

DRUG	CLASS	MECHANISM OF ACTION	DOSE	TOXICITY
Doxorubicin	Antitumor antibiotic	Topoisomerase II inhibition, DNA intercalation, free radical formation	50-60 mg/m ² Lifetime max 450-550 mg/m ²	Myelosuppression, nausea, vomiting, alopecia, cardiomyopathy Hepatic dysfunction Vesicant
Epirubicin	Antitumor antibiotic	Topoisomerase II inhibition, DNA intercalation, free radical formation	60-100 mg/m ² q3wk	Myelosuppression, nausea, vomiting, alopecia, cardiomyopathy Hepatic dysfunction Vesicant

Carboplatin	Alkylating agent	DNA adduct formation DNA intercalation DNA single- and doublestranded breaks	AUC 5-6 q3wk	Myelosuppression Neuropathy Nephrotoxicity
Cyclophosphamide	Alkylating agent	DNA adduct formation DNA intercalation	500-600 mg/m ² IV q3wk Oral dose: 50-100 mg/m ² days 1-14	Myelosuppression Hemorrhagic cystitis Alopecia Secondary leukemia Nausea, vomiting
Methotrexate	Antimetabolite	Inhibition of dihydrofolate reductase leading to decreased DNA synthesis	50 mg/m ² q3wk	Mucositis Myelosuppression Nail changes Alopecia Nausea, vomiting
5-Fluorouracil	Antimetabolite	Inhibition of thymidylate synthase leading to decreased DNA synthesis	500 mg/m ² q3wk	Mucositis Myelosuppression Nail changes Alopecia Nausea, vomiting
Taxol	Agent derived from plants (bark of western yew)	Stabilizing intracellular microtubules	135-225 mg/m ² q3wk	Neuropathy Myelosuppression Alopecia Nausea, vomiting Hypersensitivity reaction from cremophor carrier
Taxotere	Agent derived from plant (now synthetic, originally needle of European yew)	Promotes assembly and inhibits depolymerization of microtubules	60-100 mg/m ² q3wk	Myelosuppression Neuropathy Alopecia Nausea, vomiting Hypersensitivity from Tween 80 carrier

UNUSUAL CLINICAL SCENARIOS

In addition to the presentation of a palpable mass, clinicians should be familiar with the patient who presents with either Paget disease of the breast or IBC. Prompt diagnosis of both conditions leads to improved outcomes.

Paget Disease

Paget disease presents as an eczematoid lesion or ulceration of the nipple-areolar complex and is associated with an underlying malignancy. The lesions tend to be erythematous and have associated scaling of the skin, crusting, erosion, or ulceration of the skin that tends to occur late in the disease process. "Cake-icing" appearance of an erythematous nipple-areolar complex covered with translucent, scaling skin should alert the clinician to this disease process ([Fig. 45.46](#)). A high index of suspicion is necessary to aid in the diagnosis. There should be a low threshold to perform a skin punch biopsy. The prognosis depends on extent of underlying malignancy. Both IDC and DCIS can be associated with Paget disease. On clinical examination, the majority of patients will not have a palpable underlying mass; in these cases, the most common underlying process is DCIS. The presence of a palpable mass should raise suspicion of an underlying invasive malignancy.

P.1059

FIGURE 45.46 Paget disease of the nipple. Note the erythema and shiny covering over the epidermis. (Courtesy of Emilia Diego, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

Histologically, Paget cells appear in the epidermis as large anaplastic cells surrounded by a clear halo ([Fig. 45.47](#)). Immunohistochemical staining for periodic acid Schiff (PAS) and carcinoembryonic antigen (CEA) are useful in establishing the diagnosis. In order to distinguish the entity from melanoma, negative results from S100 protein and human melanoma black are useful.

Treatment depends on findings from radiographic and pathologic evaluation. Originally treated with total mastectomy with or without axillary lymphadenectomy, the option of

breast conservation exists for subsets of patients. The use of central lumpectomy with removal of the nipple-areolar complex is feasible in the majority of patients.

Inflammatory Breast Cancer

IBC is an aggressive form of locally advanced breast cancer that requires prompt recognition and management. It accounts for up to 5% of breast cancers in the United States. The symptoms of the disease process appear rapidly over the course of weeks and are often confused with mastitis. The condition is clinically characterized by erythema or discoloration of the skin of at least one third of the breast, edema with fine dimpling (peau d'orange), warmth, and the presence of a palpable ridge at the edge of edema. Many of the changes are due to dermal lymphatic invasion (Fig. 45.37). Skin punch biopsy may aid in the diagnosis, but histopathologic finding of tumor cells within the lymphatics is not necessary to make the diagnosis.

FIGURE 45.47 Photomicrograph of Paget disease. Epidermis is involved with large malignant cells with abundant clear cytoplasm and nuclei with prominent nucleoli (H&E 20×). (Courtesy of Jing Yu, MD, University of Pittsburgh School of Medicine, Pittsburgh, PA.)

Systemic signs of infection are absent. Lack of an elevated white count, fever, and a low incidence of mastitis in women who are not lactating should raise the clinician's index of suspicion to this entity. In addition to a comprehensive history and physical examination, use of mammography, ultrasonography, and MRI aids in assessing the extent of local-regional involvement. At presentation, the majority of patients will have nodal metastases and up to 25% will have evidence of systemic spread of disease. Laboratory and radiographic testing to include liver function tests, CT of the chest/abdomen/pelvis, or PET-CT imaging should be considered to determine disease extent.

Treatment involves a multimodal approach with close coordination between the surgeon, the medical oncologist, and the radiation oncologist. Given the known rapid growth and propensity for distant metastases, neoadjuvant therapy should be promptly initiated. The choice of cytotoxic agents will depend on the particular profile of the tumor. Many studies utilizing anthracycline-based therapy have shown great success. Up to 90% complete clinical response rates have been reported with four cycles of doxorubicin-based chemotherapy. Pathologic response does not mimic clinical response, with pathologic response rates only as high as 13% to 30%.

The advent of molecular targeted therapy also has altered the approach to these patients. Great success has been observed in patients with a known HER2-positive disease when they are given the combination of epirubicin, paclitaxel, and the targeted agent trastuzumab.

Subsequent to induction chemotherapy, a modified radical mastectomy is advised, followed by chest wall and axillary radiation. The addition of radiation therapy reduced the local failure rate to 4% compared to 27% in the control group in a the Eastern Cooperative Group Trial of 332 women with locally advanced breast cancer treated with neoadjuvant therapy who were randomly assigned to postoperative radiation therapy.

Breast Cancer Risk Reduction

Women with BRCA, PTEN, and TP-53 mutations as well as other family cancer syndromes are at increased risk for the development of breast cancer. Risk reduction options for breast cancer include chemoprevention, lifestyle modifications, and prophylactic (or risk-reducing) surgeries.

Chemoprevention

Both ASCO and the USPSTF developed guidelines for the initiation of endocrine therapy for breast cancer prevention. The guidelines recommend endocrine therapy in women over age 60 years, age over 35 years with LCIS or atypical ductal or lobular hyperplasia, between the ages of 35 and 59 years with a Gail model (statistical model that estimates risk of breast cancer development) risk of breast cancer of $\geq 1.66\%$ (equivalent to the risk of a 60-year-old female), or in patients with known BRCA1 or BRCA2 deleterious mutation who have not undergone prophylactic mastectomy.

The Gail model is a multivariate logistic regression formula taking into account race, age, age at menarche, age at first live

P.1060

birth, number of breast biopsies, finding of atypia or LCIS, and number of first-degree relatives with breast cancer. Risk is low if less than 1.66 and high if greater than 1.66. The risk calculator is available online at several sites (e.g., <http://www.cancer.gov/bcrisktool>).

Chemoprevention became an option for risk reduction based on information from the Breast Cancer Prevention Trial (BCPT), which launched on 1992. This clinical trial (NSABP P-1) randomly assigned 13,207 healthy women at increased risk for breast cancer (based on Gail model score ≥ 1.66 , age older than 60 years, or history of LCIS) in a double-blind manner to receive either placebo or tamoxifen 20 mg/day. The short-term risk of invasive breast cancer was reduced by 43% and that of noninvasive cancer reduced by 37%, particularly in women with a history of atypical hyperplasia ($P < 0.00001$). Tamoxifen significantly reduced the rate of ER-positive tumors but had no effect on ER-negative tumors. Tamoxifen use was associated with decreased hip fractures but with an increased risk of thromboembolic disease, endometrial cancer, and cataracts. Endometrial cancer risk was significantly increased in women over 50 years of age with a relative risk of 3.28. It accounted for 2.24 cases per 1,000 women compared to 0.69 per 1,000 women in the placebo group.

It is unclear how effective tamoxifen is in reducing breast cancer risk in women with hereditary breast cancer. Because the majority of cancers in BRCA1 mutation carriers are ER negative, one would not expect tamoxifen to be effective. However, BRCA2 carriers often have ER-positive tumors and thus are more likely to be responsive to tamoxifen chemoprophylaxis. Conversely, bilateral oophorectomy has been shown to reduce the risk of both ovarian and breast cancers in these individuals.

At the same time as the P-1 trial, two additional clinical trials were evaluating the role of tamoxifen for breast cancer prevention. The Royal Marsden Hospital Tamoxifen Randomised Chemoprevention Trial and the Italian Tamoxifen Prevention Trial both failed to demonstrate a benefit from the use of tamoxifen in women at risk for breast cancer. In the evaluation of these trials, the study populations were distinctly different. Both trials were smaller in scope; the Italian Trial enrolled 5,408 women and the Royal Marsden study enrolled 2,471 women. In the Italian trial, individuals had undergone premenopausal hysterectomy with or without bilateral salpingo-oophorectomy that, in and of itself, could lead to breast cancer risk reduction. Additionally, patients were allowed to take postmenopausal HRT that could negate the benefits of the selective estrogen receptor modulator. In the Royal Marsden trial, HRT also was allowed for this small population.

The multicenter, randomized, double-blind MORE trial revealed a 76% decreased risk of breast cancer among postmenopausal women with osteoporosis during 3 years of treatment with raloxifene. The effect was only on ER-positive breast cancer. The trial was not designed to assess breast cancer risk reduction but served as a basis for additional studies.

The subsequent chemoprevention trial, Study of Tamoxifen and Raloxifene (STAR) Trial, randomly assigned 19,747 postmenopausal women to one of the drugs for 5 years. Both tamoxifen and raloxifene were effective in reducing the incidence of invasive breast cancer by almost 50%. Raloxifene was associated with higher risks of invasive (310 vs. 247) and noninvasive breast cancer (137 vs. 111) but had a more favorable side effect profile with decreased incidence of endometrial hyperplasia and cancer (hyperplasia 0.84 events vs. 4.4 events per thousand, cancer 1.2 vs. 2.3 events/1,000 women).

The literature includes a report on the use of an aromatase inhibitor for breast cancer reduction. National Cancer Institute of Canada MAP.3 trial randomly assigned postmenopausal patients at risk for developing breast cancer to exemestane (25 mg) or placebo for 5 years. A reduction in ER-positive invasive breast cancer was seen in the exemestane arm compared to placebo; however, there was no effect on DCIS. Patients on exemestane had increased menopausal symptoms, including hot flashes, musculoskeletal pain, and arthralgias.

Other risk reduction strategies include the use of suppressants of prostaglandin synthesis. Based on epidemiologic observations, use of aspirin and other NSAIDs resulted in up to a 30% breast cancer risk reduction. In preclinical models, COX-2 inhibitors reduced the incidence and growth of ER-positive tumors. NSAIDs function through inhibition of the cyclooxygenase enzyme (COX). The COX-2 enzyme is induced in both in situ and invasive breast cancers resulting in overexpression. COX-2 catalyzes the conversion of arachidonic acid to prostaglandin E₂. This prostaglandin in turn upregulates a number of intracellular growth pathways, resulting in increased angiogenesis, induction of aromatase activity, cell growth, and division. It is postulated that inhibition of COX-2 may have a general anticancer effect via decreased blood vessel formation, decreased cell growth, and enhanced apoptosis.

Lifestyle

Lack of physical activity, alcohol consumption, smoking, high fat intake, processed foods, and red meat ingestion have been linked to the development of breast cancer. In some circumstances, there are dose-response relationships. Maintaining an ideal body weight after menopause has been associated with breast cancer risk reduction. Data continue to evolve, but, overall, regular physical exercise, smoking cessation, limiting alcohol intake, low fat diets, and avoidance of processed foods and red meat are promoters of a healthy lifestyle and provide benefits above and beyond limiting cancer risk. Individuals also should be encouraged to avail themselves of regular physical examinations and participate in screening evaluations as recommended by the American Cancer Society.

Prophylactic/Risk-Reducing Surgeries

Risk-reducing surgeries include the use of bilateral salpingo-oophorectomy and mastectomy. The primary goal is to prevent the future development of either ovarian or breast cancer. Patients with known deleterious BRCA1/BRCA2 mutations most often undergo these procedures given higher risks of developing these cancers. Timing of the procedures is generally after childbearing has been completed, by the age of 40, or prior to menopause given the escalating risk with age. The sequence of the surgical interventions may be important; patients with BRCA2 mutations may have a predilection for the development of ER-positive breast cancers, and they appear to have risk reduction for both breast and ovarian cancers with premenopausal prophylactic bilateral salpingo-oophorectomy. Analysis of case control data from women with BRCA mutations demonstrated not only a 90% reduction in ovarian cancer risk but also a 60% reduction in breast cancer risk with risk-reducing salpingo-oophorectomy. The role of HRT for women undergoing risk-reducing salpingo-oophorectomy is not yet defined. Patients with BRCA1 mutations tend to have ER-negative tumors so hypothetically should not be at increased risk with HRT.

A retrospective study by the Mayo Clinic reviewed data from women who underwent bilateral prophylactic subcutaneous mastectomy because of a strong family history of breast cancer. The authors demonstrated a 90% reduction in the risk of breast cancer and decreased mortality during 14 years of follow-up. The same group demonstrated 90% risk reduction

P.1061

in known BRCA1/BRCA2 mutation carriers. The costs (both emotional and financial) and benefits of these options must be carefully explained to the individual.

Surgical approaches include total mastectomy, skin-sparing mastectomy with reconstruction, and nipple-areolar or areolar-sparing mastectomies. Initially, subcutaneous mastectomy was performed wherein breast tissue is removed with preservation of the nipple-areolar complex; however, subsequent cases of breast cancer development were noted. This procedure has been largely abandoned because only 90% to 95% of the breast parenchyma is removed, residual ductal tissue remains adherent to the undersurface of the nipple-areolar complex, and nipple sensation was not preserved. Recently, the approach has been revised to include removing a portion of the base of the nipple. At our institution, the procedure has been reserved for women choosing to undergo risk reduction surgery and who have been counseled with regard to the risk of residual breast tissue. The procedure is limited to patients with minimal ptotic changes and breast cup size A or B, as this increases the surgeon's ability to visualize and remove the breast tissue. Nipple denervation is common, but the cosmetic outcome is superior to most reconstructive techniques.

Pregnancy-Associated Breast Cancer

Pregnancy-associated breast cancer (PABC) is defined as breast cancer diagnosed during pregnancy or within 1 year of delivery. Most experts believe that the majority of breast cancers have been present for 2 years before clinical detection. Hence, breast cancers diagnosed up to 1 year postpartum likely were present while the patients were pregnant. Approximately 10% of all women diagnosed with breast cancer who are younger than 40 years old will be pregnant. This makes PABC the second most common cancer in pregnancy with a frequency ranging from 1 in 3,000 to 1 in 10,000 deliveries. Women who have their first term pregnancy after the age of 30 years will have a two- to three-time higher risk of developing breast carcinoma than do women who have their first pregnancy before the age of 20 years. It is expected that breast cancer during pregnancy will become increasingly more common as women delay childbearing until later in life. Refer to treatment of breast cancer section in this chapter for patients who are diagnosed postpartum, as their treatment generally can follow protocols for any other breast cancer. The majority of the discussion in this section focuses on patients whose cancers were diagnosed during pregnancy.

Presentation and Evaluation

PABC is challenging to diagnose. Yearly mammographic screenings are generally performed only in women 40 years of age or older, and since PABC only occurs in young premenopausal women, these tumors generally are detected only on a clinical exam. The increase in breast density that occurs during pregnancy makes examination of the breast more difficult, leading to delays in detection from 1.5 to 6 months. Distinguishing benign from malignant masses can be difficult. Approximately 70% to 80% of masses detected during pregnancy are benign. Breast cancers may not present as a mass and may be subtle breast thickening. If discovered as a mass, these malignant masses are more likely to be mobile. It is important also to exam the axilla, as PABC is more likely to be discovered in later stages. Any masses palpated during pregnancy should undergo further evaluation with imaging modalities. Options for evaluation include the use of ultrasound and mammography. The first step in the evaluation should be breast ultrasonography. In the three published series on the use of this modality in this population, ultrasonography was able to detect the breast cancer in all patients. However, it should be noted that all three series had less than 25 patients for evaluation. With regard to mammography, the sensitivity of using the latest digital mammography technology can be as high 72% to 78% in nonpregnant premenopausal patients and patients with dense breasts. Data from the small series utilizing mammograms on patients with PABC found similar sensitivities of 78% to 90%. If breast cancer is suspected, ultrasonography and mammography should both be used for evaluation, as these tests are complementary to each other. Ultrasound alone is insufficient as 30% to 90% of patients will have calcifications that can only be seen with mammography, and, therefore, mammography may be helpful in assessing the true size of these tumors. Other testing, such as bone scans, chest x-rays, and abdominal CT, may be indicated in patients

with clinical stage IIIA or higher.

Radiologic Tests in Pregnancy

Two potential risks to the fetus exist with radiation exposure: teratogenesis and carcinogenesis. The exact dose at which teratogenesis occurs in pregnancy is unclear but is thought to be from 0.05 to 0.15 Gy. The greatest risk of teratogenesis occurs between the 2nd and 20th week of gestation. Within the first week of pregnancy, radiation exhibits an “all or none” effect in which levels that are too high can lead to a spontaneous abortion. With regard to carcinogenesis, even doses of 0.02 to 0.05 Gy can increase the risk of childhood cancer by twofold. However, it should be kept in mind that because the baseline risk of cancer is low, a twofold increase in the risk of dying of cancer only changes the actual incidence from 1 in 2,000 to 2 in 2,000. The doses of radiation exposure to the fetus with the commonly used tests in pregnancy are shown in [Table 45.31](#). The amount of radiation exposure with routine imaging studies is low. In general, the use of mammography, bone scan, and chest x-ray poses minimal risk to the fetus and should be considered in the workup of a patient with PABC when warranted. Mammograms can help detect areas of calcifications and can be a useful adjunct to breast ultrasounds; hence, mammograms should be used in the workup of a patient with known PABC. Lead shielding to the patient’s abdomen should be utilized when possible. The NCCN Guidelines recommend using a chest x-ray, CT of the abdomen with or without pelvis,

P.1062

and a bone scan in the evaluation of patients with clinical stage IIIA (i.e., patients with tumors >5 cm and positive axillary nodes) or higher. Any patients with symptoms that suggest metastatic disease (e.g., bone pain, abdominal mass, enlarged liver, pulmonary symptoms) also should undergo targeted evaluation of these organs. Doses of radiation from CTs and bone scans are low enough that the benefits outweigh the risks.

TABLE 45.31 Radiation Exposure from Radiographic Imaging to the Fetus

TEST	RADIATION EXPOSURE TO FETUS (cGy)
CXR	0.0005
Bone scan	0.076/0.13
Mammogram	<0.10
CT of chest	0.03
CT of abdomen	0.250

Risks to the fetus of radiologic procedures used in the diagnosis of maternal venous thromboembolic disease. <i>Thromb Haemost</i> 1989;61:189.	

Breast MRI is generally not recommended for PABC at this time. The Food and Drug Administration-required labeling for MRI states the safety of MRI during pregnancy to the fetus “has not been established.” Several studies in patients who have undergone MRI during pregnancy suggest that MRI is safe; these studies have follow-up as long as 9 years. The use of gadolinium in pregnancy is generally contraindicated. Gadolinium is considered to be a class C drug and is known to be teratogenic at high levels in animal studies. The American College of Radiology states that gadolinium should be avoided in pregnancy.

Risk of Genetic Mutations and Role of Genetic Testing

Little information exists with regard to the prevalence of BRCA mutation carriers in PABC. One study evaluated breast cancer tissue from nine patients with PABC for BRCA1 and BRCA2 mutations. This study found allelic deletion at the *BRCA2* locus in 8 of 9 samples. A significant limitation of this study is that only tumor tissues were evaluated; tissue expression of BRCA does not correlate with an individual having a deleterious mutation of BRCA1/BRCA2. In another study, the prevalence of PABC in 39 families with BRCA1/BRCA2 mutations was evaluated. The patients were compared to an age-matched control group. An elevated risk of PABC was found in both BRCA1 and BRCA2 families. Statistically, more women were found to have PABC in the BRCA1 families (odds ratio 3.9 [95% CI 1.4 to 10.8]). The number of patients with BRCA2 mutations was too small to have any meaningful data. Despite these small numbers and significant limitation in both studies, a thorough family history should be taken in these patients as they may be at elevated risk for carrying either a BRCA1 or BRCA2 mutation. Genetic testing for deleterious mutations of BRCA1/BRCA2 on the basis of having PABC alone may be reasonable despite the limited data.

Pathology

Pathologic features of PABC tend to be high-grade invasive ductal carcinomas. Lymphovascular space invasion also is common. This population has a higher percentage of the hormone-independent tumors, with 50% to 72% of these tumors considered to be estrogen-receptor negative. Increased expression of HER2 was also common with a prevalence of 28% to 58%; the majority of these reports consist of case series.

Treatment Algorithm

PABC diagnosed after delivery is treated the same way as in the nonpregnant patient. If a postpartum patient is being treated with chemotherapy, breast-feeding would be contraindicated. A pregnant patient diagnosed with breast cancer must first decide whether or not to continue with the pregnancy. No data exist suggesting that termination improves survival outcomes in the patient, especially since the majority of these tumors are estrogen-receptor negative. In a series of 24 patients in the 1960s, Holleb and Farrow did not find any improvement in survival with patients who underwent abortions prior to radical mastectomies. This has been confirmed in other small series. Termination of the pregnancy in the first trimester allows for the use of breast conservation surgery and removes the teratogenic risk of chemotherapy.

If the decision is made to continue with the pregnancy, the plan for treatment is dependent on the timing of diagnosis. Patients diagnosed with small operable tumors in the first trimester (≤12 weeks) are candidates for lumpectomies or mastectomies. It is preferable to wait until the second trimester before operating, since the risk of anesthesia is higher in the first trimester. If the patient opts for lumpectomy, radiation should be delayed until after the delivery. Delays of radiation therapy longer than 6 months after surgery may have significant impact on local recurrence, therefore is not recommended. Mastectomy obviates the need for postoperative radiation therapy especially in patients with small tumors (<5 cm) who have less than four positive lymph nodes. Adjuvant chemotherapy is not contraindicated during pregnancy and can be considered in patients with tumors greater than 1 cm or with lymph node involvement. In patients found to have estrogen receptor-positive tumors with negative nodes, the use of genomic assessment assays (Oncotype DX, MammaPrint) has not been examined in PABC.

In patients who have large tumors, removal of the mass without performing a mastectomy is difficult; if the patient desires breast conservation, neoadjuvant chemotherapy is a treatment option. Treatment typically will last 4 to 6 months. Surgery can then be performed at the end of treatment or can be delayed until after delivery. Delivery can be

considered after the 35th week of gestation in order to facilitate any further treatment. Delivery should be delayed at least 3 to 4 weeks after the last dose of chemotherapy to decrease the risk of complications from possible neutropenia and thrombocytopenia. If the patient opts for a breast conservation therapy, then radiation therapy is given after delivery. A summary of the treatment plan is shown in [Figure 45.48](#).

Role of Surgery

Surgical excision of breast cancer can be accomplished by either a partial or total mastectomy. For many years, a modified radical mastectomy was considered to be the standard treatment for PABC. Modified radical mastectomy would obviate the need for radiation therapy that is contraindicated during pregnancy and, therefore, can be used as initial treatment for clinical stage I-III breast cancer at any gestation. The initial treatment for stage IV breast cancers should be chemotherapy and not surgical excision.

Breast-conserving surgery consists of a lumpectomy and a 6-week course of radiation therapy to the breast. This 6-week course of radiation can expose the fetus to radiation doses ranging from 0.1 Gy early in pregnancy to 2 Gy later in the pregnancy. This amount of radiation is well above the acceptable threshold of radiation exposure of 0.15 Gy that would lead to increased risk of teratogenesis. There are no studies with regard to the APBI in pregnancy. Radiation therapy can be delayed up 4 months without increased risk of recurrence. If chemotherapy is indicated after lumpectomy, then a radiation treatment delay of 6 months may be possible. Recent recommendations from an international panel of experts state that even if patients are treated in the first trimester or early second trimester, breast irradiation can be delayed until after delivery. However, the local recurrence rate after breast-conserving surgery in pregnant women is unknown. The rates of local recurrence in women younger than 43 years have been reported to be as high as 30% in 8 years of follow-up.

P.1063

This information should be discussed with the patient to inform her decision to have breast-conserving surgery versus modified radical mastectomy.

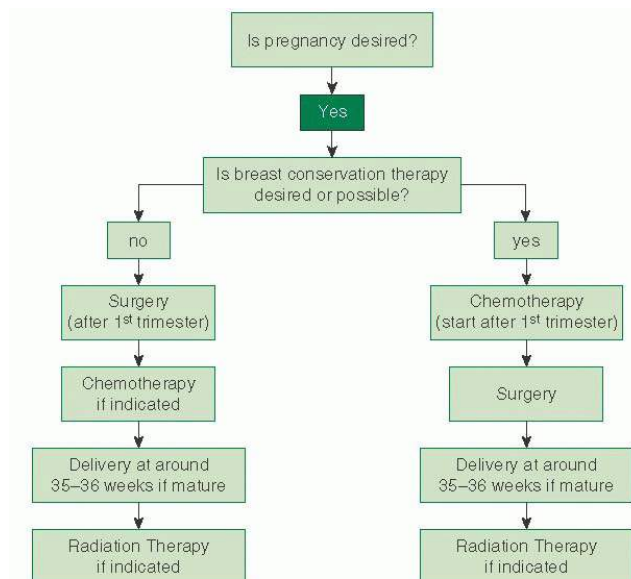

FIGURE 45.48 Treatment algorithm for pregnancy-associated breast cancer.

The current standard of care for evaluation of the axilla in a nonpregnant patient with early-stage breast cancer is to perform an SLNB. Sentinel node biopsies involve the use of ^{99}Tc -labeled sulfur colloid and isosulfan blue dye. Keleher calculated the amount of radiation exposure to the fetus with either 0.5- or 2.5-mCi injections of ^{99}Tc and found the dose to be lower than the 0.15-Gy teratogenic threshold. Mondt and colleagues were able to show in a small series that sentinel node biopsies were feasible and safe. At this time, isosulfan blue dye is not approved by the Food and Drug Administration for use in pregnant women. A possible alternative to isosulfan blue dye if an SLNB is being considered is to use indigo carmine. Indigo carmine can safely be used in pregnancy. Indigo carmine is routinely employed in sentinel lymphatic mapping procedures in Japan. A recent review of the Japanese experience has shown that the use of ^{99}Tc along with indigo carmine can result in detection rates of 98% to 100%, which is similar to the results that can be obtained with isosulfan blue. The use of SLNB in PABC requires a thorough discussion with the patient with regard to the risks and benefits of such surgery given the paucity of data on the use of sentinel lymph node dissection in PABC.

