TE LINDE'S **OPERATIVE** *Gynecology*

ELEVENTH EDITION

Howard W. Jones
John A. Rock

Wolters Kluwer

Foreword

In the early 1940s, Richard Te Linde hand wrote, page by page, in longhand the first edition of *Te Linde's Operative Gynecology*. His week was full. Two days spent in the operating room with usually five or six major cases scheduled, 3 days in the office, and grand rounds on Saturday morning until noon made for a busy week. At home after a long day's work and in a half-reclining position necessitated by a hip fracture while ice skating in earlier years, he wrote a description of the operations he himself had used to correct various gynecologic disorders.

The first edition, published in 1946 following the end of World War II, comprised 725 pages, all written by Dr. Te Linde himself. The present eleventh edition, 70 years later, has more than twice the number of pages and involves 50 authors.

Times have changed and Te Linde's text has changed with it.

The first edition in 1946 was widely read. Enhancing its attractiveness were the illustrations and the superb line drawings by artists trained under Max Brödel, the German medical artist brought to Baltimore by Howard A. Kelly (Kelly clamp), the founding gynecologic chairman at Johns Hopkins.

The use of drawings rather than photographs has continued through the various editions, including the eleventh edition. In this latest edition, most of the drawings have been colorized to even more clearly portray the location of blood vessels, ligaments, other structures, and surgical techniques. The text and illustrations are also supplemented by on line access to video demonstrations of selected vaginal surgeries.

The frequency of gynecologic operations per unit of population is declining. This is due to a number of factors, including alternate treatments for myomas, hormonal control of abnormal bleeding, alternatives to surgical treatment for infertility, and the decrease in the number of children per family, as well as the relatively high incidence of cesarean sections, all of which preserve the pelvic structures and therefore greatly reduce the need for surgical repair of musculofascial pelvic defects.

In today's environment, the gynecologic surgeon, particularly the young gynecologic surgeon, may have less personal experience with the many surgical procedures now available and the complications that can occur. This requires advanced preoperative preparation by discussions with colleagues, residents, and fellows considering the indications for surgery, choice of techniques, and potential problems, all supplemented by an authoritative volume at hand. This, of course, is the *Te Linde*.

In the eleventh edition, there has been one entirely new chapter concerning robotic surgery, which is becoming more and more frequently used. This chapter is by Jed Delmore and Kevin E. Miller.

But even though the titles of the other chapters remain largely unchanged, the freshness and contemporary aspect of the book has been maintained by having 82% of the chapters written by new and authoritative contemporary specialists.

Finally, the long experience in the operating room of John Rock and Howard Jones III ensures that the 50-odd authors speak from practical experience. It is this personal, vast surgical experience which Richard Te Linde expressed in the first edition and which has continued to the present day that makes *Te Linde's Operative Gynecology* such a valuable text for every gynecologic surgeon.

Howard W. Jones Jr
Norfolk, Virginia
September 2014

Preface

Even as surgical techniques continue to evolve and new techniques are introduced, basic surgical principles remain. With this new eleventh edition of *Te Linde's Operative Gynecology*, the reader will find an increased emphasis on minimally invasive techniques of gynecologic surgery, but there remains a strong surgical foundation based on the correct diagnosis of the clinical condition, a complete and careful preoperative evaluation and counseling, a thorough understanding of the anatomy and physiology, and a thoughtful plan for postoperative recovery with appropriate expectations. The authors are all skilled and experienced surgeons who have had careers of surgical instruction, who not only guide the reader through the well-illustrated technique of surgery but also discuss the foundations of surgery.

In this new edition, we have included a new chapter on robotic surgery, and the chapter on electrosurgical techniques has been extensively updated to include vessel sealing instruments. The chapter on professional liability has been completely redone with new authors and an emphasis on risk prevention. The eleventh edition also boasts many new authors who have brought some fresh, new ideas and approaches to this classic text. Thirty-five of the fifty-one chapters have new authors who have reorganized and updated much of the diagnostic evaluation and management approaches to various gynecologic conditions. The editors have taken pains to select the best surgeons and the best teachers so that the textbook continues to maintain Richard Te Linde's comfortable reading style and the helpful, practical "surgical pearls," which will improve the skills of both the junior resident and the experienced gynecologic surgeon.

Definitions, summary, questions/answers, and best surgical practices continue to be an important component of each chapter. In addition, where appropriate, contributing authors have added a "stepwise approach" to the performance of a specific gynecologic operation.

Illustrations have always been an important aspect of *Te Linde's Operative Gynecology*, and the excellent line drawing of Leon Schlossberg, P. L. Malone, John Deutch, and Jennifer Smith have contributed much to success of previous editions. In the eleventh edition, 167 new surgical illustrations have been added to the text and both old and new drawings have been colorized to add to the clarity and contrast of the illustrations and to provide a brighter, more modern look to the book. The compact disc that accompanies the textbook features good teaching examples of both a standard abdominal and vaginal hysterectomy—surgical techniques that are all too often neglected in today's market-driven push to perform surgery using the robot or through a single laparoscopic trocar.

All of the techniques discussed and illustrated in this text are based on the extensive experience of the authors and editors, but it is important to appreciate that every patient and every situation is unique. Readers must exercise good clinical judgment. The authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application or any other information in this book and make no warranty, expressed or implied, with respect to the contents of this publication.

Such a text requires enormous contributions from many experts. The authors and editors sincerely thank all the contributors. Special acknowledgment to the Lippincott Williams & Wilkins editorial team of Rebecca Gaertner, Executive Editor; Jamie Elfrank, Senior Acquisitions Editor; and Tom Conville, Development Editor. We also commend Rob Flewell, Certified Medical Illustrator, whose artistic skills significantly enhance this edition. A special thanks to Maria Medranda, Sandra Allen, Laura Creel, Lynne Black, and Julie Smith for their editorial assistance.

As always, we are deeply indebted to the many authors who labored so hard to incorporate their experience into the previous editions of this text. This eleventh edition would not be possible without their contributions. We cannot help but include a special work of thanks to Dr. Richard W. Te Linde who we were both fortunate to know

and to the previous editors, Drs. Richard F. Mattingly and John D. Thompson from whom we learned so much. We sincerely hope that you and your patients will benefit from the combined experience and dedication of the many contributors to this and the many previous editions of *Te Linde's Operative Gynecology*.

Howard W. Jones III, MD

John A. Rock, MD

Preface from First Edition

Gynecology has become a many-sided specialty. No longer is it simply a branch of general surgery. In order to practice this specialty in its broad sense, the gynecologist must be trained in a comprehensive field. He must be a surgeon, expert in his special field, he must be trained in the fundamentals of obstetrics, he must have the technical skill to investigate female urologic conditions, he must have an understanding of endocrinology as it applies to gynecology, he should be well grounded in gynecologic pathology, and finally, he must be able to recognize and deal successfully with minor psychiatric problems that arise so commonly among gynecologic patients. With this concept of the specialty in mind, this book has been written. It then becomes apparent, when one seeks training in gynecology beyond the simplest fundamentals such as are taught to undergraduates, that special works are necessary for training those who intend to practice it. The author is a firm believer in the system of long hospital residencies for training young men in the various surgical specialties when their minds are quick to grasp ideas and their fingers are nimble. This volume has been written particularly for this group of men. Unfortunately, there is a paucity of good gynecologic residencies in the United States in the sense that the author has in mind. Many positions bear the name of residency but fail to give the resident sufficient operative work to justify the name. Another excellent method of development of the young gynecologist is an active assistantship to a well-trained, mature gynecologist. If the assistant is permitted to stand at the operating table opposite his chief day after day, eventually he will acquire skill and judgment which he himself will be able to utilize as an operator. When such a preceptor system is practiced, it is important that the assistant be given some surgery of his own to do while he is still young. If a man is forced to think of himself only as a perennial assistant, this frame of mind will kill his ability to accept responsibility of his own. However, many must learn their operative gynecology under less favorable circumstances than those of the fortunate resident or assistant. This volume should be of value to those who, by self-instruction, must acquire a certain degree of operative skill. Finally, it must be admitted that more gynecology is practiced today by general surgeons in this country than by gynecologists. Although this is not ideal, circumstances make it necessary, and much of this gynecologic surgery is well done. It is hoped that many general surgeons will use this volume as a reference book.

In connection with general surgery, it is only fair to say that much has come to gynecology by way of general surgeons of the old school, who practiced general surgery in the broadest sense. Now that gynecology and/or obstetrics has become a specialty unto itself, it is well in our training of men not to swing too far from general abdominal surgery. In spite of the most careful preoperative investigation, mistakes in diagnosis will be made, and at times, the gynecologist will be called upon to take care of general surgical conditions in the region of lower abdomen and the rectum. With this in mind, the author has included in this volume a consideration of a few of the commoner general surgical conditions occasionally encountered incidentally with gynecology or by mistaken diagnosis.

Operative Gynecology is written with the primary purpose of describing the technique of the usual and some of the rare operative procedures. It also includes indications for and against operations as well as pre- and postoperative care of patients. Although gynecology is divided into several fields, these fields interlock so that it has been found impossible to compose a volume on gynecologic surgery to the exclusion of the other divisions of the specialty.

Gynecologic pathology, for instance, is the bedrock upon which good gynecologic surgery is practiced. Without an understanding of it, surgery becomes merely a mechanical job, and errors in surgical judgment are inevitable. Hence, it has become necessary to include in this volume a minimum of gross and microscopic pathology, as it applies directly to the surgical subject under consideration. Also, some consideration is given to psychology and psychiatry in relation to gynecologic surgery. The author believes that getting the young woman on whom a hysterectomy must be done into the proper frame of mind to accept it is as important as possessing the technical

skill to perform the operation.

About The Author

DR. THOMPSON

We are honored to pay tribute to our friend and colleague, John Daniel Thompson, MD, in this eleventh edition of Te Linde's Operative Gynecology. Dr. Thompson coedited three editions of Te Linde's Operative Gynecology in 1985, 1992, and 1997, and his attention to detail is apparent in meticulous descriptions of surgical techniques and his eloquent expression of the meaning of our work. He is credited with redefining our combined specialties:

- Obstetrics is concerned with the quality of human reproduction and all the factors and functions that affect the quality adversely or favorably.*
- Gynecology is concerned with all aspects of human femaleness in health and disease.*

Dr. Thompson's distinguished career spans many decades and is highlighted by numerous accolades. Among his greatest accomplishments is his role in training and mentoring hundreds of residents and fellows during his 25 years as Chairman of the Department of Gynecology and Obstetrics at Emory University School of Medicine and Chief of Gynecology and Obstetrics at Grady Memorial Hospital in Atlanta, Georgia. By example, Dr. Thompson instilled in his trainees the belief that "any definition of a successful life must include service to others." This commitment to serving others is, indeed, an honorable legacy that will benefit generations to come.

Chapter 1

Operative Gynecology Before the Era of Laparoscopy: A Brief History

Paul M. Allen

DEFINITIONS

Cadaveric particles—Elements associated with the transmission of puerperal sepsis as described by Dr. Ignaz Semmelweis before the development of germ theory by Robert Koch and Louis Pasteur later in the 19th century. Dr. Semmelweis hypothesized that medical students were transmitting disease to parturient patients by carrying cadaveric particles on their hands from the anatomical dissection room to the First Obstetrical Clinic of the Vienna General Hospital in 1847.

Humors and dyscrasias—Before the development of germ theory, disease conditions were thought to result from an imbalance of the four bodily humors resulting in dyscrasias.

Kelly air cystoscope—An instrument designed in 1893 by Dr. Howard Kelly to allow visualization of the female urinary bladder and catheterization of the ureters by placing the patient in the knee-chest position to allow distention of the bladder from gravity and posture. Dilatation of the urethra is generally required prior to introduction of this instrument into the urethra and bladder.

Knee-chest position—Dr. J. Marion Sims and later Dr. Howard Kelly realized the value of placing the patient in this position to allow distention of the vagina as well as the urinary bladder from the effects of gravity and posture.

Miasmas—Before the development of germ theory, diseases were thought to be transmitted through miasmas (bad air).

Modified Kelly air cystoscope—An instrument designed by Drs. Paul Allen and Gordon Davis in 1992 similar to the Kelly air cystoscope in which the shaft of the speculum is shortened, widened, and brazened to prevent reflection of a laser beam off the surface of the speculum. This instrument is used for urethral colposcopy, a technique previously undescribed. Use of this instrument requires dilatation of the urethra prior to introduction into the female urethra.

Ovariectomy—The term used by Dr. Ephraim McDowell to describe the first successful abdominal operation involving a laparotomy with drainage of the contents of an ovarian tumor followed by an oophorectomy.

Stereo clinics and stereograms—Teaching tools developed by Dr. Howard Kelly to demonstrate surgical techniques and procedures. Stereograms were photographs taken by Anthony Murray, a Baltimore photographer, showing all aspects of a surgical procedure stepwise.

Gynecology, also spelled *gynaecology*, is defined by the Oxford English Dictionary as “that department of medical science which treats of the functions and diseases peculiar to women.” The word was first used as such in the middle of the 19th century. In 1867, gynecology represented the physiology and pathology of the nonpregnant state. Although most histories of gynecology trace its roots back to antiquity, the field of medicine we call by that name today really has had a fairly recent origin. The successful removal of an ovarian tumor by Ephraim McDowell in 1809 was as rare an event as it was a spectacular one. In the preceding centuries, the history of gynecologic surgery was closely tied to the history of general surgery, and the obstacles that had to be overcome were the same. Infection, hemorrhage and shock, and pain were all effective barriers to any but emergency surgical procedures in the days before anesthesia.

"The history of gynecology," Howard Kelly wrote in 1912, "seems to me more full of dramatic interest than the evolution of any other medical or surgical specialty." Himself an accomplished historian of medicine, Kelly noted that, "It was, notably, anesthesia which robbed surgery of its horrors, asepsis which robbed it of its dangers, and cellular pathology which came as a godsend to enable the operator to discriminate between malignant and non-malignant growths." Here, in a nutshell, we have the landmarks of much of the history of gynecology of the last 150 years. Ann Dally was correct when she noted that until recently, much of what has been written about the history of gynecology was written by gynecologists themselves, who picked their own heroes. With the rise of the new history of women and the social history of medicine since the 1970s, a much more balanced view has emerged.

There are many ways to approach the history of a medical and surgical specialty such as gynecology. The usual practice in textbooks that make an attempt to include some history is to tell the story in terms of who discovered what and who did which operation first. These facts are of interest but hardly constitute the history of the field. Besides the surgical operations of gynecology, the techniques devised, and the instruments to carry them out, there is much to be learned from the changing picture of diseases and their diagnoses; from the professionalization of the field, including the societies, journals, and textbooks that have been created; and from the education required to master the science and practice of operative gynecology. It is in these terms, rather than in tracing simply the great ideas and their creators, that this historical introduction proceeds.

Any major medical textbook can itself serve as a convenient window through which we can see history unfold. Robert Hahn has vividly described the changing world view of obstetrics by examining the succeeding editions of *Williams*

P.2

Obstetrics since its first edition in 1903. Likewise, the 50 years that have elapsed since the first edition of Richard Wesley Te Linde's *Operative Gynecology* provide an equal opportunity to describe the major developments in the companion field of gynecology.

In recounting the history of the development of operative gynecology in the United States, we can appreciate that the highly energetic pioneers of the 19th century who successfully completed theretofore unprecedented surgical procedures all manifested extraordinary personal and professional attributes of courage, persistence, tenacity, dedication, and commitment, on the scale manifested by Navy SEAL and Special Forces commandoes in contemporary times.

Capturing the inventive and imaginative spirit of these pioneer gynecologic surgeons is of salient importance to understanding our heritage as pelvic surgeons for women. Despite being embroiled repeatedly in controversy surrounding their discoveries and their respective work, they all ultimately emerged from the shadow of doubt and criticism into the light of acclaim as successful pelvic surgeons with enormous contributions of epochal surgical impact. They paved the way for the development of lifesaving and life-enhancing surgical procedures for women patients. These pioneers modeled for us the professional lives we live today as surgical gynecologists. For all of us that are, will be, or ever have been gynecologic surgeons, facing our own daunting challenges and dealing with our own controversies, the stories of these Herculean historical figures offer a deep, if not bottomless, cornucopia of inspiration and strength.

Offsetting this are the equally dramatic and moving stories of patients who endured the pain and suffering of their pathologic conditions. These were their compelling motivations for undergoing early attempts at selected surgical procedures. They endured the consequent pain and suffering of withstanding these operations without the benefit of anesthesia and without the benefit of antiseptic measures for infection prevention and control as we know them today. The travails of these patients matched the drama of a Greek tragedy, and should touch us deeply as surgeons, not only to feel compassion and sympathy for

these vulnerable women patients, but also to celebrate their ultimate victories in realizing the successful outcomes of the surgical procedures they had undergone in the hope of a cure.

BARRIERS TO SURGICAL PROGRESS

In ancient times, the lack of real anatomic knowledge was a barrier to the development of surgery. It is sometimes said that because the ancient Egyptians had effective techniques for the evisceration of bodies for mummification, they must have had a good knowledge of the body. However, removal of the internal organs during the embalming process was performed by technicians who did not concern themselves with the structure of the bodies they were preparing.

Anatomy was pursued in Alexandria during the Hellenistic period, but it had few, if any, practical applications until a later time. By the end of the 13th century, anatomic dissection again became more common, but often, it was limited to one or two public dissections a year or the study of animals. Surgeons were responsible for the few autopsies that were performed to determine the cause of death. This was especially important if a crime was suspected or drowning had to be established.

Soranus, the Roman physician and writer who practiced in the reigns of the Emperors Trajan (98-117) and Hadrian (117-138), is perhaps best known for his text entitled *Gynecology*. This book is somewhat mistitled because it is mostly devoted to what we would call obstetrics. Soranus wrote about prenatal and postnatal problems, as well as those associated with delivery itself. This ancient text has been translated and has an excellent introduction by Owsei Temkin. Recently, it has been reissued in a paperback edition.

Although Soranus' *Gynecology* still makes interesting reading, it hardly qualifies as an early text on the subject of operative gynecology. However, like other physicians of his time, Soranus clearly noted that the best midwife was one who was trained in all branches of therapy, "... for some cases must be treated by diet, others by surgery, while still others must be cured by drugs."

In the 1840s, the Hungarian obstetrician Ignaz Semmelweis showed clearly that puerperal fever could be prevented by disinfecting the hands of doctors before they examined their patients during the course of delivery. Despite good statistical evidence, his method of washing hands in chlorinated lime solution was not widely adopted. In fact, it met with outright resistance from most physicians.

Another obstacle to the development of operative gynecology was the understanding of principles of antisepsis and infection control and prevention. Ignaz Semmelweis (1818-1865) was a Hungarian physician born in Budapest. He began studying law at the University of Vienna in 1837 and then switched to studying medicine at that institution the following year. After receiving his doctorate in medicine degree there in 1844, he decided to specialize in obstetrics, after failing to receive an appointment to an internal medicine clinic in Vienna. He was appointed assistant to Professor Johann Klein at the First Obstetrical Clinic at Vienna General Hospital on July 1, 1846. His responsibilities in this position included examining patients each morning before the professor made rounds, teaching obstetrics to medical students, supervising difficult deliveries, and being the clerk of records. Dr. Semmelweis was quite disturbed to know that the puerperal sepsis mortality rate was considerably higher on his service than on the second service staffed by midwives. In his publication, he said that "it made me so miserable that life seemed worthless." Dr. Semmelweis searched fastidiously for predictor variables that might account for the outcome variable, eliminating such factors as crowding, climate, and even religious factors. He realized that the only difference in operating the two clinics was the staffing pattern.

In 1847, his friend and colleague, Dr. Jakob Kolletschka, a professor of Forensic Medicine, died after an accidental puncture with a student's scalpel in performing a postmortem examination. Dr. Kolletschka's own autopsy revealed the findings similar to those of patients with mortality from childbed fever. Dr. Semmelweis

concluded that he and the medical students carried “cadaveric particles” from the autopsy table to the First Obstetrical Clinic, unlike the midwives staffing the Second Obstetrical Clinic.

It is important to understand that at this juncture in history, the germ theory of disease had not been discovered by Louis Pasteur and Robert Koch and subsequently applied to antisepsis in the operating room by Dr. Joseph Lister.

Dr. Semmelweis instituted a policy on his service of using a solution of chlorinated lime for medical students and physicians to wash their hands between conducting autopsies and subsequently examining patients in labor. He selected the chlorinated lime solution because it effectively removed the putrid smell of infected autopsy tissue. As a result of implementing this policy, the mortality rate in the First Obstetrical Clinic dropped 90%. This then became equivalent to the mortality rate in the Second Obstetrical Clinic staffed by midwives.

Dr. Semmelweis' conclusions were not consonant with established medical and scientific opinions of that era. Disease states were thought at that time to be caused by an imbalance

P.3

of bodily *humors* that resulted in *dyscrasias* and were often treated with bloodletting. Factors thought to be causative of the spread of disease were *miasmas*. Thus, Semmelweis' findings were contrary to such thought. Consequently, his ideas were rejected. Physicians felt that their social status as gentleman was inconsistent with the idea that their hands could be unclean. Dr. Semmelweis did not publish his findings until 1858, although they were reported by his colleagues. In this country, the Harvard anatomist and writer Oliver Wendell Holmes (1809-1894) met similar disbelief and resistance when he suggested in 1842 that it was the physicians themselves who were carrying the dreaded puerperal infections to their patients.

Although there were instances of anatomical study in earlier times, we generally begin the story with the work of Andreas Vesalius and the publication of his *De humani corporis fabrica* in 1543. Before this time, anatomic knowledge was not tied to the teaching and practice of medicine. The tradition of the surgeon-anatomists, of whom Vesalius was a stellar example, culminated in the late 18th century with the work of the English surgical teacher John Hunter (1728-1793) and his older brother William (1718-1783). It was William's classic book about the gravid uterus with its detailed engravings that shed new light on the structures of the female pelvis.

In the 19th century, for all types of surgery, the problems of pain, hemorrhage, and infection had to be solved before operations could be undertaken safely. The problems of surgical dressings and postoperative infections were generally a matter of trial and error. The Scottish surgeon and gynecologist Sir James Simpson (1811-1870) urged his surgical colleagues to perform their operations on the kitchen tables of their patients to avoid the dangers of hospital infections, or “hospitalism” as it came to be called.

In the middle 1860s, Joseph Lister (1827-1912), while working in Glasgow, began experiments using carbolic acid, a phenol derivative, to clean the instruments, sutures, and dressings he was using in his operations. He based his work on an understanding of the germ theory of disease, which was then just in its infancy as a major theory of disease causation. Lister believed it was important to prevent the germs present in the air or on instruments and sutures from entering the wound, which would prevent the formation of the heretofore much desired laudable pus. Lister, too, met much opposition to his method of antisepsis. Partly because of the frequent changes in the system he was developing, which made it difficult for others to follow him, and because of the inadequate understanding of the germ theory by most surgeons, it took nearly two decades for antiseptic surgery to become routine. In Lister's case, as was also true for Holmes and Semmelweis, some of the resistance undoubtedly stemmed from the fact that doctors never like being told that what they are doing is actually causing harm to their patients.

Lister encountered a great deal of opposition, particularly in his own country. Lawson Tait (1845-1899), an active and polemical gynecologist who settled in Birmingham, was staunchly opposed to Lister's system of antisepsis.

Tait paid much attention to general cleanliness when he was operating, and he actually achieved quite good results. However, his older colleague, Spencer Wells (1818-1897) of London, was a devoted follower of the antiseptic system in his many ovarian operations, perhaps because he had a clear grasp of the role of microbes. In 1864, the year before Lister began using carbolic acid in Glasgow and 3 years before he published his first results, Wells published a paper in the *British Medical Journal* entitled "Some Causes of Excessive Mortality after Surgical Operations." Wells clearly described the recent work on germs by Louis Pasteur (1822-1895) in France. There is no definite proof that Lister was aware of the paper, but it is hard to imagine that he did not know what was appearing in the national medical journal. Thus, gynecologists probably had a much greater hand in the development of safe surgery in the last century than is usually acknowledged.

Dr. Crawford W. Long was a graduate of the University of Pennsylvania School of Medicine. Practicing in his native Jefferson, Georgia, this young dandy bachelor doctor hosted ether-sniffing parties for his friends at his office. Dr. Long noticed that his frolicking, partygoing friends, when intoxicated, would sustain without wincing falls and blows that would ordinarily cause pain. He noticed his own painless bruises sustained during his ether jags. James Venables, an intimate in Dr. Long's circle of friends, complained of two small tumors on the back of his neck. Mr. Venables winced and procrastinated when Dr. Long offered to excise the tumors surgically. Visiting his patient and friend in March 1842, he offered to excise the tumors while Mr. Venables sniffed ether, and the patient was amenable to such an offer. Dr. Long had procured the bottle of ether from his friend, Robert Goodman, of Athens, Georgia.

"Dear Bob: I am under the necessity of troubling you a little. I am entirely out of ether, and wish some by tomorrow night. We have some girls in Jefferson who are anxious to see it taken, and nothing could afford me more pleasure than to take it in their presence and to get a few sweet kisses. You will please hand the order below to Dr. Reece, and if you can meet with the opportunity to send the medicines to me tomorrow, you will confer a great favor by doing so. If you cannot send them tomorrow, get Dr. Reece to send them by the stage on Wednesday. I can persuade the girls to stay until Wednesday night, but would prefer receiving the ether sooner. Your friend, Crawford W. Long."

It was in such a spirit of simplicity, good fellowship, and joy of living without pretense that Dr. Crawford Long set the stage for his revolutionary discovery at the age of 26 years. On March 30, 1842, Dr. Long invited his friend and patient to position himself on a table in his office and poured ether on a towel as he was accustomed to doing at his parties. James Venables' classmates and the headmaster at the Academy were spectators. Feeling his patient's pulse and testing sensation with pinpricks, he incised and then excised the tumor in about five minutes. The patient sat up after the towel was removed from his face and had to be shown the tumor to believe that it had been excised.

Long's discovery was not received well with his medical colleagues, who believed his claims were ridiculous and that he might kill a patient using ether for anesthesia. Dr. Long's practice dwindled because of this. We acknowledge Dr. Long and his discovery annually on Doctors Day, March 30.

Known as the Father of Modern Pathology, Rudolf Virchow (1821-1902) introduced the concept that the cell was the basic unit that had to be studied to understand disease. He founded the field of cellular pathology and pathologic histology. He was the first to discover leukemia cells. Like Dr. Howard Kelly, who studied with Dr. Virchow in Berlin on one of his trips to Europe, Dr. Virchow was an ardent civic reformer and the founder of social medicine. Here is his direct quote on this topic:

"Medicine is a social science, and politics is nothing else but medicine on a large scale.
Medicine, as a social science, as the science of human beings, has the obligation to point

out problems and to attempt their theoretical solution: the politician, the practical anthropologist, must find the means for their actual solution... The physicians are the natural attorneys of the poor, and social problems fall to a large extent within their jurisdiction.”

The pioneering works of Andreas Vesalius, Ignaz Semmelweis, Crawford Long, and Rudolf Virchow launched the processes of removing obstacles to the development of operative gynecology. Each of them was subjected to considerable criticism professionally, because they were ahead of their times with their ideas. Ultimately, each of them prevailed, and all of them are honored today for their watershed contributions.

BEGINNINGS OF GYNECOLOGIC SURGERY IN 19TH-CENTURY AMERICA

Opening the abdominal cavity to remove extrauterine pregnancies was successfully accomplished several times in the later 18th century but did not become routine until the advent of anesthesia and antisepsis/asepsis. Ephraim McDowell (1771-1830) ([Fig. 1.1](#)) made surgical history with his successful removal of a large ovarian cyst in his patient Jane Todd Crawford, who in 1809 rode 60 miles to her doctor's house in Danville, Kentucky, to undergo an untried operation without any assurance of cure and without the benefit of anesthesia. Although McDowell is often referred to as a backwoods physician, he was in fact a well-trained surgeon. His Edinburgh training probably gave him confidence in his diagnosis and courage to attempt a surgical cure rather than have his patient face certain death from her relentlessly growing tumor. During his study tour in Scotland, he probably heard that in the previous century, the popular surgical teacher John Hunter had suggested such an operation, believing that “women could bear spaying just as well as did animals.”

The drama of McDowell's case is best described in the words of the surgeon himself:

“In December, 1809, I was called to see a Mrs. Crawford, who had for several months thought herself pregnant. She was affected with pains similar to labor pains, from which she could find no relief. So strong was the presumption of her being in the last stage of pregnancy, that two physicians, who were consulted on her case, requested my aid in delivering her. The abdomen was considerably enlarged, and had the appearance of pregnancy, though the inclination of the tumor was to one side, admitting of an easy removal to the other. Upon examination, per vaginum, I found nothing in the uterus; which induced the conclusion that it must be an enlarged ovary. Having never seen so large a substance extracted, nor heard of an attempt, or success attending any operation, such as this required, I gave to the unhappy woman information of her dangerous situation. She appeared willing to undergo an experiment, which I promised to perform if she would come to Danville. ... With the assistance of my nephew and colleague, James McDowell, M.D., I commenced the operation, which was concluded as follows: Having placed her on a table of the ordinary height, on her back, and removed all her dressing which might in any way impede the operation, I made an incision about three inches from the musculus rectus abdominis, on the left side, continuing the same nine inches in length, parallel with the fibers of the above named muscle, extending into the cavity of the abdomen, the parietes of which were a good deal contused, which we ascribed to the resting of the tumor on the horn of the saddle during her journey. The tumor then appeared in full view, but was so large that we could not take it away entire. We put a strong ligature around the fallopian tube near to the uterus; we then cut open the tumor, which was the ovary and fibrinous part of the fallopian tube very much enlarged. We took out fifteen pounds of a dirty,

gelatinous looking substance. After which we cut through the fallopian tube, and extracted the sack, which weighed seven pounds and one half. As soon as the external opening was made, the intestines rushed out upon the table; and so completely was the abdomen filled by the tumor, that they could not be replaced during the operation, which was terminated in about twenty-five minutes. We then turned her upon her left side, so as to permit the blood to escape; after which, we closed the external opening with the interrupted suture, leaving out, at the lower end of the incision, the ligature which surrounded the fallopian tube. Between every two stitches we put a strip of adhesive plaster, which, by keeping the parts in contact, hastened the healing of the incision. We then applied the usual dressing, put her to bed, and prescribed a strict observance of the antiphlogistic regimen. In five days I visited her, and much to my astonishment found her engaged in making up her bed. I gave her particular caution for the future; and in twenty five days, she returned home as she came, in good health, which she continues to enjoy."

FIGURE 1.1 Ephraim McDowell (1771-1830), one of the earliest abdominal surgeons.

McDowell's patient long outlived her surgeon. He did not publish his feat until 1816, by which time he had performed several more oophorectomies. McDowell is sometimes cited as a pioneer of early ambulation, unwitting as it was in his case. If his sturdy patient had not recovered so well, her failure would surely have been blamed on rising too early from her bed after such extensive surgery. McDowell also did not mention the intense drama of this Christmas day operation. When the townsfolk of Danville heard about his plan, they were incensed. They gathered in a tense group outside his house, with a rope slung over a tree, ready to lynch the surgeon if his "experiment" proved a failure. McDowell certainly had the nature of a true pioneer.

T. G. Thomas, in his 1876 centennial review of obstetrics and gynecology, reported that Alexander Dunlap of Springfield, Ohio, claimed he did his first ovarian operation in 1843. Dunlap said he sent the report of this case to a medical journal, which sent it back to him saying that they "could not publish the case of such an unjustifiable operation."

By 1876, Thomas wrote, "It is to estimate the amount of good this operation has bestowed upon humanity.

Practiced today in every civilized country in the world, yielding the statistics of seventy to seventy-five per cent of recoveries, and daily being improved in its various steps, it may well be regarded as one of the greatest surgical triumphs of the century.”

In the middle decades of the 19th century, another American surgeon working in the South helped to popularize gynecologic surgery by another set of pioneering feats. James Marion

P.5

Sims (1813-1883) ([Fig. 1.2](#)) told the dramatic tale of his development of a successful technique to repair vesicovaginal fistulas in his widely read autobiography *The Story of My Life*, which was published the year after his death. He described his repeated attempts to achieve a permanent closure of these fistulas in a few of his young slave-women patients. Sims began his experiments in 1845 and continued them for 4 years. In these preanesthesia and preantiseptic days, Sims produced remarkable results. He had had no experience in pelvic surgery, and in fact claimed that he disliked it. It was his custom to turn away patients with pelvic disorders, referring them to other doctors in his Alabama neighborhood. Many of his planter friends owned slaves, some of whom suffered from vesicovaginal fistulas as a result of traumatic births. These wounds were considered incurable and made the young women unacceptable for household work. After several entreaties to help one of his planter friends who had such a slave, Sims began with a small group of women, operating on some of them repeatedly over the course of 4 years.

Sims' many failures only increased his determination to succeed. The colleagues who at first assisted him at the operations abandoned him, and his friends, he claimed, begged him to give up what was considered to be a hopeless effort. He trained other young slave patients to assist him, and on his 29th operation on one of the patients, he finally succeeded. In reviewing his work in 1852, Sims did cite several successful cases by other American surgeons between 1839 and 1849. He claimed originality for:

“1st. for the discovery of a method by which the vagina can be thoroughly explored, and the operation easily performed [the Sims, or lateral, position]. 2nd. For the introduction of a new suture apparatus, which lies imbedded in the tissues for an indefinite period without danger of cutting its way out, as do silk ligatures. And 3rd. For the invention of a self-retaining catheter, which can be worn with the greatest comfort by the patient during the whole process of treatment.”

The new “suture apparatus” used silver wire. This provided the breakthrough needed for the successful repair of vesicovaginal fistulas. Sims used silver in many of his other operations. In a 10th anniversary lecture at the New York Academy of Medicine in 1857, Sims somewhat immodestly told his august audience that the use of silver suture was one of the great achievements of 19th-century surgery. Sims wrote and spoke frequently about his development of a successful procedure for the definitive cure of vesicovaginal fistula, but never more eloquently than in his Anniversary Address in November 1857, in which he described his work with silver sutures over the previous 12 years. The audience included several past presidents of the academy and most of the distinguished colleagues at the Woman's Hospital. After 4 years of fruitless effort, Sims proclaimed a new dawn on June 21, 1849. Since that day, he claimed, he had used no other suture in any of his surgical work.

FIGURE 1.2 James Marion Sims (1813-1883).

It is worth noting that Sims' early patients—the slave women of Montgomery, Alabama, and the poor Irish servant girls who were predominant patients of the Woman's Hospital in New York—were equally vulnerable, so it is not hard to see why some recent historians have been very critical of Sims and his coworkers. Yet with the advent of anesthesia and the use of antiseptic techniques, such surgery became increasingly routine. The repair of vesicovaginal fistulas and the removal of ovaries for a wide variety of indications were the beginning of the field of operative gynecology as it is known today. The story is, of course, not purely an American one. The English, French, and German contributions were important and can be found in any general history of medicine or of obstetrics and gynecology. In 1876, Sims became president of the American Medical Association, and in the same year, he and others founded the American Gynecological Association.

Even with the advent of effective and relatively safe anesthesia after 1846, it was several decades before surgeons were ready to increase the number of their operations. At midcentury and during the Civil War in the 1860s, surgery was generally confined to amputations after accidents; hernia repair when the intestine became incarcerated in the hernia sac, thus threatening life; an occasional ligation of a major vessel for aneurysm; and cystotomy for bladder stones. Therefore, Sims, operating in the 1840s, was truly a pioneer.

Also pioneers in the field of gynecologic surgery by midcentury were the Atlee brothers of Lancaster, Pennsylvania. They rediscovered oophorectomy, which was also being done in England by the 1860s, and were among the early leaders who performed myomectomy for fibroid tumors of the uterus.

Of semantic interest is the changing terminology for ovarian surgery. *Ovariectomy*, often used imprecisely to refer to removal of the ovary, actually was first used in that way in the 1850s by James Simpson and other British gynecologists. Ovariectomy means to cut into the ovary for removal of a cyst or tumor. In the 1870s, gynecologists such as Edmund Peaslee of New York, in his book on ovarian tumors, stated that *oophorectomy* was a more precise and distinctive term for removal of the ovary.

John Light Atlee (1799-1885) actively practiced medicine for 65 years, during which time he performed more than 2,000 operations and attended 3,200 births. John Atlee performed 78 ovarian operations between 1843 and 1883, with 64 recoveries and only 14 deaths. Thus, he validated McDowell's work of the early part of the 19th

century. Atlee's younger brother, Washington Lemuel Atlee (1808-1878) ([Fig. 1.3](#)), also was involved in some of the ovarian cases but deserves separate credit for being one of the first to successfully treat the problem of uterine leiomyomata.

The Atlee brothers were relatively conservative gynecologic surgeons. It was their careful approach coupled with their obvious successes that gave other surgeons increasing confidence to operate. Thus, they played an important role in the early stages of operative gynecology as it developed into the

P.6

specialty it would become in the next generation. Ovariectomy, the most controversial of gynecologic procedures, was also the key to making it a surgical specialty. Indeed, some gynecologists claimed that operating for ovarian cysts and tumors laid the groundwork for all abdominal surgery in the last decades of the 19th century.

FIGURE 1.3 Washington Lemuel Atlee (1808-1878).

By the 1880s, the specialty of gynecology, or the science of women, as some historians have called it, was well on its way to being established as one of the subdivisions of medical labor. Ornella Moscucci, in her perceptive history of gynecology in Britain, quotes the eminent surgeon from Birmingham, Lawson Tait, in his aptly entitled book of 1889, *Diseases of Women and Abdominal Surgery*:

“The great function of woman's life has for years made her the subject of specialists, male and female, the obstetricians. The subsidiary relations of her special organs and the special requirements of her physique, based upon these, have necessitated the establishment of another class of specialist, the gynecologist.”

The evolving settings in which these surgical procedures were performed have a captivating history as well, from the table in the surgeon's home in which the first ovariectomy was completed on Christmas Day in 1809; through the operating rooms in the earliest Women's Hospitals in New York, Philadelphia, and Baltimore; and more recently to the safe, sanitary, and secure environment of an accredited, office-based gynecologic surgical facility, such as the one of the earliest of these venues developed by the author of this chapter some 20 years ago.

The scope of operative gynecology has evolved in a paradoxically undulating and intriguing manner as well. As the discipline of operative gynecology was unfolding in the 19th century, urogynecologic procedures were developed to treat vesicovaginal fistulas that defined and distinctively characterized the emerging discipline of surgical gynecology. These fistulas were sustained as complications of childbirth and were consequent to dystocia resulting from fetopelvic disproportion with protracted labor patterns, intrapartum fetal demise, and subsequent postpartum necrosis and sloughing of the vaginal and bladder walls prior to the development of modern operative obstetrics. As time passed, the operative urogynecology that heralded the early definition of surgical gynecology fell away from the discipline for more than 50 years in the 20th century, only to be reintegrated into operative gynecology by Dr. Jack Robertson (Fig. 1.4) more than 35 years ago. Although Dr. Robertson encountered considerable resistance on many fronts in his efforts to reintegrate urogynecology into operative gynecology, the overarching theme beyond technology that justified his efforts and sustained him through these controversies was his repeated and enduring emphasis on the historical aspects of the development of techniques for vesicovaginal fistula repair and for air cystoscopy by Drs. J. Marion Sims and Howard Kelly, respectively.

WOMEN AS PATIENTS IN THE 19TH CENTURY

The growth of interest in women's diseases began long before the 19th century. In the Renaissance, for instance, the publication of a large, encyclopedic work entitled *Gynaecia*, by Caspar Wolf (1532-1601), and later similar collections represented what had been written since antiquity. The mere existence of

P.7

such texts, however, does not mean that much attention was given to the treatment of women, except as it related to childbirth.

Any discussion of the treatment of women's diseases since the latter half of the 19th century must take into account a variety of interpretations of women's role in society and both professional and lay views of women's health. Historical assessments in our own time have contributed to the furthering of interest in the issues of women's health. Today's discussions are best understood in the light of their historical roots.

Historians of the family and the role of women in the 19th century have written much about the separate spheres for women and the cult of domesticity in which there was a rigid distinction between the home, where it was thought women belonged, and the economic world outside. Thus, the "cult of true womanhood," as historians have called it, made sharp distinctions between women's place in the family and the working world of men. As the social role of women was increasingly defined, they were, in a sense, held hostage in the home. Women were judged by the male world and themselves according to four cardinal virtues: piety, purity, submissiveness, and domesticity.

To these social distinctions between men and women were added the biologic differences. The biologic notions of women in the 19th century ranged widely, but they included the idea that women were not only physically weaker than men (although morally superior) but inherently diseased or pathologic. Their cyclical physiology was believed to make women unsuitable for sustained work or learning. Feminist historians of recent times have taken doctors of an earlier era to task for casting women as frail creatures entirely dependent on their biology, destined to be kept from the male world of education, politics, the professions, and any but domestic work. As Ornella Moscucci points out, however, the medical ideas about the social destiny of women were far more complex than has been assumed.

On both sides of the Atlantic, the view of Victorian women was influenced by the writings of eminent physicians. In Boston, a Harvard Medical School professor, Edward H. Clarke (1820-1877), wrote a book in 1873 entitled *Sex in Education; or, A Fair Chance for the Girls*. This book was widely reviewed and discussed. Similarly, Henry Maudsley (1835-1918) in England, an influential psychiatrist and medical teacher, also wrote about the supposed harm of higher education on the physiologic development of postpubescent girls. Clarke's book, which has become known as a uterine manifesto, clearly set the brain and the uterus in opposition. Higher education, Clarke claimed, might be good for developing the intellect, but that occurred at the expense of the reproductive organs, thus dooming the woman to a state of stunted womanhood and lifelong invalidism.

Sex in Education went through 17 printings and editions in the space of a few years. Because of its popularity and notoriety, it is worth citing one of Clarke's case reports:

"Miss D—went to college in good physical condition. During the four years of her college life, her parents and the college faculty required her to get what is popularly called an education. Nature required her, during the same period, to build and put in working order a large and complicated reproductive mechanism a matter that is popularly ignored—shoved out of sight like a disgrace. She naturally obeyed the requirements of the faculty, which

she could see, rather than the requirements of the mechanism within her, that she could not see. Subjected to the college regimen, she worked four years in getting a liberal education. Her way of work was sustained and continuous, and out of harmony with the rhythmical periodicity of the female organization. The stream of vital and constructive force evolved within her was turned steadily to the brain, and away from the ovaries and their accessories. The result of this sort of education was, that these last-mentioned organs, deprived of sufficient opportunity and nutriment, first began to perform their functions with pain, a warning of error that was unheeded; then, to cease to grow;... And so Miss D—spent the few years next succeeding her graduation in conflict with dysmenorrhea, headache, neuralgia, and hysteria.”

Many writings in the 1870s and 1880s attempted to refute the medical notions of physicians such as Clarke and Maudsley. In this country, Mary Putnam Jacobi (1842-1906), a physician and future champion of women in higher education and the professions, submitted a prizewinning essay that refuted Clarke's contentions that work by the brain interfered with uterine function and the menses. In Britain, the pioneer woman-physician Elizabeth Garrett Anderson (1836-1917) claimed that it was boredom that caused the medical symptoms of middle-class women, not higher education.

By the middle of the 19th century, even the use of the speculum as a diagnostic instrument stirred controversy. The speculum was known to the ancients, but it fell into disuse by the early modern period. Early in the 19th century, Joseph Recamier (1774-1852) reintroduced it in Paris, and soon the speculum was routinely used in treating inflammatory disease. It was also used in the routine examination of prostitutes in France and England.

In the Victorian climate of concern about women and their diseases, as well as their moral sensibilities, vaginal examinations were not routine. When they were performed, great efforts were made to preserve the patient's privacy and dignity, as the accompanying illustrations show ([Figs. 1.5](#) and [1.6](#)). A battle over the morality of the use of the speculum also ensued. The speculum, opponents of its use believed, could lead to sexual stimulation and sexual excesses. The term “speculum rape” was used in the debates over the Contagious Disease Acts in England in the 1860s.

Meanwhile, the surgeons went about debating the advisability of oophorectomy. One of the most prominent proponents of ovarian surgery for symptoms not just associated with demonstrable ovarian disease was an American surgeon named Robert Battey (1828-1895) of Georgia. In 1872, he removed the ovaries of a 32-year-old woman who had claimed invalidism for 16 years. Battey reported that his patient was cured after the bilateral oophorectomy. (Cured of *what* remains the intriguing question.) In succeeding years, the Battey operation became popular with some surgeons. Battey himself tried a vaginal approach to the ovaries but soon reverted to abdominal section. He advocated bilateral removal of the ovaries, whether or not they revealed any sign of disease, to ameliorate menstrual difficulties or psychological symptoms.

With historical examples such as the Battey operation, it is no surprise that feminist historians today level charges of male physicians' exploitation of their female patients. One of the most drastic charges claimed that most of the gynecologic surgery of the late 19th century was a calculated plot against women, a tacit conspiracy between insecure husbands and anxious gynecologists.

Ann Douglas, a literary historian and feminist, was one of the earliest to invoke the notion of a conspiracy of male physicians to subject their female patients to mutilating, harmful, and unnecessary surgery. She simply dismissed 19th-century doctors as ignorant because they did not receive the kind of medical training we have now come to take for granted. However, because the physician of 1870 did not yet have the understanding of physiology or pathophysiology enjoyed by his colleagues a century later, calling most earlier doctors ignorant, callous, or worse was not warranted.

FIGURE 1.5 This famous illustration of “the touch” in a gynecologic examination is from a 19th-century French text frequently used in America. Note the avoidance of eye contact between doctor and patient and the dress shielding the woman's body from view. (From Wertz RW, Wertz DC. *Lying-in: a history of childbirth in America, expanded edition*. New Haven, CT: Yale University Press, 1989:78, with permission.)

FIGURE 1.6 This 19th-century drawing illustrates another technique for preserving the patient's modesty: The doctor conducting a gynecologic examination looks directly into the woman's eyes to assure her that her private parts are safe from his gaze. (From Wertz RW, Wertz DC. *Lying-in: a history of childbirth in America, expanded edition*. New Haven, CT: Yale University Press, 1989:84, with permission.)

P.9

Those with a less conspiratorial view of history have shown that other views of both husbands and male physicians existed in the late part of the last century. The economist Thorstein Veblen, for instance, believed that nonworking wives served as status symbols for their husbands rather than as threats or temptations to eager surgeons.

Women learned and taught surgery, including gynecologic procedures, at the Women's Medical College of Pennsylvania from its founding in 1850. But it is also fair to say that there were few women actively practicing gynecologic surgery until well into this century. A notable exception was Mary Dixon Jones of Brooklyn, who by the 1890s had won respect from her male colleagues. Her story has recently been told by Regina Morantz-Sanchez, whose observations of Dixon Jones' career help us to understand how a woman made it in a man's world. Morantz-Sanchez, in her book about the libel trial of Dixon Jones in the early 1890s, charts the development of gynecologic surgery as a specialty. Dixon Jones was unusual because she was a successful woman-surgeon, but also because she was on the cusp of the developments in gynecology and its evolution from a field that viewed women in their social as well as their biologic roles to a 20th-century surgical specialty that concentrated on the pathology of diseased organs and the most appropriate and effective surgical techniques.

Morantz-Sanchez nicely illustrates this evolution of gynecology by framing the developments by the textbooks of Thomas Addis Emmet and J. C. Skene of the 1880s, still using the language of women as "other" than men, with the 1909 text of Howard Kelly and Charles Noble, *Gynecology and Abdominal Surgery*, in which there is no

discussion of women's social roles because the focus is on surgical technique. Thus, the language of medicine can be used to trace the changes in medicine itself.

THE RELATION BETWEEN SURGERY AND GYNECOLOGY

The complex relation between general surgery and gynecology played a continuing role in the professional definition of gynecology as a 20th-century specialty. Moreover, several important contributions to surgery, such as chloroform anesthesia, rubber gloves, and early ambulation, were influenced by gynecologists as well as surgeons. The latter two items are discussed subsequently.

By 1905, the Chicago gynecologist Franklin H. Martin (1857-1935) was convinced that the three closely allied fields— surgery, gynecology, and obstetrics—were making sufficient progress to warrant a new journal. There was a shared feeling, Martin wrote in the opening editorial of *Surgery, Gynecology, and Obstetrics*, "... that the field of the three allied specialties represented by its title is not over-cultivated, and that there is already a place for a creditable magazine representing in one publication these three divisions of surgery."

Another of the founding editors of the journal, the gynecologist J. Clarence Webster, wrote a provocative editorial in the first issue on "The Future of Gynecology." Webster firmly laid to rest an idea that had gained some acceptance by 1905—that gynecology was doomed to extinction, to be gradually merged with the practice of the general surgeon. Webster assured his readers that contrary to what some had claimed, much advance had occurred in the preceding decades, and, moreover, "... it is very evident that almost all the important advances have resulted from the work of men who have given their entire energies to the specialty. At the present day the leading authorities everywhere are those who still limit their attention to this sphere of work."

In a programmatic statement to the American Gynecological Society in 1920, Robert L. Dickinson (1861-1950) contended that gynecologists promote surgery. "But if we be just surgeons, by surgeons we may be displaced." In this presidential address to the society, Dickinson claimed that gynecologic procedures constituted one fourth of all surgery, but this hardly accounted for the extent of the field, "... since operation is needed by less than one-tenth of the patients that come to the doctor for ailments peculiar to women (childbearing not included)." It was true, of course, that for much of the preceding century, gynecology was a medical rather than a surgical discipline, often taught in medical schools as part of the course on diseases of women and children.

In the early decades of the 20th century, the professional battles between the general surgeons (who increasingly dominated the field of abdominal surgery) and the gynecologists (who wished to lay claim to the same territory) waxed and waned. Dr. Howard Longyear of Detroit noted in 1917 that general surgeons tended to scorn the area of the pelvis, whereas this area was being increasingly perfected by gynecologists. These surgeons wanted to move upward in the body from surgery of the female genitalia and the pelvis to the abdomen. Longyear also noted that the Sims operation for vesicovaginal fistula did more to establish operative gynecology as a specialty than did any other single procedure or development.

The complex relations between surgery and gynecology also can be traced by following the name changes in the American Medical Association specialty section. In 1903, at its founding, it was called Section on Obstetrics and Gynecology. From 1912 until 1936, it was called Section on Obstetrics, Gynecology, and Abdominal Surgery. Then the name was changed once again, dropping the abdominal surgery component.

One area of joint progress forged by surgeons and gynecologists was the introduction of the use of rubber gloves, which helped to expand the work of all surgeons. The idea of using some form of protective covering for the surgeon's hands occasionally appeared in the medical literature in the early decades of the 19th century, but it was not until the end of the century that some of the associates of Dr. William S. Halsted (1852-1922) at the Johns Hopkins Hospital in Baltimore began to use gloves routinely. About two decades after their introduction, Dr. Halsted recalled the story:

In the winter of 1889 and 1890—I cannot recall the month—the nurse in charge of my operating room complained that the solutions of mercuric chloride produced a dermatitis of her arms and hands. As she was an unusually efficient woman, I gave the matter my consideration and one day in New York requested the Goodyear Rubber Company to make as an experiment two pair of thin rubber gloves with gauntlets. On trial these proved to be so satisfactory that additional gloves were ordered. In the autumn, on my return to town, the assistant who passed the instruments and threaded the needles was also provided with rubber gloves to wear at the operations. At first the operator wore them only when exploratory incisions into joints were made. After a time the assistants became so accustomed to working in gloves that they also wore them as operators and would remark that they seemed to be less expert with the bare hands than with the gloved hands.

I think it was Dr. Bloodgood, my house surgeon, who first made this comment and that he was the first to wear them invariably, when operating. ... Dr. Hunter Robb in 1894, in his book on aseptic technic recommended that the operator wear rubber gloves. Dr. Robb was, at that time, resident gynecologist of the Johns Hopkins Hospital and had frequent opportunities to observe the technic of the surgical clinic.