Chemotherapy

Limited data exist on the use of chemotherapy for PABC. All chemotherapeutic agents are teratogenic in animals. The timing of chemotherapy administration impacts greatly on risk of fetal malformation and spontaneous abortion. Organogenesis occurs during the first semester. Chemotherapy in the first trimester can result in neural tube defects, cleft lip, amelia, cardiac defects, fetal loss, and other defects. The risk of fetal malformation is diminished when used in the second and third trimesters. Data from the Breast Cancer During Pregnancy Registry found that patients treated with chemotherapy did not have increased risk of intrauterine growth restriction, preterm delivery before 37 weeks, or obstetrical complications.

The majority of studies of chemotherapy in PABC consist of small case series. The University of Texas M.D. Anderson Cancer Center has reported the largest prospective series of PABC treated with chemotherapy. A total of 57 patients were treated in either the adjuvant ($n = 32$) or neoadjuvant ($n = 25$) setting. All patients were treated with FAC (5-fluorouracil, doxorubicin, and cyclophosphamide) for a total of 4 to 6 cycles. In the neoadjuvant group, 32% of the patients had a complete pathologic response. Breast-conserving surgery was more likely in the neoadjuvant group compared to the adjuvant group (37% vs. 19%). With a median follow-up of 38.5 months, 40 patients (70%) are alive without evidence of disease, 13 patients (23%) have died of disease, 3 patients (5%) are alive with disease, and 1 patient is of unknown status. The use of the FAC regimen appears to be safe with minimal neonatal complications. Of the patients who delivered after chemotherapy ($n = 40$), there was one case each of subarachnoid hemorrhage, clubfoot, and Down syndrome. The numbers in this series are too small to conclude if these outcomes were the result of chemotherapy administration, though the risk of subarachnoid hemorrhage in the general population is only 0.8/1,000 births.

Another large series reported on 28 patients treated with three different regimens: doxorubicin/cyclophosphamide (AC), epirubicin/cyclophosphamide (EC), and cyclophosphamide/methotrexate/5-fluorouracil (CMF). These regimens were initiated at 15 to 33 weeks' gestation. One patient was given CMF in the first trimester and had a spontaneous abortion after the first cycle. Overall, all three regimens were well tolerated with no fetal anomalies attributed to the chemotherapy. The combined survival for this cohort of patients was 67% at a median of 40.5 months of follow-up. The disease-free survival rate was 63%.

There are only case reports of other regimens used for PABC. The largest report of the use of taxanes in PABC comes

P.1064

from the Breast Cancer During Pregnancy Registry in a total of 14 patients; however, data are limited, and taxanes should be used with caution.

In recent years, newer chemotherapeutic agents targeting growth receptors such as HER2/*neu* have been part of standard treatment for patients with breast cancer who overexpress these receptors. Seven published case reports of PABC patients undergoing treatment with trastuzumab, a monoclonal antibody that blocks the human epidermal growth factor receptor 2 protein, indicate these patients were able to tolerate trastuzumab, except for the oligohydramnios or anhydramnios that was seen in five out of the seven patients. This decrease in amniotic fluid appears to be reversible with the discontinuation of trastuzumab. All patients were able to deliver a viable infant with the exception of one patient who had a twin pregnancy with loss of one twin secondary to chronic renal failure and lung disease after delivery at 31 weeks.

Hormonal therapy such as tamoxifen has been shown to be highly effective in premenopausal estrogen receptor-positive breast cancer and is routinely used once initial treatment with surgery, radiation therapy, and chemotherapy has been completed. Several case reports of patients treated with tamoxifen during pregnancy suggest that treatment is safe with no side effects; others have reported cases of Goldenhar syndrome (oculoauriculovertrebral dysplasia) or ambiguous genitalia. It appears prudent to hold off treatment with tamoxifen until the patient has delivered, given the paucity of data.

Prognosis

It is unclear whether pregnancy is an independent adverse risk factor for outcomes in PABC. Early studies reported poor overall survival in patients diagnosed with PABC. These results may have been attributable to the fact that patients with PABC tend to present with higher stages and more advanced disease. When PABC patients were compared to non-PABC cancer patients and controlled for stage, some studies have not shown any differences in outcome. In one series reported by Petrek and colleagues, patients with early-stage PABC with node-negative disease had similar survival to non-PABC patients (10-year survivals of 77% and 75%, respectively). Small numbers have hampered many studies of analysis of survival in patients with PABC. More recently, a large series using the California Cancer Registry was reported. A total of 797 PABC patients were compared to a cohort of 4,177 non-PABC patients. These authors found that even when controlled for stage, race, tumor size, type of surgery, and hormonal status, pregnancy status appears to have modest effect for poorer survival. The hazard ratio was 1.14 (95% CI: 1.0 to 1.29, $P = 0.46$) when PABC patients were compared to non-PABC patients. If one combines all the data from published studies that have reported 5-year survival, a total of 742 patients have been reported. Combining all the reported cases series, the overall 5-year survival for node-negative and node-positive PABC is 69% and 34%, respectively.

Follow-Up

Follow-up of the patient with PABC is no different than any other patient who has been diagnosed with breast cancer. The American Society of Clinical Oncology published their most recent guidelines in 2013. The guidelines recommend routine history and physical examination every 3 to 6 months in the first 3 years, every 6 to 12 months in the ensuing 2 years, and annually 5 years after treatment. In patients who have undergone breast-conserving surgery, a posttreatment mammogram should be obtained 1 year after the initial mammogram and at least 6 months after completion of radiation therapy. Thereafter, unless otherwise indicated, a yearly mammographic evaluation should be performed. Other testing such as complete blood count, chemistry panels, bone scans, chest radiographs, liver ultrasounds, computed tomography scans,

[^{18}F]fluorodeoxyglucose-positron emission tomography scanning, MRI, or tumor markers (CEA, CA 15-3, and CA 27.29) are not recommended by ASCO unless the patient is symptomatic.

SURVEILLANCE

Surveillance for patients treated for either in situ or invasive disease is directed at determining local and/or regional recurrence and identifying the development of a contralateral breast cancer. The risk of contralateral breast cancer varies depending on the age at initial diagnosis of breast cancer.

For patients with DCIS, a comprehensive physical examination every 6 to 12 months is recommended. In patients treated with breast-conserving surgery, an initial postsurgical mammogram should be conducted within 12 months. Assessment with MRI is recommended only for patients with dense breasts or for those in whom the initial diagnosis was made with this modality. Most recurrences occur in the ipsilateral breast near the previous segmental site. If the patient has undergone excisional surgery as the only therapy, this approach with or without radiation therapy is an option. If the patient previously received whole breast radiation, mastectomy is the preferred approach. In patients previously treated with APBI, decision on the surgical approach is individualized. In patients who have undergone irradiation, the majority of recurrences are in situ disease. Patients treated with mastectomy who experience a local recurrence should be treated with local excision and chest wall irradiation. If the patient is receiving tamoxifen therapy and has an intact uterus, an annual gynecologic assessment is recommended. Prompt evaluation of abnormal or postmenopausal bleeding is advised.

For patients with invasive cancer, a more intensive program of surveillance is recommended. In addition to assessing for local-regional recurrence and contralateral breast cancer, the issue of systemic recurrence exists in this population. In 2013, ASCO made recommendations for surveillance in asymptomatic women. These recommendations include a comprehensive history and physical examination every 3 to 6 months for the first 3 years, followed by every 6 to 12 months for years 4 and 5, and annually thereafter. Annual diagnostic mammographic surveillance is advised. MRI is not recommended unless the initial diagnosis was made with MRI, the patient is considered at high risk for in-breast or contralateral breast cancer as in patients with deleterious BRCA1/BRCA2 mutations, and in patients in whom breast density precludes adequate assessment. Routine radiographic testing such as CT scans, PET scans, chest radiographs, pelvic ultrasounds, and liver ultrasounds is not recommended. Comprehensive blood testing, including complete blood count, chemistries, tumor markers, and liver function testing, is not recommended if the patient is asymptomatic. Directed tests should be performed based on patient symptomatology.

For patients on adjuvant endocrine therapy, compliance with the medication should be assessed and adjustments made to increase adherence. For a patient on tamoxifen therapy and with an intact uterus, annual gynecologic evaluation is

P.1065

recommended. If the patient is experiencing abnormal or postmenopausal bleeding, an immediate evaluation with either endometrial biopsy or dilatation and curettage should occur. An ultrasound of the pelvis does not provide a histopathologic assessment and should not be used in place of obtaining a tissue diagnosis.

There is evidence that a healthy lifestyle provides benefits; hence, patients should be counseled to maintain or achieve an ideal body weight associated with improved health and survival. As previously described, smoking cessation, low fat intake, high fruit and vegetable intake, alcohol reduction, and avoidance of processed foods and red meat also have health benefits.

Individuals receiving aromatase inhibitors are at risk for osteopenia and osteoporosis. Appropriate surveillance with bone density assessment and use of bisphosphonate or other appropriate therapy should be used.

Hormone Replacement Therapy

As more breast cancers are detected at an earlier stage, resulting in increased survival, attention has been directed toward the use of HRT in breast cancer survivors. Caution is still advised, but a subset of patients may exist for whom, with appropriate counseling, placing on HRT may be an option. Premenopausal patients with ER-negative breast cancer who have lost ovarian function as a result of adjuvant therapy and menopausal breast cancer survivors may benefit from HRT to prevent long-term sequelae of estrogen deprivation. Postmenopausal women who have symptomatic estrogen deficiency and are disease-free for at least 2 years (highest risk for recurrence) may be considered candidates for HRT. A patient with localized node-negative breast cancer who is at low risk for recurrent disease may be a candidate for long-term HRT. Women with unexplained vaginal bleeding, acute vascular thrombosis, or significant liver function impairment would remain ineligible for HRT. All women should be counseled concerning the potential risk of disease recurrence.

Vasomotor symptoms can be managed through nonhormonal approaches. Gabapentin (Neurotin, Pfizer, New York, NY) has been shown in a randomized double-blind

placebocontrolled trial of 420 women to control hot flashes in breast cancer patients at 900 mg/day, demonstrating greater reduction in the posttreatment hot flash severity score compared with placebo and lower doses of gabapentin. Gabapentin is approved for the treatment of epileptic seizures but often is used for treatment of migraine headaches, restless legs syndrome, and bipolar disorder. Venlafaxine, a commonly used antidepressant, and SSRI appear to be effective treatment for hot flashes. An extended release preparation at an initial dose of 37.5 mg daily can reduce hot flashes in 50% to 60% of patients. If no response occurs within 2 weeks of starting the medication, the dose can be doubled.

Acupuncture has been reported to be of benefit for relief of vasomotor symptoms, but this has been questioned in the medical literature. Avoidance of triggers to hot flashes is a reasonable approach, such as cool and breathable clothing and minimizing hot and spicy food ingestion, hot tub and sauna use, and caffeine intake, and avoidance of smoking.

Atrophy of the urogenital epithelium can occur as a result of treatment for breast cancer. Particularly prone are premenopausal patients who enter menopause as a result of systemic use of SERMs and AIs and cytotoxic chemotherapy. Vaginal dryness can be managed using topical estrogens or with a time-released estradiol vaginal ring device (Estring, Pfizer, New York, NY). Systemic absorption of estrogen with this approach is reported to be minimal. Most of the effect is exerted locally and increases vaginal epithelium thickness and moisture. Limited data exist to guide the patient and health care provider. Additional studies should shed light on the safety of this approach.

Pregnancy after Treatment for Breast Cancer

Although oncologists generally caution patients to avoid pregnancy until 2 years after completing treatment for breast cancer, several investigators have shown no adverse effects or decreased survival for women who become pregnant after cancer therapy. Moreover, although lactation is decreased in the treated breast, radiation therapy appears to have no effect on the contralateral breast.

For patients who are premenopausal at diagnosis, a discussion should occur concerning the impact of adjuvant therapy on future fertility. Patients who desire childbearing should be afforded the opportunity to meet with a reproductive endocrinologist to review options for fertility preservation, including ovarian suppression and egg harvesting. The most efficacious approach appears to be cryopreservation of embryos.

Contraceptive options for premenopausal patients include barrier methods, surgical sterilization with tubal ligation (or vasectomy for the male partner), or use of an intrauterine device. The safety of oral contraceptives in patients, regardless of ER status of the tumor, is not known.

BEST SURGICAL PRACTICES

- Obstetrician-gynecologists, as primary providers of women's health care, are in a unique position to identify individuals at risk for breast cancer and to aid in the early diagnosis of the disease.
- One in eight women in the United States will develop breast cancer in their lifetime.
- Percutaneous sampling via FNA can aid in the diagnosis of benign and malignant masses, but the cytology cannot delineate between invasive and noninvasive breast cancer.
- Iatrogenic pneumothorax is a rare complication that may be reduced by stabilizing the lesion over a rib before needle introduction.
- Percutaneous core needle biopsy provides tissue samples for histologic analysis and can aid in the diagnosis of both invasive and noninvasive lesions. Core needle biopsy is the preferred management for palpable and nonpalpable lesions to help stratify operative interventions.
- Masses within 2 cm of the areolar margin can be removed through a circumareolar incision at the areolar margin with an excellent cosmetic outcome.
- The presence of a palpable mass and a normal or negative mammogram mandates additional evaluation.
- The most cosmetically acceptable scars result from incisions that follow the contour of Langer lines.
- Randomized controlled trials have demonstrated breastconserving surgery and radiation therapy to be equivalent to radical mastectomy with regard to overall, disease-free, and distant disease-free survival.
- For a patient with breast cancer and a clinically negative axilla, sentinel lymphatic mapping is the operation of choice to assess nodal status.
- Multimodality therapy with surgery, chemotherapy, or endocrine therapy and postlumpectomy radiation therapy are effective means of treating breast cancer.

P.1066

- IBC is a rare and highly aggressive form of breast cancer. Often, the patient will present with what appears to be mastitis but lacks systemic signs of fever and leukocytosis. Prompt diagnosis and treatment with cytotoxic chemotherapy followed by modified radical mastectomy and chest wall irradiation has improved survival from this disease.
- Most patients who undergo mastectomy are candidates for either immediate or delayed breast reconstruction.
- In a patient diagnosed with breast cancer associated with a pregnancy, careful coordination of care should occur between the surgeon, medical oncologist, and the obstetrician-gynecologist. The trimester of diagnosis determines the sequence of care.
- In a patient with PABC, referral for genetic assessment to identify either a BRCA deleterious mutation or family cancer syndrome is appropriate.
- Risk-reducing breast procedures include total mastectomy, skin-sparing mastectomy, and nipple-sparing mastectomy.

Chapter 46

The Vermiform Appendix in Relation to Gynecology

Amanda C. Yunker

DEFINITIONS

Appendicitis—Inflammation of the appendix, usually caused by obstruction of the appendiceal lumen, with subsequent distention of the appendix with secretions, venous congestion, bacterial proliferation, ischemia, and necrosis.

McBurney point—A point on the anterior abdominal wall, located 1/3 the distance between the right anterior superior iliac spine and the umbilicus.

Obturator sign—Increased pain in the abdomen, specifically the right lower quadrant, with passive internal rotation and flexion of the right lower extremity at the hip joint.

Psoas sign—Increased pain in the abdomen as the right lower extremity is moved into extension, with the patient in the left lateral decubitus position, and asking the patient to actively flex the leg at the hip joint against resistance.

Rovsing sign—Pain reported by the patient in the right lower quadrant of the abdomen while applying pressure to the left lower quadrant.

Fecalith—An intestinal stone formed around a central core of fecal matter.

The vermiform appendix, named for its wormlike appearance, is part of the gastrointestinal tract and usually falls in the purview of general surgeons. However, there are several gynecologic and obstetric associations with the appendix, some of which could be fatal, requiring the obstetrician-gynecologist to be mindful of this organ, its potential diseases, and its effects on other gynecologic structures.

The appendix is most commonly evaluated for acute abdominal pain, which could be the result of acute appendicitis. This occurs in 7% of the population over a lifetime, resulting in the most commonly performed emergent surgical procedure: appendectomy. It is estimated that approximately 300,000 emergent appendectomies are performed annually in the United States. The majority of cases occur in young patients, usually under age 20. However, appendicitis can occur even in elderly patients, and these patients have much higher morbidity and mortality rates associated with appendicitis and appendectomy, compared with their younger counterparts.

FIGURE 46.1 As illustrated in this original Max Brödel drawing, inflammatory disease of the appendix can involve the fallopian tube or vice versa. Extensive adhesions can form. The tube and the appendix can be removed as a single mass. (The original illustration is in the Max Brödel Archives in the Department of Art as Applied to Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD, USA. Used with permission.)

As an obstetrician-gynecologist, the appendix is of interest for many reasons. First, women presenting with acute-onset abdominal pain will likely be referred to a gynecologist for evaluation. Appendicitis should be included in the differential, along with pelvic inflammatory disease, ectopic pregnancy, ovarian cyst, ovarian torsion, and urinary tract infection. Second, acute appendicitis, especially if the appendix is ruptured, can have a negative impact on fertility given the anatomic proximity of the appendix to the fallopian tubes ([Fig. 46.1](#)). Third, though infrequent, appendicitis can occur during pregnancy and is associated with a higher morbidity in pregnant females

P.1072

compared to nonpregnant females. Pregnancy can complicate the differential diagnosis of abdominal pain simply because the pregnancy itself adds multiple etiologies for abdominal pain, and the anatomic location of the appendix can shift cephalad due to the gravid uterus. This can delay diagnosis. Finally, several gynecologic conditions—endometriosis, mucinous tumors, and ectopic pregnancy—can involve the appendix, thus compelling the obstetrician-gynecologist to include the appendix in the evaluation for chronic and acute gynecologic conditions.

ANATOMY AND FUNCTION OF THE APPENDIX

The appendix begins in infancy as a cone-shaped diverticulum at the base of the cecum. As the cecum grows in length and repeatedly distends with bowel function, the appendix eventually elongates and emerges 2 to 3 cm below the ileocecal valve. At full maturation, it is approximately 10 cm in length and 3 to 5 mm in width. The

teniae coli travel along the cecum and then converge at the appendix, creating the outer longitudinal muscle of the appendix. This is helpful, in that the teniae may be followed to locate an appendix that may be hidden from view. One instance in which that occurs is a retrocecal appendix, which is found in 16% of adults. In the rest, the appendix is freely mobile and usually easily seen upon mobilization of the cecum (**Fig. 46.2**). The location of the appendix thus can vary and may influence the location of perceived pain during acute appendicitis.

Early in life, the appendix is composed of large collections of lymphoid follicles that then atrophy and decrease over time. This occurs with simultaneous fibrosis of the wall of the appendix and possible obliteration of the lumen. The lumen itself is lined with colonic mucosa, and the wall of the appendix is composed of smooth muscle, similar to the large and small bowel.

The appendix is supplied by two arterial branches. The main artery for the appendix is the appendicular artery, a branch of the ileocolic artery. It runs parallel to the appendix, in the mesoappendix. The base of the appendix is also supplied by a branch of the posterior cecal artery.

Thought to be primarily a vestigial organ, current general consensus is the appendix serves no function in humans. Due to the large presence of lymphoid tissue in childhood, the hypothesis exists that the appendix once played a role in immune protection of the intestinal tract. Additionally, the appendix does secrete immunoglobulin A, a mucosal surface antibody, thus bolstering the idea that it serves some immune function. However, the amount of secretion is minimal, and the majority is not likely to breach the lumen into the cecum. Thus, removal of the appendix results in no obvious negative physiologic consequence.

FIGURE 46.2 Mobile appendix easily seen upon mobilization of the cecum.

ACUTE APPENDICITIS

Pathology arises within the appendix usually as a result of lumen obstruction. The most common cause of obstruction is fecaliths (50%), but other possibilities include lymphoid hyperplasia, malignancy, parasitic infections, endometriosis, and ingested foreign bodies (such as gum, teeth, nails, fruit pits, etc.). Once the lumen is blocked, the appendiceal secretions have no exit, resulting in venous congestion, ischemia, and necrosis. The bacteria, which are already present within the appendix lumen, become trapped and replicate, resulting in local tissue inflammation and pus formation. If untreated, rupture and abscess formation can occur. Leakage of the bacteria through the perforation and into the abdominal cavity leads to peritonitis (**Fig. 46.3**).

The lifetime risk for developing appendicitis is around 7%, with the majority of patients presenting in the second and third decade of life. The risk of mortality in this group is low, less than 1%, due to appropriate detection and early treatment. However, in individuals over age 50, although the incidence of appendicitis is extremely low, the risk of mortality from acute appendicitis is higher—5% to 15%. This group is also at risk for increased morbidity (50% to 60%) from the disease, such as longer hospitalization, wound infection, higher rates of perforation,

sepsis, and other organ failure.

The diagnosis of appendicitis is usually delayed in the elderly, thus resulting in a far-advanced disease process when treatment is eventually started. This delay is likely a result of many factors: The elderly tend to delay seeking care, their symptoms are less specific than are those of their younger counterparts, and they have decreased febrile response and less prominent leukocytosis.

Clinical Presentation

The most common presenting symptom of acute appendicitis is abdominal pain, which is present in more than 95% of patients with appendicitis. The pain usually begins as diffuse and mild and is located in the periumbilical region. Once the disease process has progressed, the pain typically moves to the right lower quadrant, specifically to an area called McBurney point. The pain can be associated with fever, nausea, vomiting, and anorexia. Many times, there will be aggravation of the pain with movement. This has led to the development of many named physical exam tests, which are aimed at eliciting peritoneal stretch and irritation. These tests will be discussed below.

It should be stressed that the typical physical symptoms— pain, fever, nausea, and anorexia—are only present in 50% of patients, leaving an atypical presentation in the remaining 50%. The location of abdominal pain is variable, depending on the location of the appendix and the stage of the disease process. Although the location of the cecum is fairly constant, the appendiceal tip can be in the right upper quadrant (retrocecal), cul-de-sac, or anywhere between these two locations. As mentioned above, age also can affect the severity of pain felt by the patient. Elderly patients tend to report less severe and more diffuse abdominal pain. In a similar manner, abdominal pain is difficult to diagnose in children and infants because of the lack of ability to effectively communicate their symptoms. The incidence of appendiceal perforation is higher in these two groups for these reasons; thus, the vigilant practitioner must rely on other signs and symptoms and have a higher degree of suspicion when evaluating these patient populations. The presence of associated signs and symptoms is even more variable.

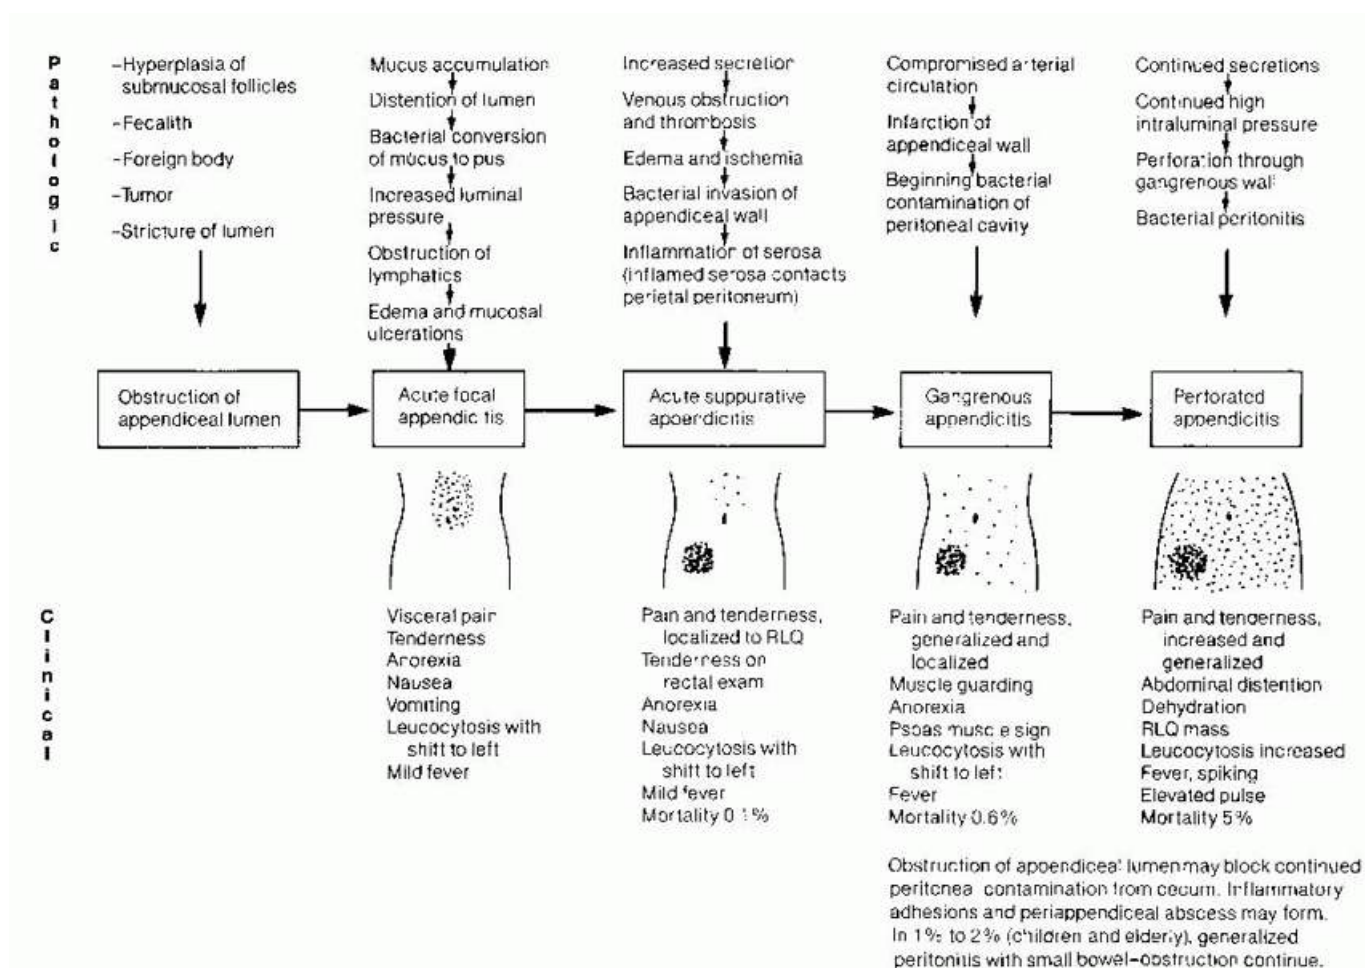

FIGURE 46.3 The clinical-pathologic correlations of appendicitis. RLQ, right lower quadrant. (From: Sabiston DC Jr, ed. *Textbook of surgery*, 14th ed. Philadelphia, PA: WB Saunders, 1991, with permission of Elsevier.)