Gynecologists were also closely involved in the form of postoperative care we have now come to take for granted: early ambulation after surgery. With the change from 2 or 3 weeks of enforced bed rest after surgery to active ambulation within a few hours of the operation, we have improved recovery,

P.10

shortened hospital stays, and reduced costs, as well as postoperative complications. But like all new techniques or practices, early rising after surgery did not win rapid acceptance.

Ephraim McDowell's patient in 1809 not only was ambulant early but also engaged in physical tasks such as making her own bed. Her surgeon clearly was not pleased with her activity, which was not in keeping with customary and usual practices of the day.

What we call early ambulation was not found again in the medical literature until the very last year of the 19th century, when Emil Ries, a professor of gynecology in Chicago, published a landmark paper, which soon disappeared from view. It was rediscovered four decades later. Ries noted in his 1899 paper that he wanted to change treatment radically by freeing patients from "... many irksome and disagreeable features of convalescence following vaginal and abdominal surgery." Ries found that his patients could be fed and allowed out of bed much sooner than was the usual custom. "Very soon I found," he wrote, "that the period for which it was advisable to confine such cases to bed could be counted by hours instead of days, so that of late I have allowed my patients to get up within twentyfour to forty-eight hours and to leave the hospital four to six days after their vaginal celiotomy." These patients, Ries also noted, did not have the listlessness or muscular weakness that was usually seen after 2 or 3 weeks in bed.

In the preoperative preparation of his patients, Ries also went against the usual custom of completely emptying the bowel. Most textbooks, he said, claimed that early action of the bowels helped to prevent peritonitis. However, in most patients with an empty intestinal tract, regular movements did not resume until after they were eating a regular diet. Ries maintained that cause and effect were confused because it was not movement of the bowels that prevented peritonitis, but freedom from inflammation that allowed the bowels to move.

At the meeting of the Southern Surgical and Gynecological Society in Baltimore in 1906, H. J. Boldt described 384 cases of early ambulation that he had accumulated since 1890. All recovered well. Ironically, Boldt reported, the most serious objection raised by his colleagues was that early ambulation increased the risk of thrombosis. This was clearly wrong, he said, from both a theoretic and an empirical point of view, because his patients had

better circulation from exercising.

Early ambulation was discussed repeatedly in the succeeding decade, but it received far from universal acceptance. Even Howard Kelly, the country's leading teacher of gynecology, noted in 1911 that great progress was made as a result of Boldt's and Ries' work, but that it was far from standard practice. Early ambulation really became a routine practice with the exigencies of World War II (which resulted in a shortage of hospital personnel) and with the work of Daniel J. Leithauser, a general surgeon from Detroit who rediscovered Boldt and Ries. Although doctors may not have prescribed early ambulation, as in the case of McDowell, patients probably were up and about far more often than we realize. Dr. Bert Dunphy of San Francisco told me that when he had a hernia repair while he was a house officer at the Peter Bent Brigham Hospital in 1938, his surgeon prescribed strict bed rest after the operation. Dunphy was up on the first day and thereafter and felt perfectly well, if a bit guilty.

GYNECOLOGY IN THE 20TH CENTURY AND DR. TE LINDE'S BOOK

In the 1890s, when Thomas Cullen (1868-1953) was a medical student in Toronto, he recalled that "... there were anteversions, anteflexions, retroversions, and retroflexions and that some of the displacements might be relieved by appropriate pessaries." Abdominal gynecologic operations, Cullen continued, "... were limited almost entirely to the removal of large ovarian cysts. An occasional myomatous uterus was removed, but the fatality in this class of cases was so high that the operation was rarely attempted." Cullen also said that he did hear of cancers of the uterus in his student days, but only cauterization or curettage was performed. Entire removal of the uterus was not yet being done.

By the turn of the 20th century, the leadership of gynecology in this country had clearly moved to the new Johns Hopkins Hospital, where Howard A. Kelly (1858-1943) ([Fig. 1.7](#)) began to train a series of young men who put gynecology on a strong academic footing in the next two generations. Kelly received both his bachelor's and medical degrees from the University of Pennsylvania. After his medical graduation in 1882, Kelly spent some time in Germany learning the latest surgical and pathologic techniques.

Like President Theodore Roosevelt, who, for similar reasons, journeyed to the North Dakota Badlands to invigorate himself and to regain his health, he journeyed west to Colorado and worked as a ranch hand and cowboy on the OZ Ranch in Elbert County.

While at the ranch, he had an intense religious experience and life-defining moment, one that his medical and surgical colleagues could not understand, which he later described in *A Scientific Man and the Bible*:

"In the midst of the cold and lonely winter far out in the plains, I had a never-to-be-forgotten experience one day during one of Colorado's three-day blizzards, while I was bedfast with snow blindness from glare of the sun on the snow striking unprotected eyes. There came, as I sat propped up in my bed, an overwhelming sense of a great light in the room and the certainty of the near presence of God, lasting perhaps a few minutes and then fading away, leaving a realization and a conviction never afterwards to be questioned in all the vicissitudes of life, whatever they might be, a certainty above and beyond the process of human reason" ([Fig. 1.8](#)).

FIGURE 1.7 Howard A. Kelly (1858-1943). (From Davis AW. *Dr. Kelly of Hopkins*. Baltimore, MD: The Johns Hopkins Press, 1959.)

P.11

FIGURE 1.8 Dr. Howard A. Kelly and other ranch hands at OZ Ranch in Elbert County, CO, 1880. (From Allen P, Setze T. Howard Atwood Kelly, M.D. (1858-1943): his life and his enduring legacy. *South Med J* 1991;84:361.)

After a year in Colorado, his health restored, Kelly returned to Philadelphia to complete his medical studies. He was awarded the Doctor of Medicine degree on March 15, 1882. He took his internship in the Episcopal Hospital in Kensington, a working-class district of Philadelphia, and subsequently established his practice there. He founded the Women's Hospital of Philadelphia there in Kensington. It was during this period that he first attracted the attention of Sir William Osler. When a woman in the medical ward died of nephritis, Kelly, being doubtful of obtaining permission for autopsy, stealthily went to the morgue and extracted the kidneys through the vaginal vault. Osler, himself a pathologic anatomist in Montreal, heard about the method and thereafter followed with interest the career of the young surgeon.

By this time, Dr. William Osler had moved from Montreal and accepted a position at the University of Pennsylvania in Philadelphia, providing an opportunity for closer observation of Kelly. Osler often visited the Kensington Hospital to watch Kelly operate, and he is said to have remarked that he had never seen a more skillful surgeon. When the position of assistant professor of obstetrics and gynecology came open at the University of Pennsylvania, Osler recommended Kelly and at that time dubbed him the “Kensington colt” because he was only 31 years old and was a “dark horse” to obtain the appointment. The trustees did accept Osler's recommendation and give Kelly the position, but he was there only about a year before events led him elsewhere.

Meanwhile, plans were being made in Baltimore to use the millions left by a wealthy philanthropist, Johns Hopkins, to establish a university and hospital. In 1884, Dr. William Welch was called from Bellevue in New York to take the chair of pathology. At his urging, Dr. William Osler was brought down from Philadelphia to head the department of medicine, and Dr. William Halsted was appointed to the chair of general surgery. Again, Dr. Osler used his influence with the trustees of the new institution to insist that Kelly be offered the position of professor of obstetrics and gynecology. Kelly was enthusiastic about working with those renowned physicians and starting his own department, but he had misgivings about a department of obstetrics and gynecology. Kelly did not like the practice or teaching of obstetrics, and his goal was to divide the chair so that he would become professor of gynecology.

In 1886, Kelly made the first of many trips to Europe to study under the great physicians there. In Leipzig, Max Saenger demonstrated the practicability of palpating female ureters in their lower pelvic portions. In 1888, Kelly dissected cadavers under the direction of Dr. Rudolf Virchow in Berlin to study the anatomic relations of the ureters and to attempt to determine the most efficacious method of ureteral catheterization.

At age 31, the youthful-appearing Kelly, who many patients thought was still a student or resident, initiated a residency program in gynecology with a strong link to the pathology department. Even more than half a century later, the leading texts in the field—*Eastman's (Williams') Obstetrics*, *Te Linde's Operative Gynecology*, and *Novak's Gynecologic and Obstetric Pathology*—were written by professors in Baltimore who had received their training at Hopkins with Kelly and his assistants.

Kelly soon found that his interests and skills were in gynecologic surgery; therefore, he turned the obstetric service over to J. Whitridge Williams (1866-1931), who became a leader in that field and the author of the most widely used textbook of the time. Kelly had a great interest in the female urinary system, realizing that the symptomatology of urinary tract disease is often intertwined with that of the reproductive organs. He invented the air cystoscope and devised ureteral

catheters. He was the first to plicate the vesical sphincter for stress incontinence of urine. Physicians from all over the world came to Baltimore to watch him operate (**Figs. 1.9** and **1.10**).

FIGURE 1.9 Dr. Howard A. Kelly's operating room at the Johns Hopkins Hospital. To the left is the door to the corridor. In the center is the door to the ether room. The rubber pad was used for drainage during irrigation of the abdomen. A similar pad was developed by Dr. Kelly for drainage of blood and amniotic fluid during and after a vaginal delivery.

Kelly's legendary operative skill was well described by Cullen, who later became one of Kelly's outstanding residents and successors to the chair at Hopkins. Kelly and Hunter Robb, his earlier resident, went to the Toronto General Hospital not long after Kelly became chief at Hopkins. Cullen was an intern in Toronto at the time and handled the instruments during an operation that Kelly and Robb had agreed to perform. Cullen's description speaks for itself:

I turned around to thread a needle and when I turned back found to my amazement that the operator had the abdomen open. Operators in the General often took ten minutes to get that far. After cutting through the skin, fat and fascia they were apt to get lost in the muscles. Kelly and Robb working together used dissecting forceps as I had never seen them used. One man pulling each way, the cleavage between the muscles was seen at once and the opening in the abdomen could be completed without difficulty. I watched, fascinated, while Kelly went ahead and finished that operation and did the second, working with clock-like precision and at a speed I had not imagined possible. By the time he had finished, the course of my professional life was decided. Up to that afternoon I had intended to be a physician. From that afternoon I knew I had to be a surgeon.

FIGURE 1.10 Howard Kelly operates. Grouped about the operating table, left to right, are Emma Beckwith, head nurse, Jay Durkee (*seated*), Thomas S. Cullen, Max Brödel (*center*), Elisabeth Hurdon, J. E. Stokes, and John G. Clark. (From Davis AW. *Dr. Kelly of Hopkins*. Baltimore, MD: The Johns Hopkins Press, 1959.)

Chance often determines the course of one's life, so it was fortunate for Cullen that he had to wait 6 months for his residency with Kelly to start. He used this time to begin the study of pathology with William H. Welch at Hopkins, and it was the close alliance of gynecology and pathology, begun by Kelly and continued by Cullen, that shaped the careers

P.13

of many future gynecologists at Hopkins and elsewhere and determined the course of the field itself.

In 1898, Kelly published a two-volume textbook called *Operative Gynecology*, certainly the direct ancestor of the volume you have in your hands. Kelly wrote in the preface, "My aim in writing this book has been to place in the hands of the many friends who have from time to time visited me and followed my work, a convenient summary of the various gynecological operations I have found best in my own practice."

Although gynecology at the end of the last century was still a very young science, in Kelly's words, change was at hand: "Although I have spent several years in the preparation of my book, so rapid have been the changes in the gynecological field that I have found it necessary to rewrite some of the chapters two and even three times." A little more than a dozen years later, in the preface to his text entitled *Medical Gynecology*, Kelly reiterated the pace of the changes: "What a transformation two generations have witnessed in the field of gynecology! From modest beginnings, as a sort of minor specialty coupled with diseases of children and often professed by general practitioners with no special training, it has grown to the dignity of a major surgical specialty, so extensive that many gynecologists of today (1912) claim the entire field of abdominal surgery as their proper domain by right of discovery and conquest." This was also a time when radical or complete removal of tumors and repair of hernias became increasingly common. Kelly and his residents were pioneers in radical hysterectomy when Hugh Young of Hopkins introduced radical prostatectomy.

Summarizing Kelly's surgical innovations, Audrey Davis wrote:

"In the first place, he developed a combined vaginal and abdominal method of examination, perfected and carried out with unusual expertness the common plastic repairs, and successfully operated through the abdomen. His suspension of the retroflexed

uterus was a signal innovation of the day and of this period of his development in surgical methods. Second, he early turned his attention to the urinary tract and began what he later considered his most important contributions to his specialty.”

When Kelly heard about the discovery of radium by the Curies in Paris in 1898, he associated this with the problem of malignancy, and he determined to obtain some of the material for the treatment of cancer. In 1904, he bought a small tube containing a few milligrams of radium and began to use it in the treatment of small external lesions. He continued to experiment with the treatment and determined to acquire more radium. In 1913, he went to Colorado to study methods of extracting radium from carnotite deposits there.

His rapid acceptance of the new treatment brought him much criticism, and he was called a quack not only by the lay public but also by some of his medical colleagues. In 1913, his friend Dr. William Mayo defended him in a letter:

“Don't you fret about what they are saying about you and radium. Your friends know what you are trying to accomplish and with your energy, persistence, and great intelligence you will succeed. But no man has tried to do something that is different from that of the average man without being subjected to abuse and criticism. It is a curious phase of human nature to attack what it does not understand. So do not think about it again.”

From 1917 on, the Howard A. Kelly Hospital on Eutaw Street in Baltimore had 5 1/2 g of radium, said to be the largest amount available at that time in any clinic in the world. That hospital was the first to use radium in packs at appreciable skin distances, the first to use a teleradium apparatus, the first to establish a large radon plant, and the first in Baltimore and one of the first in America to install an apparatus for deep x-ray therapy. For years, the Kelly Hospital administered all of the radiation for patients at Johns Hopkins and did most of the radiation work in Baltimore and the state of Maryland.

Remembering the dry lectures of his medical school days, Kelly determined to teach by demonstration and by allowing his residents the widest possible latitude in caring for their patients under his supervision. According to Harvey:

“Kelly's postgraduate discipline by means of this long-term residency was an entirely new concept in surgical training at that time. Each year the assistant residents were given increasing responsibilities in the care of patients and in procedures in the operating room. Surgery upon the ward patients was done almost exclusively by the resident and his assistants, subject to consultation and help when necessary by the senior staff. ... Judging by the quality of his many residents, one may wonder whether this was not his greatest contribution to his specialty” (Fig. 1.10).

Dr. William T. Howard, Jr., one of Kelly's residents, described his method of instruction in the operating room:

“In the new B operating room, while assistants looked after anesthetizing and otherwise preparing the patient for operation, Kelly gave the history of the patient's illness, the results of the physical examination and laboratory tests, the diagnosis, and proposed procedure. When all was in readiness, operator and assistants in position, Kelly, glancing at the large wall clock, announced the time and began. Throughout operation, in a running talk, he described each procedure, and in abdominal cases what he found, and what he intended doing at each step and why. Whenever practicable, he let the students and

visitors view each step. The operation completed, Kelly again glanced at the clock and announced the time. Often after operation, he would go to the blackboard and using both hands rapidly sketch and describe just what he had found and what he had done.”

Because he did so much medical writing, Kelly saw the need for photographs to illustrate the procedures he wanted to teach. In Baltimore, he found an excellent photographer, Anthony Murray, who filled a large folio with some 1,500 photographs of operations. Kelly then devised what he termed the “stereogram,” a photograph of each step in an operation with the written text describing it. He and his photographers then took great pains to make the stereograms as complete and as perfect as possible. He traveled to Europe to photograph the procedures of the great surgeons there. Often, it was necessary to wait for years for a particular operation. He published the stereograms in book form starting in 1908 and titled them *The Stereo Clinic*.

At times, however, the nature of the subject demanded a drawing rather than a photograph. Kelly had had a facility for sketching since childhood, and he always used his own drawings for teaching his students. When he saw the need for more elaborate illustrations for his publications, Kelly determined to obtain a medical artist for Hopkins. He heard about an artist, Max Brödel, then working in Germany. After a campaign of several years' duration, he succeeded in 1894 in bringing Brödel to Baltimore and installing him as a resident at the Johns Hopkins Hospital ([Fig. 1.11](#)).

The spectacular results of the collaboration between Kelly and Brödel are described by Davis: Four years after Brödel began work at Hopkins, Kelly's two-volume work *Operative Gynecology* (1898) appeared. Not only did these volumes proclaim to the world Dr. Kelly's leadership in gynecology, but they introduced to medical circles the illustrations that revolutionized medical illustration.

Some years later, the Department of Art as Applied to Medicine was established in the Johns Hopkins University School

P.14

of Medicine. It was the first department of its kind in the world and continues to the present.

FIGURE 1.11 Max Brödel. (From Robinson J. *Tom Cullen of Baltimore*. New York: Oxford University Press, 1949, with permission.)

At a testimonial dinner on Kelly's 75th birthday, Brödel described Kelly's method of teaching the illustrators:

“A clear and vivid mental picture always must precede the actual picture on paper. The planning of the picture therefore is the allimportant thing, not the execution. This is where we learned from Dr. Kelly. He had a way of making little modest outline sketches when he explained his operative procedure to his illustrators.... He invented diagrams to show variations of form and relationship, motion, pressure, tension, rupture, the development of a pathological process, the sequence of operative steps, the placing of ligatures, sutures, etc.; in short, every clinical phenomenon, every operative procedure flowed in simple, eloquent lines from the end of his pencil. ... Dr. Kelly always permitted the artists to make original investigation to clear up the obscure point. ... Without his sympathetic attitude we could not have learned our trade as we did.”

Kelly's brilliant 30-year career as the head of gynecology at Hopkins was equaled by his prominence in other fields of endeavor. He became a civic leader in Baltimore, at one time running for public office. His special crusades were against alcohol, tobacco, prostitution, and political corruption. He was a devout Christian and Bible scholar, reading the Bible in the original Greek and Hebrew. He never lost his early interest in natural history, and he became an authority on herpetology, mycology, and lichenology. He was ahead of his time as an environmentalist and bought wilderness land in Florida and Canada for preservation. He gave the land in Florida to the state, and it is now Kelly Park in Orange County.

As long ago as 1900, in his classic text, *Cancer of the Uterus*, Thomas Cullen, student of and successor to Kelly (Fig. 1.12), wrote that “The number of cases of cancer of the genital tract coming too late for operation is so appalling that the surgeon is ever seeking to devise ways and means by which the dread malady may be more generally detected at the earliest possible moment—at a time when complete removal of the malignant tissue is still possible. ... But since it is the general practitioner who, as a rule, is the first consulted, upon him largely falls the responsibility of arriving at a timely diagnosis.”

FIGURE 1.12 Thomas S. Cullen (1868-1953). (From Robinson J. *Tom Cullen of Baltimore*. New York: Oxford University Press, 1949, with permission.)

One of the greatest advances in gynecology in this century has been the improvement in the early detection and cure rate of cancer of the uterine cervix that has resulted from the development of cytology and the recognition of carcinoma in situ. In 1943, George N. Papanicolaou (1883-1962) and Herbert Traut (1894-1963) published their seminal monograph entitled *Diagnosis of Uterine Cancer by the Vaginal Smear*. Papanicolaou had worked on this technique since the 1920s, but, like many other innovations in medicine, it took years to find widespread acceptance. Further publications by Papanicolaou and others, notably Ruth Graham, demonstrated beyond a doubt that cytologic studies could almost infallibly detect cervical cancer.

Cancer in situ was recognized early in the century by Cullen and in 1912 by J. Schottlander and F. Kermauner, but its relation to invasive cancer was not well understood. This relation was more clearly described in 1944 by G. A. Galvin and Te Linde in several reports. Since then, the relation has been amply confirmed, and early cervical cancer has become a detectable and curable disease. Since its inception by Hans Hinselmann in Germany in the 1920s, colposcopy has given a new dimension to the assessment of cervical carcinoma, making blind, random cervical biopsies unnecessary and providing more accuracy in finding and treating localized lesions.

By the early 1970s, the editor of a new journal, *Gynecologic Oncology*, pointed out that "... the scientific importance of gynecologic oncology may be gained from the observation that the tumors that we study and treat are prototypes for cancer in other areas of the body, for the histogenesis of the two principal uterine cancers is probably understood better than that of any other tumor in the body."

The immediate post-World War II years were a period of truly astounding medical developments and saw the explosive growth of medical research funding and new hospital construction. After 1945, penicillin became available for civilian use, and this was soon followed by other antibiotics. Hormone replacement became increasingly possible, and in 1946, the year that Richard Te Linde published the first edition of this textbook, Congress passed the Hill-Burton Act, making federal funds available to localities for the construction of new hospitals. These and other developments of the time greatly changed and expanded the work of medicine.

P.15

THE BEGINNING OF THE ERA OF LAPAROSCOPY

Although the emphasis of this historical chapter is on developments before the introduction of laparoscopy, the ability to visualize and subsequently to intervene by the less invasive laparoscopic technique surely represents an important milestone in the history of operative gynecology. The details of the history of the various endoscopic possibilities are discussed in the chapters devoted to these techniques, but a few general historical reflections may be in order at this point.

Laparoscopy seems to have been developed more or less independently in the United States and in various countries in Europe. In 1911, Bertram Bernheim, a general surgeon at Johns Hopkins, reported two cases in which, through a small abdominal incision, he introduced a proctoscope to examine the upper abdomen in a procedure he called organoscopy. The source of the illumination was an incandescent light on a band around his head. The experience must not have been satisfactory, as there were no follow-up reports.

In the mid-1930s at the same Johns Hopkins, in a trial of a small series of patients that was never published, Richard Te Linde introduced a Kelly air cystoscope into the abdomen through a small subumbilical incision with the patients in a deep Trendelenburg position. The Kelly air cystoscope was simply a 10-cm-long tube, which came in various diameters up to 2 cm, with a flange at the distal end and a suitable handle. It was routinely used at Hopkins to examine the bladder. The patient was in the knee-chest position for the cystoscopic examination. The bladder distended with air and when the obturator, which normally was also a part of the instrument, was removed. The light source was an incandescent bulb placed just above the patient's buttocks and a conical head

mirror with a central hole to direct the light along the line of site. The illumination was very good with this technique. Although the pelvic organs could be seen with the introduction of the cystoscope into the abdomen, the area of inspection was so small that the concept was abandoned.

It is curious indeed that Te Linde apparently did not think of introducing the cystoscope through the posterior fornix with the patient in the knee-chest position, especially as this was the exact position used to cystoscope the bladder with the Kelly cystoscope and was a technique commonly and frequently used at Johns Hopkins during this era. At that time, female urology was part of the division of gynecology.

It remained for Albert Decker with T. H. Cherry to use the knee-chest position to introduce a lens cystoscope with a miniaturized incandescent bulb at the tip through the posterior fornix to visualize the pelvic organs. Thus, culdoscopy was born and was widely used in the United States during the era of 1950 to 1970, especially after the adoption of the fiberoptic cold light system, which gave far better illumination than the miniaturized incandescent bulb. During this era, it was not unusual at Johns Hopkins to have five or six patients per day listed in the operating room for a culdoscopic examination.

After about 1970, laparoscopy, with its fiberoptic cold light system, superseded the culdoscopic approach. About this time, operative laparoscopy blossomed, and one of the first widely used procedures was the ligation of the fallopian tubes by various techniques.

In Europe, in contrast to the United States, there was no great use of the culdoscope. The development of observational and operative laparoscopy continued uninterruptedly from about 1912, when, according to Cohen, the Swedish Hans Christian Jacobaeus described 109 laparoscopies in 69 patients using an electric cystoscope.

As previously mentioned, the historical details of procedures are included in the appropriate chapters. However, two general observations may be made.

First, developmental progress in endoscopy of the abdominal cavity has been a function of development of the physical sciences: optics, mechanics, electronics, etc. Thus, the current popular robotic laparoscopic procedures result not only from medical ingenuity but from the participation of the capitalistic industrial complex. The consequence of this is that the use of the laparoscopic instrumentation is greatly encouraged by commercial interests. The danger is—if there is a danger—that physicians may be unduly influenced by commercial as opposed to scientific priorities.

Second, the laparoscopic operative procedures have been widely adopted, often without randomized clinical trials to scientifically define and evaluate their role in operative gynecology.

These two points are made as an observation and not necessarily as a criticism, as the advantages of a shortened hospital stay and less patient discomfort are obvious. However, the fact is that there are few data on the short- and long-term results that are designed to evaluate results from laparoscopy with alternate procedures. The adoption of laparoscopic operative procedures progressed in spite of the recent emphasis on the importance of evidence-based medicine. Rock and Warshaw have elaborated on this aspect of operative laparoscopy.

Knowledge of the history of operative gynecology is not only of intrinsic interest but also allows us to appreciate our innovative predecessors and may stimulate some of us to be the subject of future historians.

OPERATIVE GYNECOLOGY, FIRST EDITION, 1946

Richard Wesley Te Linde was born in Wisconsin in 1894, and, except for the years that he attended a small liberal arts college in Holland, Michigan, he spent all his formative years in Wisconsin. When he was ready to go to medical school, he went to Madison, but in 1916, the University of Wisconsin had only a 2-year school. Te Linde completed the 2 preclinical years and then transferred to Johns Hopkins for the final 2 years. He

graduated with the class of 1920 and spent the rest of his professional career associated with Hopkins, where he became chief of the gynecology division of the department of surgery and then chair of the separate department of gynecology in 1939. He held that post until his retirement in 1960, when the newly reunified department of obstetrics and gynecology was reestablished.

Just as his teacher Howard Kelly had felt the need to compile a textbook of operative gynecology half a century earlier, Te Linde believed that the many-sided specialty that gynecology had become by World War II required a new text. With Kelly's earlier text as a model, Te Linde wished to incorporate the vast changes that had occurred in the period separating the two books. During this 50-year span, there were changes in our knowledge of hormones, new surgical techniques, and the ability to visualize the abdominal and pelvic organs.

Te Linde chose the same simple title for his own text. Although Kelly's had been published by Appleton in New York, Te Linde chose Lippincott in Philadelphia. Gynecology, Te Linde wrote in the preface in 1946, was no longer to be considered simply a branch of general surgery. The gynecologist, he stressed, must still be a good surgeon but must also master the pathology of gynecologic disorders and the newly burgeoning field of endocrinology. New books were appearing in all these fields except gynecologic surgery, and it was this void that Te Linde wished to fill.

P.16

Te Linde wrote his text with the "... primary purpose of describing the technique of the usual and some of the rarer operative procedures. It also includes indications for and against operations as well as pre- and postoperative care of patients." Gynecologic pathology, Te Linde stressed in the Hopkins tradition, is the bedrock of good gynecologic surgery. "Without an understanding of it, surgery becomes merely a mechanical job, and errors in surgical judgment are inevitable." In the organization of his text and in the subsequent editions over the succeeding half century to the present edition, one can readily see important landmarks in the history of operative gynecology. Some of these were discussed in a previous section.

The 751-page first edition of 1946, all of it written by Te Linde, had a first printing of 5,000 copies, which quickly sold out. A second printing was equally successful. The reviews have always been laudatory. Of the sixth edition of 1985, edited by Richard Mattingly and John Thompson, the *Journal of the American Medical Association* reviewer ended by saying, "I cannot imagine any gynecologist who performs surgery doing without it, first as a primer and then as a reminder." By 1962, when the third edition appeared and Te Linde had retired from the chairmanship of his department, he decided that, like all the other major medical textbooks of the time, his book needed a group of authors to bring out new revisions. In the preface to that edition, he states that his book has never been simply a manual of surgical technique—that surgical philosophy is equally important. "What does it profit a woman if the operation is technically perfect and the procedure unnecessary or even harmful?" One reason unnecessary procedures still prevailed, Te Linde noted, was the lack of knowledge of gynecologic pathology, still the "bedrock upon which good surgery is done." Therefore, Te Linde justified including a considerable amount of pathology in his text. Pathology is what has differentiated gynecologic surgery from general surgery since Howard Kelly's years at the turn of the 20th century. Surgical texts, and by implication their surgical readers, have generally not devoted nearly as much attention to pathology as have gynecologists, some of whose leaders have actually been very well versed in pathology.

The fact that Te Linde could produce three editions, each larger than the first, is a testament to his broad knowledge of his field, his ability as a writer, and his stamina for hard work. He died in Baltimore in 1989 at the age of 95.

In the decades since the third edition of 1962, the world of medicine and the society in which it is practiced have seen much change. By the mid-1960s, when significant advances in the treatment of infections, malignancies, and hormonal disorders had become evident, these successes had an impact on gynecology just as they did in

other areas of medicine. The reduction in mastoid infections, for instance, has changed the practice of the otolaryngologist considerably. In gynecology, the reduction in major pelvic inflammatory disease forced gynecologists to focus more of their attention on other disorders. Also affecting gynecologic surgery by the middle of this century were significant improvements in obstetric practices, which sharply reduced injuries to the bladder and rectum. Hysterectomies and suspensory operations were not performed for vague symptoms of illness as often as they had been.

We have also lived through social revolutions that have changed the way our society carries on its business and dispenses its social prerogatives. Especially prominent in the 1960s, a civil rights movement, greater concern for our environment, a resurgence of consumer rights, and a revitalized women's movement profoundly affected our social institutions, including medicine. Within medicine, no specialty has been more touched by these trends than obstetrics and gynecology.

The new feminism viewed abortion, childbirth, contraception, and gynecologic surgery as a means of social control of female patients by doctors, most of whom were men. The feminist movement challenged not only the domination of doctors but also the supposed benevolence of their knowledge and practices.

As the world has changed, so have our expectations. In the decades after the first edition of Te Linde's book appeared, when wonder drugs were touted as curing previously untreatable illnesses, the public began to expect much from its doctors, and we were not shy in claiming that ever-greater investments in medical research would lead to more cures. It is hardly surprising, then, that in these last few decades, as we began to spend increasing amounts of our gross national product for health, those who paid the bill became increasingly interested in seeing just what their money was actually buying. Like most other social institutions, medicine lost much of the autonomy it had for so long taken for granted. Although as a profession we did not always get all we wanted, we were for decades amazingly adept at preventing those things we did not want. Now, that, too, has changed, as has the practice of medicine.

The division of labor in all areas of medicine grew as the 20th century progressed. In the last decades of the century, what used to be called general practice became the specialty of family practice. In the Anglo-American world of the late 20th century, both obstetrics and gynecology were caught in the middle of the battles between specialists and generalists. Likewise, they became involved in the tensions among primary, secondary, and tertiary medical care. Similar strife occurred in earlier centuries among those vying for a place and for status among physicians caring for women in childbirth and in disease. If one looks at the table of contents of this edition and compares it with a simpler period of half a century or a century ago, one will see what great breadth the field of operative gynecology continues to enjoy.

BEST SURGICAL PRACTICES

- As Dr. Ignaz Semmelweis taught us, hand hygiene was and still is an important principle of antisepsis and infection control and prevention. Hand hygiene surveillance studies continue to show that there are opportunities for improvement in following nationally recognized guidelines for hand hygiene in all health care professionals, including gynecologic surgeons.
- Controversy and criticism inevitably follow the discovery of pioneering surgical principles and procedures. Bringing forth a new idea by publishing it in a peer-reviewed journal can bring balance and support to the introduction of a novel concept or other tangible contribution. Whereas Drs. Semmelweis, Long, and McDowell delayed publishing their discoveries, thus sometimes antagonizing those whom they might have convinced of the merits of their work, Drs. Sims, Kelly, Vesalius, and Virchow were quicker to publish their discoveries and accordingly were met with less resistance and more acceptance.
- Development and maintenance of an accredited officebased surgical facility can provide a safe, sanitary, and

secure environment for performing many gynecologic procedures, thus avoiding scheduling problems and nosocomial infections that may be inherent in operating in an acute care facility.

- Involvement in community affairs and volunteerism, as practiced by Drs. Howard Kelly, Rudolf Virchow, and Andreas Vesalius, adds balance and fulfillment to the professional life of the operative gynecologist.

Chapter 2

The Ethics of Pelvic Surgery

Mindy S. Christianson

Edward E. Wallach

DEFINITIONS

Autonomy—The concept describing an individual's self-determination and the right to direct his or her own life through his or her own decisions, actions, and beliefs.

Beneficence—The duty to do good on the behalf of others through an active promotion of the good of the patient and shelter from harm.

Informed consent—A process of communication between a physician and a patient that addresses the risks, benefits, and alternatives of a proposed medical intervention while meeting the core criteria of competence, exchange of information, understanding of exchanged information, and voluntary authorization.

Nonmaleficence—Literally translated as “do no harm,” this concept describes the need both to prevent harm and to refrain from harmful acts.

THEORY AND PRACTICE OF ETHICS IN MEDICINE

The practice of medicine is governed by a system of beliefs that guide the actions of physicians and other health care professionals to act and make decisions that are regarded as ethically acceptable. Throughout the practice of medicine, different sets of standards and concepts of ethically acceptable behavior have existed as the predominant code for health care professionals. Codes such as those set by the Hippocratic oath served as the mainstay of professional behavior for centuries until a different system took its place in the first half of the 20th century. This transition reflects changing societal values of health and well-being that evolved over time as a result of political, cultural, scientific, and technologic advancement.

The field of bioethics emerged in the 1950s. Before that time, ethical principles of the Hippocratic oath were regarded as the ethical standards for medicine. The guiding principle of physician action was *primum non nocere*—first do no harm. In the Hippocratic tradition, the model of paternalism structured the therapeutic relationship. The physician was designated as the most qualified person to make decisions about treatment options for a patient. As such, it was the physician's judgment that determined what was to be considered as harm or benefit resulting from a medical procedure, not that of the patient or the patient's family. This convention was based on the belief that only an expert in science and medicine was qualified enough to make the best choice among treatment options for patients. During a time when medical therapies were limited and choices were few, this approach was not viewed as problematic to patient care. However, as changes in society, science, and medicine unfolded, patients and the general public began to question these traditional views of the physician-patient relationship.

With the introduction of significant scientific and cultural revolutions that characterized the post-World War II period in the United States, these standards set by the Hippocratic oath were considered to be ineffectual to meet the growing demands of medicine and ethics. Movements advancing civil rights, women's issues, and the growing recognition of individual rights and autonomy dominated the social climate. Carried over into medicine and science, a new set of health care innovations introduced new moral debates to society and the medical profession about the purpose of medical care, the definition of health, and the ability of mankind to regulate the

physiology of the human body. The birth control pill, organ transplant, and dialysis are just a few examples of the significant lifealtering innovations of the time. The ethical questions raised in response to the cultural and scientific climate challenged the previous notions of ethical behavior of physicians. In particular, the notion that physicians were the most appropriate members in the therapeutic relationship to make choices for the patient was rejected. Decisions about the vast array of available medical therapies and choices seemed inherently incongruent with the concept of paternalism. With the rise in the importance of autonomy and individual rights, society campaigned to replace the paternalistic structure of medicine with a model that established the patient as the primary decision maker.

This movement resulted in the establishment of a system of principle-based ethics as the driving force behind modern medicine. In 1977, the Belmont Report outlined what these principles or standards should be. This massive effort to reshape modern bioethics resulted in the establishment of the following principles as the cornerstone of contemporary medical ethics: autonomy, beneficence, nonmaleficence, and justice.

Autonomy—The concept of autonomy embodies the ideal of self-determination—that a person shapes his or her own life through his or her own decisions, actions, and beliefs. As such, individuals have the right to make decisions about their lives that reflect their own beliefs of well-being and values. Inherent in the principle of autonomy is the requirement that others (i.e., physicians) must respect a patient's right of self-determination.

Nonmaleficence—Nonmaleficence, defined as “do no harm,” has its origins in the original tenets of the Hippocratic oath. This principle encompasses the need both to prevent harm and to refrain from harmful acts.

Beneficence—The definition of the principle of beneficence is to do good on the behalf of others. In the case of the principle of beneficence, physicians are expected to actively promote the good of the patient, not just shelter him or her from harm. Though this may seem to be a subtle distinction from the principle of nonmaleficence, it is critical to the principle-based theory of ethics, as it requires the performance of positive acts to advance the well-being of others.

Justice—The principle of justice addresses the need to treat all persons fairly. In the case of health care, this pertains to both the physician-patient relationship and the public health obligations of physicians in the allocation of scarce medical resources.

In this principle-based ethics model, all four core elements hold, in theory, equal importance. In many of the clinical situations that physicians routinely address, these elements may seem to be in conflict with one another. The solution to complex ethical dilemmas requires the balancing of these principles and, oftentimes, a prioritization of one over the others. An example of this is in an emergent medical situation when the principle of beneficence may temporarily overrule autonomy. However these principles are weighted, they must ultimately be used in a way that results in medical choices serving the good of the patient by reflecting his or her values and beliefs.

Though the system of principle-based ethics as established by the Belmont Report is the forerunner of ethical standards of behavior in modern medicine, other legitimate models of bioethical theory exist. They are broad in nature and are guiding principles, but all come from the view that the system of principle-based ethics does not offer enough to guide behavior in the complex setting of health care. Two examples of this are feminist ethics and casuistry. Feminist ethics is based on the notion that decisions are made in the context of relationships and personal virtues, such as compassion, friendship, and love. Principle-based ethics does not take these factors into consideration, neglecting the problems raised in a society in which men and women are not viewed as equals, and, as a result, does not serve the true interests of the patient. A second example is casuistry, or case-based ethics. This theory is founded on the principle that moral lessons gained from the resolution of actual cases in medicine have more value than do a set of theoretic and unchanging principles. Using this model,

ethical reasoning results from weighing the outcomes of real cases as examples and forming a set of modifiable principles from those conclusions. These are just two examples of the diversity of ethical theories that guide medicine and serve as solutions to ethical puzzles that cannot be solved using the standard principle-based ethics commonly in place today.

The very nature of the field of obstetrics and gynecology sets the stage for a variety of ethical dilemmas. Issues surrounding the beginnings of human life and reproductive function naturally facilitate profound and often controversial questions and debate. In addition, the women's rights movement has raised other issues specific to the care of women, such as subjugation and control of women's bodies through society and medicine. Despite this broad range of issues, ethical discussions in obstetrics and gynecology have often been perceived in terms of a single controversial issue: abortion. Yet, the field of bioethics in women's health has a rich and broad set of important implications for the practice of medicine and the health of women. Recent advances in medicine and science have introduced novel therapeutic options to many of the conditions that gynecologists face, such as cervical cancer, uterine fibroids, and infertility. Genetic and pharmaceutical therapies, new diagnostic modalities, noninvasive surgical options, and the emergence of assisted reproductive technologies, including in vitro fertilization, set the stage for a multitude of multifaceted ethical questions and debates. This chapter will present some of the foundational concepts in bioethics and women's health that serve as a launching point for addressing the more complex and novel ethical issues as they arise in the present setting of medicine and the future.

AUTONOMY AND INFORMED CONSENT

Informed consent is a mechanism whereby the autonomy of a patient is recognized, respected, and preserved in health care decisions. It is the result of a process whereby a patient makes a voluntary decision to proceed with a medical intervention with a sound understanding of the benefits and risks of the procedure, as well as alternative therapies if the procedure is declined. The respect of informed consent has two purposes. On the one hand, the process of achieving informed consent respects and recognizes the patient's autonomy. On the other hand, patients benefit when they make decisions on their own behalf because they themselves are most familiar with their own values, beliefs, and ideas of well-being and health. When patients make informed and voluntary decisions about their health care, they can make choices that meet their own concept of what's good and what's beneficial.

The term *informed consent* has legal and ethical dimensions. Legally, informed consent can be viewed as an end point. The legal requirements of informed consent are met when the conversation between the physician and the patient is documented, either on an informed consent form or in the medical record. Often, getting a signature on a form is synonymous with achieving informed consent, but informed decision making goes well beyond the legal form. Ethically, informed decision making involves a process of communication between the physician and the patient through which the patient is able to make an autonomous decision either to authorize the intervention (informed consent) or reject it (informed refusal).

The legal and ethical dimensions of informed consent are often used interchangeably but can have very different meanings and implications. Unfortunately, the function and meaning of informed consent is often misinterpreted, and it is viewed primarily as a legal document with a patient's signature denoting full understanding and authorization. It is important to keep in mind that both the legal and ethical requirements of informed consent are essential in health care. However, as important legal documentation is, it should not be placed before the ethical duties to the patient. Legal documentation in a chart or on a form does not substitute for the process of communication and autonomous decision making. Not all legal documents with a patient's signature reflect that an adequate informed consent process has taken place.

A valid informed consent is both informed and autonomously authorized. To achieve this, the physician must

ensure that five core components are met in the decision-making process: (a) competence, (b) voluntariness, (c) disclosure, (d) understanding, and (e) authorization or refusal. These core components serve as a guide for physicians when discussing medical interventions with patients to ensure that a patient makes the most appropriate decision possible. Without satisfying all five of these core components, an adequate informed consent process has not been achieved.

Competence

In the usual clinical setting, other than situations involving formal psychiatric evaluation, the determination of competence tends to be more of a working judgment than a formal assessment. Beauchamp and Childress describe decision-making capacity as follows: "Although the properties most crucial to the determination of competence are controversial, in biomedical contexts a person has generally been viewed as competent if able to understand a therapy or research procedure, to deliberate regarding major risks and benefits, and to make a decision in light of this deliberation."

Voluntariness

Ethically valid informed consent can only be obtained through the voluntary authorization by a patient for a medical intervention. It is not sufficient merely to meet the criteria of decisionmaking capacity, disclosure, and understanding. The patient must be able to use this information to formulate a decision that is not controlled by others. If a patient is manipulated or coerced into making a decision, then valid informed consent will not have been achieved.

Disclosure

Autonomous decision making must be made in the context of information about the medical intervention. The physician must disclose sufficient information that allows the patient to make an informed decision reflecting his or her beliefs and values, including the risks, benefits, and alternatives of the

P.20

proposed medical intervention. The core of ethical disclosure is about facilitating the patient's autonomous choice to accept or reject health care. Although there is no definitive rule about how much information should be given to the patient, a valid informed consent does not require that the patient be informed of every conceivable risk that could occur, no matter how remote or how trivial. Listing risks, either verbally or in writing, that do not have applicability to the patient does not promote autonomy. Instead, a balance must be achieved between the patient and the physician to determine how much information and detail is necessary for the patient to make a meaningful decision.

Understanding

The patient must make a decision based on an understanding of the information provided. It is not sufficient to mention or list the possible risks to an intervention. The patient must comprehend the ramifications of these risks when considering whether to proceed with an intervention. The physician must be certain to convey information about the risks, including the possible procedures involved to address a bad outcome if it occurs. The patient should then be able to weigh the risks and the benefits of the procedure in his or her own terms.

Authorization

The corollary of informed consent is informed refusal. Informed refusal is the decision of the patient to decline the proposed medical intervention. The respect for the patient's autonomy that is implicit in informed consent extends to the choice to refuse treatment, even when the decision is made against the recommendation of the physician. Informed refusal can be as minor as refusing a simple elective procedure to refusing lifesaving treatments. A patient may refuse treatment for a variety of reasons. One reason may be that the intervention or the outcome is

misaligned with his or her concept of good. For example, a patient may refuse a medical therapy because he or she believes it to be harmful or incongruous with his or her personal beliefs (e.g., blood transfusion refusal for a Jehovah's Witness).

A balance must be met between respect for the autonomy of the patient and the physician's duty to beneficence. It is the job of the physician to be as certain as possible that this decision is informed and consistent with the values and beliefs of the patient. In situations when the refusal may result in significant impairment, pain, or death, the physician should make every attempt to ensure that these decisions are consistent with the patient's beliefs and have been so over time. Physicians may still be considering their patient's best interest by giving preference to his or her spiritual or personal convictions over the medical good. Another important aspect of informed refusal is that it can occur either at the initiation of a treatment or later during the course of the treatment. This becomes apparent when a patient refuses to continue a treatment or undergo a similar or identical intervention. The willingness of the patient to undergo a therapy in the past does not mean that consent is implied in the future.

Under certain circumstances, a physician must proceed with a medical intervention without the informed consent of the patient. Generally, these circumstances involve emergent situations. For example, the patient may be suddenly incapacitated or unconscious and therefore incapable of providing any sort of autonomous authorization. Alternatively, the patient may be conscious and otherwise able to make decisions but, because of the emergent and critical nature of her condition, it is medically necessary to initiate an immediate intervention, and there is no time to engage in a discussion with the patient. In the first situation, there may be time to obtain authorization from an appropriate family member or designated medical decision maker. In the second situation (and sometimes in the first), there is no time, and the physician must make a decision on behalf of the patient. This decision should be made based on what is judged to be in the best medical interest of the patient and usually assumes most people would opt on the side of instituting lifesaving measures.

Informed consent plays a vital role in the practice of obstetrics and gynecology because this field of medicine pertains to the anatomy and function of a woman's reproductive system and sexuality. Issues specific to women's health have been brought to the forefront because of concerns of historical control and subjugation of women and their bodies through society and medicine. In addition, there is a growing trend to recognize the vital role of relationships in a patient's medical decision making with respect to reproductive issues. Patients rarely make decisions about their sexuality and reproduction in a vacuum but instead do so within the context of relationships with others, whether friends, partners, or families. It is critical to recognize these qualities inherent in obstetrics and gynecology when obtaining informed consent for a medical therapy or procedure to maximize the autonomous expression of the patient's personal preferences.

ETHICAL ISSUES IN SURGICAL TRAINING

Competence of the surgeon is a moral commitment to the patient, especially before undertaking a novel surgical procedure. Adequate preparation in the basic and clinical sciences and training in surgical techniques must have been accomplished before any new surgical procedure is introduced into clinical medicine. An overenthusiastic rush into the use of a procedure is exemplified by the sudden popularity of cardiac transplantation in the 1960s. The preparatory laboratory work in cardiac transplantation started in 1905, but the first successful replacement of the heart in a dog took place in 1960. Immune suppression, which is crucial to the procedure, was introduced in 1958, and longtime survival of grafts occurred by 1965. Christian Barnard reported the first successful human heart transplantation in December 1967 in South Africa. By the end of 1968, 101 human heart transplantations had been performed by 64 surgical groups in 22 countries. Most patients improved briefly and then died of rejection of the transplant or infections. In 2 years, the procedure was largely discredited, and it took more than 10 additional years to reestablish wide acceptance of the operation. This experience illustrates the need to limit difficult and complex procedures to specialized centers that have the resources and adequately trained surgeons

to perform them.

This is equally true for complex pelvic surgery. The adoption of subspecialty boards by the American Board of Obstetrics & Gynecology, each with requirements for postresidency fellowship training and evaluation standards for certification, has helped to emphasize the need for specialized training in surgical techniques for pelvic surgeons. The rapid expansion of the use of robotic surgery training procedures prompts the responsibility for providing future gynecologists who are technically skilled to serve society effectively and safely. In addition to underlying knowledge, clinical experience, training, and practice, the competent surgeon operates with the attentiveness and focus commensurate with the surgical theater. Indeed, legitimate concerns regarding the potential impairment of overfatigued house staff managing and operating on patients have led to changes in house staff work hours and training.

P.21

Training programs are now charged with the simultaneous challenge of vigilantly protecting the welfare of their patients from potentially suboptimal care while ensuring that their surgeons, after completion of training, operate competently under emergent and suboptimal conditions.

Many surgeons trained before World War II participated in residency programs affiliated with large inner-city hospitals where patients without adequate resources or health insurance received care. It was accepted that these patients would receive treatment or even surgery by physicians-in-training (including senior medical students, interns, and residents), preferably under the supervision of skilled volunteers or paid clinical faculty and only when the trainee had reached the necessary level of competence. When health care became an entitlement under Medicare and Medicaid government-funded health insurance became more prevalent, many patients sought the services of private physicians. The so-called free care or resident services were often unable to recruit sufficient patients to provide adequate training for new surgeons. This was particularly true in pelvic surgery; given the choice, these patients sought refuge from the clinic, where privacy and dignity were hard to maintain, and fled in large numbers to private doctors' offices. Surgical teaching thereafter often involved the private patient, with the resident now performing complete procedures under the supervision and assistance of the patient's private physician. This arrangement potentially left patients either poorly informed or uninformed about the participation of physicians-in-training. This arrangement often became apparent when complications arose or the medical records were reviewed during litigation. Although patients are typically better informed now, it remains ethically necessary to inform them about teaching or training in each case so that objections can be dealt with before the planned procedure. Most surgeons involved in teaching programs inform their patients that surgery demands a team effort and that residents may be involved in assisting or operating with them, but that, as the private surgeons of record, they not only will be present but also will be in charge and responsible for everything that takes place during the procedure. Teaching should not take place in the operating room without such a disclosure and the patient's informed consent in this regard. The resident's role, status, and experience should be clear to the patient. We are long past the era of introducing medical students to patients as doctors rather than revealing their actual status.

Because of the limitation on the number of hours a doctor-in-training may work, producing competent surgeons today has become even more challenging than in the past. This situation has necessitated approaches to supplement and amplify the residency program specifically as it affects surgical training. Novel training methods designed to accelerate the learning curve have been devised. These are directed at familiarizing the trainee with instrumentation and the handling of surgical instruments, improving manual dexterity, sharpening hand-eye coordination, and heightening awareness of pelvic anatomy. In addition, decision-making skills and essentials of emergency management need to be developed during the course of residency training. One valuable approach in use is the animal surgical laboratory, for instance, using pigs for training in laparoscopic surgery. Obviously, the size of structures in laboratory animals does not precisely simulate that in humans, and anatomic

relationships do not reflect those of a human patient. Simulation training has expanded in residency training. For example, computer simulators have been developed to enhance resident training in laparoscopic and robotic surgery. Simulators for endoscopic surgical procedures use mannequins or human models. Fabricated pelvic models are also frequently used to heighten skills for practicing maneuvers for normal and operative delivery. These innovative exercises assist in preparing the student for experiences encountered in the operating room and may even succeed in refreshing the already practicing surgeon in performance of specific techniques. Simulated programs have also been developed that incorporate computerized lessons for improving history-taking skills and for simulating emergency management in the form of skill stations. The final arbiter for gaining surgical skills is the surgical procedure itself, carried out in actual patients under the guidance and supervision of an accomplished surgeon who has the ability to communicate effectively about both the procedure and techniques. The only way to learn to manage surgical complexities adroitly is through personal experience while under the direct tutelage of a preceptor who has previously experienced unplanned occurrences. In addition to foundational medical and surgical knowledge, clinical experience, training, and practice, the competent physicians must act in a responsible and professional manner, whether in the clinical or surgical setting. Impairment of a physician's skills must be fully evaluated so that he or she may be given assistance to improve and injury to his or her patients is avoided. Health care institutions must have peer-accessible mechanisms in place to facilitate this process.

EXAMINATION UNDER ANESTHESIA

Concern arose several years ago that medical students were performing preoperative pelvic examinations on anesthetized patients without having obtained specific prior consent. Because of public concern, both the American Congress of Obstetricians and Gynecologists (ACOG) and the Association of American Medical Colleges (AAMC) released statements emphasizing the predominance of patient autonomy and appropriate informed consent over the exigencies of medical education.

In actual practice, examination under anesthesia (EUA) is routinely performed only by members of the surgical team to enable better appreciation of the patient's pelvic anatomy. The surgical team typically numbers between one to four members; at its largest, it includes an attending surgeon, senior resident, junior resident/intern, and medical student. Although the major portions of the surgery are performed by the senior experienced surgeons, the junior assistants, such as the medical student, perform the essential and ancillary tasks of retraction, exposure, and minor suturing.

An ACOG committee opinion issued in 2011 noted: "If a pelvic examination that is planned for an anesthetized woman undergoing surgery offers her no personal benefit and is performed solely for teaching purposes, it should be performed only with her specific informed consent, obtained when she has full decision-making capacity." One can legitimately argue that all surgeons and surgical assistants, including the medical student, require maximum appreciation of the surgical field to optimize their performances during the procedure. Accordingly, the pelvic examinations should not be construed as offering "no personal benefit" to the patient. Furthermore, the EUA should not be considered as separate from the procedure itself but as a necessary adjunct. This ability of the members of the house staff, who provide intraoperative and postoperative assistance, should not be curtailed by exclusion from an essential component of the gynecologic procedure.