Evaluation

Evaluation for appendicitis begins with the history and physical exam, then usually also includes several laboratory and imaging tests. The physical exam typically focuses on the abdomen and includes several “signs” that indicate peritoneal inflammation. Patients with appendicitis usually have tenderness to direct palpation (especially over McBurney point—located 1/3 the distance from the right anterior superior iliac spine to the umbilicus), rebound tenderness, and guarding of the abdomen. The Rovsing sign is often present and is described as pain in the right lower quadrant when pressure is applied to the left lower quadrant. Additionally, the patient may be positive for the psoas sign (increased pain in the abdomen as the right lower extremity is moved into extension, with the patient in the left lateral decubitus position, and asking the patient to actively flex the leg at the hip joint against resistance) or the obturator sign (increased pain in the abdomen, specifically the right lower quadrant, with passive internal rotation and flexion of the right lower extremity at the hip joint). A complete exam should include rectal and pelvic exams, which, in addition to identifying peritoneal tenderness, also can help rule in the presence of a mass or pelvic abscess.

The most common abnormal laboratory finding in a patient with appendicitis is leukocytosis. The average increase is to 15,000 WBC/mL; however, elevations in WBC are not specific for only appendicitis. Thus, leukocytosis is significant for appendicitis in the setting of the above classical presenting symptoms. Alone, leukocytosis, even with fever, is not a reliable test for appendicitis. Other causes of infection should be ruled out. Other laboratory tests that have been used included C-reactive protein and erythrocyte sedimentation rate. Because these two tests are nonspecific indicators for inflammation, they also are not helpful as individual tests for appendicitis.

Radiologic evaluation for appendicitis has increased over time and has come to include multiple different modalities. Imaging studies can be helpful in that they can image not only the appendix but also the adjacent abdominal structures, thus ruling in or out other diagnoses that can cause abdominal pain. Currently, computed tomography (CT) is usually the initial imaging technique used in emergency departments across the United States. Its diagnostic ability has been reported to be as high as 87% to 100% sensitivity and 95% to 99% specificity. Findings on CT that indicate acute appendicitis include enlarged appendix (≥ 6 mm), appendiceal wall thickening, periappendiceal fat stranding, and appendiceal wall enhancement (Fig. 46.4). CT may also diagnose an appendicolith, abscess, or the presence of free air. The Surgical Infection Society and Infectious Disease Society of America recommend helical CT with IV contrast only as the test of choice in patients with suspected appendicitis, if imaging is indicated and necessary. One benefit of preoperative imaging in patients with suspected appendicitis is the reduction in negative appendectomies (those with no pathology).

Ultrasound, unlike CT, is operator dependent, and its accuracy for diagnosis of appendicitis varies from institution to institution. However, in a comparison between the two imaging types, both CT and US were highly specific (93% to 95%) in both adults and children, whereas CT was more sensitive.

P.1074

FIGURE 46.4 Computed tomography of appendiceal abscess. Note complex fluid mass with an enhancing rim in the right lower quadrant (*arrows*). (Courtesy of Ronald Arildsen, MD, Vanderbilt University.)

Ultrasound is beneficial in that it does not expose patients to ionizing radiation and thus can be used safely in pregnant patients. Most young women presenting for acute abdominal/pelvic pain, even those who are not pregnant, usually undergo US evaluation of the reproductive organs. Thus, performing US evaluation of the appendix is efficient, convenient, and costeffective. The technique involves directing gradual pressure over the right lower quadrant in an attempt to collapse the overlying bowel and visualize the appendix. A typical “target appearance” identifies the appendix by characteristic changes within its wall (Fig. 46.5). Findings on US that are associated with acute appendicitis include increased appendiceal diameter (≥ 6 to 7 mm), loculated pericecal fluid, luminal distention, lack of compressibility, prominent pericecal fat, and loss of the submucosal layer.

Magnetic resonance imaging (MRI) is currently being investigated as a potential diagnostic tool for acute appendicitis. Its disadvantages include its much higher cost, when compared to CT or US, and its decreased availability to smaller/more rural institutions. However, there may be some advantages in special patient populations, such as pregnancy, which is discussed later.

FIGURE 46.5 Transabdominal ultrasound of acute appendicitis. Note the “target-like” appearance produced by the thickened, inflamed wall of the appendix. (Courtesy of Arthur Fleischer, MD, Vanderbilt University.)

Laparoscopy can be both diagnostic and therapeutic for acute appendicitis. If clinical suspicion is high enough, then surgical evaluation is justified. However, appendectomy for a nonpathologic appendix is not without risk. The goal of the presurgical evaluation—history, physical exam, and laboratory and imaging tests—is to determine who will most benefit from surgery and to decrease the negative appendectomy rate, which still hovers between 10% and 20%. Close inpatient observation may be indicated when there is an atypical presentation to allow progression of the clinical picture and completion of the diagnostic workup. If the gynecologist is the admitting attending physician, the consultation of the general surgery service should occur during this time interval.

Patients with persistently confusing findings may benefit from laparoscopy. In almost all circumstances, a laparoscopy with negative findings is preferable to delaying while an appendix ruptures or pelvic inflammatory disease progresses or an ovarian torsion results in a necrotic ovary. An unnecessary delay increases the likelihood of perforation, peritonitis, abscess formation, and sepsis. In a young woman, this also increases her risk of future adhesions, pelvic pain, and infertility. When surgery is performed within 24 hours of the onset of symptoms, less than 20% of infected appendices are perforated, compared with 70% when appendectomy occurs greater than 48 hours after symptom onset.

Treatment

As a rule, the best treatment of appendicitis is appendectomy. However, there are circumstances in which appendectomy can be or should be delayed. In those instances, other options include antibiotic therapy and interventional radiologic drainage of abdominal abscess.

Antibiotic therapy should be initiated promptly and include broad-spectrum coverage. A common combination of antibiotic treatment is cefazolin and metronidazole. Patients should remain nil per os during antibiotic treatment, in the event that the clinical picture worsens and immediate surgery is required. Antibiotics given prior to surgery have been shown to reduce the incidence of postoperative wound infections. The duration of antibiotic treatment after appendectomy varies. If the appendix was not ruptured at the time of surgery, then antibiotics can be discontinued immediately after. If perforation occurred, most surgeons advocate continued use of wide-spectrum antibiotics for several days after appendectomy, until

the patient shows significant clinical improvement and resolution of the infection.

Several studies have been reported over the last few years comparing nonoperative versus operative management of

P.1075

acute, uncomplicated appendicitis. In many of these studies, patients were offered antibiotics as their sole therapy if they desired and their surgeons agreed. If their symptoms improved on intravenous antibiotics, they were discharged on oral antibiotics with close follow-up. Failure of antibiotic therapy, either by physical exam or laboratory, resulted in immediate appendectomy. The majority of patients who were treated with antibiotics alone was adequately treated and did not require subsequent surgery. While overall the data look somewhat promising, there is still great hesitancy to adopt this antibiotic-only strategy as the primary treatment for appendicitis.

Another nonsurgical option for treatment of acute appendicitis is catheter drainage of periappendiceal abscess under CT or US guidance. This treatment option may be helpful in controlling the spread of infection prior to appendectomy. Limitations of percutaneous drainage include the inability to drain multiloculated abscesses, inaccessible location, and the possible need for anesthesia. If possible, once the abscess is drained and antibiotics have allowed the infectious process to “cool,” an interval appendectomy can be performed. Most surgeons wait 6 to 12 weeks after nonoperative therapy to perform an interval appendectomy.

Open Appendectomy

STEPS IN THE PROCEDURE

Open Appendectomy

- Dorsal supine position.
 - Foley catheter.
 - Prep for RLQ incision over McBurney point.
 - Divide muscles and adjacent fascia.
 - Enter the peritoneum.
 - Obtain any abnormal-appearing fluid for culture.
 - Identify the cecum and bring to the incision (may need to incise attachment to lateral peritoneum for mobilization).
 - Use moist lap sponges for tissue handling and to protect wound (if ruptured).
 - Deliver the appendix through the incision.
 - Separate the mesoappendix from the appendix to the base of the appendix (may use suture/cautery).
 - Place clamp at the base of the appendix to “crush” the stump and repeat 1 cm distally.
 - Ligate the base of the appendix with suture at proximal crushed edge.
 - Place a purse-string stitch in serosa of cecum at base of appendix.
 - Transect the appendix above the ligature and send for pathology.
 - Bury the stump through purse-string suture and tie down.
 - Check for hemostasis, and replace the cecum into the abdomen with omentum overriding.
 - Irrigate and place a drain if needed.
 - Close the incision in layers.
-

As mentioned above, the best treatment for appendicitis is surgical removal (appendectomy). Prior to the technical advances of modern laparoscopic surgery, open appendectomy was the norm. Open appendectomy is advantageous for several reasons. In the patient with an uncertain diagnosis, it provides wide exposure for evaluation and surgical management of pathologic conditions of the bowel, fallopian tube, and ovary; it is quick and simple and does not require sophisticated equipment or set up by experienced personnel.

After adequate general anesthesia, field preparation, and draping, the open technique is begun by making a small right lower quadrant incision. A modification may be made in the location of the incision if a palpable abdominal mass is noted. If this is the case, then it is presumed the mass is a loculated abscess, and the incision should override the mass to allow easier drainage. The right lower quadrant incision should be centered over McBurney point, can be made transversely or obliquely, and then extended medially a few centimeters over the underlying rectus muscles, if necessary (**Fig. 46.6**). The incision is then carried through the subcutaneous tissue. The external oblique fascia is incised in the same direction that the muscle fibers course, and the muscle fibers then separately bluntly. There should be no incision involving the rectus muscles. The peritoneum is then easily identified and incised transversely. Upon entry into the abdominal cavity, cultures are obtained of the peritoneal fluid.

After an initial cautious sweep of the abdominal cavity, retractors are placed around the incision and the cecum is brought to the wound. Adhesions can be bluntly or sharply dissected in order to free the appendix and allow it to be delivered through the incision and grasped with an atraumatic clamp. If this maneuver still does not result in easy access to the appendix, the incision can be extended medially into the

P.1076

rectus abdominis sheath to allow medial retractor of the muscles. Also, the lateral attachment of the cecum to the abdominal side wall can be lysed to further mobilize the cecum.

FIGURE 46.6 Common incisions for appendectomy. The classic McBurney incision over the cecum is not as easily extended to perform gynecologic procedures if needed.

The appendix can be located by following the tenia coli as they converge at the base of the cecum. The appendix is elevated through the incision and the mesoappendix grasped at the base with a Kelly clamp. The mesoappendix is then serially clamped with a series of Kelly or hemostat clamps and ligated with delayed absorbable suture (**Fig. 46.7A**). The ligation of the mesoappendix is necessary in that the blood supply to the appendix, the appendicular artery, runs parallel to the appendix within the mesoappendix. Additionally, in some instances, there may be an additional vessel, an accessory branch of the posterior cecal artery, which requires ligation. This branch is typically located at the base of the appendix, very near its exit from cecum. If bleeding is encountered in this area, a suture can be placed through the muscularis of the cecal wall near the base of the appendix.

The surgeon has several options when approaching ligation and excision of the appendiceal stump. Traditionally, this has been accomplished by placing two clamps across the base of the appendix, with sufficient spacing between the clamps to allow passage of a scalpel or scissors (**Fig. 46.7B**). The appendix is then passed off the field, with the attached clamp, to prevent contamination. The stump is doubly ligated with delayed absorbable suture (**Fig. 46.7C**). Some advocate using a small amount of electrocautery on the residual mucosa at the stump, thereby preventing a future mucocoele.

FIGURE 46.7 Technique of open appendectomy. **A:** The appendix is elevated by a Babcock clamp, and the mesoappendix is ligated. Alternatively, small clamps may be used to clamp, cut, and tie the mesoappendix. **B:** The operative field is isolated with gauze packs, and the appendix is crossclamped and divided between the two closely placed clamps. **C:** The stump of the appendix is ligated with a 2.0 absorbable ligature. **D:** The stump is usually cauterized and covered with the adjacent mesoappendix.

P.1077

At this point, the surgeon may choose to invert the stump with a purse-string or Z-stitch in the cecum, placed 1 cm from the stump, or leave the stump as is ([Fig. 46.7D](#)). One randomized trial of ligation and invagination versus ligation alone found no differences in wound infection, fever, or hospital stay. There is a small increased risk of early small-bowel obstruction after invagination.

Another option for ligation/excision of the appendix at the stump is a stapling device. Several handheld stapling devices are available on the market. The stapler crushes, seals, and transects the tissue in a single pass, making it very efficient and easy to use. It requires that the operator include a small portion of the distal cecum in the transection to ensure removal of the entire appendix. Care must be taken to avoid including too much of the

cecum—and potentially the ileocecal valve—in the device.

Once the appendix is removed, the surgical field is copiously irrigated, and the abdominal incision is closed in layers. If an abscess is encountered at the beginning of the surgery, then a drain should be left in place at the time of closure.

Laparoscopic Appendectomy

STEPS IN THE PROCEDURE

Laparoscopic Appendectomy

- Lithotomy or dorsal supine position.
 - Foley catheter and NG/OG tube.
 - Trendelenburg with left lateral tilt.
 - Three trocars: supraumbilical, LLQ or suprapubic, and RUQ.
 - Obtain fluid for culture.
 - Retract the cecum in the direction of the left upper quadrant.
 - Identify and elevate appendix.
 - Create a window through the mesoappendix at the base of the appendix.
 - If using stapler: one pass at base of appendix and one pass across mesoappendix.
 - If using suture: divide and ligate mesoappendix with cautery/clips, place double ligation at base of appendix, and transect with laparoscopic scissors.
 - Remove the appendix through trocar or place in laparoscopic bag/pouch for removal.
 - Irrigate and check for hemostasis.
 - Place a drain in pelvis through small port site or new incision if abscess/rupture is encountered.
 - Remove instruments and close port sites.
-

Removal of the appendix via the laparoscopic route was first described by Kurt Semm in 1983; however, widespread use of this technique did not occur until the 2000s. In 1999, 20% of appendectomies were performed laparoscopically. This increased to 43% in 2003. A recent pediatric surgery study revealed an even more striking trend, with an increase from 22% laparoscopic appendectomies in 1999 to 91% in 2010. The laparoscopic approach is favored in the pediatric population for similar reasons as the adult population: ease of recovery, decreased risk of wound infection, shorter hospitalizations, and cosmesis.

Initially, laparoscopic appendectomy was performed as an incidental procedure during another planned surgery. Since then, multiple studies, including randomized controlled trials and meta-analyses, have compared laparoscopic versus open appendectomy, both in the acute and nonacute settings. Laparoscopic appendectomy is associated with decreased incidence of wound infection, less postoperative pain, shorter hospital stay, and quicker return to normal activities. The disadvantages of the laparoscopic approach include longer operative times (adding approximately 10 minutes) and higher rates of intra-abdominal abscess. Laparoscopic equipment and experienced surgical nurses to set up and operate the equipment are widely available these days. Laparoscopy also allows the experience surgeon to evaluate and, in most cases, surgically manage nonappendiceal causes of right lower quadrant pain. Overall, the clinical differences between the two approaches are very small.

Laparoscopic appendectomy can usually be accomplished with a 3-trocar technique, using a combination of 5- and 10-mm trocars. After general anesthesia is induced, the patient is prepped and draped in sterile fashion, and

a urinary catheter and orogastric tube are placed. Entrance is gained to the peritoneal cavity through trocar or Veress needle placement, and the abdomen is insufflated with carbon dioxide gas. The initial trocar can either be 5 or 10 mm (depending on the laparoscope diameter) and is usually placed in the umbilicus. A second trocar is placed under direct visualization in the right upper quadrant and a third in suprapubic regions. If a stapling device is planned, the suprapubic trocar should be 10 to 12 mm in size in order to accommodate it. Placing trocars in these locations allows the surgeon to “triangulate” around the appendix.

FIGURE 46.8 Creation of a window between the appendix and the mesoappendix near the base.

Initially, the abdominal cavity is surveyed to look for other abnormalities or causes of pain. The patient may be placed in Trendelenburg position with a left lateral tilt in order to facilitate visualization of the cecum and appendix. With an atraumatic grasper, the cecum is elevated and retracted superiorly and medially. If this retraction does not produce the appendix, it is possible that the appendix is in a retrocecal location. Lysing the peritoneal attachment of the cecum to the lateral abdominal wall may help reveal the appendix. Once seen, the appendix is grasped and extended anteriorly. With a Maryland grasper (or similar), a window is created between the appendix and the mesoappendix near the base (**Fig. 46.8**). Through this window, the mesoappendix is sealed/ligated and divided with a stapler, bipolar cautery,

P.1078

ultrasonic energy, or surgical clips (**Fig. 46.9A, B**). The appendix is then transected, using either a stapling device or ligating suture loops and scissors (**Fig. 46.9C-E**). If a stapler is used, the transection should include a short cuff of cecum as well. If loops are used, then three loops are placed at the base of the appendix, and the incision is made between the middle and distal loop. There is no invagination performed with the laparoscopic approach.

FIGURE 46.9 A, B: Sealing/ligating/dividing of mesoappendix with the use of stapler, bipolar cautery, ultrasonic energy, or surgical clips. **C-E:** Transecting of appendix using ligating suture loops and scissors.

For removal, an endoscopic bag is passed through one of the larger trocars, the appendix placed in the bag, and then both removed from the abdomen (**Fig. 46.10A**). The procedure is completed with irrigation of the surgical site, removal of the trocars, and closure of the incisions (**Fig. 46.10B**).

Single Incision

A novel method for appendectomy recently described in the literature is the single-incision laparoscopic approach. The first single-incision laparoscopic appendectomy was reported in 1992. This first report was in the adult population; however, soon after initial report, the pediatric surgeons were quick to adopt the technique. Single-incision appendectomy is comparable to the traditional 3-port technique in lower infection rates, decreased pain, faster recovery times, and improved cosmesis. A large, U-shaped incision is typically made at the umbilicus, allowing a multichannel port to be secured to the abdominal wall. The camera and laparoscopic instruments are passed through this port simultaneously. Often, a flexible scope is used to allow more operative space between the scope and instruments. Initially, there were longer operative times reported (during the period when this technique was novel), compared to traditional laparoscopy, but the surgery times for single-incision approach have decreased as the technique has gained momentum and surgeons have become more proficient

FIGURE 46.10 A, B: The appendix is removed with the use of an endoscopic bag and irrigation of the surgical site.

APPENDICITIS IN PREGNANCY

Appendectomy is the most common nonobstetrical operation in the pregnant patient. Acute appendicitis occurs in 1/1,400 to 1/6,600 pregnancies. In addition to the baseline risks of appendectomy and acute appendicitis in a nonpregnant patient, pregnancy itself exposes the patient to delayed diagnosis, risk of fetal effects, and preterm birth, difficulties with surgery, and increased risk of postoperative complications.

Delayed diagnosis of appendicitis in pregnant women occurs as a result of multiple factors. First, there are many pregnancy-related causes of abdominal and pelvic pain that typically distract the clinician from nonpregnancy-related causes. Ectopic pregnancies, threatened abortion, preterm/term labor, urinary tract infection/pyelonephritis, and uterine rupture are just a few of the pregnancy-related causes of abdominal pain that are typically ruled out first. Thus, the appendix, though on the list of differential diagnoses, is usually not the primary focus in the workup.

To confuse matters more, the typical clinical presentation of appendicitis may be altered in a pregnant patient.

Acute appendicitis occurs more often in the second trimester (42%) compared with the first (32%) or third (26%) trimester. Thus, the majority of appendicitis occurs after the gravid uterus has moved out of the pelvis. The location of the appendix may move cephalad as the gravid uterus grows and displaces most pelvic structures with it; however, this theory is somewhat controversial. In a study by Baer et al. in the 1930s, the appendix was shown to be above the level of the iliac crest in 88% of women after the 7th month of pregnancy. More recent studies have disproved this idea and demonstrated that pain in the right lower quadrant (the typical presentation of appendicitis), regardless of gestational age, is the most common presenting symptom of appendicitis in pregnant women. It is possible, though, that the location of appendicitis-related pain in a pregnant female can be anywhere in the right abdomen, thus confusing the diagnosis. Additionally, pregnancy-driven physiologic changes may result in leukocytosis and tachycardia, thus confusing the clinical and laboratory evaluation for acute appendicitis.

Typically, ultrasound and CT imaging studies are the methods of choice for radiologic diagnosis of acute appendicitis. In pregnancy, diagnostic abilities with ultrasound are limited due to changes in body habitus (i.e., increase in maternal BMI, soft tissue edema, and overriding gravid uterus), and CT is relatively contraindicated due to potential radiation exposure to the developing fetus. Several studies have evaluated MRI as the preferred imaging modality for acute abdominal conditions in pregnant women. The sensitivity of MRI for acute appendicitis is 80% to 100%, with a specificity of 94% to 99%. MRI has been shown to decrease the number of unnecessary laparotomies in pregnant patients.

When appendicitis is diagnosed, or strongly suspected, then appendectomy must be performed, regardless of gestational age. Delay of treatment puts both the mother and fetus at risk. While laparoscopic surgery is often the route of choice in a nonpregnant patient, it is not always feasible or recommended in the pregnant patient. Two major considerations of laparoscopic surgery in pregnancy are (a) the effects of increased abdominal pressure, uterine and maternal circulation, and fetal acidosis with CO₂ pneumoperitoneum and (b) risk of trocar or instrument perforation into the gravid uterus. The potential fetal effects of pneumoperitoneum have been studied, and the results suggest there is no substantial negative effect on the fetus at intra-abdominal pressures below 12 mm Hg and operative times under 30 minutes. The risk of trocar or instrument injury to the uterus is decreased if laparoscopic surgeries are limited to pregnancies under 18 weeks' gestational age (although safe laparoscopic appendectomies have been reported at every stage of pregnancy). A recent systematic review and meta-analysis of laparoscopic versus open appendectomy in pregnant patients found that the risk of fetal loss was significantly worse in the laparoscopic group with no differences in risk of preterm labor, hospital stay, wound infection, birth weight, operative times, or Apgar scores. Based on the above concerns and often later gestational ages at diagnosis, most appendectomies in pregnant women are performed via the open route.

Overall, the diagnosis of appendicitis during pregnancy is associated with low birth weight, preterm delivery, small for gestational age infants, congenital anomalies (when appendicitis occurs in the first trimester), and cesarean delivery. Premature labor and delivery are the most serious fetal risks with up to 30% fetal mortality reported if perforation occurs. Because there is often a delay of diagnosis of appendicitis in pregnant women, these patients are more likely to have preoperative systemic infections before they undergo a treating procedure. Compared to their nonpregnant counterparts, some studies have shown they are also more likely to undergo an emergent procedure and have postoperative pneumonia. Although maternal mortality is rare, obstetric complications still occur in 10% to 20% of patients.

If a pregnant woman presents with suspected appendicitis, she should be immediately admitted with the plan for

P.1080

appendectomy. Appropriate antibiotic treatment should be initiated. The decision for route of appendectomy should be made based on gestational age, stage of appendicitis, body habitus, preexisting abdominal scars, and surgeon preference. A McBurney incision allows for easy access to the appendix in the first and early second

trimesters. In the late second and third trimesters, this incision should be made higher in the abdominal wall to allow for manipulation of the cecum around the gravid uterus. A high midline incision may be used as well.

If the laparoscopic route is chosen, trocars are placed similarly as in the nonpregnant patient. The level of the trocars on the abdominal wall may be moved superiorly to adjust for gestational age. In the later stages of pregnancy, the three trocars can be grouped together toward the right of the gravid uterus. The abdominal pressure from CO₂ insufflation should remain below 12 mm Hg. Prior to any trocar or Veress needle placement, the surgeon should confirm the location of the uterine fundus either by palpation or ultrasound. Retraction or mobilization of the uterus (if absolutely necessary) should be performed by grasping the round ligament or utero-ovarian ligament, rather than the uterus itself.

Antithrombus prophylaxis may be indicated based on patient characteristics, length of procedure, gestational age, and type of surgery. Some authors advocate the use of tocolytic therapy during the procedure in all patients greater than 12 weeks' gestation. Others only recommend its use in patients showing signs of uterine irritability or preterm labor. Tocolytic therapy should be used with caution as it can increase the risk for pulmonary edema, which can compromise pulmonary status if systemic infection and pneumonia are already present.

If appendicitis occurs in the third trimester, concomitant cesarean delivery should only be performed for emergent obstetric indications. In the absence of fetal distress, the pregnancy should remain intact; otherwise, a hysterotomy exposes the fetus to infection and the mother to postoperative endometritis/parametritis.

The most important tenet of treating appendicitis in this special patient population is expediency. Delay in operating can result from concern about harming the pregnancy; however, removal of a normal appendix is rarely associated with negative maternal or fetal effects. Thus, the benefits of appendectomy, even if not completely assured of the diagnosis, outweigh the risks of delaying treatment. Heightened suspicion, early detection, lower treatment threshold, and performance of appendectomy within the first 24 hours of symptom onset are associated with markedly improved overall outcome, for both patient and fetus.

APPENDIX AND CHRONIC PELVIC PAIN

The appendix has long been considered a key component in the evaluation of chronic pelvic pain in women. Appendix-driven etiologies of chronic pain include endometriosis, chronic appendicitis, carcinoid tumors, and mucinous cystadenomas, with endometriosis being the most common in women.

The prevalence of appendiceal endometriosis on pathology specimens ranges between 0.05% and 0.6% in all patients to 1% to 5% in patients with pelvic pain. In patients with known pelvic endometriosis, the prevalence of appendiceal endometriosis has been reported in up to 22%. Similar to pelvic/gonadal endometriosis, preoperative diagnosis of appendiceal endometriosis is difficult, and imaging often yields negative results. Thus, evaluation during diagnostic laparoscopy is the gold standard. The appearance of serosal lesions, such as endometriotic lesions or periappendiceal inflammation/adhesions, is an indication for appendectomy. However, most cases of appendiceal endometriosis cannot be seen grossly and require microscopic evaluation and diagnosis. This creates a conundrum for the surgeon who desires to treat the patient's pain without exposing the patient to unnecessary surgical risk.

At the minimum, expert consensus recommends visual evaluation of the appendix during diagnostic laparoscopy for pelvic pain. In addition, there is evidence to suggest appendectomy is warranted in those patients with no other obvious source of pelvic pain and symptoms suspicious for appendix involvement (i.e., right lower quadrant pain), those with severe pelvic or bowel endometriosis, and those with obvious appendix pathology on gross inspection. Some studies have shown that up to 40% to 50% of women undergoing surgery for pelvic pain will have an appendiceal pathology.

INCIDENTAL APPENDECTOMY IN GYNECOLOGIC AND OBSTETRIC SURGERY

Now called an elective coincidental appendectomy by the American Congress of Obstetricians and Gynecologists, removal of an otherwise normal-appearing appendix during an unrelated surgical procedure is still somewhat controversial. The main advantage of removing an appendix in women undergoing gynecologic surgery is the prevention of future appendicitis, which could require an emergent surgery. This could be especially helpful in populations who may have decreased ability to identify or complain of classic peritoneal symptoms (such as the mentally disabled or neurologically impaired) and in patients who have extensive abdominal adhesive disease or who are at risk of developing severe adhesions. It may also be beneficial in ruling out the appendix as an etiology for unexplained chronic pain and in removing a vulnerable structure in women who are planning to undergo radiation or chemotherapy.