At least three steps can be taken to ensure that the rights of the patient are respected while ensuring appropriate surgical care: (a) explicitly incorporating the EUA on the operative consent form, (b) openly discussing with the patient the

importance and participation of all team members in the EUA, and (c) ensuring an atmosphere of patient respect and dignity by agreeing in advance to a specific, limited number of pelvic examinations.

MEDICAL LEGAL ASPECTS OF GYNECOLOGIC CARE

Obstetricians and gynecologists pay among the highest premiums for professional liability insurance of all medical specialties. In many states, this factor has led to early retirement, elimination of obstetrical and/or surgical procedures from practice, or relocation to another state. Being named in a malpractice suit leads to endless hours of effort unrelated to medical practice, undesired anxiety, and, in some instances, withdrawal from practice. A number of factors contribute to the cost of insurance coverage. Obstetricians and gynecologists can exercise control over some of these factors to minimize the chances of being cited in a claim. Two simple principles are helpful in preventing a legal claim or in providing a defense should a claim be filed. These two concepts form the basis of all risk-management and loss-prevention strategies. Plaintiff and defense attorneys have reached consensus that these two factors, documentation and communication, improve the odds that a lawsuit will not be filed or that a lawsuit, once filed, can be successfully defended.

By way of documentation, the following basic and simple initiatives should be a component of each physician's protocol for charting and record keeping.

1. Recording of date and time of each entry in the chart
2. Legible handwriting
3. Contemporary entry of all notes in the chart
4. Appropriate correction of inaccurate entries
5. Avoidance of conflict among physicians and nurses in the charting of patient information
3. When using electronic medical records, individualization of each entry instead of "cutting and pasting" prior notes, especially when using templates, which are becoming more commonly utilized

The alacrity with which a physician responds to a patient's symptom or concerns can be established with certainty if notes are complete, properly dated, and timed. This chronology is instrumental in establishing a timeline for a patient's care and will be more credible in a courtroom or in a hearing than a plaintiff's client's recollection weeks or months after the fact. Because an adverse surgical outcome is not synonymous with negligence, expression of reasons for clinical judgment in choice of a diagnosis or treatment plan demonstrates that alternatives have been considered by the physician. The physician should document these alternatives in the chart and indicate that they were each discussed with the patient before treatment.

Entries in the chart should clearly demonstrate the course of care rendered and rationale underlying the choice of a specific treatment plan. If handwritten, notes should be legible and interpretable by anyone who reviews the chart. An inability to read one's own handwriting can only negatively affect the physician's credibility. The time frame of management is crucial, and prompt recording of events will prevent doubt when events occurring before a complication are documented only after the complication has occurred. Notations regarding telephone conversations with consulting physicians or family members should also be entered in the chart with the date and time of contact. Similarly, electronic mail correspondences with patients should be part of the medical record. An incorrect entry in the chart should be corrected properly by striking out the erroneous entry and initialing and dating the changes. If a supplemental note is written, it should be listed as an addendum. A patient's chart should not be used as a vehicle for expressing opinions on the intelligence of or decision rendered by another health care provider or for the purpose of criticism.

When an unanticipated adverse event occurs, the insurance company or risk-management representative should be notified promptly. The communication of a physician with legal and/or insurance representatives and health care providers is important in anticipating legal problems. However, a cornerstone of medical care is the physician's sensitivity in communicating with the patient with understanding and compassion. She should be

given ample time to ask questions, and these inquiries should be answered truthfully. Breakdown of communications in the patient-physician relationship is a recurring theme in the pathway leading to litigation.

A physician may appear in court to testify in three possible scenarios: as a *defendant*, as a *material witness*, or as an *expert witness* on behalf of either the plaintiff or the defendant. Although each instance has its unique aspects, in all cases, the physician will have an opportunity to prepare the testimony with the attorney who is representing him/her. As a *defendant* at either a sworn deposition or in a courtroom, the physician will have received general and specific instructions from the attorney representing him/her with regard to how to respond to questions. Each response should be concise, to the point, and directed only at the specific question raised by the plaintiff's attorney. Most of all, the answers must be honest and forthright, as well as accurate with respect to the patient's clinical course and management as described in the medical records. The defendant should request the opportunity to view the medical record at any time should there be need to recall specific details such as dates, times, and sequences of events.

A physician may be called as a *material witness* because of his/her association with the specific case as a participant or observer, but not as a defendant. The same principles of deportment apply as for an appearance as a defendant. The material witness testifies on the facts of the case and should not express opinions that require personal expertise.

The physician who chooses to serve as an *expert witness* is called on to do so because of his/her personal experience and training with the particular clinical situation under consideration. The role of an expert witness carries with it significant responsibilities. First and foremost is the possession of knowledge, skills, and experience to fulfill this role. Second, the expert witness should be objective and unbiased and able to discuss standards of care on a broad scale rather than be constrained by his/her personal approach. It is clearly unethical for an expert witness to lack the appropriate credentials and/or to misrepresent the standard of care reflected in the case for which he/she is testifying. Fundamentally, *standard of care* refers to a level of care that is generally thought to represent the norm. Standard of care rendered in specific conditions may differ from one locale or group of physicians to another, simply because standards are arbitrarily developed and not universally held. If an adverse event occurs, a distinction must be made between a bad outcome that is independent of the quality of rendered care and a bad outcome that is clearly due to negligence or to substandard care.

A number of safeguards exist to protect patients from faulty or unethical clinical practice. At the local level, hospital credentials committees, as required by the Joint Commission on Accreditation of Hospitals and Health Care Organizations, are given the responsibility for reviewing the credentials

P.23

of applicants for initial and continuing staff privileges. This responsibility mandates attention to the volume of cases attended per annum and the quality of care rendered. Privileges can be curtailed for performance of specific procedures or may be suspended for practice in general in cases in which the physician provides inappropriate care or exhibits ethical infractions. The American Board of Obstetrics & Gynecology (ABOG) credentials specialists and subspecialists on the basis of training, experience, and performance on examinations. Over the past three decades, a periodic reexamination is required for maintenance of specialty certification. This maintenance-of-certification (MOC) process involves evaluation of performance on didactic examinations and assessment of cognitive skills. In addition, physicians take MOC tests to maintain board certification and earn continuing medical education (CME) credits. Recently, the Accreditation Council for Graduate Medical Education or ACGME and the American Board of Medical Specialties (ABMS) have stressed the importance of education and achievement of six core competencies (patient care, medical knowledge, communication skills, professionalism, practice-based learning and improvement, and systems-based practice). In addition, certifying boards require proof of licensure in good standing for certification and recertification. State medical societies are empowered to review patients' complaints and charges of unethical behavior of licensees. The National

Practitioner Data Bank receives and makes available data regarding infractions of practice standards. This device was established by Congress to prevent physicians with past disciplinary action and malpractice awards from relocating from one state to another without detection.

Unfortunately, there are too few safeguards aside from collegial observation that can monitor surgical technique and/or interaction with patients. The responsibility of the physician requires introspection and candor, especially when factors such as physical and mental impairment or substance abuse infringe on the physician's ability to practice safely and effectively. Currently, there is no formal assessment of surgical skills. Professionalism is implicit in day-to-day behavior and self-assessment. A *New England Journal of Medicine* report (Papadakis et al., 2005) addressed the association of disciplinary action against physicians with unprofessional behavior in medical school and emphasized the importance of professionalism as a core competency. The report's conclusion was that disciplinary action among practicing physicians by state medical licensing boards correlated strongly with a history of unprofessional behavior in medical school. The strongest association was in those who had demonstrated irresponsible behavior or diminished ability to improve their behavior as students earlier on.

PRIVACY AND THE HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT

In 1996, Congress passed the Health Insurance Portability and Accountability Act (HIPAA), establishing minimal national standards to ensure confidentiality of protected health information (also referred to as *individually identifiable health information*). This move was due, in part, to the mainstream use of electronic technology in health care, which promoted concern over patient confidentiality. The subsequent additions to the original HIPAA provisions included the Privacy Rules, extending jurisdiction to health plans, billing services, hospitals, and individual health care providers. At the time of compliance deadlines, all of these covered entities were required to implement the established standards to protect patients' individually identifiable health information. The caveat to the Privacy Rules was that the protection of patients' privacy could not negatively interfere with the quality of care or create unnecessary burdens to patient care.

Quoting from the guidelines published by the Centers for Disease Control and Prevention and the U.S. Department of Health and Human Services (DHHS), the HIPAA Privacy Rule:

- Gives patients more control over their health information
- Sets boundaries on the use and release of health records
- Establishes appropriate safeguards that the majority of health care providers and others must achieve to protect the privacy of health information
- Holds violators accountable with civil and criminal penalties that can be imposed if they violate patients' privacy rights
- Strikes a balance when public health responsibilities support disclosure of certain forms of data
- Enables patients to make informed choices based on how individual health information may be used
- Enables patients to find out how their information may be used and what disclosures of their information have been made
- Generally limits release of information to the minimum reasonably needed for the purpose of the disclosure
- Generally gives patients the right to obtain a copy of their own health records and request corrections
- Empowers individuals to control certain uses and disclosures of their health information

The complexity of the HIPAA regulations has made their implementation challenging and controversial. Specific confusion regarding disclosures to family members abounds, particularly in cases when the patient has

authorized his or her family to be an active participant in health care. This also arises among health care providers when seeking information about their patients to provide continuity of care. Ultimately, HIPAA does afford latitude for professional judgment as to the “best interests” of the particular patient, so long as the disclosures conform to the “minimum necessary standards.” In addition, the Privacy Rule does not replace federal or state laws and makes an allowance for individual institutions to adopt more stringent policies to protect patients' privacy.

CONFIDENTIALITY

The foundation of the physician-patient relationship is trust. This is based on two premises: that a patient has the right to privacy and respect of privacy allows for patients to disclose the necessary information to their physician. This is particularly relevant in gynecology, in which patients share sensitive information with their physicians about intimacy and sexuality. For this reason, confidentiality is one of the most essential aspects to the successful therapeutic relationship.

It is the exception, more than the rule, for patient confidentiality to be violated. Tension and ambiguity, however, have long surrounded the parameters wherein breaches of patient confidentiality are justified. The Code of Ethics of the American Medical Association (AMA), revised in 1957, stated: “A physician may not reveal the confidences entrusted to him in the course of medical attendance, or the deficiencies he may observe in the character of patients, unless he is required to do so by law or unless it becomes necessary to protect the welfare of the individual or of the community.” Exceptions to the breach of confidentiality include times when the withholding of information may harm a third party or threaten public health. Mandatory exceptions include cases of violence

P.24

and violent crime and the negligence and abuse of individuals, including women, children, and the elderly. Some states also require mandatory reporting of infectious diseases that may pose a serious public health risk, such as certain sexually transmitted diseases and tuberculosis. A notable case of the need to violate patient confidentiality is *Tarasoff v. Regents of the University of California*. In this case, a court found the University of California negligent for failing to forewarn murder victim Tatiana Tarasoff and her family after Prosenjit Poddar confided in one of his therapists that he intended to kill her. Two months after the temporary detainment of Poddar for this initial threat, he acted on it by murdering Tarasoff. As the majority opinion in the 1976 Tarasoff case emphasized: “The protective privilege ends where the public peril begins.”

Gynecologists are confronted with a variety of complex and difficult scenarios in the clinical and surgical arenas when it comes to maintaining or breaking patient confidentiality. In this setting, physicians must balance their legal obligations with their medical obligations of trust to the patient. Challenging and not uncommon conflicts of patient confidentiality occur in obstetrics. An example is when a woman seeks a pregnancy termination or sterilization procedure while requesting confidentiality from her partner. Counseling such a patient, especially after having attained her trust and confidence, may help defuse the situation. Yet, physicians must keep their duty to the patient and her confidentiality in mind before acting in situations such as this. When in doubt, either over personal convictions or professional duties, a hospital ethics committee may be required to intervene. Ultimately, however, in the absence of a countervailing public health or legal mandate, the obligation of patient confidentiality predominates.

ETHICAL ISSUES IN RESEARCH ON HUMAN SUBJECTS

Although the Nuremberg medical war crimes trials of Nazi doctors and the ensuing Nuremberg Code in 1949 represent a landmark in research ethics involving human subjects, they made little impact on research practices in the United States. Biomedical research expanded exponentially after World War II without significant regulation or oversight. The Nuremberg Code established the need for the “voluntary consent of the human subject.” It

covered such other matters as the need to justify a study in terms of expected beneficial results and risks, avoiding harm and injury to subjects, freedom for the subject to withdraw, and obligation of the investigator to stop a study if continuation would likely cause injury, disability, or death.

In 1966, the U.S. Public Health Service introduced the requirement that all human subject research funded by the government must be peer-reviewed by a local institutional review board (IRB). The objective was to protect the rights of the individuals involved and review the quality of the informed consent and the risks and benefits of the study. This regulation was the result of a growing awareness that these kinds of safeguards often were not followed even in the best academic institutions in the United States.

Several unethical studies reached the attention of the public during the 1960s and 1970s. Of highest notoriety was the Tuskegee study, which was organized by the U.S. Public Health Service to follow the natural history of syphilis in a cohort of 400 rural African American men. The lack of meaningful informed consent in 1932, when the study began, and the subsequent withholding of penicillin treatment until the study was exposed and halted in 1972 shocked the public and spurred Congress into action. The end result, as described above, was the issuance of the Belmont Report and its articulation of the prevailing principles of bioethics: autonomy, justice, and beneficence.

Federal regulations mandate the creation of ongoing IRBs with appropriate oversight of human subject research. Pursuant to the doctrine of autonomy, informed consent procurement is now a formalized process. In randomized controlled trials, potential participants must be notified of the risks, benefits, and alternatives to the care provided by the study. Beneficence and justice dictate that equipoise exists between the alternative treatments and between these treatments and the standard of care and that potentially beneficial findings of the study will be meaningful and relevant for the study population.

This evolution of research ethics is applicable for students of surgery as well. Although federal regulations cover research funded by the government, their ethical underpinnings should apply to all research involving human subjects, regardless of the source of funding. Surgeons continually try to innovate and improve their skills and the procedures used, but they must be mindful of the possible need for antecedent work in basic science and the animal laboratory and the need for informed consent and peer review when significant deviation from standard practice is contemplated. In most instances, new surgical procedures should be developed in appropriately controlled research trials with all the safeguards needed for the protection of human subjects. Most institutions require anyone investigating and co-investigating to complete a curriculum that includes research ethics.

INFORMED REFUSAL AND THE JEHOVAH'S WITNESS PATIENT

Founded in the late 19th century, the Jehovah's Witness community is governed by the Watchtower Society, which issues doctrinal positions via its official journal, the *Watchtower*. On July 1, 1945, an article in that journal established the familiar Jehovah's Witness prohibition against blood transfusions. The biblical sources cited—Genesis 9:4, Leviticus 17:13-14, and Acts 15: 19-21—are understood by conventional Judeo-Christian theology as proscriptions against consuming the blood of animals. Nevertheless, Jehovah's Witnesses forbid transfusions of whole blood or its constituents: plasma, packed red blood cells, platelets, and white blood cells. The penalty for transgression is severe: eternal damnation and, more immediately, social ostracism and “disfellowshipping” by other Witnesses. In the June 15, 2004, edition of the *Watchtower*, however, explicit clarifications were issued revealing that transfusion of fractionated components of plasma, packed red blood cells, platelets, and white blood cells was permissible and subject to the individual's discretion.

The wrenching ethical quandary arises when a Jehovah's Witness patient asserts her autonomy to refuse transfusion, thereby risking exsanguination during surgery or from medical conditions such as dysfunctional uterine bleeding. Could or should physician beneficence override a competent patient's refusal of treatment? When locked in conflict, which bioethical principle prevails: autonomy or beneficence? In these instances, it is

also important for physicians to consider the concept of good and well-being from the perspective of the patient. Physicians often are in situations in which they cannot provide medical beneficence, but that does not prevent them from assisting in spiritual or emotional beneficence. In the case of a Jehovah's Witness, a physician may appeal to the principle of beneficence while withholding treatment at the request of a competent patient.

American courts have not reached consensus concerning the withholding of blood products for Jehovah's Witnesses, but several dominant trends appear. Surgeons who choose to

P.25

respect the wishes of a competent Jehovah's Witness patient to refuse blood products in the face of imminent exsanguination are, in general, protected from wrongful death liability. Likewise, courts generally endorse a patient's right to refuse treatment. However, when the patient has dependents who would be otherwise abandoned, or in obstetric situations in which the fetal well-being will be placed in jeopardy, courts have intervened to order transfusions.

From an ethical perspective, a gynecologist contemplating a surgical procedure for a Jehovah's Witness should take the following steps to ensure that the patient and surgical team are prepared for the potential decision to withhold blood products:

- Extensive, confidential preoperative counseling to ascertain informed consent. Specifically, the surgeon should verify the patient's understanding and acceptance of Watchtower Society doctrine, understanding of the potential repercussions of refusing transfusion, and awareness of the views of dissident Jehovah's Witnesses. This should be thoroughly documented in the chart. In cases in which the patient's decision-making capacity may be in question, the physicians should request additional professional input from a psychiatrist.
- Consultation, as needed, with the hospital ethics committee.
- Preoperative consultation with the anesthesiologist.

There are several prophylactic steps that can be taken to avoid the likelihood of a transfusion. These include preoperative iron and/or recombinant erythropoietin therapy and intraoperative use of vasopressin, volume expanders, hypotensive anesthesia, hypothermia, and ligation of major vessels. An intraoperative cell salvage machine, commonly referred to as a "cell saver," is also a viable alternative for patients with religious objections to receiving blood transfusions. These devices suction, wash, and filter blood so it can be given back to the patient's body as needed.

ADVANCED PLANNING AND END-OF-LIFE DECISION MAKING

Policies and regulations regarding death and dying have been set largely by the courts on a case-by-case basis when intractable controversies have arisen with doctors, patients, patients' families, or hospital administrators that must be resolved before a judge. The introduction of life-sustaining technology, such as the respirator that can keep the human body functioning biologically even in cases when the prospect of a return to normalcy is unlikely, has introduced a host of new dilemmas and questions about medical decisions at the end of life. When terminally ill patients, their families, and their health care teams all agree on the use and withholding of treatment at the end of life, there is usually no overt dilemma, except the question of the prudent use of scarce resources. When there is agreement among all parties, there is seldom a need to go to court, and courts discourage bringing these cases before them. When there is disagreement among the patient, the patient's family, the physician or team of physicians, and/or the hospital, the stage is set for conflict that often must be decided by an arbitrator. The courts have traditionally provided guidance in such cases. These rulings, however, often are not universal and are influenced by contemporary public attitudes. Although each case and its outcome is not comparable, the general consensus is that the patient's autonomous choices are binding and that the ultimate

goal of medicine is not to preserve life at any cost, but to relieve pain and suffering in keeping with the patient's wishes.

A recent ACOG committee opinion statement in 2007 addressed the issue of medical futility for today's obstetriciangynecologist. The statement described the concept of medical futility to justify a physician's unilateral refusal to provide treatment requested by a patient or a patient's family. This decision may be based on the physician's perception that further treatment will not obtain a specific physiologic goal or will not achieve a reasonable quality of life. The statement also recommends that physicians and health care institutions develop policies dealing with conflicts relating to the concept of medical futility and patient care.

Since the development of these life-sustaining interventions, there have been several landmark cases: Karen Ann Quinlan, Nancy Cruzan, and Terri Schiavo. Each of these cases represents a different scenario in which physicians and family members struggle to make difficult decisions in surrogate for their loved one. The situation of Karen Ann Quinlan is one example of the type of disagreement that can occur between a patient's family and the providing health care institution. Karen Ann Quinlan was a 21-year-old woman who had been in a prolonged coma and sustained on a respirator. When the likelihood of recovery disappeared, her family's request to remove the respirator was challenged by the hospital. The courts ultimately ordered the removal of the respirator, and she died 10 years later.

In the case of Nancy Cruzan, a difficult decision had to be made when the wishes of the patient were unknown. Nancy Cruzan was in a prolonged coma, and her parents wanted to withdraw food and fluid. There was no record of her prior stated or documented wishes, and, as a result of a Missouri state law forbidding withdrawal without such evidence, this did not take place. The case was taken to the U.S. Supreme Court, which ultimately found the Missouri statute constitutional and, therefore, did not grant the request to the parents. This case is landmark because, in the course of handing down this decision, the U.S. Supreme Court established the right of competent patients to refuse any kind of treatment, also including life-sustaining treatment. In addition, the Supreme Court determined that no distinction was necessary between artificial feeding and other forms of therapy. Ultimately, evidence was found of Nancy Cruzan's prior wishes that she would not want to be kept alive in a permanent coma, and she was allowed to die after treatment was withdrawn.

The Terri Schiavo case is another example of the complexity of surrogate decision making. In contrast to the two previous cases, this one represents disagreement between the family members of the patient. On February 1990, Terri Schiavo suffered a myocardial infarction resulting in severe brain damage leaving only minimal brain stem function intact. At the time of this initial event, Schiavo did not have a living will or written documentation of her medical care wishes. Her husband and parents worked together to care for her with the hope that she would recover all or part of her cerebral functions, having a feeding tube inserted and placing her in a skilled nursing facility. Eight years later, Terri's husband came to the conclusion that her status had not and would not improve. Stating that his wife had previously expressed her wishes not to live under such circumstances, he appealed to the courts to take on the role of the ward's surrogate to remove the feeding tube and allow her to die. A court order to remove the feeding tube in April 2001 was immediately followed by an appeal by her parents claiming that they had evidence that Schiavo would want to live. Furthermore, they believed that novel medical therapies would be able to improve Schiavo's condition and restore some of her ability to function. They felt that Schiavo was conscious and responsive and, given the ability to speak for herself, would express her desire to live.

P.26

In response to this new information, the court reversed its ruling and, 2 days later, the tube was reinserted. Over the course of 15 years, Schiavo's feeding tube was placed and removed a total of three times in response to different court rulings. After several attempts for appeal, the final ruling ordered the removal of the feeding tube in March 2005, and, less than 2 weeks later, Terri Schiavo passed away.

Many such cases did not deal directly with the issues pertaining to terminal illness, but they provided the moral and legal environment in which such requests can more readily be honored by the physician. Sufficient consensus among patient advocacy groups and professional medical organizations led to the Patient Self-Determination Act, passed by Congress in 1990. This act required hospitals to promote the use of advance directives by their patients to qualify for federal funds for Medicare and Medicaid. Almost every state in the country has enacted laws that allow for advanced-care planning to direct the care of and protect the rights of patients who are terminally ill and suddenly incapacitated. These are referred to as *advanced directives*, and they include a variety of different mechanisms whereby a patient can direct his/her medical care in the case of his/her sudden or gradual decline in decisional capacity. The different forms of advanced directives include:

Durable power of attorney for health care—A legal document in which a patient designates a specific individual to make health care decisions in the setting of loss of decisional capacity

Living will—A legal document in which the patient describes his/her treatment preferences in the setting of loss of decision-making capacity, such as the continuation of nutrition, hydration, or ventilator support

Health care proxy (attorney-in-fact for health care)—The individual designated by the patient to make surrogate decisions in the case of loss of decision-making capacity

Do not resuscitate (DNR)—A type of advanced directive that specifically directs the withholding of lifesaving procedures in the case of cardiopulmonary arrest, such as cardiopulmonary resuscitation and defibrillation

Gynecologists should familiarize themselves with different forms of advance directives and the applicable laws. They should also discuss these issues with their patients and their families to ensure that the best arrangement can be made. The ideal time to do this is preferably before such decisions are actually needed for implementation, such as before significant illness or surgery.

RELATIONSHIPS WITH INDUSTRY

While development of pharmaceutical agents and medical devices is important for improving health care, the goals of industry may conflict with a physician's duty to his/her patients. ACOG has recognized this challenge in recent years and has produced several committee opinions regarding this since 1985. The most recent update was issued in 2012. Specifically, ACOG warns that gifts tied to promotional material may influence professional behavior and are therefore discouraged. Use of samples should be limited to those patients with a true financial need. Training on the proper use of medical devices should ideally be provided through professional societies with CME accreditation. When this is not possible, industry-provided training should be limited to FDA-approved indications for using the equipment or device for the shortest time possible. ACOG provides specific guidelines for industry sponsorship of research.

ETHICAL CHALLENGES SPECIFIC TO GYNECOLOGIC CARE

Several issues specific to the care of women and their reproductive health represent ethical dilemmas unique to gynecology. These include abortion, assisted reproductive technologies, and sterilization of women. In each case, the nuances of addressing the health care issues of women require additional consideration to ethical topics mentioned above.

Abortion

Termination of pregnancy is entertained in a variety of settings in obstetrics and gynecology. A patient may seek an abortion for a broad spectrum of circumstances, ranging from an unintended and undesired pregnancy (failure or nonuse of birth control, sexual assault, failure of emergency contraception), severe fetal anomalies (aneuploidy, congenital abnormalities incompatible with life), or threatened maternal health (preeclampsia, severe hyperemesis gravidarum, cardiomyopathy). Because of the many diverse clinical scenarios for the

termination of a pregnancy, it benefits physicians to be aware of the issues relating to abortion, regardless of whether or not they have personal objections to the procedure.

The core ethical and legal issues surrounding abortion include the right of the woman to control her own body and reproduction, the moral and legal status of the fetus, the rights and interests of the fetus to be protected from harm, and the degree to which outside parties such as national and state governments have authority to protect or restrict these rights. These issues tend to polarize the general public and government into two camps: prolife or prochoice. Because of the two extremes of positions that exist in the debate about abortion, little headway has been made to reach a common ground since legalization of abortion in the United States in 1973.

The two major legal cases that have shaped most abortion law in the United States in the past century are *Roe v. Wade* and *Planned Parenthood v. Casey*. Although these decisions do not encompass all laws pertaining to abortion, they are the two most well known and influential. In 1973, *Roe v. Wade* recognized the following rights: the fundamental right of privacy, protection of an individual's bodily integrity, and protection of an individual's decisional autonomy. The rights outlined in *Roe v. Wade* were weighed against the interests of the state in terms of the protection of a potential human life and the health of the mother. However, *Roe v. Wade* did not address questions such as the moral or legal status of the fetus. Under these three rights, the Supreme Court interpreted the Constitution as granting significant protections to an individual's right not to have a child. As such, a woman's choice to terminate a pregnancy was given specifically to her and not to the government. At the same time, the Supreme Court recognized the states' interests in protecting both women's health and the potential life of the fetus, giving the individual states the authority to enact laws imposing strict safeguards and even restricting procedures.

Roe v. Wade also accomplished several other legal milestones. It intended to limit states' restrictions on a woman's right to terminate a pregnancy by establishing a "strict scrutiny standard." By this standard, individual states that proposed laws, such as mandatory husband consent requirements and mandatory waiting periods, were determined to be unconstitutional. In addition, *Roe v. Wade* established a trimester framework for outlining the degree of the state's interests in abortion law. During the first trimester, the woman's interests had precedence above the interests of the state to protect the potential life. During the second trimester, a woman's privacy interests

P.27

and the state's interest in the protection of the woman's life and the potential life of the fetus were balanced. After the time of viability, the state's interest in protecting the potential life had priority unless the life of the woman was at stake. Minors were also addressed under the *Roe* framework. Under *Roe v. Wade*, minors were required to inform or involve their parent or guardian in the decision to terminate the pregnancy. In cases when this was not possible, either because of fear of the consequences of disclosure or when the guardian was unavailable, minors were required to obtain a waiver of parental involvement mandate from the court, also known as a judicial bypass. Finally, *Roe v. Wade* placed federal and state limitations for the use of public funding of abortions for Medicaid patients.

Planned Parenthood v. Casey (1992) reaffirmed the central tenets of *Roe v. Wade* but changed the law significantly by removing the trimester framework based on the notion that it did not adequately recognize the state's interest in the potential life before viability. Under *Casey*, the states' interests take priority from the outset of pregnancy, not just during later gestations, and, as such, states were permitted to make laws to restrict abortion in the process of protecting their interests. These individual state-by-state laws were constitutional only if they met the "undue burden" standard. Under this standard, the state's restrictions could not place an undue burden on the woman in deciding to terminate her pregnancy. Such a restriction had the effect of placing a substantial obstacle in the path of a woman seeking an abortion of a nonviable fetus. Many states have interpreted "undue burden" in different ways, creating restrictions—such as increased parental involvement,

mandatory waiting periods, unwieldy requirements for abortion centers, and counseling biased toward continuing the pregnancy—that are deemed constitutional. A more recent example of such an obstacle is the requirement for a woman to undergo transvaginal sonography prior to voluntary pregnancy termination.

Abortion is one of the few medical procedures from which physicians may opt out in nonemergent situations because of ethical or religious objections. Under this situation, legislatures have recognized that professionals may legally refuse to provide abortion services. “Conscience” or “refusal” clauses make abortion services one of the few areas in which a physician legally may opt out of performing a medically indicated procedure because of personal objections; however, the scope of the right to opt out differs from state to state. Legally, under the protections of conscientious objection, no physician is required to do a procedure if it is in conflict with his or her ethical, moral, or religious beliefs. This principle applies only in situations in which the patient's life is not at stake. In cases when the life of the woman is threatened by the ongoing pregnancy and no other providers are immediately available, a physician cannot refuse to treat the woman.

The statutes of conscientious objection do not exempt physicians from making a responsible, truthful, and timely referral to another practitioner or health care facility that provides the service or from rendering care in a life-threatening emergency when an alternate health care provider is not available. Failure to provide an appropriate referral can constitute malpractice (i.e., fall below the legal standard of care) and also may violate ethical standards of care. Many states have patient abandonment laws that put specific burdens on physicians to refer or transfer care of patients before terminating a relationship. At minimum, the physician is expected to guide the patient to valid resources to identify an abortion provider.

The most recent debates about abortion pertain to the issues of partial birth abortion (D&X) and RU-486. Many professional organizations for women's health have rebuked the validity of the partial birth bans. Legislation addressing partial birth abortion has been described by ACOG as “inappropriate, ill advised, and dangerous” because “intact D&X may be the best or most appropriate procedure in a particular circumstance to save the life or preserve the health of a woman, and only the doctor, in consultation with the patient, based upon the woman's particular circumstances, can make this decision.” Arguments against partial birth abortion have been criticized for being a rhetorical strategy to place greater restrictions on the present abortion statutes.

Special Issues for Assisted Reproductive Technology Patients

The rapidity of developments in the field of assisted reproductive technology (ART) continues to raise ethical dilemmas. Basic to all is whether the preimplantation embryo has special significance and when personhood is established. The variety of technologic advances highlights this concept. All of the new offshoots of ART, including embryo cryopreservation, preimplantation genetic diagnosis and screening with discarding of embryos, and new approaches to fertility preservation, raise ethical issues, most of which focus on the sanctity of the embryo. The principles of autonomy, beneficence, nonmaleficence, and justice all enter into the equation and have been addressed by the American Society for Reproductive Medicine Ethics Committee in its reports beginning in 1986 and by ongoing publications in its journal.

Sterilization of Women

Sterilization of the female patient is subject to the same ethical principles as any other surgical procedure. Unique to the issue of sterilization is that it is often a social choice rather than a medical necessity. It is critical that the physician address nonmedical factors associated with sterilization without bias, particularly when a patient seeks counsel in deciding whether or not to pursue sterilization. A 2007 ACOG committee opinion specifically addresses special issues related to sterilization. For instance, hysterectomy for the sole purpose of sterilization is deemed inappropriate. Women with mental disabilities, who have an impaired ability to participate in the informed consent process, are not automatically justified to undergo sterilization. However, these women should not necessarily be denied the procedure, if desired. In these situations, the physician should consult with

the patient's family and her caregivers to devise a plan that suits the best interest of the patient while respecting her autonomy.

CONCLUSION

This chapter has presented a sample of the issues pertinent to the practice of gynecology. As a field that combines the challenges of medicine, surgery, and the complex issues specific to the care of women and their reproductive health, several other important ethical aspects may not have been addressed here. Moreover, innovative technologies and therapeutic procedures present new dilemmas to the practicing physician on a regular basis. Physicians have many resources with which to approach some of the difficult questions that may arise in their own practices. Institution or individual practice ethics committees, oversight committees, and ethics consult services are available for multidisciplinary and peer review of challenging ethical cases. Physicians at all levels of practice should feel confident to turn to these mechanisms for guidance in the case of difficult ethical situations.

P.28

BEST SURGICAL PRACTICES

- Informed consent is a mechanism whereby the patient's autonomy is respected.
- Physicians are responsible for maintaining medical and surgical competence.
- The confidentiality of the patient should be protected. Only in special circumstances can it be overridden.
- Physicians should be familiar with the different forms of advance directives and discuss end-of-life decision making with their patients.
- Gynecologists should be aware that several issues specific to the care of women and their reproductive health present ethical dilemmas that are often unique to gynecology.

Chapter 3

Psychological Aspects of Pelvic Surgery

Betty Ruth Speir

DEFINITIONS

Anxiety—A feeling of apprehension, uncertainty, and fear without apparent stimulus and associated with physiologic changes (tachycardia, sweating, tremor, etc.).

Grief—The normal emotional response to an external and consciously recognized loss; it is self-limited, gradually subsiding within a reasonable time.

Insanity—Mental derangement or disorder. The term is a social and legal rather than medical one and indicates a condition that renders the affected person unfit to enjoy liberty of action because of the unreliability of his or her behavior with concomitant danger to self and others.

Regression—A return to a former or earlier state; a subsidence of symptoms or of a disease process; the turning backward of the libido to an early fixation at infantile levels because of inability to function in terms of reality.

Ethnicity—Ethnicity is a socially defined category based on common culture or nationality. Ethnicity can, but does not have to, include common ancestry.

Iatrogenic injury—An inadvertent adverse effect or complication resulting from medical treatment or “originating from a physician.”

Gender identity—Gender identity refers to a person's private sense of, and subjective experience of, the person's own gender.

Psychodynamics—Psychodynamics is the theory and systematic study of the psychological forces that underlie human behavior.

Vaginismus—Vaginismus is vaginal tightness causing discomfort, burning, pain, penetration problems, or complete inability to have intercourse.

Robotics—Robotic surgery is a technique in which a surgeon performs surgery using a computer that remotely controls very small instruments attached to a robot.

P.29

INTRODUCTION

Neuroscientific research over the past decade continues to validate the oneness of the psyche and the soma (**Fig. 3.1**). Gynecologic surgery, in particular, does not simply alter the soma, but temporarily and sometimes permanently alters the psyche of the patient. The modern gynecologist needs to be more than a skilled technician: he or she must be willing and able to identify the potential psychological effects of the surgery performed and must be prepared with the knowledge and skills to address these effects with the patient.

Sir William Osler taught, “The good physician knows the disease the patient has. The great surgeon knows the patient who has the disease.”

The technologic revolution has presented today's surgeon with a vast array of sophisticated equipment. In capable hands, miraculous surgical feats can be performed on a woman's body, but at what cost to her

psychological self? The removal or reconstruction of diseased or dysfunctional anatomy may set off a chain reaction of parallel events in a woman's psyche.

For a surgeon, the gynecologic operation may be a quotidian event of usually simple dimension. For the patient, however, each procedure is a unique and intimidating experience. Her sense of well-being and health may be threatened. She may lose control over her body for some indefinite period of time. She may perceive the planned procedure as temporarily or even permanently affecting her sexual identity.

As complicated procedures become routine, the surgeon risks losing perspective about the impact of surgery on the life of the individual woman. The patient who experiences ablative genital (or breast) surgery is strongly influenced by her emotions. These vary in degree but are usually cumulative. As the patient passes through the presurgical, surgical, and postsurgical experiences, she may be stressed beyond her capacity to compensate. If help is not available to facilitate emotional healing and rehabilitation, permanent psychological damage may result.

FIGURE 3.1 *Inseparable psyche-soma*: Sculpture and photo by James Sardonis—<http://www.sardonis.com>.

The majority of women do heal and take up their lives, raise their children, work at their jobs, and relate well to their husbands or lovers. For them, the healing interval is relatively quick, and the stress is modest. Do not underestimate what can be learned from this psychologically healthy segment of women patients. In the 1940s, Abraham Maslow studied people with exceptional mental health to develop his hierarchy of needs theory. He discovered that these people's potential had never been weakened by negative thinking, a defeatist outlook, or a destructive self-image. "The rest of us," he declared, "fixate at a lower level because someone or something has implanted notions of limitations."

Once you become cognizant of the success statistics in your own patient population, you may discover why most women recover after gynecologic surgery to zestfully reembrace life, whereas others begin to slowly turn away from its possibilities.

It will never be enough for a surgeon to be a trained mechanic, able only to diagnose and repair. He or she must also be prepared to predict, recognize, and begin treatment of the psychological consequences of gynecologic

disorders. This chapter is designed to help surgeons and other physicians better understand the female perspective and to use that knowledge to facilitate multidimensional healing.

ANKH

The ansate cross, Egyptian emblem of generation, symbol for life and soul and eternity, is a mark universally designated to depict femaleness (Fig. 3.2). By using this hieroglyph, modern scientists continue an ancient tradition of respect and reverence for women. Within the inner sanctum of every woman's mind lie symbols that are powerful and personal. These feminine

P.30

identity markers are guarded and guided by her instincts, and no surgeon can successfully maneuver in this labyrinth of psychological and psychosexual emotion and cause no harm unless the female patient acts as a guide.

FIGURE 3.2 The ansate cross, or ankh amulet, is an ancient Egyptian symbol of life and sexuality.

Egyptian writings from almost 4,000 years ago in the Kahun Papyrus depict the uterus as having an important and powerful effect on mental life. Current research tends to agree with the ancient scribes. The uterus has great symbolic value for many modern women, too. Beginning with the rite of passage called menstruation, a strong invisible bond is formed between a woman and her body. Her biologic clock has been set. For the next 40 years or so, she will be reminded each month that she is a woman, and menstruation is regarded by many as palpable proof of their femininity.

Others believe that menstruation is part of a natural cleansing cycle that purges the body of poisons that accumulate during the month. They know from experience that the premenstrual symptoms of edema, bloating,

headaches, and emotional tension will be washed away in the tide of their monthly flow.

For some, the rhythm of the menstrual cycle is used as a way to time and order their lives. Like the phases of the moon, this cycle bestows a sense of routine, regularity, and predictability that has emotional significance. With the onset of menstruation, a woman is forever changed. Surgical removal of any of the reproductive organs will change her again, but how?

The effect of a woman's menstrual cycle on many medical conditions is well documented. Medical suppression of ovulation is commonly used as a way to evaluate and treat such chronic conditions as migraine, epilepsy, asthma, rheumatoid arthritis, irritable bowel syndrome, and diabetes. Research at the National Institutes of Health (NIH) and other leading institutions has shown "how nerves, molecules and hormones connect the brain and immune system, how the immune system signals the brain and affects our emotions, and documents how our brain can signal the immune system, making us more vulnerable to illnesses." What we have known intuitively is now understood scientifically. Hormones secreted during a woman's menstrual cycle affect her mood. Could the decline of these hormones during the natural aging process contribute to dementia? The future is alive with fascinating neuroscientific and neuroimmunomodulation elucidation, but today's woman is backlit by the skepticism of some scientists. Her concerns about her body and the way it will work after surgery are immediate and quite often, heart wrenching.

A woman about to undergo a hysterectomy might wonder if her lover will be able to detect the absence of her uterus. After the surgery, will she be thought of as less of a woman? Will her partner abandon her for someone who is still complete, either in the sense of being able to offer the possibility of a child or complete in the sense of having experienced no unnatural surgical transformations?

Will orgasm be as pleasurable for her after the surgery? For many women, the uterus has symbolic significance as a sexual organ. The uterus contracts during orgasm. Some women perceive this as most pleasurable. If the patient believes the uterus is essential to sexual response, then, in fact, it often becomes so, and women with this mindset may become sexually dysfunctional when it is removed.

Once the procedure is accomplished, will she still look and sound like a woman, or will she become noticeably more masculine? For others, the uterus is closely tied to feelings of attractiveness and sexual desirability. To a few women, removal of the uterus or ovaries or both constitutes a desexing, a permanent destruction of female identity and function. Sadly, certain members of the medical community as well as the feminist community perpetuate this notion and increase the attendant fear when they refer to women who must have their ovaries removed as "castrates."

Some women become distressed when they learn they must deal with the certainty of absolute sterility. For those who choose motherhood, the uterus, ovaries, breasts, and vagina work in harmony with other factors to attract a necessary mate and get down to the business of creating new life. These organs are vital to the sexual and reproductive aspects of a woman's life; thus, impending loss of these physical structures because of disease or dysfunction sometimes creates deep angst that must be resolved before surgery is attempted. Many women who have all the children they want and who do not wish to get pregnant again are still sometimes disturbed by the finality of the decision. The gynecologist should assure these maternal women that, although they will no longer be able to conceive a child, the powerful urge to create will never leave them. In time, they will learn to direct this primal energy into other areas of their lives and be immensely satisfied with the results. Studies such as the Ethnicity, Needs, and Decisions of Women project (ENDOW), a 5-year, three-phase, multicenter collaboration, are focusing on many of these issues and will help the gynecologist better understand the patient.

Today's modern woman, for the most part, is an avid information seeker. She surfs the Internet, buys the latest books, reads magazine articles, and conducts in-depth interviews with peers who have experienced similar gynecologic problems. A certain proportion of the harvested material is useful to her and perhaps even

illuminating for the physician, but unfortunately, some of the sources are inherently flawed, prejudicial, illogical, or without scientific basis. It is the physician's responsibility to separate the grains of truth from the chaff. All the information the patient has gathered represents her attempt to prepare herself psychologically for the ordeal ahead, and she must never be condemned or made to feel small for trying to protect herself.

For the gynecologist, it is not necessary, or even possible, to change a patient's basic attitude or feelings. It is, however, vital to acknowledge them. The right information, reassurance, and support usually quickly modify many negative factors and lead to a healthier attitude and understanding of the surgical process. It is crucial that the patient be allowed to vent her anxiety and give voice to her fears.

COMMUNICATION

Patients in General

Diplomats the world over understand the significance of effective communication. Indeed, the prospect for world peace depends on their ability to interact efficiently. A female patient's psychological bearing before, during, and after the gynecologic procedure can depend on the communication techniques used by her physician. You must establish rapport, speak of the real and present danger to her health, and then elaborate on your plans to protect her.

Whenever possible, provide pleasant surroundings where you and your patient can comfortably hold a private conversation. Push all other thoughts out of your mind. These few minutes belong exclusively to her, and the quality of the time you spend actively communicating will pay healthy dividends for you both.

Whether explaining the simplicity of a needle-directed breast biopsy or the intricacies of hysterectomy, you must be able to highlight the technical details of the procedure and its postsurgical realities in a nonthreatening but utterly

P.31

truthful manner. Begin the presentation using simple but thorough explanations and examples of the procedures. Your patient will let you know how much information she can or wishes to process by the questions she asks.

Your patient needs confidence in your technical ability, to know that her problem is being taken seriously and that you are qualified to competently help her cope with all of the ramifications of this new experience.

Dealing with the patient's feelings is not usually difficult if the surgeon accepts the viewpoint that many of the patient's emotions are part of the gynecologic situation. To the physician, the presurgical tension is predictable, familiar, transient, and simply comes with the territory; but to each new patient, it epitomizes an unfamiliar, dramatic, and life-altering experience.

To interpret the patient's true feelings, simply listen to her. Listening well is both an art and a skill, and the surgeon who cares about the patient's complete health as well as her quick recovery works diligently to hone a sharp edge on this valuable tool. Listen and you will hear the woman give a name to her most profound doubts and fears. Repeat her words so that you are absolutely certain you understand what she said, and so that she is absolutely assured that you are listening to her.

Begin the communication process by finding out what the patient perceives will be done to her body and why the procedure is necessary. Find out what she believes the consequences of the surgery will be. How does she think the surgery will impact her life? As she discusses the implications of her decision, her knowledge, fears, and biases will emerge. At this point, you should be able to supplement the patient's perspective with appropriate explanations about anatomy, physiology, and pathology. After this, it is time to describe in detail the usual preoperative, operative, and postoperative routines. Address the patient's questions and fears in as many ways as it takes for her to become confident that she understands what will happen to her.

Carefully explain what you are going to do to help her. If she wants or needs to know, describe the common physical sensations, bandages, incisions, catheters, tubing, and medications that are associated with her particular procedure. Define the patient's role in her own convalescence and recovery. Give her a general timetable for how long she will feel discomfort and need to use pain medication, when she will be ambulatory, and finally, when she will be discharged from the hospital or outpatient center.

Relate the most common complications that might occur as the result of her surgery. Injuries that might affect the quality of her life, even temporarily, should never come as a postsurgical surprise, nor should they be glossed over during the signing of the consent forms. Every patient wants to trust the doctor.

Informed Consent/Ethical Issues

Tell a patient that she has the option of robotic surgery and you'll probably get an exuberant response. "A robot! How cool is that! What's its name?" Angelos, who runs the first surgical ethics program in the United States, understands that most people automatically think new anything is better than old everything and that robots are magnificent manifestations of technology. He knows that many surgeons prefer to walk on the cutting edge, too, but in reality, is this a slippery ethical slope?

Before a proper informed decision can be made, the patient should know that in the beginning, a new procedure or system has fewer data on outcomes on which to base a decision, and the patient's surgeon should be honest about his or her level of experience. The ultimate decision must be based on what benefits the patient is expecting from the procedure and which choice is the most likely to produce that benefit.

Iatrogenic injury remains the most common cause of lower urinary tract trauma. An understanding of the prevention, recognition, and treatment of urologic complications is important for every surgeon performing major pelvic surgery. Injury to a woman's genitourinary system may take 10 to 20 years to develop full-blown symptoms, about the same time line as from multiple childbirths, but it remains a possibility. Physicians, however, disagree on whether or not to tell the patient that, because of damage to the pelvic nerves or pelvic supportive structures, urinary incontinence after hysterectomy could be a long-term adverse effect. Only 4% of the hysterectomies performed are for relief from symptoms of incontinence.

Complications such as the formation of adhesions may occur in as many as 55% of patients after gynecologic surgery. These adhesions can become a critical issue from the standpoint of reproductive potential. Their presence is also strongly associated with pelvic pain, abnormal bowel function, and small bowel obstruction.

The mentally competent patient has a moral, legal, and ethical right to make an intelligent informed decision and can only do it if she is privy to all of the available facts concerning her situation. It is essential for her to be involved in the decision-making processes, because the more committed she is to the proposed treatment, the more invested she will become in her own preparation and rehabilitation. This point is supported by the findings of the ENDOW Study.

The art of touching, the therapeutic laying on of the hands, is important. Being lonely, frightened, and sick is a reason for the patient to be touched by her physician, especially if she seems particularly overwhelmed by her situation. To touch the patient's shoulder or hold her hand while talking to her is therapeutic. Even a comforting hug is appropriate if it fits the circumstances and the patient reaches out to you. Before fetal monitoring, quality of labor was evaluated by sitting at the patient's bedside with the physician's hand on her abdomen to feel uterine contractions. Often, the presence of the physician and a warm hand on her abdomen made the patient relax, rest, and become calmer during active labor. Cancer patients, especially, on hearing bad news need immediate human-to-human contact to stay grounded enough to face that terrible moment. The professional boundaries of roles, time, place, space, gifts and services, chaperoned examinations, physical contact, money, and formal language were never intended to be an impermeable membrane separating a doctor's ability to

administer human kindness. A healer's touch can often comfort a distressed patient when words are inadequate. A patient's family is a vital part of her support system and can be a potent ally, or not, to the health care team. If your patient requests that family members be present during her consultation, allow it, but speak directly to her whenever possible.

Once the initial presurgical discussions are complete, your patient may need some time to digest all the new information she has received. After assimilation, allow her to contact you for clarification or to ask more questions. This is especially important if the procedure involves new techniques or technologies.

Patients have the right to know the physician's level of experience regarding surgical techniques, as well as a thorough description and performance history of any device that will be used or implanted in their bodies. Rosen believes this is especially important because different procedures have different risks, and the patient should know why her physician prefers one method or product over another. Other countries have government registries that track the outcomes and complications of

P.32

medical devices so surgeons can quickly determine superior and inferior performers. A physician expert in a Swedish hip registry disclosed, "The risk in the United States that a patient will need a replacement procedure because of a flawed product or technique can be double the risk of countries with databases... and doctors in Sweden are much less likely than American doctors to embrace new devices until registry data show they work." The American patient should know the status of Food and Drug Administration (FDA) surveillance and whether the physician and device manufacturer have any financial connection.

Patient-clinician communication has never been more important. Paget et al. list seven basic principles as a starting point:

- Mutual respect
- Harmonized goals
- A supportive environment
- Appropriate decision partners
- The right information
- Transparency and full disclosure
- Continuous learning

Patients from Other Cultures

In the United States, the number of patients from other cultures is increasing dramatically. In many cases, these patients are situated in dense clusters, and physicians in these areas are either multilingual or have assistants who are able to act as interpreters. However, no matter where your practice is located, chances are that at some point during your career as a physician, an individual from another culture will need your help.

Mull makes the following suggestions for communicating effectively with a person whose language you do not speak and whose culture is foreign to you: Make sure that your office staff are courteous and respectful. Show the genuine concern you feel. Be friendly and helpful to build rapport and develop a repertoire of knowledge. Familiarize yourself with the general principles of their traditional medicine. Whenever possible, have an interpreter present. Learn a few key phrases in their language, and use these for initial greeting and during examinations. Electronic linguistic assistants, such as the Franklin devices, are available in most languages. Include, at least in discussion, any family members your patient considers influential. Always ask what they have done to treat themselves. Have they consulted an influential family member? A healer? Have they used home or

herbal remedies?

Physicians should be aware of common themes that exist in cross-cultural medicine, including the following:

- Fear of blood loss
- Fear of cold
- Tradition of male dominance
- Conservatism in sexual matters relative to teenage girls
- Poorly developed concept of preventive medicine
- Intolerance of side effects from medication
- Expectation of expeditious wellness
- Reluctance to discuss emotions with people who are not family members

Diaz-Gilbert cautions health care professionals to check their prejudices at the door and not to assume that a non-English-speaking person is uneducated. The following are some guidelines for effective communication with patients from other cultures:

- Allot extra time for the patient from another culture.
- Address every patient initially in English.
- Ask if the patient carries a bilingual dictionary.
- Gesture or write down simple words or phrases.
- Use visual cues, such as insurance forms, calendars, medication bottles, or anatomical sketches. If necessary, draw a picture to convey what you mean.

If the patient needs to perform a specific task, such as disrobing, carefully pantomime each step. Remain aware that direct eye contact, certain hand or finger gestures, and physical touch are offensive, are disrespectful, or can be construed as sexually suggestive in certain cultures.

When a cultural language barrier exists, reliance on body language becomes crucially important. Work at learning to read it. These patients experience the same emotional responses to surgery and need the same education and reassurances. Having to use the services of a foreign doctor in an alien land makes the surgical process even more frightening for them.

PSYCHOLOGICAL PREPARATION FOR SURGERY

Massler and Devansan said that there is an emotional response to any physical assault on the body. The magnitude of the response is expected to be proportional to the degree of emotional investment one has in the part of the body under siege. Among women, anatomic entities most vulnerable to this emotional reaction are the face, hair, breasts, genitalia, and abdominal wall.

Second only to cesarean birth, hysterectomy is the most frequently performed major surgical procedure done on reproductive-aged women. Over 600,000 women a year have hysterectomies in the United States. Newer, minimally invasive procedures have shortened hospital stays and have lessened visible disfigurement of the body. Schwartz and Williams of the Mayo Clinic concluded that detrimental psychological effects reported to occur after hysterectomy are not supported by prospective studies. Indeed, in most patients, mood was elevated.

The majority recover quickly from the procedure and enjoy the new freedom that comes to an individual when a chronic health problem has been resolved. Your patients, however, are not always older, wiser women, and they

do not always recover quickly. If you know the signs to look for, you will be able to help that patient who is having a harder time adjusting to pelvic surgery, especially if it was a radical, life-threatening, or unexpected event.