The lifetime risk of acute appendicitis is estimated at 7%. Among these women, the risk of an emergent appendectomy is 23%. It is more common in younger patients, with the greatest incidence in those ages 10 to 19. After age 50, the incidence decreases to 2% to 3%; however, acute appendicitis in this age group is typically more complicated, resulting in a higher mortality rate. The risk of appendicitis-related complications, such as increased hospitalization, wound or pelvic infection, perforation, and death, can be as high as 50% to 60% in this older age group.

The advantages of removing a nondiseased appendix are balanced by the risk of appendectomy itself. Complications of appendectomy include postoperative infection, ileus, bowel leak/perforation, abdominal adhesions, bowel obstruction, bleeding, and death. It is difficult to estimate the overall complication rate in incidental appendectomies because of the heterogeneity among study populations and the varied risks associated with the concomitant surgical procedures. However, the morbidity is considered to be overall quite low at 3%. There is also the issue of the additional cost associated with what would otherwise be an unnecessary procedure.

When balancing the above factors, the current recommendations support elective coincidental appendectomy in patients undergoing benign gynecologic procedures who are under age 35. Patients between ages 35 and 50 may benefit also from incidental appendectomy if there are other concerning clinical circumstances, such as those listed above. Currently, there

P.1081

are no data to support elective appendectomy after age 50. If appendectomy is considered as a concomitant procedure, patients should be appropriately counseled regarding risks and benefits of this procedure.

BEST SURGICAL PRACTICES

- Acute appendicitis occurs in 7% of the population over a lifetime, resulting in the most commonly performed emergent surgical procedure for abdominal pain. Approximately 300,000 emergent appendectomies are performed annually in the United States. The majority of cases occur in young patients, usually under age 20. Overall mortality rate is low, less than 1%, due to appropriate detection and early treatment. However, in individuals over age 50, the risk of mortality from acute appendicitis and subsequent complications may be as high as 15%. Delayed diagnosis is the primary reason for increased mortality in this group.
- The most common presenting symptom of acute appendicitis is abdominal pain, which is present in more than 95% of patients with appendicitis. The pain can be associated with fever, nausea, vomiting, and anorexia. Acute appendicitis is diagnosed primarily by physical exam, although imaging and lab studies may be helpful to confirm the diagnosis. CT and US imaging have contributed to decreased rates of rupture and negative appendectomies. A pelvic and rectal exam should be included to rule out other gynecologic causes of acute abdominal pain.

- The standard treatment of appendicitis is appendectomy, which has been shown to be safe and effective. This can be accomplished via the open route or laparoscopically. Preoperative use of antibiotics is important to reduce morbidity and mortality, especially in the setting of appendiceal rupture. Postoperative antibiotics may be warranted, as well. An additional treatment option is CT or US-guided percutaneous drainage of an abdominal abscess, which manages the infection while awaiting an interval appendectomy.
- The advantages of open appendectomy are quick access to the abdominal cavity, the ability to run the bowel, a larger incision in which to manage a variety of surgical findings, and more universal acceptability as it is technically less complicated than is laparoscopic surgery. The advantages of laparoscopic appendectomy are decreased wound infection, less postoperative pain, shorter hospital stays, quicker return to normal activities, and the ability to visualize the entire abdominal cavity—which can be helpful in ruling out other causes of acute abdominal pain. Overall, the clinical differences between the two approaches are very small and usually come down to surgeon preference.
- Appendectomy is the most common nonobstetrical operation in the pregnant patient. In the setting of acute appendicitis, pregnancy itself exposes the patient to delayed diagnosis, risk of fetal effects and preterm birth, difficulties with surgery, and increased risk of postoperative complications. US and MRI are the imaging modalities of choice for the pregnant patient with suspected appendicitis. When appendicitis is diagnosed, or strongly suspected, then appendectomy must be performed, regardless of gestational age. Both open and laparoscopic routes are options in the pregnant patient, with the choice dependent on gestational age, stage of appendicitis, body habitus, preexisting abdominal scars, and surgeon preference.
- The appendix is a key component in the evaluation of chronic pelvic pain in women. Appendiceal endometriosis, chronic appendicitis, carcinoid tumors, and mucinous cystadenomas can all lead to chronic pelvic pain, with endometriosis being the most common in women. In patients with known pelvic endometriosis, the prevalence of appendiceal endometriosis has been reported to be up to 22%. The appendix should be evaluated during diagnostic laparoscopy. Appendectomy may be warranted in those patients with no other obvious source of pelvic pain and symptoms suspicious for appendix involvement.
- Elective coincidental appendectomy is the removal of an otherwise normal-appearing appendix during an unrelated surgical procedure. The appropriateness of this procedure is widely debated and should be evaluated on a case-by-case basis. In general, the current recommendations support elective coincidental appendectomy in patients undergoing benign gynecologic procedures who are under age 35. Patients between ages 35 and 50 may benefit also from incidental appendectomy. Currently, there are no data to support elective appendectomy after age 50.

Chapter 47

Intestinal Surgery for the Gynecologic Surgeon

Mitchel Hoffman
Emmanuel Zervos

DEFINITIONS

Bubble test—Transanal instillation of air into the submersed and proximally compressed rectum for the purpose of looking for a hole or an anastomotic gap.

Closed loop obstruction—Anatomic state wherein a segment of bowel is excluded from the fecal stream due to malignancy, adhesions, or a surgically induced state.

Complicated diverticulitis—Refers to the presence of a perforation, obstruction, abscess, or fistula. Approximately 25% of patients diagnosed with diverticulitis for the first time present with complicated diverticulitis, and nearly all of these cases require surgery.

Cytoreduction—Refers to surgical reduction of the metastatic tumor load in the context of surgery for ovarian cancer.

Diversion—Indicates preclusion of passage of stool to the portion of the intestinal tract distal to the stoma in an ileostomy or colostomy.

Enteric fistula—Epithelialized tract from a portion of the intestine to the skin or mucosa of another organ.

Enterolysis—Division of adhesions involving the intestinal tract.

Enterostomal therapist—Specialist who provides education and assistance to patients who are planned for or have undergone a stoma.

Enterotomy—Hole or laceration in the wall of the intestine.

Hartmann pouch—Healed segment of retained rectosigmoid colon following sigmoid resection with end colostomy.

Inanition—Condition of exhaustion due to starvation.

Laplace law—Explanation for the propensity of the cecum to be the first site of colonic perforation due to dilatation from distal colonic obstruction. The law ($T = PR$) directly correlates tension (T) to the radius (R) and internal pressure (P) of the bowel.

Lembert sutures—Series of sutures incorporating only the serosa and muscular layers of any portion of the GI tract and designed to reinforce and relieve tension on mucosal suture lines.

Malecot catheter, mushroom catheter—Rubber catheter ranging in size from 6 to 38 French with a mushroom-shaped tip ideally suited to drain large spaces that communicate with the skin through considerably smaller tracts.

Mucous fistula—Portion of defunctionalized bowel exteriorized to a stoma for the purpose of drainage and avoidance of an intestinal mucocele.

Obstipation—Severe constipation, usually due to intestinal obstruction.

Pelvic exenteration—Operation undertaken for pelvic malignancy in which the bladder, vagina, and uterus (anterior); vagina, uterus, and rectum (posterior); or all four organs (complete) are removed.

Percutaneous endoscopic gastrostomy (PEG)—Percutaneous placement of a gastrostomy tube under gastroscopic guidance without laparotomy.

P.1083

Proctosigmoiditis—Inflammation of the sigmoid colon and/or rectum.

Rectal stump—Segment of rectum remaining after a rectosigmoid resection.

Short bowel syndrome—Any clinical circumstance wherein the inherent small bowel provides insufficient absorptive capacity to maintain a noncatabolic state.

Tenesmus—Urge to defecate, despite empty colon or bladder.

Uncomplicated diverticulitis—Diverticulitis without the complications noted above and accounts for 75% of diverticulitis cases. The majority of cases respond to medical therapy, although up to 30% require surgery.

INTRODUCTION

The female pelvic cavity is a confined space occupied by the female genitalia, the lower urinary tract, and the rectosigmoid colon. Anatomically, these structures are intimately associated. Other portions of the intestinal tract may occupy the pelvis as well, such as the cecum, appendix, and/or small intestine. It is not surprising, therefore, that gynecologic diseases and the complications resulting from their treatment often involve the urinary tract, the intestinal tract, or both. Similarly, diseases of the urinary and intestinal tract may often mimic or influence manifestations of gynecologic disease.

The complete pelvic surgeon must have medical and surgical expertise in the management of specific types of intestinal disorders. With any type of operation, the abdominal surgeon must be prepared for the eventuality of intestinal injury. For the gynecologic oncologist, common indications for intestinal surgery include resection of tumor and bowel obstruction. Oncologists also perform exenterative surgery, urinary diversion, fistula repair, and surgery for severe radiation damage to the bowel. Pelvic reconstructive surgeons are called on to repair rectal prolapse. Bowel resection is occasionally indicated for infiltrating endometriosis. When operating for presumed gynecologic pathology, the pelvic surgeon occasionally discovers a primary bowel disorder that must be managed surgically.

The purpose of this chapter is to provide the pelvic surgeon with basic information necessary for the surgical management of the more common

intestinal problems encountered in the management of presumed gynecologic disorders and complications of their treatment.

ANATOMY

Knowledge of the anatomy of the gastrointestinal tract is essential for the performance of intestinal surgery and management of complex pelvic pathology. The relevant anatomy is reviewed here.

Stomach

The stomach is the uppermost organ of the gastrointestinal tract, residing completely in the abdominal cavity. The intraabdominal esophagus ranges from 3 to 6 cm in length under normal anatomic conditions. It is located in the left upper quadrant of the peritoneal cavity. The stomach is composed of the cardia, the portion immediately surrounding the gastroesophageal junction and the largest portion of the stomach; the fundus, the upward extension of the stomach toward the dome of the diaphragm on the left side; the body; and the antrum, the portion of the stomach between the incisura and the pylorus. The incisura is a notched portion of the stomach along the lesser curvature. Being a derivative of the foregut, the stomach receives its arterial blood supply from the celiac trunk, the lower thoracic aorta, and collaterals arising from the superior mesenteric artery (SMA) (Fig. 47.1).

Small Intestine

FIGURE 47.1 Blood supply of the stomach.

The small intestine averages 21 feet in length. From the pylorus of the stomach, the duodenum curves retroperitoneally to the ligament of Treitz, left of the second lumbar vertebrae. In the left upper quadrant of the peritoneal cavity, the intestine then

P.1084

becomes intraperitoneal as the jejunum, which is approximately 8 feet in length. An arbitrary transition to the ileum occurs, which is approximately 12 feet in length and terminates at the ileocecal junction in the right lower quadrant of the peritoneal cavity. Clinically, the jejunum is slightly thicker and greater in diameter, more vascular, and of deeper color.

FIGURE 47.2 Blood supply of the jejunum and ileum.

The blood supply of the jejunum and ileum is derived from the SMA ([Fig. 47.2](#)). There is a progression of arcades from the intestinal branches that are single in the jejunum and increase to four or five in the ileum. The mesentery of the small intestine is fan shaped and is positioned obliquely over the posterior abdominal wall. From its body attachments at the ligament of Treitz, the mesentery travels to the right iliac fossa.

Large Intestine

The large intestine extends from the cecum to the anus and is approximately 5 feet in length. Beginning at the base of the appendix and merging in the rectum, the external muscle layer of the colon is arranged in three longitudinal bands known as taenia. The colon also has small projections of peritonealized fat, known as appendices epiploicae.

The blood supply to the right colon ([Fig. 47.3](#)) and the left colon ([Fig. 47.4](#)) are derived from the superior and inferior mesenteric arteries, which form a rich collateral network within the mesentery as the arc of Riolan (proximal branches) and the marginal artery of Drummond (distal branches).

The appendix arises near the base of the cecum distal to the ileocecal junction. From the cecum in the right lower quadrant, the partially peritonealized ascending colon extends cephalad to the hepatic flexure. The second portion of the duodenum is intimate with the hepatic flexure, and care must be taken when mobilizing the flexure or resecting this part of the colon. Similarly, the right ureter is also intimately associated with the appendix and ileocecum and should be identified when mobilizing this portion of the colon.

The transverse colon is the longest and most mobile colonic segment, extending from the hepatic to the splenic flexure. It is further attached to the stomach by the gastocolic ligament (greater omentum), which is intimate with the transverse mesocolon and ventral surface of the colon. Careful separation of the gastocolic ligament gains access to the lesser sac and is necessary for complete omentectomy. Again, care must be taken when mobilizing this portion of the colon, as excessive traction on the splenic flexure can cause downward tension on the splenocolic ligaments and thus lead to tears in the splenic capsule.

The partially peritonealized descending colon extends from the splenic flexure to the sigmoid colon. The upper descending mesocolon is intimate with the kidney, which is close to the proper plane of dissection as this part of the colon is mobilized. The anastomotic blood supply to the splenic flexure is less robust, is frequently referred to as the watershed area, and may be prone to compromise during dissection.

At the pelvic brim, the descending colon becomes the completely peritonealized and mobile sigmoid colon. The sigmoid mesentery (with its root at the inferior mesenteric artery [IMA]) is generous and extends to the posterior cul-de-sac. This is the rectosigmoid colon, and the blood supply transitions to the lateral sides of the rectum.

FIGURE 47.3 Blood supply of the right and transverse colon.

FIGURE 47.4 Blood supply of the left colon.

FIGURE 47.5 Blood supply of the rectum.

The rectum follows the curve of the sacrum, increasing in size to form the ampulla (i.e., fecal reservoir) just above the levator ani. The anorectal angle is formed here. Ventrally, the rectal wall is invested with a delicate layer of connective tissue known as “Denonvilliers” fascia. This fascial layer extends from the base of the cul-de-sac to the perineal body, separating the rectum from the lower two-thirds of the posterior vaginal wall. During cephalad mobilization of an infiltrating cul-de-sac tumor, division of this fascia is useful for mobilizing the tumor and gaining additional rectal length before transection. The blood supply of the rectum is derived from the terminal branches of the IMA and branches of the internal iliac arteries ([Fig. 47.5](#)). There are vast anastomoses between these vessels along the rectal wall.

INDICATIONS

Enterolysis

Adhesions in the peritoneal cavity commonly occur in patients who have undergone prior surgery or have experienced an inflammatory process such as endometriosis or salpingo-oophoritis. Such adhesions frequently involve the intestinal tract and may lead to obstruction, obstipation, or pain. Bowel adhesions may interfere with access to the pelvis during surgery and/or may involve pelvic structures with which the gynecologic surgeon is concerned. Any surgeon who operates in the peritoneal cavity must be competent in intraperitoneal adhesiolysis.

It is important for the surgeon approaching adhesiolysis to have an understanding of the likely cause of the adhesions and to know what operations the patient has previously undergone. The approach to intestinal adhesions is modified by factors such as prior radiotherapy, known inflammatory bowel disease, prior intestinal resection (with potential risk for short gut syndrome), and/or the presence of carcinomatosis.

In a patient with normal intestinal function and intestinal adhesions that will not interfere with the planned operation, lysis of such adhesions may not be indicated. In the setting of small bowel obstruction due to peritoneal carcinomatosis, examination of the entire small bowel is necessary to ensure that downstream adhesion is not overlooked, as a transition point may not be present in the setting of more proximal obstruction.

When adhesiolysis is indicated, some general principles should be followed. Some adhesions are well exposed with clear lines for separation. Dividing these adhesions first will help further restore normal anatomy and improve exposure to remaining adhesions. To the extent possible, define the direction of involved bowel loops before embarking on separation. Use gentle traction-countertraction to define lines of adhesion and to facilitate separation while avoiding traction injury and serosal tears. When segments of the intestine are adhered tightly, use sharp dissection. In general, as adhesions become denser, their separation requires progressively sharper instrumentation. When known or suspected intestinal injury occurs, control any gross contamination with bowel clamps or sutures, and tag these areas for later inspection or repair. When partial enterolysis fails to address adhesions posing a risk for intestinal obstruction, these adhesions must also be divided. It is critical to define a fixed

P.1087

point—either at the ligament of Treitz (moving forward) or at the ileocecal valve (moving backward)—to ensure complete adhesiolysis.

FIGURE 47.6 Repair of a simple enterotomy.

Incidental Injury

In addition to the intimate anatomic relationship between the female genital tract and the rectosigmoid colon, intestinal adhesions in the pelvis are common. The widespread use of laparoscopy in gynecologic surgery places other portions of the intestinal tract at risk. During gynecologic surgery, occasional injury to the intestinal tract can be expected. Certain disease processes or operations may increase the likelihood of injury, such as obliteration of the posterior cul-de-sac (by endometriosis, salpingo-oophoritis, or malignancy), radical pelvic surgery, and extensive enterolysis. Most injuries will consist of a simple seromuscular tear or full-thickness laceration, which is closed with one or two layers of suture. More significant injuries, such as multiple enterotomies within a short distance of each other, require bowel resection.

Management of thermal bowel injury is highly individualized according to the surgeon's impression of the extent of damage. Blanched, contracted tissue should be considered nonviable. There may be at least several millimeters of less apparent damage beyond the apparent injury. A limited, superficial cautery burn witnessed by the surgeon generally requires no treatment. If concern exists, the area may be oversewn with inverting seromuscular sutures. More substantial thermal damage requires at least seromuscular resection (including a normal-appearing margin) and repair.

Full-thickness injury of the small bowel should be repaired perpendicular to the lumen to avoid constriction ([Fig. 47.6](#)). This is less important when closing a colotomy, since the lumen is larger.

Cytoreduction

Most women who develop ovarian cancer present with intraabdominal metastases. Following a combination of radical surgery and chemotherapy, clinical remission is achieved for a large percentage of these women, who can subsequently enjoy longterm survival. Cytoreductive surgery for ovarian cancer appears to improve survival only when no residual tumor (or a minimal volume residual tumor) is left behind. To achieve optimal clearance of tumor, a large percentage of women require procedures that extend beyond simply the removal of gynecologic organs; the most common of these is colon resection.

In recent published series and as shown in [Tables 47.1 and 47.2](#), more than 33% of women with ovarian cancer underwent colon resection as part of their primary ([Table 47.1](#)) or secondary ([Table 47.2](#)) cytoreductive operation. Based on proximity alone, the rectosigmoid colon is the segment of bowel most frequently resected during cytoreductive surgery for ovarian cancer ([Fig. 47.7](#); [Table 47.3](#)). In such cases, the internal genitalia, rectosigmoid colon, and cul-desac peritoneum become agglutinated as a tumor mass. Original descriptions of radical cytoreductive surgery for ovarian cancer, dating back to the 1960s, were in fact surgical techniques designed to resect such tumors en bloc. In recent series of such operations, nearly all women underwent primary colorectal anastomosis without a protective ostomy, with an average leak/fistula rate of 2.6%, and a mortality rate of 0.8% ([Table 47.4](#)).

FIGURE 47.7 Extensive tumor infiltration of the sigmoid mesentery.

Colon resection is central to ovarian cancer cytoreduction due to its frequency of involvement (over 50% in some recent series), technical considerations, and complications of resection. It is therefore not surprising that the rectosigmoid colon is the most frequent segment of the bowel resected during cytoreductive surgery. However, as seen in [Table 47.3](#), other portions of the colon may also become involved with disease to the point of requiring resection.

The high incidence of bulky omental metastasis readily explains growth onto the transverse colon and/or its mesentery ([Fig. 47.8](#)). Omentectomy en bloc with transverse colectomy is a straightforward operation. Such metastases may extend to involve the splenic hilum, the greater curvature of the stomach, and, less frequently, the tail of the pancreas. Complete cytoreduction of such disease requires extensive left upper quadrant resection ([Fig. 47.9](#)).

Due to its location in the pelvis, it is not surprising that the ileocecum is the second most frequent portion of the bowel to become extensively involved with ovarian cancer ([Table 47.2](#)). Inasmuch as possible, resection of such tumors is carried out en bloc with the pelvic tumor. Reconstruction generally consists of an ileoascending colonic anastomosis ([Fig. 47.10A, B](#)). More extensive involvement may require a right hemicolectomy; the same is true of rectosigmoid involvement (left hemicolectomy).

FIGURE 47.8 Tumor encasing the mesentery and growing onto the wall of the transverse colon.

Because of the haphazard and often widespread intraabdominal distribution of ovarian cancer metastases, multiple bowel segments may become involved in a single patient. In the authors' experience, the most frequent manifestation has been extensive tumor involving both the rectosigmoid colon and ileocecum. Resection of these two sites leaves the patient with the majority of the colon, although restoration does require two anastomoses.

When metastatic ovarian cancer involves the transverse colon and separately involves either the rectosigmoid colon or ileocecum, surgical management is less straightforward. The segments may be excised separately, followed by two bowel anastomoses; alternatively, an en bloc resection can be performed, which then requires only a single ileocolic or colorectal anastomosis. Factors to be taken into account when considering these two options include length of normal colon that can be saved, integrity of blood supply to the two anastomoses, technical ability to restore bowel continuity with each option, tension on the anastomosis, quality of bowel preparation, condition of the colon (particularly of the left side), length of the small bowel remaining, and overall condition of the patient.

The authors prefer to perform en bloc resection with a single restorative anastomosis. Less frequently, there is extensive multifocal involvement of the colon. Intervening segments of colon might be saved in some women, but this may require three colon anastomoses. Subtotal colectomy with an ileostomy, ileoproctostomy, or cecoproctostomy are all reasonable alternatives. Defecatory function is acceptable as long as at least 12 cm of rectosigmoid colon and the full length of the small bowel remain. With a shorter rectal segment, many authors advocate creation of an ileal pouch for anastomosis to the rectum, in an attempt to augment the reservoir capacity and minimize bowel frequency.

FIGURE 47.9 Metastatic omental tumor mass extending in the left upper quadrant to involve the splenic hilum and stomach.

Endometriosis

Endometriosis occasionally involves the bowel, especially when severe. The most common sites of involvement are located in the pelvis, including the appendix, rectosigmoid

P.1091

colon, cecum, and terminal ileum. Appendiceal endometriosis is generally an incidental finding not clinically significant. The most important potential consequence of bowel involvement is obstruction, which is more likely to occur in the small intestine. Other clinically significant consequences include pain (from dyschezia, tenesmus, dyspareunia, or nonspecific pelvic, or rectal), cyclic rectal bleeding, and nonspecific bowel symptoms. Further, the fibrotic mass effect and symptoms of bowel endometriosis may create the suspicion of malignancy.

FIGURE 47.10 A: Ovarian cancer involving cecum. **B:** Right hemicolectomy with ileo-ascending enterocolostomy.

Asymptomatic endometriosis of the bowel does not require surgical treatment. A trial of medical management is warranted for symptomatic disease but is not effective against large, fibrotic lesions. A small percentage of patients require bowel resection for endometriosis. Indications for bowel resection include obstruction, suspicion of malignancy, or other severe symptoms. A common scenario requiring bowel resection involves extensive endometriosis in the posterior cul-de-sac, including the anterior wall of the rectosigmoid colon. When focal, resection can be limited to a portion of the anterior rectal wall. With larger and more extensive involvement, segmental resection is necessary.

In patients with a known history of endometriosis and prior abdominal surgery, deposits of endometriosis may manifest in the abdominal wall in

and around the prior incision. These implants are often confused with soft tissue tumors, especially when the interpreting radiologist is unaware of the patient's past medical or surgical history.

Bowel Obstruction

The gynecologic surgeon must be familiar with the management of bowel obstruction. In women who have undergone prior surgery or have experienced an extensive inflammatory process (e.g., infection, endometriosis), small bowel obstruction may develop secondary to surgically induced adhesions or internal hernia formation. When persistent obstruction is secondary to adhesions, simple adhesiolysis may resolve the problem. Occasionally, however, resection of a nonviable portion of the bowel is required.

The gynecologic oncologist must manage bowel obstruction in a variety of settings. As previously described, epithelial ovarian cancer has a propensity toward intra-abdominal spread and may present with bowel obstruction. When the disease recurs and progresses, it is especially common for the patient to develop intestinal obstruction. Although other gynecologic malignancies may also cause bowel obstruction secondary to intra-abdominal carcinomatosis, ovarian cancer is by far the most common risk factor. Small intestinal obstruction is most common, but colonic obstruction or both can also occur (**Fig. 47.11**).

The prognosis for patients with small intestinal and colonic obstruction is extremely poor, and decisions regarding surgical intervention must be carefully considered. A recent analysis of patients with malignant bowel obstruction due to ovarian cancer undergoing surgical intervention found symptomatic improvement in 88% of patients at 30 days and 61% at 60 days with median survival just over 6 months. Endoscopic intervention (with palliative, decompressive procedures) yielded much less durable relief of symptoms at just over 2 months. The same authors reviewed 141 patients undergoing surgical or endoscopic procedures for symptoms of malignant bowel obstruction of all types; this review showed that the presence of carcinomatosis, ascites, or multifocal obstruction predicted the application of decision to pursue palliative decompression (percutaneous endoscopic gastrostomy [PEG], G-tube, or stoma) rather than resection.

Regardless of the origin of malignant bowel obstruction, a thorough discussion must be embarked on with patients and their families regarding goals and objectives of the proposed intervention, ensuring to ensure that each party understands the implications of aggressive surgical management—and the potential for extended recovery—in the setting of limited life expectancy.

FIGURE 47.11 Abdominal plain film showing small and large bowel obstruction.

Where there is an occurrence of extensive ascites, bulky intraabdominal tumor, or an ileus-type pattern, or when the patient is malnourished (albumin <3 g/dL) or in generally in poor condition, surgical management of the obstruction is unlikely to be beneficial. A gastrostomy tube may provide substantial relief and free the patient from the discomfort of a nasogastric tube. In most instances, a gastrostomy tube may be placed percutaneously. Some women with left colon obstruction may be palliated with an endoscopically placed, expandable metallic stent. Select patients with advanced ovarian cancer and persistent obstruction do appear to benefit from surgical intervention. Due to extensive carcinomatosis, the intra-abdominal anatomy in these patients may be difficult to establish. The unobstructed proximal small bowel is freed to the extent possible, and a simple bypass to the proximal colon is carried out. In the presence of large bowel obstruction, a proximal diverting ostomy will generally be necessary. Even in the presence of obvious small bowel obstruction, whenever possible, the large bowel should be evaluated preoperatively for concomitant obstruction. Gastrografin enema performed prior to exploration for malignant small bowel obstruction provides assurance that resected or bypassed small bowel obstruction will not be undermined by existing or impending downstream colonic obstruction. Small bowel obstruction following radiotherapy for a gynecologic malignancy requires a more calculated approach. These obstructions typically occur in the terminal ileum, although coexistent rectosigmoid colon injury is not uncommon. As such,

both areas should be evaluated prior to surgical intervention. Surgical management of radiation-related small bowel obstruction remains controversial. Some experts recommend bypass of the obstruction while others believe the damaged bowel should be resected with primary reanastomosis. Simple bypass involves a side-to-side anastomosis of the proximal uninvolved small bowel to a relatively nonirradiated portion of the colon (Fig. 47.12). This is the fastest and least complicated surgical intervention. Advantages include the avoidance of extensive dissection of matted loops of the bowel—which dissection presents a potential for injury—in the resultant raw, previously irradiated pelvis. The side-to-side anastomosis ensures a good blood supply, avoids the need for a mucous fistula, and may allow the remainder of the bowel to provide some absorptive capacity in cases of partial obstruction; this is especially important when there is a short afferent limb. It also minimizes the risk of injury to other organs or structures, such as the ureter or vascular system. Overall, the results of simple bypass for these patients are reasonably good.