In his book, *Matters of Life and Death*, Daniel Bruns writes, “Even the strongest person can be shaken by the horrors of some medical cures. Beyond this, life anxiety is even more common in persons with pre-existing emotional difficulties or characterologic disorders. These persons may go through life like eggshells, intact and functioning, but with psychological fragility. When faced with an extreme life stressor, such a person may simply shatter.” How will you, as the physician, recognize the vulnerable?

Roeske researched 13 factors related to poor prognosis for excellent mental health after hysterectomy. The following factors begin to define the patient who might react negatively to genital surgical stress:

- Gender identity
- Previous adverse reactions to stress
- Previous depressive episodes
- Family history of mental illness
- History of multiple physical complaints, especially lower back pain

P.33

- Numerous hospitalizations or surgeries
- Age less than 35 years at time of hysterectomy
- Desire for a child or more children
- Fear of loss of libido
- Significant other's negative attitude toward procedure
- Marital dissatisfaction or instability
- Cultural or religious disapproval
- Lack of vocation or hobbies

Barnes and Tinkham's research also indicates that patients tend to react to current stress in much the same way as they reacted to past crises and personal losses. Well-established patterns of behavior repeat themselves. By taking a patient's history, the surgeon can be forewarned about which patients are likely to have the most difficulty handling the emotional aspects of gynecologic surgery. Equipped with this information, the surgeon can prepare to offer extra support in the form of reassurance, educational information, and—if indicated or requested—the names of psychotherapists who are trained to deal with women's health issues.

The Psychology of Pelvic Pain

Andrews said the problem of chronic pelvic pain (CPP) is very common. “About one in ten outpatient gynecologist appointments, up to 40 percent of laparoscopies, and up to 12 percent of hysterectomies are for chronic pelvic pain. We spend over a billion dollars just on outpatient management of chronic pelvic pain.”

Singh, Rivlin, et al. list the following psychophysiologic therapies as possible interventions to reduce the severity of the symptoms: reassurance, counseling, relaxation therapy, stress management, and biofeedback techniques. They caution that consultation with a psychologist, urologist, neurologist, and gastrointestinal or other specialist is very important before considering invasive or aggressive management.

Management of the pain is difficult because there could be so many possible causes: Endometriosis, pelvic inflammatory disease, adhesive disease, pelvic congestion syndrome, ovarian retention syndrome, ovarian

remnant syndrome, adenomyosis, and leiomyomas, and the list goes on. Benjamin-Pratt and Howard believe the best approach may be to use a combination approach that treats the disease and also teaches pain management.

Chronic or constant pain causes immense suffering because the patient cannot escape it or never knows when it will strike. Acute pain, like that of childbirth, has a beginning and a real end. The woman knows that no matter how much she hurts, there will be relief soon. While awaiting diagnosis or surgical treatment, the patient should be encouraged to keep a pain diary.

Pelvic Pain Support Network lists helpful suggestions to describe pain. These are useful for self-illumination for the patient as well as a diagnostic aid to present to the doctor:

- On a scale of 0 to 10, how bad is the pain?
- How long have you been having the pain?
- Where is the pain?
- Has the pain ever been diagnosed? If so, what was the diagnosis?
- What investigations have you had in the past?
- Describe the pain in your own words (burning, stabbing).
- What makes the pain worse? What makes it better?
- Is there a pattern? Diaries are useful for this.
- Have you been prescribed medication? Did it help or not?
- What activities does the pain prevent you from doing?
- How long can you do a certain thing before you have to rest?

Common Emotional Responses to Surgery

Insecurity

Giving up control of one's body, even temporarily, is uncomfortable for all of us, but it is terrifying for people who feel generally insecure. One of the most common defense mechanisms against feelings of insecurity is to institute rigid controls over all aspects of life. These patients may have no control over getting sick. They will have little if any control during the surgical procedures. The postsurgical setting will be a hospital room where the staff tell the patient when to awake, take medicine, eat, bathe, walk, have visitors, and have blood drawn. The health care workers will probe such personal matters as urination, defecation, and passage of flatus. Anxiety, anger, and feelings of being assaulted combine with insecurity to produce an unhappy, fearful, and sometimes raging patient.

These feelings are greatly diminished when the patient believes the surgery will improve her quality of life. There will eventually be relief from pain, removal of cancer, an end to heavy bleeding, restoration of fertility, or some other positive result. She will be better than she was before the surgery. The transition to becoming this healthier person is made easier when she trusts and believes in her physician.

Anxiety or Fear

Anxiety or fear associated with surgery is essentially universal. Most common is fear of the unknown or of what the patient imagines she will be forced to endure during hospitalization. Factual information about the surgical and recovery process and competent care by a compassionate hospital staff help to diminish this fear. Surgeons should assume responsibility for the behavior of the hospital staff toward their patients. When a patient

complains of ill treatment by any of the health care providers, the physician should deal with the situation personally to decrease the probability of a future recurrence of the offensive or thoughtless behavior.

Patients may fear the loss of economic competence. A woman who has worked for many years may lose her sense of usefulness when disabled for some length of time. Whether she plays a major or minor role, the contribution she makes to her family's economic stability will be important to her. The sense of identity and self-esteem she derives from her job may also be threatened by the outcome of her surgery.

Fear of anesthesia is often a thinly disguised fear of dying as well as a fear of loss of control. It may be appropriate to confront the fear of dying directly so that the patient has the opportunity to express why she is afraid. Is the fear general or specific? Did a close relative suffer from the same affliction and die during or shortly after surgery? Does the patient have a strong intuitive feeling that something will go wrong? If so, ask her what you can do to modify the surgical situation. Determine whether the scheduled date of surgery or the particular hospital is significant. The fact that you consider her feelings an important issue and a normal part of the gynecologic disease process may be enough to calm her fears.

Regression and Dependency

In most people who are ill or who undergo surgery, regression to a more dependent state is fairly common. Dealing with a woman who is no longer self-sufficient or emotionally stable is difficult for the patient's family and friends. These members of her supporting cast are accustomed to her presurgical roles as wage earner, wife, mother, friend, cook, adviser, shopper, housekeeper, taxi driver, entertainer, and more. When she becomes ill and can no longer function to make their lives easier, family

P.34

members and friends often become frustrated and angry. They may apply overt or subtle pressure to try to force the woman to exert herself and fulfill her usual roles. A change in roles is difficult, but often the illness teaches family and friends why this particular woman is valuable to them. In many cases, those who temporarily assume her normal duties or help her cope with the surgical experience discover strengths of hers of which they were previously unaware.

When the disease and prospect of surgery are new to the patient, all these factors, as well as a feeling of ill health, contribute to an emotional fragility that yields extremely labile emotions, including feelings of sadness, despondency, tearfulness, and irritability. The usual defense mechanisms are often temporarily weakened or destroyed. The woman is vulnerable to attack on all personal and professional fronts. She needs time with people she cares about, and she needs time alone to sort out her thoughts and emotions.

Grief

Grief is a normal, natural reaction to illness or loss of any kind; it is essential to emotional healing. Recognizing the various stages of grief allows the surgeon to help the female patient understand what is happening to her.

Denial is the first and most primitive emotional response to loss, and it can take many forms. The patient may demonstrate denial by not going to the doctor when she finds a lump in her breast or when she notices abnormal bleeding. She may pretend the symptoms do not exist or are a temporary nuisance. Not remembering instructions the physician gave her could be a manifestation of denial. She may forget important facts or deny the seriousness of the problem. Denial allows people to function for a little while in a make-believe world. With this primitive mechanism, they survive emotional stresses they might otherwise be unable to handle.

Bargaining with a higher power is the second stage of grief. Many patients feel they have carte blanche to bargain when they are experiencing a loss. "Make this bad thing that has happened to me go away, and I swear I will become a better person."

Guilt can surface before or after a loss. Most guilt feelings are completely inappropriate, in that the focus of the

guilt rarely is directly related to the cause of the loss. When they are sick, many people feel that they are being punished for not being perfect. Explain to your guilt-ridden patients that their feelings are normal under the circumstances. Although guilt can sometimes deliver devastating, incapacitating blows, the good news is that it is usually transitory.

Depression comes in varying degrees to most people experiencing grief; it is characterized by feelings of helplessness, hopelessness, and worthlessness. Other symptoms include middle-of-the-night insomnia, nightmares, loss of appetite or excessive eating, lethargy, difficulty making decisions, psychosomatic symptoms, and fatigue unexplained by activity.

Ask the patient if she has any of these symptoms. Postsurgical depression is common. Depressed patients usually admit that the sad feelings are routine and occur daily. When prolonged, they indicate the patient has been unable to work through the grief process. Something emotional has yet to be resolved.

Rage turned inward often manifests as depression. When the patient is able to identify what she is angry about, to ventilate the rage, the depression usually begins to lift. When she takes charge of her life again and makes decisions, even small ones, she begins to feel better, and feelings of helplessness, hopelessness, and worthlessness abate. However, when the depressed patient becomes suicidal, stringent intervention must occur. The suicidal patient presents serious challenges and will be discussed in specific detail later in this chapter.

The stage at which the patient ventilates her anger can be difficult for those providing care, but it should be accepted as healthy. The patient may go to extremes, writing letters to the newspaper or speaking of suing her physician. She may complain bitterly about the nursing staff and the hospital. Such actions are a form of protest at the stress that has been dealt to her body and mind. In most instances, this behavior means that the depression is lifting and the patient is beginning to move toward the resolution of her grief. The depressed patient should be encouraged to ventilate by talking, to establish an enjoyable form of physical exercise, and to begin to take charge of her own life.

Resolution and integration eventually occur. The stressful experience of loss finally becomes an accepted part of her life. The memory causes sadness and regret, but no longer the devastating immobilization found in the earlier stages of grief. Integration does not mean the experience is forgotten, only that it has less trauma associated with it. After integration, certain stimuli can provoke flashback grief. The painful emotional tapes begin to play again, but the patient learns that the bad time is a rerun and will not last long.

The stages of grief do not always occur in order. The patient may feel fragments of several of them at the same time. If a female patient's behavior seems bizarre, excessive, or out of the realm of what would usually be anticipated during her particular surgical experience, look for the role grief might be playing in her life.

PSYCHODYNAMICS SPECIFIC TO DIAGNOSIS AND SURGERY

Patient-Physician Bonding

Neither scalpel nor laser can divide the psyche from the soma. As technical skills have improved and multiplied, robotic surgery has become commonplace, and comprehensive care of the gynecologic patient has declined. However, a knowledgeable and compassionate PA (physician's assistant) can be invaluable to both the surgeon and the patient. Increased emphasis on scientific and procedural care usually means less time in the consultation room and more time in the examining or procedure rooms. This is unfortunate for all concerned, because it takes time to explore the concepts, fears, and psychological wellbeing of the individual patient both before and after surgery.

It takes time to scan the books and magazines women read, to search the same Internet sites, to listen to the voices of their advocates, and to evaluate, critique, and learn from their sources of information; but it is important

to make the effort. Otherwise, you run the risk of being out of touch, or worse still, appearing arrogant and condescending. Women in general have a sixth sense about these attitudes, and women about to undergo surgery or those recovering from surgical trauma to their bodies are hypersensitive to all manner of psychological stimuli.

The medicolegal climate has also potentiated perioperative anxiety. When you inform your patient, as she prepares for surgery, that she can bleed to death, be subjected to blood transfusions, have an adverse reaction to anesthesia, or sustain bowel or urinary tract injuries, you augment her innate fear of surgery. Some patients experience strong pressure from extreme feminist groups to seek and maintain a controlling role in her life, over her destiny, and over the surgeon. Under these circumstances, it is more necessary than ever for the pelvic surgeon to take the time to explore the patient's psyche in

P.35

the preoperative and postoperative periods in order to avoid undesirable psychological sequelae. Having personable, competent health care workers in your office who assist in preparing your patient for surgery is also indispensable. Anatomical charts have become works of art, and they, as well as videos and other teaching aids, are useful in explaining the technical details; however, despite all the educational tools and staff assistance, the most important person remains you, the doctor. Unless you sit and answer questions on a one-to-one basis, you are neglecting your responsibility to her.

Much of the time, the questions will deal with information the patient has gleaned from literature, popular talk shows, and the Internet. Some of the opinions she reads or hears will frighten her or make her suspicious, and a few patients may initially come to your office thinking of you as a potential enemy. A staunch feminist may express the belief that you are just another insistently prosurgical doctor out to hijack her womb and add it to your trophy collection.

Popular literature today often stresses sexism, ageism, and greed on the part of doctors. *The Silent Passage* and *Our Bodies, Ourselves* were among the first widely read books on which patients depended for their gynecologic information. In these, they read that "for well over a century in the United States, women's uteri and ovaries have been subject to routine medical abuse," and "one should not be railroaded into hysterectomy nor onto hormones." Hysterectomy is described as "devastating" surgery, and for some women, it certainly can be. These books found a wide audience and led to the publication of other books, which took an even more radical approach, all in the name of protecting women from castrating medical experts who might use their position of authority to hurt, not help, them.

The Ultimate Rape: What Every Woman Should Know About Hysterectomies and Ovarian Removal was inspired after the author underwent a hysterectomy. She suffered extreme physical and emotional trauma following the surgery, but when she complained to her physicians, they advised her to go see a psychiatrist, because all her symptoms were in her head. The book's title is evidence of the rage she felt at their pronouncement. Now her voice is joined by others who believe every woman has the right to be thoroughly informed about procedures and consequences before consenting to gynecologic modifications. And certainly, a woman should.

In *No More Hysterectomies*, touted as the first living textbook on the Web, the reader learns how the male-dominated medical profession and the insurance industry have sanctioned millions of unwarranted hysterectomies. One testimonial to the ideas presented in the book describes the current medical environment as a "woman's hormonal holocaust."

The enlightening news is that interest generated by these sources and their legions of followers has had a positive and direct effect on women's health research. Global studies are numerous and are concentrating on traditional as well as alternative methods of treatment for menopause, hysterectomy, hormone replacement

therapy (HRT), cancer, endometriosis, fibroids, and dementia. For the first time in the history of medical science, research is being conducted on a large scale to determine how women of various ethnicities and cultures and with differences in their physiology react to menopause, gynecologic surgery, hormone therapy, and sexual function. The ENDOW Study has found ethnic/racial differences in women's perceptions of hysterectomy and their decision making regarding elective surgery. Negative connotations were found to be more prevalent among African-American women, thus indicating a need for added support and preoperative information. Future generations of women will reap the benefits from this research, but the overwhelming aura that prevails in today's gynecologic patient is one of confusion.

After reading just a sampling of the lay literature, some women feel that surgical removal of their female organs and commencement of hormonal therapy constitutes an unnatural, chemotherapy-like assault on their physical bodies. It is the task of the physician to admit into evidence the medical facts necessary to correct any gross misconceptions that could affect patient care. Sometimes, it may seem as if the patient, armed with advice about natural remedies for her severe pelvic pain, heavy bleeding, or hot flashes, wants to drag you with her back into the Dark Ages. Be patient and also prepared, if necessary, to explain the medically sound benefits of life lived outside the cave.

Be compassionate. No matter how routine the job becomes, compassion is a vital requisite to becoming an exceptional communicator and healer. Empathy often follows experience, and those times when you are able to make a noticeably positive difference in your patient's life are inspirational. To try the one new thing that might help many patients in the future, it is necessary to earn the trust of a single patient in the present.

The days are gone when a doctor was considered omnipotent, when he—and rarely, she—received a hock of ham for the birth of a child or had to tell a woman that she would have to live with the eventual hump on her back because it was a natural process of aging. Patients know about osteoporosis and heart disease and about reproductive technology and brain neurotransmitters. The media have turned every living room into a medical school. Some patients present videos and clippings detailing current research and experimental treatments relative to their specific diagnoses. They know a little, and they want to know more. Many patients want to participate in their health care and absolutely should be encouraged to do so. Unlike the doctors of old, who, for the most part, had to contend with an uneducated populace, the modern physician must form a partnership with the modern patient. Mutual responsibility, respect, and trust eventually strengthen this bond.

The cornerstone of the initial work is truth. Use good judgment about when to tell all the facts, particularly those that point to a devastating diagnosis, but never lie. In 1961, 90% of physicians surveyed in a single, large urban hospital stated that they withheld the diagnosis of cancer from their patients. Today, the position has been totally reversed, with 97% reporting that they reveal the true diagnosis of cancer.

Doctors, however, are not the only members of the team with ethical obligations. Patients also have the responsibility to tell the physician the truth relative to their symptoms, medications, allergies, and past medical histories and to relate any significant traumas or family history that could affect their current situations.

Question your patient specifically about stressful life events. Did she respond to these in a positive or negative way? Of all inquiries, this is the most important indicator of how the patient will respond to any current stress. Once the physician knows the answer, psychological preparation for diagnosis or surgery can begin in earnest.

Researchers in the United Kingdom have compiled data from multiple trial studies confirming that psychological preparation for surgery is effective. The general hypothesis was that communication and counseling are important determinants of numerous factors, including the following:

- Accuracy of the diagnosis
- Effectiveness of disease management

- Disease or problem prevention
- Patient satisfaction

- Adherence to treatment
- Psychological well-being
- Patient understanding of procedures
- Professional satisfaction and levels of stress

Information about each of these parameters was compiled, and considerable evidence existed to support all the hypotheses. In review, Davis and Johnston reported that psychological preparation is effective in reducing negative effect, pain, medication, and length of hospital stay and in improving behavioral recovery and physiologic functioning.

Surgical Whispers

The surgeon should make it a point to be with the patient while anesthesia is administered. Knowing that you are there with her from the beginning will help her feel safe. At the end of each surgical procedure, whisper into your patient's ear, "You're going to be well very soon." You may be surprised to find she needs less pain medication and recovers more quickly than do patients without the benefit of this positive prophecy. The mind itself is a powerful force, as evidenced by neuroscientific research. Dr. Esther M. Sternberg, Director of Integrative Neural Immune Program and Chief of the Section on Neuroendocrine Immunology and Behavior at the National Institute of Mental Health and National Institutes of Health, says that "With stress reduction endogenous opiates are produced that decrease pain. These come from the same cells in the hypothalamus that make the stress hormone CRH." Understanding these brainimmune connections will help the surgeon understand how his or her support and encouragement can decrease the patient's pain. Youngs et al. believe the surgeon or a familiar associate should also be present immediately after surgery to reassure the patient, orient her to her surroundings, and make certain she has adequate pain relief. Even if the patient appears unresponsive during the immediate postoperative phase, a familiar voice and reassuring word can be immensely beneficial.

Immediate Postoperative Care

Hospital stays have become much shorter. Some hysterectomies are being performed as outpatient procedures. These factors are having a positive psychological effect on patients. She knows that she is getting well when she no longer requires needles and is able to ambulate and urinate without assistance. It has long been known that early ambulation significantly reduces morbidity as well as the incidence of phlebitis and pneumonia. As long as intravenous therapy and urethral catheterization are maintained, the patient remains immobile and consequently at higher risk for venous stasis, ileus, and pulmonary complications. The incidence of pulmonary embolus in the postoperative hysterectomy patient has decreased in the past decades with shortened stays and early ambulation.

Crisis Intervention

It is important to recognize a patient who is overwhelmed by stress. A stress crisis can occur during any phase between diagnosis and recuperation. A crisis has been described as an obstacle to important life goals that becomes insurmountable when the individual employs customary methods of problem solving. Kaplan highlighted the following four phases of crisis:

1. Arousal occurs, and attempts are made at problem solving.
2. Increased tension leads to distress and disorganization, because arousal hinders rather than promotes coping

behavior. Insomnia and fatigue frequently result.

3. Internal and external emergency resources are mobilized. Novel methods of coping are tried.
4. A state of progressive deterioration, exhaustion, and decompensation ensues as the problems drag on and on without resolution.

Dennerstein and van Hall report that the types of problems dealt with in crisis therapy include loss, change in status or role, interpersonal problems, and problems of choice between two or more alternatives. As an advocate, encourage your patient to communicate her feelings and to understand the problem enough to identify and define it; then help her rehearse alternative ways of coping.

One of the best concepts to apply during any stressful situation is to give the assurance that this particular moment, no matter how painful, is temporary. The surgical procedure and all the stages of mending that follow will have a beginning, a middle, and an end.

PSYCHOSEXUAL REHABILITATION

Goal

The goal of psychosexual rehabilitation after gynecologic or breast surgery is to restore sexual function, sexual identity, body image, and self-esteem. Most of the work must be done by the patient herself, but she may need assistance from her doctor and other health care providers because the experience is new to her. She has no gauge to measure what is normal for her particular situation and what is aberrant. You do.

Improving Communication

Even women who are not gynecologic surgery patients sometimes have sexual difficulties and find it embarrassing to talk about the difficulties with a doctor. Combine this intrinsic modesty with the stress of disease and not knowing how her surgery will affect her sexual life, and broaching the topic can be very difficult for a woman. When women do seek help, they are confronted with the barriers of mutual embarrassment, lack of research, limited treatment options, stereotypes, ageism, clinician reluctance to pursue the subject matter, and clinician misinformation or lack of training.

Many women and their physicians, who sometimes fear they are not qualified to help, are reluctant to speak of personal problems such as libido, arousal, coital pain, or past traumatic sexual events. Much of this reluctance can be overcome if the gynecologist knows what questions to ask when taking a sexual history, preferably during an initial or annual examination prior to any body-altering surgery. It is incumbent on the surgeon to begin this conversation.

Simon conducts personal sexual history interviews using questions he divides into the following broad categories:

- Biologic and hormonal
- Lack of appropriate stimuli
- Intrapersonal relationship
- Interpersonal history
- Contextual—lack of privacy, safety, and emotional rapport

The patient will elaborate on the areas of most concern to her.

Davis suggests that the physician ask the following openended questions to obtain a sexual history: Are you sexually active? Are you or your partner having any sexual difficulties at this time? Has there been any change in

sexual activity? Another good question is: What sort of sexual problems do you have?

Even if the patient is initially reluctant to discuss such personal issues, she will have learned that you are willing to discuss them should the need arise. Davis also believes that a physician's confidence in dealing with sexual issues increases when the cycles of sexual response discussed below are learned and when the factors that affect them (e.g., psychological, environmental, and physiologic) are understood.

Sexual Cycle Primer

One of the ways to broach the subject of sexual function is to educate the patient about the cycle of normal female sexual response. In a sexual and sexual dysfunction tutorial, Davis describes the following stages: desire, arousal, plateau phase, orgasm, and resolution phase.

Desire is the motivation and inclination to be sexual. It is dependent on internal (fantasies) and external sexual cues and also on adequate neuroendocrine functioning.

Arousal is characterized by erotic feelings and vaginal lubrication as blood flow increases to the vagina. In addition to feelings of sexual tension, the sexually excited woman may experience tachycardia, rapid breathing, elevated blood pressure, breast engorgement, muscle tension, nipple erection, and other physical signs of arousal such as a flush. This is the stage where the vagina lengthens, distends, and dilates, and the uterus elevates partially out of the pelvis.

During the plateau phase, sexual tension, erotic feelings, and vasocongestion reach maximum intensity. The labia become more swollen and turn dark red, and the lower third of the vagina swells and thickens to form the orgasmic platform. The clitoris becomes more swollen and elevated, and the uterus elevates fully out of the pelvis. Eventually, women reach the threshold point of orgasmic inevitability. Orgasm is a myotonic response mediated by the sympathetic nervous system and is experienced as a sudden release of the tension built up during previous phases. Women, unlike men, experience no refractory period but can experience multiple orgasms during a single cycle. They can also experience orgasms before, during, and after intercourse provided they receive enough clitoral stimulation.

The last phase is called the resolution phase. Women experience a feeling of relaxation and well-being. The body returns to a resting state. Complete uterine descent, detumescence of the clitoris and orgasmic platform, and decongestion of the vagina and labia take about 5 to 10 minutes.

Sexual Dysfunction

Over 50% of *all* women are affected at one time or another by female sexual dysfunction (FSD). The Women's Health Foundation lists seven classifications for FSD disorders:

- Hypoactive sexual desire
- Sexual aversion
- Sexual arousal
- Orgasmic
- Dyspareunia
- Vaginismus
- Noncoital sexual pain

Feldhaus-Dahir reports on the many barriers to helping patients with sexual dysfunction, which is multifactorial

and abysmally misunderstood. Since the FDA has approved nothing to treat premenopausal or postmenopausal women's sexual dysfunction, the menopausal woman and her physician have limited choices, but they do have a few.

A well-estrogenized vagina is essential for normal sexual function, but many women still believe estrogen therapies (discussed in more detail below) will harm them. Clinicians in the United States who prescribe androgen therapy use testosterone marketed for hypogonadal men, but at 10% of the dosage. A premenopausal woman naturally produces 10% of the amount produced by a normal male.

Some neurotransmitters, widely in use for other reasons, show promise treating sexual dysfunction. Simon lists bupropion, nefazodone, and buspirone as effective agents for desire, arousal, and orgasm. SSRIs have a negative effect on sexual desire.

Sexual Function after Surgery

Patients who talk about their sex lives frequently describe four pleasures associated with sexuality. These universal elements are touching, genital caressing, orgasm, and gratifying a partner. When a patient is recovering from surgery or has experienced surgical loss of coital function, genital caressing as a receiver or giver can be satisfying. Once a woman learns early in life how to be orgasmic, she can often learn to be so again despite major genital loss, including of her clitoris. When the ability to experience orgasm by one favorite means is destroyed by disease, the patient can be encouraged to experiment with alternative methods that do not conflict with her value system. Women who will never experience vaginal intercourse again can discover they are able, with education and imagination, to fulfill their feminine role as givers of pleasure if they choose to do so.

When a patient's psychosexual rehabilitation after surgery seems to be impaired and she fails to make steady progress toward resumption of her usual role, appropriate self-esteem, energy, identity, and ability to handle stress, she should be offered help. Help should be offered as soon as she mentions the problem. Early intervention is often easy and brief. The surgeon should be the first person to help the patient, with counseling and, if necessary, suitable medications.