FIGURE 47.12 Simple side-to-side anastomosis of proximal small bowel to transverse colon in order to bypass radiation-related obstruction of the terminal ileum.

If the fecal stream is incompletely diverted, there is the potential for development of blind loops and/or fistulization of the remaining damaged and potentially necrotic bowel. Certain individuals may be at increased risk for subsequent fistulization, including those who have received greater than 50 Gray to the pelvis, are thin or elderly, or have arteriosclerosis, hypertension, or diabetes and those who have had prior pelvic surgery, chemotherapy (i.e., doxorubicin or actinomycin D), or pelvic inflammatory disease. An end-to-side or end-to-end enterocolostomy without resection and with one or two mucous fistulae is an alternative to simple bypass (Fig. 47.13). The main advantage is complete diversion of the fecal stream from the damaged segment and thus avoidance of subsequent fistulization from this area. This type of procedure is often used to manage a postirradiation enterovaginal fistula. Bypass with isolation for management of radiation-related obstruction has not been carefully evaluated separately from simple bypass.

Resection with anastomosis involves removal of all diseased intestine and anastomosis of minimally radiated bowel (Fig. 47.14) and prevents the development of a mucous fistula. This is an often extensive and time-consuming surgery that frequently leaves the remaining bowel exposed to a raw, irradiated pelvis. Other potential disadvantages of resection include a less optimal blood supply at the anastomosis; the functional maintenance of portions of the bowel that have been dissected out (many experts resect all of this bowel) and, though not obstructed, are still radiated and potentially damaged subclinically (e.g., blood supply, enterotomies, aperistaltic); and the injury of other structures during dissection, such as bladder, colon, ureter, and major blood vessels.

FIGURE 47.13 Enterocolostomy that both bypasses and diverts the fecal stream from the obstructed ileum.

FIGURE 47.14 Resection of obstructed, damaged bowel with anastomosis of small bowel to unirradiated transverse colon.

P.1093

The surgical approach to a patient with radiation-related small bowel obstruction must be individualized. If the overall condition of the patient is poor or there is recurrent disease, the most expeditious and least complicated procedure (i.e., simple bypass) should be carried out. If there is potential impending necrosis of the involved bowel, there are multiple injuries to the bowel as a result of dissection, or the involved bowel is a simple loop that is not densely adherent, resection with end-to-end enterocolostomy is preferred. Isolation bypass may still be applicable in some of these cases. Matted loops of bowel in the irradiated pelvis should be left in place as long as a reasonable length of proximal small bowel can be bypassed to nonirradiated proximal colon. It is preferable to avoid resection, but the bypassed bowel should be diverted from the fecal stream in the event that further necrosis with potential fistulization should develop.

Colon resection secondary to benign gynecologic disease is infrequent. Gynecologic malignancy, especially ovarian cancer, may encase and partially obstruct the sigmoid or transverse colon. When such disease is surgically resected, the decision for left colon anastomosis is individualized. Radiation-related stricture of the rectosigmoid colon is discussed below. Rarely does endometriosis cause partial obstruction of the rectosigmoid colon.

Fistulae

The common sources of an intestinal fistula include anastomotic failure, occult operative injury, incorporation into wound closure, inflammatory bowel disease, tumor erosion into adjacent bowel (e.g., enterovaginal), radiation necrosis of the bowel wall, an exposed and/or compromised bowel following fascial dehiscence, or any combination of these factors. In the general surgery literature, the majority of fistulae communicate with the skin and can arise from any portion of the gastrointestinal tract. The reported overall mortality rate is between 5% and 20%, with most deaths resulting from uncontrolled sepsis. The mortality rate is significantly enhanced in the setting of small bowel fistulae, inflammatory bowel disease, cancer, or previous abdominal radiation.

Enteric fistulae occurring in gynecologic cancer patients encompass a much different population. The majority of patients have active intra-

abdominal cancer, prior extensive radiotherapy, or both. Most fistulae develop, at least in part, as a consequence of these factors. A large percentage of the fistulae in these patients communicate with the vagina (**Fig. 47.15**), and the majority arise from the terminal ileum or rectosigmoid colon.

A leaking small bowel anastomosis may form a communication with the abdominal wall or vagina, resulting in an enterocutaneous or enterovaginal fistula. During the process of fistulization, intra-abdominal leakage of bowel contents may result in peritonitis or abscess formation, and in some cases there may be continued intraperitoneal leakage. Uncontrolled sepsis in these patients is the major factor associated with mortality. In the presence of active malignancy or prior radiation, these complications are more likely to occur and more difficult to detect.

More proximal small bowel fistulae cause other types of difficulties and, fortunately, are less commonly seen in the gynecologic cancer patient. Jejunal fistulae have a high output of caustic succus that is corrosive to the skin and results in substantial loss of fluids and electrolytes. As fistulae become more proximal, total parenteral nutrition (TPN)—and its associated complications and expense—becomes less a matter of preference and more a matter of necessity. In some cases, however, the distal small bowel may be intubated with a catheter or feeding tube to allow for nutritional support/supplementation as the fistula contracts and heals.

FIGURE 47.15 Contrast study demonstrating enterovaginal fistula. Note that the contrast passes from the distal small bowel into the vagina in the center lower area of this radiograph.

Initial management of the patient with a small bowel fistula consists of bowel rest with nasogastric suction, fluid resuscitation, electrolyte replacement, local management of the fistula output to prevent skin erosion, and control of sepsis. The extent of intra-abdominal contamination requiring laparotomy, washout, and drainage must be assessed either radiographically or by physical exam, specifically eliciting signs of peritonitis, such as rigidity, guarding, or rebound tenderness. In the setting of a contained leak, sepsis may resolve with bowel rest and antibiotics but in some cases will require drainage of an abscess and/or prompt proximal diversion.

TPN is often used to enable complete bowel rest in patients whose fistulae have a high probability of spontaneous closure (i.e., long tract, incompletely diverting, absence of radiation injury, or distal obstruction). With TPN, the overall condition of the patient improves, and time can be allowed for the inflammatory reaction of the bowel and peritoneal cavity to subside. After sepsis and local wound issues are addressed, oral or enteral feeding can be reinstituted.

Once sepsis is controlled, spontaneous closure of the fistula is reported to occur in 30% to 60% of cases, and nearly all spontaneous closures occur within 4 weeks. During that time, placement of a gastrostomy tube may be considered as a replacement for the nasogastric tube if necessary. After the patient has been initially stabilized, a thorough radiologic evaluation of the fistula and the remaining small and large bowel is undertaken. An early attempt at closure of a postoperative fistula is associated with a low likelihood of success and a high rate of morbidity. The use of somatostatin (or octreotide) has been shown in some series to shorten the interval to spontaneous closure, improve the spontaneous closure rate, and reduce gastrointestinal secretions through the fistula. A recent metaanalysis comprising 14 randomized controlled trials supported early use of somatostatin or its analogues in increasing both the likelihood and rate of fistulae closure.

P.1094

In certain clinical situations, spontaneous closure is unlikely to occur, and indeed, the majority of fistulae in gynecologic cancer patients will not close spontaneously. These situations include intestinal obstruction distal to the fistula, malignancy at the fistula site, fistula location in a previously irradiated field, the presence of a foreign body, epithelialization of the fistula tract, and a fistula related to inflammatory bowel disease. The mnemonic F.R.I.E.N.D.S. is often used to remember factors that prevent fistulae from closing spontaneously: foreign body, radiation, inflammation, epithelialization, neoplasm, distal obstruction, and short (≤ 2 cm) tract fistulae.

In patients with fistulae that have not closed spontaneously, operative intervention should be postponed as long as the patient is doing well. If spontaneous closure has not occurred after 4 to 5 weeks of stabilization, then surgery will be eventually required to restore continuity. The actual point at which decision regarding when closure should be attempted surgically is dependent on a number of factors, including the patient's

remaining life expectancy, nutritional state, overall medical condition, and his or her ability to manage the fistula as is.

Surgical management of a small bowel fistula must be highly individualized. Occasionally, it is possible to excise the fistula opening from the bowel and close the defect in layers or to resect the involved segment and perform an end-to-end anastomosis (EEA). However, small bowel fistulae to the vagina encountered in gynecologic cancer patients must often be bypassed, leaving the irradiated or tumor-involved adherent loops of bowel in the pelvis. As with the case of obstruction, the proximal uninvolved small bowel is followed as far as possible, avoiding dissection of densely adherent loops from the pelvis. At this point, the small bowel is divided and anastomosed to a relatively nonirradiated portion of the large intestine. This should be a functional EEA so as to completely exclude the fistula from the fecal stream. Mucus fistulae should be utilized whenever the risk of closed loop obstruction exists.

As a consequence of advancing pelvic malignancy, prior extensive pelvic radiotherapy (possibly combined with the effects of prior extensive pelvic surgery), or a combination of these factors, occasionally develops between the bowel and the bladder. The first concern is to stabilize the patient and control sepsis, which may be more difficult due to involvement of the urinary tract. After short-term stabilization, surgical intervention will be required.

For relatively simple cases of small bowel involvement, the fistulized loop is resected. Repair of the bladder is individualized. It is less preferable to bypass the fecal stream due to the persistent ill-effects of mucus or partially contaminated drainage into the bladder. Usually, management of a sigmoidovesical fistula will require a diverting colostomy, at least temporarily. In more complicated cases of fistula development between the bowel and bladder—and especially when there is evident involvement of the bladder by radiation necrosis or tumor, or when there is persistent sepsis, bypass, or diversion of both the intestinal and urinary tracts will be necessary. The mortality rate for such cases is high.

The other type of fistula commonly encountered in gynecologic patients arises from the sigmoid colon to the vagina or from the rectum to the vagina. Such a fistula may develop as a complication of surgery (delayed leak from a partial or segmental resection or from an inadvertent injury) or radiation therapy. A postmenopausal woman presenting with a sigmoidovaginal fistula most likely has ruptured diverticulitis. Women may develop an intestinal fistula to the vagina as a result of inflammatory bowel disease, or as a consequence of advanced colorectal cancer, although the latter is uncommon. In gynecologic cancer patients, a sigmoidovaginal fistula may be related to the malignancy, occurring often as a result of or associated with distal obstruction. A large percentage of these cases is due to radiation injury or perhaps to a combination of factors. After short-term stabilization, a diverting or end (if permanent) colostomy is performed.

Severe Radiation Injury of the Rectosigmoid Colon

Severe proctosigmoiditis develops in a small percentage of patients following pelvic radiotherapy for gynecologic cancer. Abdominal cramping, diarrhea, and/or bleeding may result. With medical management, some of these symptoms improve over time. However, if progressive or left unattended to, the injury may progress to perforation or a fistula. As previously discussed, the area of injury may be mapped out with the use of contrast studies through the normal GI tract and fistula and with endoscopy. Resection is performed accordingly, and in some cases, colorectal continuity can be reestablished. A diverting colostomy is advisable until it is certain that the anastomosis has healed (i.e., at least 6 months).

Radiation stricture of the rectosigmoid colon may also develop, causing obstruction ([Fig. 47.16](#)) and necessitating surgical intervention. The area of involvement should be mapped out preoperatively with radiologic and endoscopic studies. When feasible, this portion of the large bowel may be resected and anastomosed. The anastomosis should be wrapped with transposed omentum when available. Proximal diversion is strongly considered. The colon anastomosis is reevaluated 6 months postoperatively, and if healing is satisfactory, the ostomy is taken down.

As in the case of severe radiation sigmoiditis, the patient with a radiation-induced sigmoidovaginal fistula can sometimes undergo resection and colorectal anastomosis in hopes of eventually restoring bowel continuity. Some radiation-induced rectovaginal fistulae can eventually be surgically closed. Boronow et al. described local repair of such fistulae after a period of diversion. Park described resection of the rectum beyond the fistula (and the region of severe radiation damage) with transanal anastomosis of the colon to the anus.

P.1095

Bricker described the technique of folding the rectosigmoid colon over itself to cover the fistula with anastomosis of the colon to the top of the loop.

FIGURE 47.16 Contrast study of a symptomatic radiated patient, demonstrating stricture of the rectosigmoid colon.

Perforated Bowel

Perforated bowel with intraperitoneal leakage is infrequently encountered in gynecologic and nongynecologic cancer patients. The complication may develop as a result of radiation-induced necrosis (usually of the terminal ileum or sigmoid colon), leakage from an intestinal anastomosis or occult operative injury, or bowel ischemia related to obstruction. When perforated bowel with intraperitoneal leakage is due to radiation injury, diagnosis is often delayed, and the mortality rate is high.

Surgery is performed on an emergent basis. If the perforation is highly localized and walled off, resection or exclusionary bypass of the small bowel may be considered. In general, however, proximal exteriorization should be carried out. The peritoneal cavity should be thoroughly lavaged with an antibiotic solution. Several months of stabilization should elapse to allow the inflammatory reaction of the bowel and peritoneal cavity to resolve before considering an attempt at reestablishment of bowel continuity.

Exenteration

Pelvic exenteration is occasionally performed for recurrent or persistent gynecologic cancer in the central pelvis and is covered in [Chapter 54](#).

Diversion or reconstruction of the urinary and/or intestinal tract is necessary in these patients, requiring one or more surgical procedures involving the bowel. The majority of these patients have received prior radiotherapy, which further complicates treatment. For purposes of urinary tract reconstruction, a portion of the bowel is isolated from the fecal stream and intestinal continuity is reestablished. In the case of an ileal conduit performed in a previously radiated patient, it is recommended that the anastomosis occur between the ileum and the nonirradiated transverse colon to ensure better healing.

When the rectum or anus must be removed, a permanent colostomy is performed. When a portion of the rectum can be preserved, it may be possible to perform a colorectal (i.e., coloanal) anastomosis. Strong consideration is given to proximal diversion. Even when continuity cannot be restored, it may be preferable in some cases to leave a very short rectal stump to avoid potential morbidity of a perineal wound.

Urinary Tract Reconstruction

Urinary diversion and bladder reconstruction utilize intestine that has been isolated from the fecal stream. These procedures are covered in detail in [Chapter 24](#). Another infrequent use for intestine in urinary tract reconstruction is ureteral substitution, generally done with a portion of ileum.

Vaginal Reconstruction

One of the myriad types of vaginal reconstruction in gynecologic patients is intestinal substitution. There are few reports on this type of neovagina in the gynecologic cancer patient, and the results obtained are unclear. After pelvic resection, a portion of the sigmoid colon or ileum is diverted from the fecal stream. In exenterative surgery, this should be coordinated with other necessary intestinal components to minimize the number of anastomoses. The intestinal segment with its blood supply is mobilized so that one end may be anastomosed to the introitus or vaginal stump. The other end is closed to form a pouch.

PRIMARY INTESTINAL DISEASE

Diverticulitis

Acute diverticulitis can mimic benign adnexal pathology, such as torsion, ovarian cysts, abscesses, or malignant pathology of either gynecologic or colorectal origin. Perhaps the most useful means of distinguishing diverticulitis from these diagnoses is a history of radiographically or endoscopically diagnosed diverticular disease or a prior acute episode resulting in emergency department presentation or inpatient hospitalization. In patients without a diagnosis of diverticular disease, arriving at the correct diagnosis may be difficult, especially in the absence of absolute indications for exploration (e.g., free intra-abdominal perforation, uncontrollable hemorrhage, or obstruction). In these cases, the diagnosis relies on the combined efforts of an astute radiologist and clinician, with an abdominopelvic computed tomography (CT) scan being the most useful diagnostic maneuver.

In most cases, pericolonic inflammation, abscess, or colonic wall thickening in association with left lower quadrant pain and normal-appearing ovaries and uterus is sufficient to establish a diagnosis of diverticulitis. Based on CT findings, diverticulitis can then be subcategorized into complicated or uncomplicated diverticulitis. Nonoperative therapy through bowel rest and antibiotics is successful in 70% to 100% of patients with uncomplicated diverticulitis. A CT scan demonstrating uncomplicated diverticulitis is shown in [Figure 47.17](#). More recently, prospective randomized data have brought the routine use of antibiotics in uncomplicated diverticulitis into question. Complicated diverticulitis—as manifested by obstruction, abscess, perforation, or fistula—may be managed with percutaneous drainage with a low threshold for surgical exploration in the setting of progressive peritonitis or in high-risk patients (i.e., older, deconditioned, or immunocompromised patients).

Distinguishing diverticulitis from colorectal malignancy in both complicated and uncomplicated diverticulitis is critical and can be challenging. Missing or delaying the latter diagnosis may have devastating consequences for the patient and, as soon as clinically feasible, a limited endoscopic evaluation should be undertaken to rule out a mucosal-based lesion. This can be safely undertaken as early as 2 to 6 weeks after the acute inflammatory phase has resolved (normal white blood cell count, afebrile, resolved left lower quadrant pain, and

resumption of normal bowel activity). At initial presentation, if the suspicion for cancer is high, then surgical exploration with Hartmann procedure (i.e., resection, end colostomy, rectal pouch) is the safest and most effective diagnostic and therapeutic intervention ([Fig. 47.18](#)).

FIGURE 47.17 CT scan showing acute, uncomplicated diverticulitis.

FIGURE 47.18 Hartmann procedure indicating resection, end colostomy, and rectal pouch (A, B).

Acute Appendicitis

Due to the profound overlap in presenting symptoms, age, and prodrome illness in a patient, acute appendicitis is the gastrointestinal diagnosis most difficult to distinguish from gynecologic pathology. Pregnancy, especially in the second and third trimesters, may further confound the diagnosis as the gravid uterus displaces not only the appendix but also the focal point of pain. Delayed diagnosis of appendicitis due to pregnancy is a source of significant added morbidity. Although female patients are slightly less likely to develop acute appendicitis than are males, the high prevalence of this disease in the third decade of life continues to make this a diagnostic challenge.

The classic presentation consists of three fundamental components: periumbilical pain migrating to the right lower quadrant, anorexia, and nausea/vomiting. Most surgeons trained prior to the CT-scan era relied heavily on the presence of fever and/or leukocytosis to establish the diagnosis of appendicitis. More recently, several scoring systems have been established that assign a relative numeric value to those presenting signs and symptoms most predictive of appendicitis. These scoring systems are designed to avoid axial imaging in patients with a high probability of acute appendicitis based on clinical presentation alone.

The Alvarado score is the most popular of these scoring systems and takes into account leukocytosis (2 points), iliac fossa tenderness (2 points), migratory pain, anorexia, nausea/vomiting, rebound pain, and fever (all 1 point). A high Alvarado score (≥ 7) generally supports exploration without further diagnostic studies, while lower scores, especially in diagnostically challenging subgroups (e.g., children younger than 3 years, adults older than 60 years, and pregnant women in the second and third trimesters) supports further diagnostic imaging such as CT scan. In one recent review in 71 patients with appendicitis and 167 patients with alternative diagnoses, CT findings consistent with appendicitis identified enlarged appendix (93% sensitive/92% specific), appendiceal wall thickening (66% sensitive/96% specific), periappendiceal fat stranding (87% sensitive/74% specific), and appendiceal wall enhancement (75% sensitive/85% specific).

Ultrasound is similarly useful in establishing the diagnosis with sensitivity, specificity, and positive and negative predictive value all as high as 99% in some series. Sonographic findings consistent with appendicitis include diameter greater than 6 mm, noncompressibility, presence of appendicolith, periappendiceal fat changes, or nonvisualization of the appendix (i.e., negative finding). In patients whose diagnosis remains uncertain despite all imaging modalities, early engagement of the general surgery team for serial abdominal exam is essential.

Meckel Diverticulum

Meckel diverticulum is a relatively common diagnosis occurring in 1 % to 2% of adult patients in autopsy studies. Since the majority of patients with Meckel diverticulum are asymptomatic, the disorder is most commonly diagnosed as an incidental finding during celiotomy for other intra-abdominal pathology. Meckel diverticulum represents a remnant of the vitelline yolk duct and usually occurs within 2 feet of the ileocecal valve along the antimesenteric border of the ileum (Fig. 47.19). Most Meckel diverticula are lined by small bowel mucosa, but as many as 20% of patients have ectopic gastric or pancreatic tissue in the lining that causes symptoms of bleeding or pain. In addition to bleeding,

P.1097

patients with Meckel diverticulum may obstruct or develop diverticulitis. Symptomatic diverticula should be resected, while those found incidentally in adult patients may be safely observed and should not be resected; the likelihood of a Meckel diverticulum becoming symptomatic during adulthood is less than 2%. Resection should be undertaken in patients being explored for abdominal pain or gastrointestinal hemorrhage who demonstrate no other intra-abdominal pathology. In cases where the diverticulum is lined by gastric or pancreatic mucosa and bleeding in the adjacent ileum has occurred, complete resection of the segment of ileum bearing the diverticulum is necessary.

FIGURE 47.19 Appendix with metastatic implants, Meckel diverticulum.

Volvulus/Intussusception

Spontaneous small intestinal volvulus and intussusception are rare diagnoses in adult patients, usually presenting as a bowel obstruction. Radiographic findings may be subtle; as such, patients are often definitively diagnosed during celiotomy for nonspecific obstruction. Small bowel intussusception rarely occurs spontaneously in adult patients; rather, it is a manifestation of some type of lead point within the lumen, such as a small bowel or extrinsic compression from adjacent pathology or obstructive processes.

Occasionally, a radiologist may suggest the diagnosis based on the presence of CT findings consistent with internal hernia (e.g., dilated small bowel loops ending in a mass or mesenteric twist). As more women (and men) undergo surgical weight loss procedures, the incidence of internal hernias and small bowel volvulus is increasing. These hernias occur through newly created spaces, including the mesenteric defect of the jejunojunostomy, the defect between the transverse mesocolon and the Roux limb mesentery commonly known as Petersen defect, and the mesocolic defect through which the Roux limb is passed (Fig. 47.20). As with any other obstructive process, volvulus and hernia commonly present as pain, obstipation, and abdominal distention.

Colonic volvulus most commonly presents as a sudden onset of abdominal pain, distention, and obstipation (sometimes accompanied by nausea and vomiting), and may occur in the cecum or the sigmoid colon. Care must be taken to distinguish cecal volvulus from sigmoid volvulus, as subtle differences in diagnosis and management exist.

Cecal volvulus accounts for 10% to 40% of colonic volvuli and can be more difficult to diagnose radiographically than sigmoid volvulus, due to its varied findings on plain films. In general, cecal volvulus manifests as a dilated cecum, with the long axis extending from the right lower quadrant to the midepigastrium and decompressed distal colon. It is frequently associated with small bowel dilatation as well. Cecal volvulus can be decompressed endoscopically but has a recurrence rate as high as 75%. Surgical management is therefore recommended. Retrospective series have shown ileocectomy to be more effective than less invasive maneuvers such as cecostomy or cecopexy.

FIGURE 47.20 Internal herniation following jejunojejunostomy.

Sigmoid volvulus is the most common colonic volvulus. Whereas cecal volvulus can be distinguished by the long axis extending to the midepigastrium from the right lower quadrant, sigmoid volvulus demonstrates dilated large bowel with the long axis extending from the left lower quadrant to the midepigastrium or to the right upper quadrant. The classic radiographic finding is known as the coffee bean sign, where the apex of the bean originates in the right upper quadrant (**Fig. 47.21 A, B**).

Flexible sigmoidoscopy is both diagnostic and therapeutic, with immediate relief of obstruction manifested by a rush of fecal material, which can soil the naïve endoscopist. High-risk patients responding to nonsurgical therapy on their first presentation may be safely observed; however, recurrence rates have been reported in up to 61% of patients at a median of 31 days. As such, recurrent sigmoid volvulus is a strong indication for sigmoid colectomy.

Pelvic Malignancy

The origin of advanced pelvic malignancy may be impossible to establish without immunohistochemical analysis of tissue obtained by open, percutaneous, endoscopic, transvaginal, or cystoscopic procedures. Cancers of colorectal origin typically express CK20 and CDX2 and may be associated with elevated serum CEA levels. Pelvic tumors of gynecologic origin typically express CD7, CA-125, estrogen/progesterone receptors (i.e., endometrioid tumors), and WT1 (i.e., serous ovarian tumors,); these pelvic tumors are additionally associated with

P.1098

elevated serum CA-125 and/or CA 27-29. Absence of CK20 and CEA strongly favors gynecologic primary.

The origin of advanced pelvic malignancy is of critical importance in determining neoadjuvant chemotherapy strategy. Pelvic malignancy involving multiple organ sites should be palliated with diversion of the fecal and urinary stream (when completely obstructed) and chemoradiotherapy utilized to downstage. In those patients who manifest tumor shrinkage or downstaging with neoadjuvant treatment, multivisceral resection including anterior, posterior, or complete pelvic exenteration may be indicated for long-term palliation or even cure.

Colorectal Cancer

In addition to rectosigmoid cancer locally, advanced ileocecal and appendiceal cancer may manifest as a pelvic process. At the level of the pelvic brim, it is not uncommon for the sigmoid flexure and the ileocecum to abut one another, thereby creating a potential that T4 lesions (i.e., the extension of primary tumor into surrounding organs) arising from either site may require en bloc resection of the rectosigmoid and right colon as they fall or are pulled into the pelvis. This necessitates two anastomoses: an ileocolostomy and a coloproctostomy. In the absence of obstruction, this is an acceptable approach.

FIGURE 47.22 Obstructing “apple core” carcinoma of the sigmoid colon.

Obstructive pathology (as manifested by the inability to adequately prepare the colon and/or a significant size discrepancy between the anastomosed segments) mandates resection with ileostomy and mucus fistula or ileocolostomy and end colostomy with rectal pouch. Occasionally, patients with obstructing upper rectal and sigmoid cancers ([Fig. 47.22](#)) can have limited (i.e., liquid diet only) continuity restored with endoscopic stents to facilitate preoperative colonic decompression and preparation, thereby alleviating the need for temporary colostomy ([Fig. 47.23](#)). A recent prospective study in 182 patients with obstructing cancers of the rectosigmoid or descending in the left side of the colon reported successful stent placement in 98%. Subsequently, 94% of 150 patients undergoing elective resection avoided colostomy.

FIGURE 47.21 A and B: The classic radiographic “coffee bean” sign of a sigmoid volvulus with the apex of the bean originating in the right upper quadrant.

FIGURE 47.23 Decompressive stent in patient with near-complete sigmoid obstruction.

P.1099

As surgeons have become increasingly specialized in colorectal and pelvic malignancy, the technique of total mesorectal excision first described by Heald in 1986 has become the de facto standard of care for rectal cancer. Heald originally described the technique—as “the painstaking downward development of the avascular plane between visceral structures (rectum and mesorectum) and somatic structures (autonomic nerve plexuses; sympathetic above and parasympathetic below).” This technique not only yielded superior lymph node harvest but significantly lowered patient incidence of pelvic recurrence (3% to 7%) and improved long-term survival (80%). Total mesorectal excision may now be accomplished sharply or with thermal energy devices.

Pelvic recurrence of rectal cancer is a devastating manifestation of suboptimally resected primary rectal tumors or nodal recurrence. In either event, opportunities for curative resection are limited and usually involve limited (e.g., anterior or posterior) or complete exenteration. Factors limiting this resection—one of the most invasive of all cancer interventions—are pelvic sidewall and sacral (above S3) involvement of the tumor. Sacrectomy below the level of S3 may be accomplished while still maintaining stability of the pelvis and is usually undertaken with the assistance of neurosurgery or orthopedic spinal surgeons.

Rectal Prolapse

Rectal prolapse (**Fig. 47.24**) shares similar pathophysiology with prolapse of the uterus and bladder. It can result from progressive weakening or stretching of the mesocolon of rectosigmoid and can eventually lead to prolapse. This process may be exacerbated in patients with redundant sigmoid colon and chronic constipation. In contrast to uterine or bladder prolapse, definitive surgical therapy for rectal prolapse involves either rectopexy or resection of the prolapsed segment with an open or laparoscopic approach and primary reanastomosis with or without rectopexy.

FIGURE 47.24 Rectal prolapse.

Since rectal prolapse most commonly occurs in elderly patients—oftentimes deconditioned patients with medical comorbidities—the morbidity and mortality of this intervention for a benign process is high. As such, many patients are either forced to live with their prolapse or to undergo “less invasive” intervention, such as the Altemeier procedure (**Fig. 47.25**). Undertaken in a manner similar to a vaginal hysterectomy, the Altemeier procedure involves delivery of the prolapsed segment through the rectum with resection and primary coloanal anastomosis.

FIGURE 47.25 Altemeier procedure.

P.1100

Most series of this ostensibly less invasive intervention report complications commensurate with those of open laparotomy; in the laparoscopic era, the technique has been supplanted by minimally invasive approaches. A recent review of the American College of Surgeons Quality Improvement Program (NSQIP) database demonstrated in 685 patients decreased length of stay and decreased incidence of surgical site infections (SSIs) with a trend toward decreased morbidity in patients managed with laparoscopic versus open rectopexy or sigmoidectomy and rectopexy.

Ogilvie Syndrome

Ogilvie syndrome, also known as acute colonic pseudo-obstruction, presents with abdominal distention, nausea, vomiting, and diarrhea. Plain radiographs demonstrate dilated cecum and right colon (**Fig. 47.26**). Ogilvie syndrome rarely occurs spontaneously and is rather associated with an underlying medical condition in over 90% of cases. Such conditions may include (in decreasing prevalence) trauma, sepsis, cardiac disease, gynecologic disease, recent abdominopelvic surgery, neurologic conditions, orthopedic surgery, and miscellaneous medical/surgical conditions.

Ogilvie syndrome can be differentiated from mechanical bowel obstruction and toxic megacolon with the use of CT scan or Gastrografin enema. Treatment initially consists of conservative measures (e.g., NPO, IVF, NG, electrolyte replacement) followed by neostigmine if after 24 to 48 hours if there is no resolution. Neostigmine, administered at a dose of 2 mg IV, results in rapid resolution (range 3 to 30 minutes) in 80% to 90% of patients. Patients with underlying asthma, recent myocardial infarction, or those who are actively taking beta-blockers should be approached with caution, as severe bradycardia can result with the use of Neostigmine. Atropine should be readily available, and patients should receive continuous ECG monitoring for at least 30 minutes following neostigmine therapy.

In patients who fail to respond to conservative or medical management, colonic decompression achieved either endoscopically or with rectal tube should be pursued, especially as the colonic diameter approaches 12 cm (beyond which Laplace's law predicts a high likelihood of spontaneous perforation). Surgical decompression is rarely required and is reserved for refractory patients at high risk for colonic perforation or for immunocompromised or neutropenic patients in whom colonic perforation would be catastrophic.

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) are spindle cell tumors arising from the muscular layers of the stomach (75%), duodenum (12%), and small bowel (9%). As such, they have typical appearance on axial imaging (**Fig. 47.27**) and oftentimes no mucosal abnormality on endoscopic exam; a bulge is frequently the only endoscopic finding. GIST tumors can also infrequently arise from the esophagus and colorectum. Most GIST tumors stain positive for cKIT (80%), which is a defining characteristic. A smaller (5% to 7%) percentage of these tumors stain positive for platelet-derived growth factor receptor alpha, and the remainder are wild type.

Primary resection represents the mainstay of treatment for nonmetastatic GIST tumors isolated to a single organ. Prognosis after resection is based on size and mitotic rate. In general, primarily resected tumors less than 5 cm in size with fewer than 10 mitoses per high-power field have low risk of recurrence; they seldom require adjuvant chemotherapy with imatinib (Gleevec). Bulky, locally invasive (i.e., multiorgan) or metastatic tumors that cannot be completely resected are best treated preoperatively with imatinib to downstage, followed by resection if possible. High-risk and incompletely resected tumors should all be treated with imatinib in the adjuvant setting.

Inflammatory Bowel Disease

Crohn disease and ulcerative colitis represent distinct pathologic disease states easily confused by nonspecialists. Terminal ileitis is a catchall

diagnosis for anything presenting as inflammation in the right lower quadrant. In the absence of malignancy or chemotherapy-induced neutropenia, terminal ileitis is a common manifestation of Crohn disease or, occasionally, of ulcerative colitis that spills into the terminal ileum. Even more confounding is the distinction of Crohn disease

P.1101

from ulcerative colitis, resulting in the diagnosis of nonspecific colitis. Unfortunately, the cause of terminal ileitis can be a difficult diagnosis to establish based on gross or endoscopic findings, due to the relative inaccessibility of this portion of the GI tract. A skilled endoscopist may, however, reach the terminal ileum with the colonoscope to obtain tissue for histologic assessment.

FIGURE 47.26 Postoperative radiograph of a patient with Ogilvie syndrome demonstrating dilation of entire colon.

FIGURE 47.27 CT of GIST tumor.

The pathologic distinction between Crohn disease and ulcerative colitis requires integration of both the histologic and gross findings. Crohn disease manifests as a transmural process with epithelioid granulomas and fissuring ulcers, while ulcerative colitis is confined to the mucosa with crypt abscesses and absence of granulomas. Grossly, proper categorization of the acutely inflamed colon will aid in ultimately arriving at the correct histologic diagnosis and may aid intraoperative decision making. Crohn disease manifests with a skip lesion and fat creeping around the antimesenteric portions of the affected intestine ([Fig. 47.28](#)), while ulcerative colitis begins in the rectum and moves proximally in a continuous manner.

In the absence of obstruction, abscess, or nutritionally significant internal fistulae, Crohn disease is a medical illness that occurs primarily in adolescents and young adults. Ulcerative colitis is a surgical illness with significant malignant potential. While it is possible for ulcerative colitis to remain quiescent for prolonged periods of time, the chronic inflammatory state associated with it 10 years after initial diagnosis leads to malignant degeneration of the involved segments at a rate of 0.5% to 1% per year. Twenty percent of patients with ulcerative colitis eventually undergo surgical resection to manage symptoms and mitigate cancer risk.

Toxic megacolon, an extreme manifestation of ulcerative colitis, is defined by pancolonic distention, bleeding with associated leukocytosis, and constitutional symptoms. This is a life-threatening emergency that demands expeditious surgical intervention. When inflammatory bowel disease is

suspected or encountered during otherwise routine gynecologic assessment or as an incidental intraoperative finding, long-term medical and surgical management is most appropriately undertaken by gastroenterologists or surgeons specializing in this area.

Hemorrhoids

Hemorrhoids are one of the most common diagnoses seen by general surgeons. External hemorrhoids occur outside of the dentate (or pectinate) line, while internal hemorrhoids occur proximal to it. Internal hemorrhoids are further categorized as those that spontaneously reduce, those that reduce with digital aid, and those that are irreducible (**Fig. 47.29A**). In the absence of the latter subtype or extreme symptoms (e.g., pain, rupture, tenesmus), most hemorrhoids are managed medically. The mainstay of medical treatment is stool softeners and local anti-inflammatory agents.

FIGURE 47.28 Crohn disease of the terminal ileum.

FIGURE 47.29 A: Types of internal hemorrhoids. **B:** Thrombosed hemorrhoid.

Thrombosed hemorrhoids present with extreme pain, frequently bringing the patient to the emergency department (**Fig. 47.29B**). An acutely thrombosed hemorrhoid causing pain may be immediately relieved with incision and drainage. Unfortunately, this does not prevent recurrence, and whenever possible, hemorrhoidectomy is the preferred treatment. The ubiquity of hemorrhoid clinics in this country and the multitude of treatment options, including excisional, stapled, and ablative intervention, are a testament to the pervasive nature of this diagnosis and the absence of any one defined superior method of treatment.

PREOPERATIVE PREPARATION

Consent

When planning a major gynecologic operation, the likelihood of an intestinal resection and/or an ostomy can frequently be anticipated. Informed consent for this must be obtained from

P.1102

the patient, especially in regard to a potential or likely stoma. In the event that the patient adamantly refuses consent for a stoma, the physician must respect the patient's wishes but should make her aware of the possibility that this may compromise the benefits and goals of the operation. In situations where any otherwise-curative procedure would be precluded by a patient's refusal for stoma, surgical intervention should be avoided, as the benefit of such intervention would be negated by any residual cancer except in certain settings, such as carcinoid tumor or mucosal melanoma of the anorectum.

Planning for a Stoma

Any pelvic surgeon must develop the knowledge and judgment necessary to properly place intestinal stomas. A working knowledge of stomal management is also important. However, an enterostomal therapist is very helpful in the care of these patients.

Preoperatively, an enterostomal therapist can provide the patient with information and reassurance, better preparing her for a stoma postoperatively. The preoperative stoma therapy consult also serves to reinforce the inevitability of fecal diversion. The enterostomal therapist can also suggest optimal sites for stoma placement, though the surgeon must ultimately make this decision based on patient-specific and intraoperative factors.

The surgeon can anticipate, to some extent, the quadrant(s) of the abdomen where a stoma or stomas are likely to be placed. The abdomen is carefully inspected in the supine, sitting, and standing positions, with the surgeon noting the presence of any abdominal wall folds that could interfere with the application of the stomal appliance. Ideally, the stoma site is within the boundaries of the rectus muscle, with at least 3 inches of flat skin around the stoma and good visibility for the patient. A lower abdominal stoma (e.g., ileostomy or end sigmoid colostomy) is placed somewhere between the umbilicus and the anterior superior iliac spine, whereas an upper abdominal stoma is placed lateral to the umbilicus or somewhere between the umbilicus and the rib cage, as in a transverse colostomy (Fig. 47.30). The stoma must be kept far enough from bony prominences and the belt line to avoid interference with appliance application. Potential stomal sites are marked, and in the operating room prior to scrubbing the abdomen, the mark is preserved using a scratch or an intradermal injection of dye.

Nutrition

Preoperatively, it is important to assess the nutrition of a patient undergoing major surgery. The nutritional status of the majority of patients will be reasonably good. A few women will benefit from intensive preoperative nutritional support; many of these women can be identified during initial history, physical examinations. Examples of those likely to be severely malnourished at presentation include elderly patients, patients with advanced ovarian cancer, recent history of significant (>10%) weight loss, prolonged anorexia, generalized weakness and inanition, end-stage liver disease, and slowly developing bowel obstruction. Physical examination findings, including anthropometric measurements, laboratory values, and skin tests, are used to corroborate the presence of severe malnutrition.

The decision to intervene preoperatively with nutritional support is based on a number of factors. Mild to moderately malnourished patients are unlikely to benefit. When surgery is needed on an urgent basis, there will not be adequate time for meaningful preoperative nutritional support. Severely malnourished patients who are to undergo very extensive surgery or are elderly are more likely to benefit from this support. The major complication rate of patients undergoing intestinal surgery may be reduced by intensive preoperative nutritional support.

FIGURE 47.30 Placement of intestinal stomas in the abdominal wall.

When the decision is made to administer preoperative nutritional support, the surgeon must individualize the use of enteral and parenteral routes. A period of 7 to 14 days of hyperalimentation has been recommended as the time frame necessary to provide optimal benefit. Nutritional support is continued postoperatively for an appropriate period of time. Hospitalized patients with malignant bowel obstruction will benefit most from TPN, while malnourished patients with normal GI function should be replenished with nasogastric or nasoduodenal supplements that can be administered in the outpatient setting. Nasogastric supplementation has the advantage of bolus feeding every 4 to 6 hours and does not require a feeding pump. Nasoduodenal feeding minimizes the risk of aspiration, especially in patients with delayed gastric emptying, but requires more home resources.

Bowel preparation

Routine use of mechanical bowel preparation (MBP) for colonic resection has become a matter of controversy in recent years. This is due to the paucity of data that support reduced postoperative complications, from rare but significant complications associated with MBP and from overall patient discomfort with the procedure. A recently published review of 14 randomized controlled trials and 8 meta-analyses analyzing the efficacy of MBP in patients undergoing elective colorectal surgery showed no difference in postoperative infectious complication rates. The utility of MBP in low anterior resection is neither supported nor refuted by this review, and its use in this setting is at the discretion of the operating surgeon. Other studies, though, show that combining MBP with oral antibiotics does reduce risk of postoperative complications.

P.1103

A recent review of the Veterans Affairs Surgical Quality Improvement program comprising 9,940 patients undergoing elective colectomy—while showing no difference in SSI in patients receiving MBP only versus no preparation—did demonstrate a 67% decrease in SSI for patients receiving oral antibiotics alone. A 57% decrease in SSI was noted in patients receiving oral antibiotics and MBP. The authors conclude that the data strongly support the use of preoperative oral antibiotics, while the benefits of antibiotic administration in conjunction with MBP remain uncertain.

Preoperatively, the likelihood of intestinal colonic surgery and subsequent necessity of bowel preparation must be assessed. Proper bowel preparation will reduce the risk of fecal spillage into the peritoneal cavity, infectious morbidity, anastomotic leak rate, and the need for colostomy. Bowel preparation has two components, mechanical and antibiotic. Mechanical preparation is aimed at clearing the majority of fecal material. Antibiotic prophylaxis is used to protect surgical sites from colonic flora.

Currently, there are two alternative methods of MBP: whole gut lavage and the traditional multiday cathartics and enemas. The traditional method generally takes about 3 days, during which the diet is restricted to clear liquids, and the patient ingests multiple doses of a cathartic, such as magnesium citrate. The diet may be supplemented with elemental nutrients to help maintain the patient's nutritional status. Toward the latter half of this regimen, several rounds of enemas are given.

The whole gut lavage method is done the day before surgery with a commercially available preparation of polyethylene glycol and a balanced electrolyte solution. Ranges of 1 to 4 L/hour have been recommended for lavage to extend over a 3- to 4-hour period. If the lavage cannot be tolerated orally, it may be administered via a nasogastric tube. Metoclopramide has been recommended by some to improve the tolerance and passage of the lavage.

The advantages of the lavage method are minimal alterations in fluid and electrolyte balance (it is nonosmotic), maintenance of weight and nutrition, simplicity, and the convenience of 1-day administration. The disadvantages are intolerance and/or the requirement of a nasogastric tube in some patients. The lavage method should not be used in patients who may have a bowel obstruction. In patients with partial obstruction of the colon or rectum, as is often encountered with advanced ovarian cancer, a 3-day cathartic-enema mechanical preparation or slow lavage is more appropriate. Studies comparing the 3-day cathartic-enema and whole gut lavage methods have demonstrated similar efficacy.

Antibiotic prophylaxis for colonic surgery consists of intravenous administration of antibiotics effective against the gramnegative (i.e., *Escherichia coli*) and anaerobic (i.e., *Bacteroides fragilis*) colonic bacteria, such as *Klebsiella* and *Enterococcus*. The effect of these antibiotics on the colonic bacterial flora is probably negligible, their aim being to provide antibiotic concentrations in blood and tissue to deal with fecal spillage.

Bowel Obstruction

Preoperative preparation of the patient with bowel obstruction begins with optimization of fluid and electrolyte balance and with gastrointestinal decompression. A nasogastric tube is placed and connected to low, intermittent suction, and the likelihood of ischemia or necrosis of the bowel wall is assessed. As previously discussed, bowel obstruction in gynecologic cancer patients tends to occur in the context of certain clinical scenarios. Some patients will be candidates for aggressive surgical management as deemed necessary (i.e., adhesion-related), while others will not (i.e., advanced recurrent intra-abdominal malignancy). When a patient has a small bowel obstruction thought to be amenable to surgical management and when there is evidence of compromise of the bowel, surgery proceeds promptly after initial correction of hypovolemia. Broad-spectrum antibiotics should also be initiated in these patients. However, most gynecologic cancer patients who develop small bowel obstruction will not require prompt surgical intervention, and many patients deserve an attempt at conservative management in the hope that the obstruction will resolve.

In addition to hydration and nasogastric suction, passage of a long intestinal tube into the small bowel may be beneficial. After passing into the jejunum, the tube is connected to low intermittent suction and allowed to continue to pass, hopefully to the point of the obstruction. The long tube will decompress the small bowel more effectively, which may improve the chances for the obstruction to resolve and will improve the condition of the proximal small bowel, should surgery be necessary. TPN may also be advisable on an individualized basis. After initial stabilization, radiologic studies should be performed to evaluate the possibility of coexisting large bowel obstruction. With large bowel obstruction, surgical intervention will be necessary.

During the period of conservative management, if the patient develops any signs of compromised bowel, surgery must proceed. If, however, the patient remains stable and the bowel decompresses well, there is no urgency in the situation. The patient can be maintained on TPN while allowing 5 to 10 days for the condition of the bowel to improve and a chance for the obstruction to resolve. If the bowel does not decompress by 48 to 72 hours,

then surgery should proceed.

OPERATIVE TECHNIQUES

This section deals with descriptions of actual surgical techniques. It is not meant to be an exhaustive review of methods or techniques, but rather is designed to convey basic principles and techniques commonly used in the management of the intestinal tract as it relates to gynecologic patients.

Gastrostomy Tube Placement

For palliation, a gastrostomy tube can most often be placed percutaneously with either fluoroscopic or gastroscopic guidance. If the procedure is an isolated open one, the operation may be performed through an upper midline, or through a left subcostal or transverse epigastric incision that incorporates the tube. When there is extensive bulky intra-abdominal carcinomatosis, the surgeon should attempt to make the incision over a relatively free space in the region of the stomach.

To gain exposure, the inferior border of the stomach is grasped with Babcock clamps (avoiding injury to the gastroepiploic vessels), and with gentle traction the fundus is brought into the operative field. A site for the gastrostomy is selected in the distal fundus midway between the two curvatures and is grasped with another Babcock clamp. A purse-string suture of 0 chromic catgut is placed around the clamp and held (**Fig. 47.31 A**). If there is carcinomatosis, inflammatory reaction of the peritoneal surfaces, or other concerns about healing, silk sutures should be used. A second purse-string suture is used at this point or after the tube is in place, designed to imbricate the gastrostomy. A 28-French Malecot catheter or 24-French MIC tube is brought through a separate stab wound in the abdominal wall at a selected site several centimeters from the incision (**Fig. 47.31B**). The stomach should easily reach the abdominal wall at the chosen site.

P.1104

FIGURE 47.31 A: Purse-string suture being placed into stomach wall around selected site for gastrostomy. **B:** Gastrostomy tube being pulled through abdominal wall incision at selected skin site. **C and D:** Small opening being made in stomach within purse-string sutures.

P.1105

Within the purse-string suture, the gastrostomy is carefully made with cautery between two Allis clamps and the tube is placed into the stomach, directed distally (**Fig. 47.31C, D**). The balloon (MIC tube) is inflated and the inner purse-string suture is tied. The second purse-string suture is tied while carefully manipulating the tube and stomach to allow imbrication of the first purse-string suture and the folding of a short segment of the stomach wall around the tube. This is done to reduce the risk of leakage of gastric contents.

The stomach is then secured to the anterior abdominal wall with interrupted 2-0 silk sutures placed around the gastrostomy site. These are tied while traction is applied to the tube, which draws the balloon against the abdominal wall. The tube is secured to the skin with sutures through the MIC apparatus. The tube is irrigated with saline and aspirated of gastric contents to confirm position and patency.

Bowel Resection

This operation begins with careful planning for the resection and anastomosis, followed by mobilization of the involved portion or portions of the bowel. The bowel portions to be anastomosed must be healthy, have adequate blood supply, and approximate one another without tension.

The blood supply of the small bowel is based on the SMA, with branches extending through a widely fanned out mesentery. In the mesentery, the arterial branches form anastomosing primary and secondary arcades, with the terminal arcades supplying small parallel vessels (vasa recta) that extend to the bowel. Resection of a segment of small bowel must preserve an adequate arterial arcade, including the vasa recta, to supply the remaining divided ends of bowel. Small bowel resection in gynecologic cancer patients generally does not necessitate associated wide resection of the mesentery. Accordingly, resection of the mesentery should be as conservative as possible.

Following mobilization of the bowel, the remainder of the operative field is carefully isolated from contamination with moist packs. At the points of planned bowel division, a hemostat is placed through an avascular area of the mesentery immediately under the bowel wall. Along the planned mesenteric resection, the peritoneum on both sides is divided. The mesentery is then hemostatically divided. A linear gastrointestinal stapler or noncrushing bowel clamps are placed across the bowel, directed toward the mesentery, and slightly angulated to give a mesenteric advantage. The angulation avoids an ischemic corner of bowel and creates a slightly larger EEA. The bowel is divided by the GIA stapler or between bowel clamps (**Fig. 47.32**).

Colon resection is carried out utilizing similar principles. Depending on the segment, mobilization of the colon involves incision of the peritoneal attachments laterally and caudally, separation from the omentum, and division of the hepatic and/or splenic flexures (**Fig. 47.33A, B**). As previously described, the blood supply of the colon is derived from branches of the superior and inferior mesenteric arteries. These branches feed an anastomosing marginal artery, which extends from the ileocecal valve to the sigmoid colon (**Figs. 47.3 and 47.4**). From the marginal artery, vasa recta extend to the colon. With resection of the colon, the marginal artery and vasa recta supplying the two remaining ends must be preserved. As with small bowel resection, wide resection of the mesentery with the colon is generally not necessary in gynecologic cancer patients. The exception is rectosigmoid colon, the mesentery of which is often extensively infiltrated in cases of ovarian cancer. In resection for primary colonic malignancy, the rule of thumb is to extend the mesenteric resection to the first-named vessel proximal and distal to the site of pathology.

Rectosigmoidectomy in the context of extensive gynecologic disease is more difficult. It is one of the more common segments of the bowel that the gynecologic oncologist must resect. Removal of this portion of the bowel in gynecologic cancer patients is sometimes done as an isolated procedure (e.g., because of complications from radiation therapy) but is more often done in concert with an extensive pelvic resection for tumor. In most instances, the majority of the rectum

P.1106

may be preserved and an immediate anastomosis carried out. In other situations, the nature of the disease process or other factors prohibits an anastomosis and a permanent colostomy is performed. Finally, some cases—usually by virtue of tumor extent—require resection of the entire rectum and anus.

FIGURE 47.32 Planned resection of small bowel, dividing intestine with a gastrointestinal stapler (**A, B**).

FIGURE 47.33 A: Division of the hepatic flexure. **B:** Together with division of the lateral peritoneal, retroperitoneal (duodenum), and omental attachments, this mobilizes the right and proximal transverse colon.

FIGURE 47.34 A and B: Division of the sigmoid colon cephalad to the tumor as one of the preliminary steps to extensive pelvic resection. The line of pelvic peritoneal incision is dictated by tumor extent. All of the pelvic peritoneum extending across the infundibulopelvic ligaments and the posterior cul-de-sac is resected en bloc with the rectosigmoid colon (**C**). In some cases, all of the pelvic peritoneum must be removed, requiring additional dissection of the lower urinary tract.

P.1108

As mentioned previously, the blood supply to the sigmoid colon and upper rectum is based on the IMA that branches through the sigmoid mesentery. The remainder of the anorectum receives blood through the internal iliac artery. The midrectum receives blood by the middle hemorrhoidal artery; the blood reaches the rectum in an anterior-lateral fashion and through the lateral rectal stalks, which are also the major support structures of the rectum to the levator ani. These stalks must be ligated to achieve mobilization of the midrectum. The region of the rectosigmoid junction was previously thought to have a rather tenuous blood supply. However, arteriographic studies have documented rich collateral circulation with anastomoses between the middle and superior rectal arteries, and modern surgical experience with this region bears that out.

Resection of the rectosigmoid colon generally begins with division of the sigmoid colon at a selected site, followed by complete division of the sigmoid colon mesentery cephalad to the tumor infiltration (**Fig. 47.34A, B**). At the base of the mesentery is the superior rectal artery; this is also ligated. It is important to safely retract the ureters prior to this. During mobilization of the specimen, the pararectal spaces should be opened carefully—but widely—down to the levator muscles. Further mobilization is achieved by incision of the posterior pelvic peritoneum from the points of the completed mesenteric dissection anteriorly to meet the remainder of the pelvic dissection (often dictated by peritoneal tumor extent). The rectum is carefully freed from the presacral space all the way to the levator muscles if necessary. Depending on the additional pelvic resections being performed (e.g., hysterectomy, exenteration, etc.), the rectovaginal space may be developed and additional vascular/supportive structures will need to be divided.

FIGURE 47.35 End-to-end rectosigmoid staple anastomosis. **A:** A purse-string suture holds the anvil and spike within the sigmoid lumen. The EEA stapler is inserted transanally. Clockwise rotation of the central wing nut advances the sharp trocar to pierce the apex of the rectal stump. In this illustration, the trocar has been removed, and the hollow center shaft of the EEA remains in place. **B:** The spike and hollow center shaft are locked into position. Further rotation of the EEA central wing nut brings the sigmoid and rectum into direct opposition. The stapler is fired to deliver dual circular staple rows as the knife transects the central tissue core to complete the anastomosis.

P.1109

When the distal aspect of the dissection has been reached, the pelvic specimen is mobilized such that the only remaining attachment is the rectum. This portion of the rectum should be mobilized for anastomosis prior to resection if possible. At the planned level of transection, the fat around the rectum is cleaned. A stapler, automatic purse-stringer or right-angled bowel clamp is placed across the rectum at this level, and transection is completed against the instrument. Immediately following resection, it is our habit to irrigate the pelvis with antibiotic solution, particularly if any stool has spilled. Transanal irrigation of the rectal stump is done at this time.

Colorectal Anastomosis with a Circular Stapler

Anastomosis of the colon to the rectum is difficult, due to the rectum being recessed within the pelvic cavity, particularly when the remaining rectal stump is short. Anastomosis is greatly facilitated by a circular stapler. If the rectum was transected with a stapler, the only additional preparation is to clear the fat from the area where the anastomosis will take place.

During surgery, the colon should be mobilized so that the end will reach the rectum without tension. Excessive mobilization from the mesentery will compromise the blood supply. By transilluminating the sigmoid mesentery, the surgeon may see that proximal portions may be divided while still leaving adequate blood supply to the end of the colon. Incising the lateral peritoneal, avascular retroperitoneal, and splenic flexure attachments will achieve additional mobility. Infrequently, the IMA must be divided. The end of the colon is opened and irrigated if necessary. It is the authors' habit to irrigate the rectal stump transanally.

Sizers are then used to determine which stapler is appropriate. The largest stapler that the colon will comfortably accommodate should be used in order to avoid anastomotic stenosis. A size 28 or 31 instrument can be used in most instances. A purse-string suture with 2-0 monofilament is placed along the edge of the proximal colon. The separated anvil of the stapler is placed into the open end of the colon, and the purse-string is secured around the shaft. The stapler (with completely withdrawn trocar) is then introduced transanally. Directed into the proper position by the abdominal and perineal surgeons working together, the trocar is advanced through the rectal staple line; a small incision may be made into the middle of the staple line to facilitate this. The anvil shafts are then connected (**Fig. 47.35A, B**).

The stapler is closed while applying gentle, inward pressure to ensure that the colon stays aligned and does not fall into the stapling device. The instrument is fired, creating an inverted circular anastomosis with staggered rows of metal staples, while simultaneously cutting from the staple line

the portions of the two bowel ends within the instrument. While the instrument is still in place, it can be used for careful manipulation in order to place seromuscular imbricating sutures or other sutures designed to protect the suture line. These sutures should not be tied until after the instrument is removed and the anastomosis is tested.

The stapler is then opened and removed transanally again with gentle inward pressure to allow complete separation of the anvil from the staple line. Allis clamps or sutures are used to facilitate retrieval of the instrument past the anastomosis. The instrument is completely opened and separated, and the two pieces of removed tissue are inspected. There should be two complete mucosal rings. The pelvis is then irrigated with antibiotic solution; a small amount of antibiotic is left in the pelvis just over the top of the anastomosis. The rectum is then filled with air, and the anastomosis is inspected for leaks (i.e., bubble test) (**Fig. 47.36**). Any leak is closed with suture.

FIGURE 47.36 Testing the anastomotic integrity. The pelvis is filled with sterile crystalloid. The descending colon is manually occluded as air is insufflated via a rigid sigmoidoscope to create pressure across the anastomosis. Holding the anastomosis under water, it is examined for the air bubbles that would suggest an anastomotic leak.

Endoscopic inspection of the anastomosis for hemostasis is also recommended by some authors. If omentum is available, it is transposed into the pelvis and wrapped completely around the anastomosis. The role of prophylactic drains in these patients is unclear.

If the colorectal anastomosis will be low (within 6 to 8 cm from the anal verge), consideration should be given to replacement of the rectal reservoir with a colonic J-pouch (**Fig. 47.37**).

Open Hand-Sewn Anastomosis

The technique illustrated in **Figure 47.38** is an EEA. However, this circular technique is easily adaptable to an end-to-side or side-to-side anastomosis. The technique used is identical for the large and small bowel. Some surgeons, particularly in the past, have preferred a closed technique of anastomosis to reduce contamination by bowel contents. This technique is done by first aligning the two bowel ends being held by noncrushing clamps and then placing interrupted anastomosing seromuscular sutures across the clamps. The sutures are pulled tight as the clamps are removed and then immediately tied. This technique is considered by some to be cumbersome and less accurate than the open or stapled anastomosis.

To begin the anastomosis, the ends of the bowel are approximated and aligned by an assistant. Using 3-0 silk (or delayed absorbable suture) Lembert sutures, a row of seromuscular stitches placed 3 to 4 mm apart and 4 to 5 mm from the edges of the bowel are placed to create a back row. If bowel clamps were used, these are left in place and used for alignment and manipulation during placement of this back row. If staples were used, these are also initially left in place. The first and last back row stitches are held long with hemostats for purposes of orientation and alignment.

FIGURE 47.37 Rectal J-pouch coloproctostomy.

Padded or rubber-shod bowel clamps are placed several inches from the bowel ends in order to occlude the lumens and thereby prevent spillage of bowel contents. The clamps on the bowel ends are then removed, or the staple lines are excised, and the open portions of the bowel are emptied. The bowel walls approximated by the posterior row of seromuscular sutures will also have been inverted by these sutures.

Using 3-0 chromic or delayed absorbable monofilament suture, the full thickness of the two inverted bowel walls are sutured together to form an inner layer (**Fig. 47.38A-C**). The sutures should be about 3 mm apart using a running or interrupted technique. If a running technique is used, sutures should be placed slightly closer than 3 mm apart to help prevent stenosis.

The anastomosis proceeds by continuing the inner layer until it is completed. As the inner suture line continues beyond the inverted posterior row, it is desirable to continue to invert the bowel edges into the lumen, while at the same time suturing through all layers. With a running technique, this is best accomplished using Connell stitches. Using an interrupted technique, the edges may be inverted by taking a slightly larger bite of the bowel wall relative to a small bite of mucosa. The outer layer of interrupted Lembert sutures is then completed (**Fig. 47.38D, E**); a carefully performed single layer is acceptable as well. The occluding bowel clamps are then removed and the anastomosis palpated for adequacy. Finally, the mesenteric defect is carefully closed, avoiding injury or ligation of blood vessels. A hand-sewn side-to-side anastomosis is shown in **Figure 47.39A, B**.

Anastomosis with a Linear Stapler

Stapled bowel anastomoses are comparable to that of handsewn anastomosis with regard to leak and anastomotic stricture rate. Advantages include reduced operative time and relative simplicity. Disadvantages include cost, requirement of a more mobilized bowel, and a theoretically higher potential for stricture. The technique illustrated in **Figure 47.40** is a functional EEA. As with the hand-sewn method, this technique is easily adaptable to end-to-side and side-to-side anastomoses. The stapler simultaneously places two rows of staggered staples side by side and cuts between them.

To begin the anastomosis, the two ends of bowel are aligned in a side-to-side fashion. Along the borders of the mesenteries, the bowel walls are aligned with interrupted 3-0 silk seromuscular sutures for a length of approximately 6 to 10 cm. The suture at the end of the bowel is held with a hemostat for the purpose of orientation.

As before, occluding clamps are placed to reduce contamination. If the resection was done with staplers, antimesenteric corners of the staple lines should be excised to accommodate the forks of the stapler (**Fig. 47.40A**). One fork is inserted fully into each lumen; care must be taken to ensure that the bowel ends are aligned evenly and that their mesenteries are clear (**Fig. 47.40B, C**). The instrument is then carefully closed and fired, creating an anastomosis. Before opening the instrument, a few seromuscular stitches may be placed to imbricate and take tension off of the anterior row of staples. The stapler is then opened in situ, and prior to removal the staple line is carefully inspected for bleeding (**Fig. 47.40D**). Bleeding sites may be sutured or carefully cauterized. The remaining common opening is then closed with sutures or a stapler (**Fig. 47.40E, F**). The additional staple line

may also be imbricated with Lembert sutures. The occluding bowel clumps are removed, and the anastomosis is palpated for adequacy. A side-to-side anastomosis is performed in a similar manner.

Ileostomy

Depending on the situation, an ileostomy may be formed from the end of the transected functional ileum (end ileostomy) or from a loop of ileum. The main role of a loop ileostomy is temporary diversion. If an isolated procedure, an ileostomy can sometimes be done through a small right lower quadrant incision or with laparoscopy.

P.1111

FIGURE 47.38 End-to-end hand-sewn double-layer small bowel anastomosis. **A:** The bowel segments are aligned end to end and secured by stay sutures placed midway between the mesenteric and antimesenteric borders. Each luminal diameter is increased via a linear incision along the antimesenteric border (Cheatele slit). **B:** The inner running layer is started on the mesenteric (posterior) bowel edges. A double-arm needle facilitates bidirectional sewing as the closure continues around the corners onto the antimesenteric (anterior) edges. **Inset:** Conventional inner layer inverting technique. **C:** The anterior inner layer is completed with a continuous over-and-over or Connell suture (as shown). **D:** The bowel is rotated 180 degrees to expose the posterior wall. Interrupted seromuscular 3-0 silk sutures are placed to finish the posterior outer layer. **E:** The bowel is rotated back into its normal alignment, and the anterior outer layer is closed with interrupted silk sutures. The mesenteric defect is reapproximated, and the adequacy of the lumen is assessed.

FIGURE 47.39 End-to-end hand-sewn single-layer colon anastomosis. **A:** The bowel edges are brought together, and their alignment is stabilized with stay sutures. Sewing is started on the mucosal surfaces of the posterior bowel edges. A double-arm suture enables bidirectional sewing in a continuous fashion. **Insets:** The needle enters near the transected mucosal edge and passes obliquely through the bowel wall to exit 5 mm from the serosal edge. The needle is passed through the adjoining segment in the same oblique fashion, which inverts the tissue edges as the running suture is secured. **B:** Suturing is continued around the corners onto the anterior edges, which are closed from the serosal side. **Inset:** Alternative method of single-layer closure known as the Gambee technique, which results in end-to-end opposition of the tissue edges without puckering the mucosa.

FIGURE 47.40 A: Preparing for an end-to-end stapled anastomosis. The two ends of the bowel are aligned with sutures, and a corner of each staple line is excised in order to accommodate a fork of the stapler. **B:** A fork of the stapler is placed into each end of the aligned bowel. **C:** The two forks of the stapler are aligned and closed, avoiding inclusion of mesentery. The stapler is fired, and additional front row seromuscular sutures may be placed. **D:** The stapler is removed. After inspection of the internal anastomosis for patency and hemostasis, the open end (which accommodated the stapler and is now common) is held closed and aligned with sutures or a series of Allis clamps. **E and F:** A stapler is placed underneath the Allis clamps across the common opening and fired. This closes the opening and completes the anastomosis.

The technique of end ileostomy is relatively straightforward. The mesentery is carefully mobilized so that the end of the ileum may be brought through the right lower quadrant with adequate blood supply. A site is chosen and a circular, quarter-sized segment of skin and underlying fat is excised. The fascia is exposed, and a cruciate incision is made (**Fig. 47.41A**), followed by completion of the incision into the peritoneal cavity. The entire opening should be large enough to accommodate the end of the ileum without compromising the mesentery. The ileum is brought up through the opening with a Babcock clamp until it extends approximately 6 cm above the skin without tension (**Fig. 47.41B**). The bowel wall is then secured to the peritoneum with interrupted 2-0 silk sutures. The ileostomy is matured after closing the abdomen and isolating the abdominal incision with an occlusive dressing to avoid soilage (**Fig. 47.41C**). The maturation should create a protruding nipple-like stoma (as described by Brooke), which directs the liquid bowel contents directly into the appliance bag. If circumstances dictate that the transected end of the defunctionalized ileum should be exteriorized as a mucous fistula, this may be brought out at a separate site as a small, flat stoma or with the functional end as a modified loop ileostomy.

A loop ileostomy is brought through a similar opening in the right lower quadrant of the abdominal wall. The loop is delivered with a Babcock clamp until it protrudes approximately 5 cm above the skin, at which level it is secured to the fascia with interrupted 2-0 delayed absorbable sutures and to the peritoneum with interrupted 2-0 silk sutures. A supporting bridge is generally not necessary. After closing the abdomen, the ostomy is matured by making a transverse incision

P.1113

across the efferent limb just above the skin (**Fig. 47.42A**). The efferent opening is sutured to the skin with interrupted 2-0 sutures. The functional end is then matured in a protruding fashion in the manner described with the end ileostomy (**Fig. 47.42B**).

Colostomy

A colostomy may be formed either from the transected end of the colon (usually sigmoid or end descending) or from a loop of colon (usually transverse). The main role of a loop colostomy is temporary diversion. Most end colostomies are intended to be permanent. In certain situations, a colostomy may also be performed as an isolated procedure laparoscopically or through a small incision placed over the anticipated location of that part of the colon.

FIGURE 47.41 A: Circular skin and cruciate fascial incisions made for the ileostomy. **B:** Stapled end of ileum delivered through the ostomy incision. **C:** Creation of the protruding, nipple-like ileostomy stoma.

A transverse loop colostomy is brought through a circular incision in the right or left upper quadrant. A mobile portion of the transverse colon is selected, to come through the chosen site of the abdominal wall. To accomplish this, it is occasionally necessary to take down the hepatic and/or splenic flexure. This portion of the colon is separated from the omentum and to a limited extent is cleared of fat. A defect is made in the mesentery and a Penrose drain passed through and held. The loop of colon is then delivered through the ostomy incision until it protrudes approximately 5 cm above the skin (**Fig. 47.43**).

P.1114

A plastic bar is then placed through the mesenteric defect across the skin to ensure maintenance of colostomy elevation and complete diversion of stool (**Fig. 47.44**).

FIGURE 47.42 A: Bowel incision for loop ileostomy. Length is maintained on the functional side so that it can be matured as a protruding stoma. B: Maturation of the loop ileostomy.

FIGURE 47.43 Loop of colon delivered through the ostomy incision by a Penrose drain through the mesentery.

FIGURE 47.44 The Penrose drain has been replaced by a supporting skin bridge rod. The loop has been partially divided and matured into a colostomy in a manner similar to that described for ileostomy.

An end sigmoid or descending colostomy is placed at a selected site in the left lower quadrant. This portion of the colon is adequately mobilized and the end is cleared of fat. With a Babcock clamp, the end is then delivered through the ostomy incision until it extends approximately 3 to 5 cm above the skin. In order to reduce complications, consideration may be given to tunneling a permanent end sigmoid colostomy extraperitoneally before bringing the end through the ostomy incision. After closure of the abdomen, the colostomy is matured as described for the end ileostomy (**Fig. 47.45**). With the expectation of solid stool, the end sigmoid colostomy need only protrude 1 to 2 cm.

Loop Ostomy Closure

Takedown of a loop ileostomy or colostomy is done using a similar technique and can generally be accomplished through a peristomal incision. An elliptical incision is made, which includes a margin of skin along the stomal edges (**Fig. 47.46**). The loop is then freed to the fascia and separated from the fascial ring. If necessary, a small ring of fascia may be excised to safely free the loop. The loop is separated from the peritoneum and nearby adhesions until it is freely mobile for closure and replacement into the peritoneal cavity. Depending on the circumstances, the surgeon may elect to simply excise the stomal margin and close the anterior intestinal wall defect transversely, insert a linear stapler through the two ends of the colon and close the transverse colostomy with a stapler or sutures, or resect the stoma and perform an EEA.

End Colostomy Takedown

This description is restricted to takedown of an end sigmoid colostomy with anastomosis to the rectal stump. Such a situation is infrequently encountered in patients with benign or malignant gynecologic nonpathology.

P.1115

Prior to preparation of the abdomen, the stoma is closed with a purse-string suture or with a running monofilament suture to approximate the skin edges surrounding the stoma in a linear fashion. Alternatively, a large-bore catheter may be placed to occlude the stoma, drain the colon, and aid in identification of the intraperitoneal colon segment. The abdomen is opened through the previous incision, and adhesions are taken down. The colostomy is mobilized by making an elliptical incision around the skin and freeing the colon from the fascia and peritoneum. Alternatively and if length allows, the colon may be transected with a stapler just under the abdominal wall; the stoma is excised separately. The end is prepared for anastomosis and sized, and the purse-string suture is placed. The rectal stump is mobilized only so far as to define an apex that allows proper placement of the stapler. From this point, the procedure is identical to that of the colorectal anastomosis previously described using the circular stapler, with the exception that the trocar simply penetrates the apex of the rectal stump.

FIGURE 47.46 Peristomal incision in preparation for closure of a loop colostomy.

FIGURE 47.45 Sutures placed for maturation of the end colostomy that will protrude in a manner similar to that described for the end ileostomy.

POSTOPERATIVE CARE AND COMPLICATIONS

Patients who have undergone intestinal surgery are maintained at bowel rest until return of bowel function, or until diet is cautiously advanced at the discretion of the surgeon. Maintenance of a nasogastric tube for 24 hours or longer postoperatively may be associated with an increased risk of respiratory complications and causes discomfort to the patient. The benefit of the nasogastric tube is unclear but is utilized at the discretion of the surgeon. In theory, the tube helps to keep the intestinal tract somewhat decompressed, which may protect the anastomosis and reduce the time to return of bowel function and which will guard against aspiration until gastrointestinal function returns. As previously discussed, when slow return of bowel function or the need for prolonged bowel rest is anticipated intraoperatively, it is reasonable to place a gastrostomy tube. Most of the tubes used for this purpose are not sump tubes and are best placed to allow postoperative gravity drainage. In general, a gastrostomy tube should not be removed before the 10th day to ensure that the intestine has become well adhered to the anterior abdominal wall.

When the patient is severely malnourished, is anticipated to have slow return of bowel function, needs prolonged bowel

P.1116

rest (more than 55 to 77 days), or has undergone very extensive surgery (e.g., exenteration), TPN is begun or reinstituted as soon as the patient is stabilized postoperatively. This should be anticipated so that a central venous catheter may be placed intraoperatively.

Wound Management

Wound infection rates following intestinal surgery are generally in the range of 5% to 10%, but this complication is much more likely to occur in some settings than in others. Wound infection is more likely to develop if the bowel (particularly the colon or obstructed small bowel) has been opened or if a colostomy has been constructed. Wounds that have been extensively contaminated with stool should undergo delayed primary closure. All of these wounds require vigilant surveillance for infection, which tends to appear 7 to 14 days postoperatively. Other major risk factors for wound infection, such as obesity and poorly controlled diabetes, must be considered as well.

Enterostomy Tubes

Significant gastrostomy-related complications occur in approximately 5% of patients. Lapses in technique are the most important factors related to these complications. Early complications include dislodgement, hemorrhage, gastric or esophageal perforation, gastric prolapse through the opening, pressure necrosis of the gastric wall, and subphrenic abscess. Accidental removal of the tube within the first week poses a risk of intraperitoneal leakage, and reoperation is required if signs of peritonitis develop. If the tip of a large-bore catheter or a balloon migrates to the pylorus, it can cause gastric outlet obstruction. After being in place for several weeks, leakage may develop around the tube. This will usually resolve with replacement of the tube, which is done readily in the office. When a gastrostomy is placed for early postoperative management, our practice is to send the patient home with the tube plugged and remove it in the office 2 to 3 weeks later. If nausea or vomiting due to chemotherapy is anticipated early in the postoperative period, the tube may be opened to gravity on an as-needed basis.

The use of PEG tubes has been associated with the same low rate of complications as with the use of a surgically placed gastrostomy tube. Significant complications have also been reported with jejunostomy and needle jejunostomy, including hemorrhage, intestinal obstruction, and intraperitoneal leakage. As with a gastrostomy, technique is the most important factor related to these complications.

Small Bowel Anastomosis

Complications specifically related to small bowel resection and anastomosis include anastomotic leak with its attendant sequelae—hemorrhage, stricture, internal herniation, folate or vitamin B₁₂ deficiency, and short bowel syndrome. The chief concern regarding complications in the immediate postoperative period is the possibility for the occurrence of an anastomotic leak. This is a potentially devastating occurrence that may lead to sepsis and death. The leak can be contained with resultant intra-abdominal abscess, fistulae formation, or both. Management of enteric fistulae was previously discussed. Certain factors increase the likelihood of an anastomotic leak including prior radiotherapy, carcinomatosis, severe malnutrition, peritonitis or intra-abdominal sepsis, and poor condition of the bowel, such as marked dilation or extensive inflammatory reaction. Following a small bowel anastomosis or enterocolostomy, oral intake is restricted until return of bowel function. In the presence of the above risk factors (especially prior radiotherapy), TPN should be started or reinstituted and bowel rest maintained for a minimum of 7 to 10 days.

If a long tube was passed into the intestine preoperatively, it should be maintained at low intermittent suction following surgery. By keeping the bowel decompressed, the tube may protect the anastomosis. In addition, the tube acts as a stent and may prevent recurrent small bowel obstruction. The tube itself is partially obstructing, is uncomfortable, and may produce complications; it should be removed once bowel function begins to return or once the period of planned bowel rest is completed. These tubes have been associated with intussusception, especially upon removal. This complication is best prevented by gradual removal of the tube, topping as resistance is encountered.

Recurrent or persistent small bowel obstruction related to extensive dense adhesions is an uncommon occurrence that frustrates the patient and the surgeon and appears at the time to be an unsolvable dilemma. Although investigations continue, there is no proven available method for preventing redevelopment of the adhesions. Rather, described operative techniques for managing such patients have consisted of attempts to control the pattern in which the bowel adhesions form, such that there are smooth, gradual, nonobstructing turns in the small bowel. Plication of the small bowel and mesentery upon itself in smooth, gradual loops was described by Nobel in 1937. This method, considered outdated for the most part, has been associated with significant bowel dysfunction and morbidity.

Transmesenteric plication, introduced by Childs and Phillips in 1960, appears to yield improved results. A modification of the Nobel procedure, this technique involves placement of transmesenteric mattress sutures with a long needle in such a manner so as to fold the bowel into gentle, back and forth curves. There is the potential for mesenteric vascular injury with hematoma and/or bowel ischemia with this method. Currently, the main approach to patients with primary or recurrent small bowel obstruction related to complex adhesions consists of complete adhesiolysis alone or together with internal bowel stenting.

The value of decompression with adhesiolysis is unclear, but it is the authors' practice to perform retrograde decompression concomitantly. In such cases, the authors place a gastrostomy tube for management in the event that the obstruction fails to open up. When adhesive small bowel obstruction fails to resolve postoperatively or develops subsequent to very extensive surgery, patients should remain on TPN and bowel rest for at least several weeks prior to considering reoperation, provided that the condition is nonacute. Early reoperation on such patients may prove difficult and morbid due to an intense inflammatory reaction with edema and friability involving the bowel and peritoneal cavity.

Significant postoperative hemorrhage from a bowel anastomosis is an uncommon occurrence. It usually occurs early and has been related to intestinal stapler malfunction. As previously discussed, this complication is best prevented by careful inspection of the staple lines following removal of the stapling instrument.

After extensive small bowel resection, functional capacity of the intestine may be markedly reduced, resulting in a number of problems for the patient. The ability of the patient to adapt and maintain homeostasis with the remaining small intestine is dependent on several factors, including the length and specific segment of remaining bowel, the presence of an ileocecal valve and length of intact colon, the age of the patient (minimal intestinal adaptation after age 65), and hormonal factors. Significant problems occur when fewer than 5 to 10 feet of functional small bowel remain, including severe diarrhea, dehydration, perianal or stoma excoriation, electrolyte imbalance, and malnutrition. Over several months, adaptation of the preserved

P.1117

intestine occurs, with variable improvement in diarrhea and malabsorption depending on the previously cited factors.

Gastric hypersecretion is another recognized phenomenon in these patients; it may result in gastrointestinal ulceration, but the problem is transient and best managed with proton pump inhibitors. Cimetidine (an H₂ blocker) has been found effective in correcting malabsorption in patients with short bowel syndrome or those with exceptionally high ileostomy outputs (>1.5 L/day). Somatostatin (and octreotide) has been of limited benefit in the management of severe diarrhea in these patients. Other complications that may develop in patients with short bowel syndrome include cholelithiasis and nephrolithiasis. At the time of surgery, if fewer than 3 feet of small bowel segment is preserved, especially in the absence of an intact ileocecal valve and colon, consideration should be given to bringing the segment out as a stoma to improve patient comfort and dietary freedom.

In patients expected to be long-term survivors dependent on TPN, another consideration is prophylactic cholecystectomy. Following surgery, intestinal adaptation is dependent on stimulation by luminal nutrients. Maintenance of the patient with TPN should be supplemented as much as possible with oral/enteral feeding. Depending on the length of remaining functional bowel, supplementation may vary widely from vitamins only to complete reliance on TPN. Investigational surgical techniques for the management of patients with short bowel syndrome include intestinal valves and sphincters, interposition of an antiperistaltic segment of intestine, colon interposition, recirculating loops and pouches, intestinal pacing, intestinal tapering and lengthening, new intestinal mucosa growth, and intestinal transplantation.

Colorectal Anastomosis

Postoperatively, oral intake should be restricted until gastrointestinal function returns (a minimum of 5 to 7 days) and until there is no sign of an anastomotic leak. Routine nasogastric suction is not necessary but should be maintained in complicated cases. Patients at increased risk for an anastomotic leak from malnutrition, diabetes, heavy tobacco use, severe vascular disease, prior irradiation, and severe blood loss/shock should be kept at complete bowel rest and on TPN for at least 10 days. Once the patient is on solid food, a bulk-forming agent should be added to the diet.

Anastomotic leak is the most serious complication of colorectal anastomosis, with a reported incidence in approximately 5% of patients and an

associated mortality ranging from 10% to 30% of patients. Depending on the level of the anastomosis and the length of time since surgery, the leakage may present as diffuse peritonitis and sepsis (if leak occurs within the first 48 hours), localized peritonitis, abscess, or a rectovaginal fistula. If there is clinical uncertainty about a leakage, then a gentle Gastrografin enema should be performed. Feculent or purulent drainage may be noted from a pelvic drain. A pelvic drain positioned away from the anastomosis and placed at the time of surgery is generally removed after 24 to 48 hours. If a clinically occult or localized small leakage is noted and the patient is otherwise well, the drain should be left in place and the patient placed on bowel rest and TPN in hopes of spontaneous healing. Most clinically evident anastomotic leaks require prompt laparotomy (emergent if the patient has peritonitis) with resection of the anastomosis, proximal colostomy, irrigation of the abdomen, and closure and/or wide drainage of the rectal stump.

Anastomotic stenosis occurs in 1% to 10% of patients undergoing colorectal anastomosis. As with anastomotic leakage, the likelihood of this complication occurring may be much higher in patients who have undergone full pelvic radiotherapy for carcinoma of the cervix. In patients who have a protective colostomy, it is particularly important to evaluate the anastomosis for the presence of stenosis prior to taking the colostomy down. After healing, some anastomotic strictures can be successfully dilated.

Postoperative bleeding from the anastomosis is uncommon in the absence of a bleeding diathesis. The diagnosis may be difficult to make and should not be aggressively pursued unless the bleeding is significant. If the bleeding persists, hemostatic agents administered through an arterial catheter can be considered, although this may result in ischemia at the site of the anastomosis. If the anastomosis was to the anus, an attempt should be made at suture ligation transanally. In the presence of significant bleeding not amenable to the above approaches, a laparotomy will be necessary.

Like all extensive pelvic operations, surgery involving the colorectum carries the risk of ureteral injury that may be recognized during the postoperative period.

Following colorectal resection, a Foley catheter should be left in place for a minimum of 55 days. If there has been an associated extensive pelvic resection under the bladder for gynecologic malignancy or dissection under a previously radiated bladder, the catheter should be maintained for at least 3 to 4 weeks. As with extensive radical hysterectomy, bladder dysfunction is to be expected after extensive pelvic resection.

Following colorectal anastomosis, the patient may experience problems with rectal function including incontinence, tenesmus, and frequency of defecation. These difficulties are more likely to occur with anastomoses to the distal rectum and particularly those below the anorectal angle. Medical management of such patients generally consists of diet modification and constipating agents (including narcotics). As long as a reasonable rectal stump length was maintained, these problems will largely resolve within 6 months in a majority of patients.

Intestinal Stomas

Postoperative care begins in the operating room, where the surgeon must take responsibility for proper placement of the initial ostomy appliance so that contamination of the incisions and the psychological effects that early leakage can cause are avoided. The initial bag should be transparent so that the stoma can be checked for viability. Once the patient begins to recover from surgery, postoperative teaching about the stoma begins. Along with continued emotional support, this includes information about the anatomy of the stoma and its function, potential complications, and detailed aspects of day-to-day care. As with preoperative teaching, an enterostomal therapist is a valuable resource who should continue patient involvement intermittently on a long-term basis.

A comprehensive discussion of ostomy care is beyond the scope of this chapter, but specific areas to be addressed with the patient include peristomal skin care, diet, activities, odor, and emotional support. Some patients with an end-descending or sigmoid colostomy are candidates for routine irrigation that may allow predictability of bowel movements and better control over odor and gas. A few experimental techniques and devices aimed at producing a continent colostomy have been described or are available; however, results are variable, and it appears that their use should be individualized.

Complications of ileostomy and colostomy are similar. Many gynecologic oncology patients undergoing ileostomy

P.1118

have advanced malignancy and will not be subject to late complications. One complication unique to ileostomy is food bolus impaction, which occurs close to the stoma. This situation may be difficult to differentiate from mechanical small bowel obstruction. In either case, the initial management consists of bowel rest with nasogastric suction and intravenous fluids. The ileostomy is then gently irrigated in an attempt to dislodge the impaction. A windsock enema may be applied to allow gentle irrigation using gravity of an impacted small or large bowel stoma. Other common ostomy-related complications include peristomal wound infection, peristomal skin problems, site choice problems, ischemia, retraction, stenosis, prolapse, peristomal hernia, and carcinomatous involvement.

Peristomal skin problems include contact dermatitis, fungal dermatitis, and hyperplasia. Attention to appliance application and removal, avoidance of leakage, and meticulous skin care can help avoid and resolve most of these problems. An improperly placed stoma will make appliance placement and general stomal care more difficult for the patient and can contribute to the above skin problems.

Ischemia of the ostomy is more likely to occur with a descending colostomy and usually develops in the early postoperative period. The stoma must be closely monitored during the first 24 hours, and if it appears dusky or black the extent of ischemia must be evaluated. This may be done by placing a test tube into the stoma (Fig. 47.47) and shining a penlight inside of it. If the level of involvement is superficial, then it is best managed by local wound care with later revision as necessary. Recession of the stoma and/or stenosis are potential consequences of ischemia. Frank stomal necrosis requires close monitoring and exploration if peritoneal signs develop.

Significant retraction of the stoma is more common with colostomies and occurs in approximately 3% of cases. With a retracted stoma, leakage under the stomal appliance is much more likely. Revision can usually be accomplished locally by freeing the stoma completely so that it can be elevated, secured to the fascia, and resutured to the skin in a rosebud fashion.

Significant stomal stenosis may be a consequence of ischemia or infection, or may result from a too-small skin or fascial opening. This complication occurs in approximately 3% of colostomy patients. Initial gentle dilation may resolve the problem, but persistent stenosis requires revision. Local

revision with excision of the constricting scar tissue is the best approach.

Stomal prolapse (**Fig. 47.48**) develops as a consequence of a too-large fascial opening and more commonly involves the proximal limb of a transverse loop colostomy. This complication occurs in approximately 3% of colostomy patients. Local revision with resection of the redundant colon, closure of the fascial defect, and fixation to the fascia is usually successful. If the colostomy is temporary, then the prolapse may be managed conservatively.

A peristomal hernia develops in approximately 4% of patients after colostomy and is also a result of a too-large fascial opening. The hernia is repaired by excision of the sac and closure of the fascial defect (with mesh if necessary), although relocation of the stoma is sometimes necessary.

Carcinomatous replacement of the stoma occasionally occurs in patients with advanced intra-abdominal malignancy. Resection and relocation of the stoma is ideal but often not feasible. Local radiotherapy may also be considered. Patients face difficulty with odor, pain, and control of ostomy effluence and tumor discharge.

Ostomy Closure

Many significant complications that occur after colostomy closure in gynecologic cancer patients are related to the extensively radiated and/or extensively resected colorectal area that has been protected. Complications specifically related to closure of a loop ileostomy or colostomy are similar to those of other bowel anastomoses. These include wound infection (12%), anastomotic leak or fecal fistula (6%), anastomotic stricture or obstruction (2%), and incisional hernia (6%).

Factors that have been related to the complication rate of colostomy closure include patient age, timing of operation, underlying pathologic abnormality, type and site of colostomy, presence of steroid dependence, moderate to severe malnutrition (albumin <3.0), use of oral preoperative antibiotics, method of closure, and experience of the surgeon. Timing of closure is controversial, but should be delayed until the condition of the patient is optimal, especially when there has been an inflammatory process of the colon or peritoneal cavity or when the colon has been radiated. Closure of an end colostomy to a Hartmann pouch has been simplified by the use of a

P.1119

stapling device; the closure-related complication rate is probably not significantly greater than that of a transverse loop colostomy. However, closure of a transverse loop colostomy is simpler and does not require laparotomy.

FIGURE 47.48 Prolapsed loop colostomy.

BEST SURGICAL PRACTICES

- The pelvic surgeon must have medical and surgical expertise in the management of specific types of intestinal disorders. With any type of abdominal operation, the surgeon must be prepared for the eventuality of intestinal injury.
- When operating for presumed gynecologic pathology, the pelvic surgeon occasionally discovers a primary bowel disorder that must be managed surgically.
- Knowledge of the anatomy of the intestinal tract is necessary for the performance of intestinal surgery and management of complex pelvic pathology.
- Bowel adhesions may interfere with access to the pelvis during surgery and/or may involve pelvic structures with which the gynecologic surgeon is concerned. Any surgeon who operates in the peritoneal cavity must be competent in intraperitoneal adhesiolysis.
- In a patient with normal intestinal function and intestinal adhesions that will not interfere with the planned operation, lysis of such adhesions is not indicated.
- Management of thermal bowel injury is highly individualized according to the perceived extent of damage. Blanched, contracted tissue should be considered nonviable. There may be at least several millimeters of less apparent damage beyond the apparent injury.
- Laceration of the small bowel should be repaired perpendicular to the lumen to avoid constriction.
- In order to achieve optimal clearance of tumor, a large percentage of patients require extended procedures, the most common of these being colon resection.
- Likely a result of its location in the pelvis, the rectosigmoid colon is the bowel segment most frequently resected during cytoreductive surgery for ovarian cancer.
- The most important potential consequence of bowel involvement by endometriosis is obstruction, which is more likely to occur in the small intestine. Asymptomatic endometriosis of the bowel does not require surgical treatment.
- For a patient with recurrent ovarian cancer and bowel obstruction, the presence of extensive ascites, bulky intraabdominal tumor, an ileus-type pattern, or generally poor condition indicates that surgical management of the obstruction is unlikely to be of benefit.
- The surgical approach to a patient with radiation-related small bowel obstruction must be individualized. If the overall condition of the patient is poor or there is recurrent disease, the fastest and least complicated procedure (i.e., simple bypass) should be carried out. If there is apparent impending necrosis of the involved bowel, multiple injuries to the bowel have occurred during dissection, or the involved bowel is a simple loop that is not densely adherent, resection with end-to-end enterocolostomy is preferred. Isolation bypass may still be applicable in some of these cases. Matted loops of bowel in the irradiated pelvis should be left in place as long as a reasonable length of proximal small bowel can be bypassed to nonirradiated proximal colon.
- A leaking small bowel anastomosis may form a communication to the abdominal wall or vagina resulting in an enterocutaneous or enterovaginal fistula. During the process of fistulization, intra-abdominal leakage of bowel contents may result in peritonitis or abscess formation, and in some cases there may be continued intraperitoneal leakage. Uncontrolled sepsis in these patients is the major factor associated with mortality.
- Initial management of the patient with a small bowel fistula consists of bowel rest with nasogastric suction, fluid and electrolyte resuscitation, local management of the fistula output to prevent skin erosion, control of sepsis, and institution of TPN.
- Perforated bowel with intraperitoneal leakage is infrequently encountered in gynecologic and nongynecologic cancer patients. The complication may develop as a result of radiation-induced necrosis (usually of the terminal ileum or sigmoid colon), leakage from an intestinal anastomosis or occult operative injury, or bowel ischemia related to obstruction. Surgery is performed on an emergent basis.
- During conservative management of small bowel obstruction, if the patient develops any signs of compromised bowel, surgery must proceed. If, however, the patient remains stable and the bowel decompresses well, there is no urgency to the situation. The patient can be maintained on TPN while allowing 5 to 10 days for the condition of the bowel to improve and a chance for the obstruction to resolve. If the bowel does not decompress by 48 to 72 hours, surgery should proceed.
- The operative approach to bowel resection begins with careful planning of resection and anastomosis followed by mobilization of the involved portion or portions of the bowel. The bowel to be anastomosed must be healthy, have an adequate blood supply, and appose without tension.
- Significant gastrostomy-related complications occur in approximately 5% of patients. Careful attention to technique is the most important factor related to these complications.
- Following anastomosis of the small bowel, the chief complication of concern in the immediate postoperative period is an anastomotic leak. This is a potentially devastating occurrence that may lead to sepsis and death.
- After extensive small bowel resection, functional capacity of the intestine may be markedly reduced, resulting in a number of problems for the patient. Significant problems occur when less than 5 to 10 feet of functional small bowel remain, including severe diarrhea, dehydration, perianal or stoma excoriation, electrolyte imbalance, and malnutrition.
- Anastomotic leak is the most serious complication of colorectal anastomosis, with a reported incidence of approximately 5% and an associated mortality ranging from 10% to 30%.
- Following placement of an abdominal wall stoma, postoperative care begins in the operating room where the surgeon must take responsibility for proper placement of the ostomy appliance. This is important so that contamination of the incisions and psychological effects that early leakage will

cause are avoided.

Chapter 48

Nongynecologic Conditions Encountered by the Gynecologic Surgeon

Kellie L. Mathis

William A. Cliby

DEFINITIONS

Hartmann procedure—Resection of the diseased colon (usually for diverticulitis) with end colostomy and oversewn rectal stump.

Mechanical bowel preparation—Vigorous oral preoperative cleansing of the bowel most commonly with balanced electrolyte solutions.

Phlegmon—An inflammatory mass with ill-defined borders; often precedes a defined abscess.

P.1125

INTRODUCTION

In the majority of patients proceeding to the operating room for surgery in the pelvis, an accurate diagnosis has been made preoperatively. Advances in imaging should reduce the number of unanticipated findings intraoperatively for the pelvic surgeon. But, occasionally, the gynecologic surgeon will encounter an unexpected finding in the abdomen or pelvis intraoperatively arising from outside of the reproductive tract. This is commonly a problem in obese patients and elderly patients with atypical or ill-defined pelvic pathology and requires methodical consideration of the differential diagnosis preoperatively to appropriately triage and plan for these unanticipated findings. We discuss the most common nongynecologic findings in this chapter.

PREOPERATIVE EVALUATION

A thorough history and physical exam is absolutely critical. This should include presenting symptoms and past medical history as well as family history. The examination should include a thorough pelvic exam as well as a digital rectal examination. If the patient has any gastrointestinal complaints, a fecal occult blood test should be performed as well. Perianal abnormalities such as fistulae, atypical fissures, and large skin tags should raise the suspicion of Crohn disease.

If the patient complains of abdominal pain, low-grade fevers, changes in bowel habit, or blood in the stool, then a complete gastrointestinal workup should precede surgery. This may require endoscopy as well as computed tomography (CT) imaging. CT enterography should be ordered when there is a concern for small-bowel disorders. Patients suspected of having gynecologic infections and possible tuboovarian abscesses should be screened for sexually transmitted diseases.

If the patient has urinary symptoms, a urinalysis and culture should be done. If there is evidence of hematuria and/or bacteria, the patient should be treated for a urinary tract infection and reevaluation done to confirm clearance. If hematuria persists, further urinary workup should be considered to evaluate the upper urinary tracts as well as rule out intrinsic bladder pathology. This may include CT imaging, cystoscopy, or renal ultrasound.

PREOPERATIVE PREPARATION

The most important preoperative consideration is to make an accurate diagnosis or when not possible to define

the differential diagnosis so the appropriate surgical expertise can be involved in the case. If there is any uncertainty about the diagnosis, an extensive discussion with the patient and informed consent about possible findings and interventions should occur. If there is any suspicion that intestinal surgery may be necessary, then the patient should be informed that a protective ostomy may also be necessary, and the abdomen should be marked preoperatively by a wound ostomy nurse. Emerging evidence suggests that postoperative complications are less common when a wound ostomy nurse sees, marks, and educates the patient preoperatively. Other subspecialists should meet and counsel the patient as appropriate. Other principles of safe surgery should be followed, including ensuring adequate nutritional and hydration status. Mechanical bowel preparation is no longer recommended or necessary for safe intestinal surgery. If the surgeon anticipates possible leftsided colon resection, and most commonly for pelvic pathology where pelvic colon involvement is always a possibility, we recommend that the patient be given two tap water enemas upon admission on the morning of surgery. The rectum should also be irrigated with dilute Betadine just before prepping the abdomen and perineum.

INTRAOPERATIVE FINDINGS AND MANAGEMENT

The patient should be placed in the modified lithotomy position, and a sterile Foley catheter should be placed. Appropriate antibiotics timed correctly should be given, and in most cases, venous thromboembolism prophylaxis would be recommended according to current standards of care. Ureteral stents should be considered, especially in the setting of multiply recurrent surgeries and large pelvic masses. Consider a minimally invasive approach (laparoscopic/robotic) to perform the operation, or in cases of uncertain etiology, a diagnostic laparoscopy can be performed to aid in the diagnosis or incision planning or to determine if triage to a higher-level care center is necessary. If an open approach is followed, careful placement of the abdominal incision is essential to ensure that the upper abdomen can be reached if necessary; a midline incision is preferred, particularly when the diagnosis is uncertain. Adhesiolysis should be performed first if necessary followed by a full abdominal exploration. Self-retaining retractors should be placed to minimize the risk of neurologic injury, particularly femoral nerve injuries, and avoid undue tension on the abdominal muscles. If the small intestine is uninvolved, then it should be packed away into upper abdomen. Generally, the patient is put in the Trendelenburg position, and the pelvis should then be assessed.

We now consider some of the nongynecologic pathology that may be encountered in the abdomen and pelvis.

GASTROINTESTINAL DISORDERS

Appendicitis

If appendicitis is in the differential diagnosis preoperatively, laparoscopy should be performed. A 12-mm Hasson trocar should be placed at the umbilicus with two additional 5-mm trocars in the suprapubic midline and left lower quadrant. The patient should be positioned with the right side up. If the appendix is grossly inflamed and dilated in the absence of other pathology, the appendix should be removed. The appendix should be gently grasped with a Babcock clamp. The mesoappendix can be transected using hemostatic clips or vessel-sealing device or with an endoscopic linear stapler. A stapler should be used to transect the appendix at the base of the cecum. The specimen can then be pulled through the umbilicus in a bag or glove to avoid wound contamination. If there is gross purulence due to perforation, the area should be copiously irrigated with saline prior to closure. If a phlegmon is encountered in the right lower quadrant and the cecum is involved, it is reasonable to abort the procedure and treat the appendicitis with intravenous antibiotics and percutaneous drainage if an abscess develops. Surgery in this setting is associated with higher morbidity. If an organized abscess is seen, placement of a drain at the time of surgery is suggested; in the case of a phlegmon, no drain is recommended.

Diverticular Disease

Diverticulosis is common among Americans, with prevalence rates up to 45%. Diverticulitis is inflammation of the

diverticulum, usually occurring in the sigmoid colon, and it is generally managed nonoperatively. Uncomplicated diverticulitis accounts for 75% of all cases and is initially treated with bowel rest, antibiotics, and possible hospitalization (**Fig. 48.1**). Only when the attacks become recurrent and frequent enough to affect lifestyle is elective sigmoid resection entertained. Complicated diverticulitis (presence of abscess, perforation, fistula, or stricture) generally requires surgery (**Figs. 48.2, 48.3** and **48.4**). These cases often present to, or are referred to, a gynecologist because pain localizes to the pelvis and imaging demonstrates a pelvic mass, so a high index of suspicion is required when evaluating patients with preoperative gastrointestinal symptoms or systemic signs of infectious etiologies. When a contained abscess is seen on CT imaging, percutaneous drainage is attempted (**Fig. 48.5**). Surgery is ideally performed a few weeks after drain removal in an effort to avoid an end or diverting stoma. Patients with an acute perforation will present with an acute abdomen and require emergency surgery (**Fig. 48.6**).

FIGURE 48.3 Complicated diverticulitis versus tuboovarian abscess (*arrow*).

FIGURE 48.4 Perforated diverticulitis with abscess involving left adnexa (*arrow*).

If inactive diverticulosis is found intraoperatively, it should be ignored. Diverticulosis is common, and the majority of patients will never require resection. If the patient has acute diverticulitis or chronic smoldering diverticulitis, it is reasonable to consider a sigmoid resection. The technique of sigmoid resection is outlined in the Steps in the Procedure box.

FIGURE 48.5 Acute sigmoid diverticulitis with a contained abscess (*arrow*).

FIGURE 48.6 Acute diverticulitis with noncontained perforation (*arrow*).

P.1129

STEPS IN THE PROCEDURE

Sigmoid Resection for Diverticulitis

- Retract the sigmoid colon medially and separate the colon from the white line of Toldt and Gerota fascia. Identify and protect the left ureter and ovarian vessels.
- Mobilization of the splenic flexure may be necessary if there is not a natural redundancy in the colon.
- Divide the mesentery to the sigmoid colon, staying close to the bowel wall. This is done with right angle clamps and ligatures in the open technique and with a vessel-sealing device in the laparoscopic technique.
- Identify and transect the upper rectum with a TA stapler.
- Identify and transect the descending colon. Secure the anvil of the circular stapler into the proximal lumen with a purse-string suture.
- Perform a tension-free end-to-end stapled anastomosis using a circular stapler.

In order to avoid recurrence of diverticulitis, it is critical that the surgeon resects the entire sigmoid colon and perform the anastomosis between the soft and nonedematous descending colon and the upper rectum. It is not necessary to resect all of the diverticula from the proximal colon. Mobilization of the splenic flexure may be

required to perform an anastomosis without tension. If the setting of significant inflammation around the new connection, it is prudent to consider a temporary proximal diversion. If the tissue quality is poor (due to inflammation, edema, size mismatch, etc.), a Hartmann procedure is the safest approach.

Diverticulitis with an abscess involving the adnexa can sometimes be mistaken for a tuboovarian abscess, and this should always be in the differential diagnosis of a pelvic mass in the older female patient. In such cases, moderate elevation of CA-125 is common secondary to inflammation, which can further complicate the diagnostic challenge.

Colorectal Cancer

Cancers of the colon are common with over 100,000 new diagnoses in the United States every year. Ninety percent of colon cancers occur after the age of 50, but they can occur in every age group. Surgical resection is the primary treatment colon and rectal cancer. If a cancer of the colon is unexpectedly encountered intraoperatively, a decision should be made as to whether to proceed with bowel resection immediately or close the abdomen and perform the definitive surgery at a later date. If an operating surgeon experienced in oncologic colon resections is immediately available, then resection and primary anastomosis can be done. As stated before, mechanical bowel preparation is not necessary, but enemas are generally given preoperatively to empty the colon of the bulk of the stool for a left-sided resection. The most frequent tumors unexpectedly encountered by the gynecologic surgeon are cecal ([Figs. 48.7](#) and [48.8](#)) or rectosigmoid in location. Due to locations, these can often be mistaken for an adnexal mass. Techniques for each are described in the “Steps in the Procedure” boxes. The liver and peritoneal surfaces should be closely inspected for metastatic lesions prior to closure of the abdomen.

FIGURE 48.7 Advanced cecal cancer (*arrow*).

FIGURE 48.8 Large cecal cancer with local invasion into the sigmoid colon (*arrow*).

STEPS IN THE PROCEDURE

Right Colectomy Technique for Cecal Cancer

- Explore for resectability (omentum, peritoneum, liver, duodenum, superior mesenteric vessels).
 - Retract the colon medially and separate the colon from the white line of Toldt and Gerota fascia. Identify and protect the ureter, gonadal vessels, and duodenum.
 - Dissect the gastrocolic ligament to complete the mobilization of the hepatic flexure.
 - Identify the appropriate vessels. Divide the ileocolic, right colic, and right branch of the middle colic vessels near their origins.
 - Complete the mesenteric dissection. There is an expectation that at least 12 lymph nodes (LNs) are harvested because of a known survival advantage associated with increasing number of LNs.
 - Wait for the demarcation of the bowel after vessel ligation, and then transect the terminal ileum and the transverse colon.
 - Perform a side-to-side anastomosis using either a stapled or hand-sewn technique.
-

STEPS IN THE PROCEDURE

Sigmoid Colectomy Technique for Cancer

- Explore for resectability (omentum, peritoneum, liver).
- Retract the colon medially and separate the colon from the white line of Toldt and Gerota fascia. Identify and protect the left ureter and gonadal vessels.
- Mobilization of the splenic flexure may be necessary if there is no redundancy in the colon.
- Identify the appropriate vessels. Divide the inferior mesenteric vessels just beyond the takeoff of the left colic vessels and divide the sigmoidal branches.
- Complete the mesenteric dissection. There is an expectation that at least 12 LNs are harvested because of a known survival advantage associated with increasing number of LNs.
- Wait for demarcation of the bowel after vessel ligation to ensure adequate perfusion to the bowel outside the planned lines of resection.
- Identify and transect the upper rectum with a TA stapler.
- Identify and transect the descending colon. Secure the anvil of the circular stapler into the proximal lumen with a purse-string suture.
- Perform a tension-free end-to-end stapled anastomosis using a circular EEA stapler.

If a rectal mass concerning for cancer is encountered unexpectedly, it is best to close the abdomen and perform a thorough workup and staging. The management of rectal cancer is stage dependent with many patients benefiting from neoadjuvant chemoradiotherapy ([Fig. 48.9](#)).

Crohn Disease

Crohn disease is a chronic recurring inflammatory disorder that can affect the entire gastrointestinal tract. The most common site of midgut involvement is the ileum. There is a bimodal age distribution, with the first peak occurring in the second and

P.1131

third decades and the second peak occurring in the elderly. Symptoms are often vague and include chronic abdominal and pelvic pain. Patients can present with bowel obstructions from fibrotic strictures in the small and large bowel ([Fig. 48.10](#)). They can also suffer from intra-abdominal and pelvic fistulizing disease or abscess formation ([Fig. 48.11](#)). The diagnosis is usually made preoperatively by endoscopic findings in the case of colitis (ulcerations, pseudopolyps, skip lesions, granulomas, etc.) and by axial imaging with CT or magnetic resonance (MR) enterography in the setting of small-bowel disease. Surgery is not curative and is, therefore, avoided until the patient develops medical intractability or failure to thrive. Intraoperatively, the surgeon may find inflammation of the ileum and cecum with the classic “creeping fat” along the antimesenteric side of the bowel. If this is found, it is best to close the abdomen and refer to gastroenterology for consideration of medical treatments. However, if the inflammation is associated with a proximal obstruction, a surgeon with experience treating inflammatory bowel disease should assist with ileocecal resection to grossly negative margins or stricturoplasty. If a contained abscess is found preoperatively, percutaneous drainage is preferred over surgical drainage. And if a phlegmon is encountered in the OR, conservative measures should be taken to avoid the risk of short-gut syndrome. Intestinal bypass procedures are not recommended due to the risk of blind loop syndrome and malignancy in the bypassed segment.

FIGURE 48.9 Recurrent rectal cancer with associated smallbowel obstruction (*arrow*).

FIGURE 48.10 Stricturing disease in the terminal ileum in Crohn disease (*arrow*).

FIGURE 48.11 MR enterography showing a supralelevator pelvic abscess in a patient with Crohn disease (*arrow*).

Carcinoid Tumors

Carcinoids are neuroendocrine tumors and may be found in the GI tract, lungs, and kidneys. Carcinoid tumors are the most common neoplasms of the appendix; they are usually asymptomatic but a common incidental finding at the time of pelvic surgery (**Figs. 48.12** and **48.13**). When a small mass at the tip of the appendix is found, a formal appendectomy as described earlier is appropriate. If the carcinoid is greater than 2 cm or located at the base of the appendix, a right hemicolectomy would ideally be performed. Carcinoids of the small intestine can be associated with extensive mesenteric lymphadenopathy and a small-bowel resection with careful mesenteric dissection is required. The liver should also be evaluated for evidence of metastases. Given the benefits of a systemic workup prior to extensive surgery, we would generally recommend a minimal initial procedure (e.g., appendectomy) in cases where an unexpected finding is encountered to allow a more complete workup and resection at a later date with appropriate expertise.

Meckel Diverticulum

Meckel diverticulum is the most common congenital abnormality of the GI tract and results from failure of the omphalomesenteric/vitelline duct to be obliterated. It is most commonly located in the ileum within 2 feet of the ileocecal valve and appears as an outpouching of the bowel at the antimesenteric border (**Fig. 48.14**). If a Meckel's is encountered, it should be palpated. If there are any masses palpable within the lumen of the Meckel's, our practice is to resect. A linear TA stapler can often be used to transect the base of the Meckel's, taking care not to narrow the lumen of the small intestine. If there is a concern of narrowing with a diverticulectomy, then a small-bowel resection with a two-layer hand-sewn end-to-end closure is preferred.

Small-Bowel Lymphoma

Surgery is not generally first-line therapy for this broad group of tumors, so a specialist should be consulted to determine if the patient should be closed or resection performed (**Fig. 48.15**). Generally, an excisional biopsy of an involved mesenteric LN is preferable over smaller biopsy or fine-needle aspiration to allow accurate pathologic diagnosis and subtyping of lymphomas. Lymphoma may also present as a retroperitoneal mass and should be considered in the differential of pelvic lymphadenopathy as management would be medical after appropriate biopsy.

Small-Bowel Adenocarcinoma

Localized adenocarcinomas of the small bowel are treated with resection of the primary tumor and the draining mesentery. Adjuvant therapy is often given, but no survival advantage has been shown. In patients with carcinomatosis, debulking therapy and intraperitoneal chemotherapy have been described.

P.1133

FIGURE 48.12 Appendiceal carcinoid tumor (*arrow*).

Intussusception

Intussusception refers to the invagination of a part of the intestine into itself, essentially an “internal prolapse.” If this is identified in the operating room in an adult patient, the surgeon should search for a lesion (polyp, malignancy, Meckel's) that may be acting as a lead point. If a lead point is seen, a small-bowel resection should be performed. Preoperative CT scan will often show a “target sign.” Colonic intussusception is caused by cancer until proven otherwise.

Gastrointestinal Stromal Tumors