A postsurgical patient may expect too much too soon from herself, or she may head off in the opposite direction and begin to assume the role of invalid. In most cases, however, she will be caught somewhere in between these two extremes. Once she begins to exhibit her normal patterns of relating to others, you will know she has officially begun the process of genuine healing.

You will be able to tell when she enters the healing phase because she will become less dependent on you, the nurses, and even her family members. As her strength increases, she will want to resume her usual activities. The inevitable, normal, uncomfortable grief process will commence. Encourage the patient to talk about her feelings rather than repressing them or brooding, because worry and rumination are forms of repetitive thought that are concomitant with and predictive of depressed mood. Dreary thoughts fuel a depressed mood and turn it into something ugly and dangerous; this has the potential to cause long-term or permanent psychological damage.

The patient has the power within to effect change in herself. Family members and friends should be cautioned, at this point, to allow verbal ventilation. It's a form of healthy discontent that frequently provides the impetus to hurry up and lose the sick image and begin to see herself as well and strong again.

Cosmetics, dress, and grooming are important parts of the rehabilitation process. When a postoperative patient combs her hair, puts on lipstick, and demands her own nightgown instead of hospital garb, she has begun to heal. When a patient feels that the surgery was disfiguring, she needs to compensate by learning new ways to dress or groom. She needs to feel whole and complete and responsible again as quickly as possible.

Most of the time, the mate or lover of the woman is caring and considerate of her. There is genuine concern for her health, hope for a quick recovery, and the willingness to assume many aspects of her role until she is well. Often there is a deepening of affection between the partners as gifts of love and concern are given and received. That special someone is in the waiting room during the surgical ordeal and by the patient's bedside when she awakes. There are flowers and gifts and promises made and kept. There is an abundance of reciprocal love. Adjustment to new roles is relatively smooth, causing new bonds to form and old ones to strengthen.

The surgical patient begins to see herself as a sexual person when her sexual identity is validated by her sexual partner, friends, family, and even admiring strangers she passes on the street. The woman who has had a mastectomy or other body-altering surgery needs to know her partner still finds her attractive and desirable. Without this affirmation, she may have a great deal of trouble seeing herself as a sexual being.

A potential roadblock to healing, however, is the fact that some sexual partners cannot accept an incomplete person. Some surgical procedures result in the loss of vulva, clitoris, or vagina. Radical pelvic surgery can leave a woman with a colostomy or urinary diversion. A severely altered body image concurrent with loss of health and vigor poses a serious threat to a woman's self-esteem. The woman who has lost her sexual identity feels damaged beyond repair. Some complain of continuing pelvic pain without obvious structural cause. Interest in sex vanishes, and the patient may actually leave her sexual partner or force the partner to abandon her. As she terminates her sexual identity, she feels old before her time and begins to draw in the edges of her life. These women need intense psychosexual therapy if they are ever to heal emotionally. **Table 3.1** outlines the major factors that occur with psychosexual dysfunction.

In some cases, the woman's partner becomes a bigger problem than her physical disability. It is possible her significant other constructed a fragile emotional bond with body parts rather than with the actual woman. If she had or has cancer, the partner may irrationally feel that the cancer is contagious. If she is receiving radiation treatment, he may feel that if he resumes sexual relations with her, he, too, might absorb radiation from her body and be burned. The couple may be accustomed to frequent sex, and any change in the woman's availability stresses the relationship. The fear of causing pain also has an inhibiting effect. Emotional isolation and loss of nurturing occur in both partners when the woman experiences physical disability. As surgeon to the postoperative patient, you are her first line of psychosexual defense, and yours will not be an easy job.

TABLE 3.1 Major Factors in Psychosexual Dysfunction

Symptomatic

- Interpersonal (discord with significant other)
- Organic (disease, malnutrition, malfunction of body organs)
- Psychiatric (anxiety, depression, schizophrenia)
- Alcohol or drug abuse
- Iatrogenic (suggestions, medication, surgery)

Learned

Family (childhood negative sexual associations, experiences)

Religion (imposed prohibitions internalized)

Early unpleasant sexual experiences

Gynecologic disorders (damaged genitalia, loss of breasts, uterus)

Intrapsychic conflict

Failure to develop psychosexually

Restrictive childrearing

Religious influences

Sexual adjustment is often significantly impaired in women after pelvic exenteration and gracilis myocutaneous vaginal reconstruction. In one of the few studies that exist, 84% of the patients resumed sexual activity within the first year after surgery. A modified version of the Sexual Adjustment Questionnaire was used; the responses outlined the most common problems patients face after the surgery: self-consciousness about a urostomy or colostomy, being seen in the nude by their partner, vaginal dryness, and vaginal discharge. It is hoped that future modifications in surgical technique, more realistic patient counseling, and aggressive postoperative support will minimize these problems in the future. Less serious matters can cause self-esteem and body image problems, too, if their aftermath includes or leads to bowel incontinence, urinary incontinence, vaginal vault prolapse, and scarring.

Bowel incontinence is rarely discussed even with a woman's physician because it is so embarrassing. Whether from obstetric injuries, injury to the anal muscles, infections, or diminished muscle strength from aging, once the cause and severity are determined, treatment can begin. This might include dietary changes, constipating medications, muscle strengthening exercises, biofeedback techniques, and sometimes surgical repair of the muscle. Some or all of these remedies help the woman control the discharge of embarrassing gas or stool. It is most important to discuss possible remedies because many women feel there is nothing that can be done for them but the frightening colostomy, when in actual fact, colostomy is a procedure that is rarely required.

As many as 50% of all women experience occasional urinary incontinence. In an attempt to lessen the blow to a woman's ego and make the event more socially acceptable, manufacturers hire movie stars to make commercials about the effectiveness of diapers for grown women. Diapers do treat the symptoms and allow for more freedom of movement, but not in an intimate setting. For many years, gynecologists have instructed patients about Kegel exercises to tighten the muscles of the pelvic floor, but this may not be enough to stop the embarrassing leakage of urine. The patient needs to know that there are tests that can determine the exact cause of the problem, and treatments using bladder retraining therapy, medications, and surgery. Urinary incontinence may be more socially acceptable today, but it is never normal, no matter what the woman's age.

Both bowel and urinary incontinence can be caused by vaginal vault prolapse, and this condition must be ruled out because it drastically affects sexual functioning. The presence of a mass can cause painful intercourse, difficulty accepting penetration, and a great deal of psychological anxiety when the tissue can be seen in the vaginal opening. This condition, if left untreated, only worsens with time, but techniques that correct female

organs supporting defects in the pelvis can restore sexual functioning and with it, a woman's sense of vitality and feminine allure.

Hormonal Therapy

HRT remains a controversial issue. It is imperative that HRT be discussed preoperatively with the patient facing surgery and the loss of her ovaries. Initial misinterpretation of the results of the Women's Health Initiative (WHI) Study has created much

P.39

fear and angst for both the gynecologist and the patient. The harmful effects were overestimated, and the media created undue alarm regarding breast cancer.

Pines et al., in careful evaluation of the data in the estrogen-progestin arm, show the risk for breast cancer and cardiovascular events to be most minute, about 0.1% for every year of use. No risk was observed for women younger than 60 years of age. It must be remembered that the WHI Study recruited women in their late 60s. Even so, the trees of thought planted during this and other massive studies continue to bear fruit.

Davey's analysis reveals there are multiple risks for breast cancer, not just HRT. In the Nurse's Health Study, HRT used continuously from age 50 to 60, benign breast disease, and family history played equal triplet roles in determining who was at risk for breast cancer.

With WHI, the incidence of breast cancer was increased in the women who currently used estrogen plus progestin HRT, but the incidence progressively *decreased* after stopping HRT. When placebo was compared to women taking estrogen-only HRT, the incidence of breast cancer was reduced and *stayed reduced for 10.7 years* after stopping HRT. Also in the placebo arm, the incidence was reduced if they had *ever* taken HRT.

Good things appear in the near future of menopausal women who use the 10-year window of opportunity after menopause to protect themselves with HRT. The development of micronized progesterone and transdermal estrogen seem to promise more good than harm.

The Kronos Early Estrogen Prevention Study of 727 recently menopausal women over 4 years found that hormone therapy improved symptoms of depression and anxiety without loss of cognition or increase in blood pressure.

Another 16-year study that involved 60,000 postmenopausal female nurses found that those who took HRT for 10 years reduced their risk of dying from all causes by 37%, with the most dramatic reduction being death from cardiac disease. After 10 years, the reduced risk for all causes was 16% because of the increased risk of dying from breast cancer. That risk rose to 43%, but the women who contracted breast cancer during the first 10 years had a lower death rate from the disease than did women who had never taken hormones, probably because of early detection. Chances of early detection of breast cancer are probably better for hormone users because they receive regular checkups.

In an extensive review of current literature on the subject, dubbed "the New Science of Estrogen," Hammond provides an overview of the risks and benefits of HRT and also includes information on therapeutic alternatives. Cardiovascular benefits of estrogen outweigh the risks. With combined estrogen-progestin therapy, studies have shown some increase in stroke and venous thromboembolism. Hammond feels that steroid hormonal therapy should be considered an integral part of the appropriate and necessary care of American women after menopause. The anticipated reduction of cardiovascular disease (CVD) and osteoporotic fractures by nearly 50% should be laudable goals for any health care system.

Statistics show overwhelmingly that CVD—not cancer—is the leading cause of mortality for postmenopausal women. In fact, 1 in 2 women will eventually die of heart disease or stroke, whereas only 1 in 25 women will die of breast cancer. Although the incidence of heart disease, including coronary artery disease and stroke, is low in

premenopausal women, heart disease is the most frequent cause of death in women over the age of 50. Since 1984, the death rate from CVD in men has decreased, whereas the death rate for women has increased. Numerous epidemiologic studies support the long-term benefit of estrogen in preventing CVD. Observational studies, such as the Postmenopausal Estrogen/Progestin Intervention Study sponsored by the National Institutes of Health, revealed that HRT can increase high-density lipoprotein cholesterol and decrease low-density lipoprotein cholesterol. The Nurses' Health Study demonstrated a reduction in the risk of CVD of up to 50% among current HRT users. Women who use estrogen have significantly less coronary artery stenosis than do women who do not use it. Takahashi et al. found that longterm HRT (for more than 2 years) may delay carotid intimal-medial thickness in healthy postmenopausal women.

Moreover, patients with the most advanced coronary artery disease experience the most benefit from HRT. Only 35% of women surveyed were aware of the connection between heart disease and menopause.

Current theories indicate that estrogen has extraordinarily complex biologic effects that translate into a variety of actions in diverse tissues. There is growing scientific evidence that estrogen exerts its beneficial actions on tissues of the skeletal, urogenital, digestive, cardiovascular, ocular, and nervous systems.

HRT is also first-line therapy for osteoporosis for most women, and treatment should begin as soon as possible after the menopause. Enough time has elapsed since the WHI media scare and cessation of estrogen therapy by users that a marked and rapid loss of bone density is being noted in those who stopped their replacement therapy. Yates and Barrett-Connor studied the association between HRT cessation and hip fracture risk. Concurrent with WHI, women in National Osteoporosis Risk Assessment currently on HRT had a 40% lower incidence of hip fracture compared to those who had never used HRT. Women who stopped using HRT more than 5 years earlier had similar hip fracture use to women who had never used HRT. Preliminary data suggest that even the elderly respond to estrogen replacement. However, there are therapeutic alternatives and lifestyle modifications (diet and routine exercise) that perimenopausal women must be counseled about to create a comprehensive prevention program. Such an effort can have a significant impact on long-term morbidity and mortality associated with osteoporosis.

Because one of their jobs is to find every needle that gets lost in the proverbial haystacks of their homes, women have phenomenal memories. When they become less adept at remembering where they and other people put their things, they fear the worst—that they are losing their minds—and this fear is not illogical. Women constitute 72% of the population over the age of 85 years, and roughly half of this group has Alzheimer disease (AD). Not only do women constitute a greater proportion of this older population, but AD is expressed earlier in women than men. This may be related to the estrogen loss that occurs with menopause. Hammond cites a study that found women who took estrogen for more than a year experienced a dramatic delay in AD onset. But even the group of women who averaged only 4 months of estrogen therapy, and most likely took the medication to control symptoms such as hot flashes, experienced a delay in AD onset. It has been speculated that a brief exposure to estrogen influenced AD expression 20 to 30 years later by preventing an irreversible loss of neurons associated with the occurrence of hot flashes. Research is ongoing, but one study found that estrogen replacement therapy in postmenopausal women is associated with a 50% reduction in the risk of developing AD because it slows the decline of visual memory. Lebrun's study in clinical endocrinology supports findings that endogenous estrogens protect against cognitive decline with aging.

Colon cancer occurs more often in women than men and is a leading cause of cancer incidence and deaths in women.

Even though mortality rates for colon cancer have decreased 25% among women in the last 20 years, it remains the third leading cause of cancer deaths in this group. The concept that postmenopausal estrogen replacement therapy may decrease the risk of colorectal cancer has received considerable attention, even though the

hormone has no indication for this use. Multiple epidemiologic studies have been published that examined this relationship. The majority of these suggest an inverse, protective effect for estrogen, particularly with current use. Although the precise mechanism by which estrogen reduces colon cancer risk is unknown, it has been hypothesized that it affects bile acid metabolism or promotes tumor suppressor activity. The inclusion of estrogen as a measure to prevent colon cancer should be part of the discussions between menopausal women and their physicians. Counseling should include the American Cancer Society recommendations for annual digital rectal examination and fecal occult blood testing as well as a flexible sigmoidoscopy every 5 years or colonoscopy every 10 years.

Age-related macular degeneration (AMD) may be reduced by estrogen administration. This disease is the leading cause of legal blindness in the United States, accounting for as many as 60% of all new cases. There is no medical treatment, and surgical management in the form of photocoagulation is effective in only a small percentage of patients with the wet type of the disease. In the Rotterdam study, women who experienced menopause at an earlier age had a 90% increased risk of exhibiting signs of late AMD compared with those who experienced menopause at a later age. These data suggest that HRT reduces the risk of developing AMD.

Counseling women about replacement therapy must be combined with discussions about the importance of lifestyle changes, including the following:

- Normalization of weight
- Dietary intervention
- Smoking cessation
- Regular exercise
- Control of hypertension
- Control of diabetes
- Control of alcohol consumption
- Control of lipid elevations

Routinely, HRT counseling should go beyond simple symptom control to include both short- and long-term benefits, contraindications, common patient concerns, and misconceptions.

The contraindications to estrogen replacement that have been established by the FDA include known or suspected pregnancy or breast cancer, estrogen-dependent neoplasia, undiagnosed abnormal genital bleeding, and active thromboembolic disorders. However, ongoing research suggests that some of these contraindications may not be absolute. In the meantime, all of the relative contraindications must be carefully discussed and weighed against the risk of not prescribing HRT. This is also a good time to discuss the common concerns and misconceptions that women have about estrogen, even if patients do not raise them. For example, many women are concerned that estrogen may bring on the return of monthly bleeding, restore fertility, or produce weight gain.

When bilateral oophorectomy is anticipated in a premenopausal patient, HRT should be discussed before surgery, because one of the greatest fears of younger women is surgery-induced menopause. Patients should be told that estrogen therapy can be started immediately after surgery and that hot flashes and other menopausal symptoms can be avoided. The natural conjugated estrogens do not cause hypercoagulability and are safe during the immediate convalescent period.

Parker et al., in a recent lead study in *Obstetrics and Gynecology*, recommend ovarian conservation until at least age 65 because of their benefit to long-term survival. With ovarian preservation, the need for exogenous hormones is delayed.

The long-term benefits of HRT in preventing osteoporosis, CVD, and colon cancer are well established. The health of the vagina and lower urinary tract is also maintained. *The Journal of the British Menopause Society* says that various studies have demonstrated the efficacy of estrogen replacement in improving urinary and stress incontinence. The vagina lubricates more easily with sexual arousal, and intercourse is more comfortable with an estrogenic vaginal mucosa. Many women report an increased interest in and enjoyment of sex.

For women who do experience a loss of libido, even while taking estrogenic hormones, the new androgen therapies look promising as a way to improve sexual function and psychological well-being. Testosterone delivered via transdermal patches or gel bypasses the liver and has no negative effect on cholesterol. The skin serves as a constant reservoir; therefore, blood levels show fewer fluctuations.

However, there are physicians who believe hormonal balances induced by prescription medications should only be offered for relief of extreme menopausal symptoms and only for a short while. The author of *Dr. Susan Love's Hormone Book* and *Dr. Susan Love's Breast Book* is one such physician. She is a staunch supporter of eating soybean products and using herbal remedies such as black cohosh to maintain estrogen levels, the use of acupuncture and paced respiration for hot flashes, exercise, and using vitamin and calcium supplements. But even she admitted in an interview, "If my symptoms [for menopause] worsen, I may feel that I want to take some kind of drug. I certainly would be open to that."

By 2030, 1.2 billion women will be menopausal or postmenopausal. Wu et al. reported that if the surgery rates for pelvic floor disorders remain unchanged, the number of women expected to undergo inpatient and outpatient procedures for stress urinary incontinence (SUI) and pelvic organ prolapse (POP) will significantly increase. In 2010, records show 210,700 SUI surgeries performed. This number will increase over 47% by 2050. During the same time frame, POP surgeries will increase from 166,000 to 245,970.

The National Institutes of Health recommends human sexuality courses for all health care professionals in graduate schools. A majority of medical schools offer 3 to 10 hours of human sexuality instruction, usually embedded in other courses; this is not nearly enough to help a sexually dysfunctional patient. Even trained professionals who are members of the American Urogynecologic Society underestimated the prevalence of the problem. Only 22% of urogynecologists reported they had developed the habit of screening their patients for sexual dysfunction.

Professionals don't realize the tremendous societal burdens that the angst resulting from sexual dysfunction creates, as reflected in divorce, domestic violence, single-parent families, quality of life issues, and problems in forming enduring relationships. A few in the medical community are working for international standardization and continuing education and training in the area of sexual dysfunction. If successful, this will directly translate into greater competency and help for 50 million women in the United States alone.

SPECIAL CASES

Every patient is special and deserves to be treated with compassion and sensitivity. Women who are already in tumultuous life situations at the time of surgery present the greatest challenge.

P.41

The Teenager

Bluestein and Starling report that one million teenagers a year conceive. Of these million pregnancies, 400,000 end in abortion and 100,000 in miscarriage. Childbearing teenagers face a 60% excess in maternal mortality compared with adults and are most likely to suffer toxemia, anemia, hemorrhage, cervical trauma, cephalopelvic disproportion, excessive weight gain, and premature labor. These complications are due more to social and behavioral correlates than inherent adolescent aspects. Correlates include inadequate prenatal care, poor nutrition, substance abuse, and emotional distress.

Among 1,000 teenagers who have first-trimester abortions, one or two will experience fever, hemorrhage, and emergency abdominal surgical procedures. These numbers are lower than for older women, but the rate for cervical injury, which could affect future childbearing, is 5.5 per 1,000 teenagers, notably higher than the 1.7 to 3.1 per 1,000 for adults. Bluestein and Starling recommend the following communication techniques for the teenage patient:

- Guarantee confidentiality to build trust. Conduct the initial interview alone. Teenage girls may want to relate private information to the physician but not in the presence of a parent.
- Be patient. Gear communication to the patient's emotional and intellectual development.
- Be nonjudgmental. Gently explore the teenager's family and social environments. Will family members and friends support or harm your patient?
- Discuss the teenager's long-term plans. Be aware of ethnic differences in health-related matters.

Female patients who belong to local or national gangs come into the health care system with a unique set of problems and values. It is imperative that the surgeon not add to the patient's stress more than is absolutely necessary. Sometimes, the simple act of being treated like a human being worthy of consideration is a novel and humbling experience.

The Senior Woman

The new kid on the block for the next many years will be the senior woman. Kuzmarov et al. caution family doctors that they will need to be able to evaluate and manage sexual problems in the senior couple. Of spouses over the age of 76, 24% reported having sex within the last month. This same group averaged 2.75 episodes per month. The numbers soar upward relative to younger more active seniors.

The study found many women take a cerebral, cognitive approach and respond to their partners for reasons of intimacy, bonding, commitment, love, affection, and the acceptance of it all rather than simply to scratch a vascular itch.

It is easy to imagine a grandmother baking cookies or rocking a new baby in the family. Our culture makes it a little more difficult to imagine this same woman flushed and happy from an energetic romp in the sack with her favorite beau. Sex after 60 is a reality for many women and men. These people enjoyed sex when they were young, they perfected it as the years flowed by, and the thought of doing without expression of the natural urges, even temporarily, is discomfiting.

When an older woman faces gynecologic surgery, therefore, do not assume she is asexual. She may simply view her sex life as her private business and be loath to discuss it. Do not antagonize or humiliate the senior patient by assuming her sexuality is a thing of the past ([Table 3.2](#)).

TABLE 3.2 Excerpted from “Communicating with Seniors/Advice Techniques and Tips” Your Attitude Is Showing!
<ul style="list-style-type: none">• Avoid stereotyping or reinforcing incorrect perceptions about seniors. Show older people as you know them to be; active participants, using a full range of abilities in a full range of roles and activities.• Shun ageism, racism, and sexism in conversation, text, illustrations, and photographs. They are prohibited by law.• Especially avoid ageist language (that categorizes seniors negatively), such as “the aged,” “the elderly,” “oldsters,” “senile,” “feeble,” etc.• Use “seniors,” “older persons,” or “older adults” if you need to indicate the age group.

- Beware of patronizing, condescending, or childish expressions and tone when talking with or about seniors.
- Keep in mind that seniors are generally wise shoppers whose lifelong experience comes in handy in detecting flattery and insincere deference.
- Remember that the way you use language reflects your attitudes and your respect for the audience.

Source: Communicating with Seniors, Health Canada, 2001. Reproduced with the permission of the Minister of Public Works and Government Services Canada, 2013.

If the surgical procedure will affect her sexually, explain the consequences. Assure her that the surgery will leave her as whole and as functional as possible. Give this woman the opportunity to express her anxieties and to ask questions. If her mate or lover is present, include this person in the discussion. In the senior woman who has a large cystocele, rectocele, or uterine or vault prolapse, every effort should be made to avoid colpocleisis. Sacrospinous colpopexy and vaginal reconstructive surgery are indicated. The fact that a woman is older and sexually inactive at the time of surgery does not mean that she will never be active again. Much preparation and explanation must be given to evaluate and prepare her for the closing off of her vagina or its subsequent reconstruction should that become necessary.

Butler et al. advise that, when taking a sexual history, ask if the symptoms started after a period of sexual activity. Excretory urogram and cystoscopy can sometimes be avoided with a diagnosis of postcoital cystitis and subsequent antibiotic treatment. A history of traumatic intercourse in the presence of an atrophic vagina may indicate a need for estrogen therapy and lubricants rather than dilation and curettage. Butler et al. also caution physicians not to assume an older woman is sexually inactive. They advise checking for sexually transmitted diseases in older women as you would in younger ones.

When surgery is indicated, perform it as if the senior woman was still young and had many years of sexuality ahead of her, because she probably does. If the surgery occurs in the genital area, do not shave her pubic hair. The procedure is archaic and microbiologically unnecessary if competent sterilization procedures are followed. As men age, they sometimes lose hair on the head. As women age, the pubic hair sometimes thins, and once shaved, it may never grow back.

Many older women have had to curb their sexual appetites to compensate for physiologic changes that have occurred in a mate. Removal of excessive vaginal mucosa during pelvic surgery compromises the vagina, which is already losing elasticity.

P.42

This inhibits penetration during coitus and can cause painful intercourse. Be understanding and helpful if solutions are possible. If the dysfunction resulting from the surgery will be permanent, encourage the couple to experiment with various ways to please each other or seek the advice of a sex therapist that is knowledgeable about creative sexual play.

Butler instructs physicians to educate themselves about the effects of medications on sexuality. More than 200 medications have sexual dysfunction as a side effect. Many are effective in lower doses that do not harm the libido or the patient's physical ability.

The positive benefits of a healthy sex life are multiple. Emotional intimacy and the ability to connect physically with another human being bring great joy and satisfaction. This need to connect intensifies rather than diminishes with age.

The Sexually Assaulted Patient

According to FBI statistics, reported rapes and sexual assaults in the United States are up nearly 5% since the year 2000. It is estimated that only about 16% of rapes that occur are ever reported. One third of sexually assaulted victims are under the age of 12. Convicted rape and sexual assault offenders testify that two thirds of their victims are younger than 18. Two thirds of the victims older than 18 knew their attacker prior to the rape. A sad fact is that almost one fifth of the women who are raped before the age of 18 are raped again after the age of 18. Many require medical attention: Up to 22% suffer genital trauma, up to 40% incur sexually transmitted disease, and 1% to 5% become pregnant as a result of the rape. Rape survivors are 13 times more likely than the general population to attempt suicide.

Most hospital emergency rooms have strict protocols to follow when treating sexually assaulted patients. The proper collection of evidence and initial treatment of injuries is a priority. The surgeon who repairs the gynecologic damage done to these female patients should be aware of the general characteristics of psychological trauma associated with rape.

The symptoms of rape trauma syndrome compiled by Blair and Warner can be found in [Table 3.3](#).

Many of these symptoms are the same as seen in posttraumatic stress disorder (PTSD). These authors also outlined the necessary skills that any caregivers attempting to help a sexually assaulted victim should possess:

TABLE 3.3 Symptoms of Rape Trauma Syndrome

Recurrent, painful recollections or dreams of the event
Suddenly acting or feeling as if the event were recurring
Demonstrations of fear, anger, or anxiety
Crying, restlessness, or tenseness
Controlled feelings masked by a false demeanor of calmness, composure, or subdued attitude
Matter-of-fact answering of questions
Inappropriate smiles or laughter
Inability to remember parts of the event because reexposure to stimuli present during the traumatic moment reinvokes the associated pain
Decreased interest in important activities
Lack of future plans
Limited range of affect
Detachment toward others
Sleep disorders

Difficulty concentrating

Hypervigilance

Irritability

Angry outbursts

- Understand rape and sexual assault.
- Assess how the patient perceives the act.
- Identify and reinforce the patient's ability to cope.
- Assist significant others.
- Coordinate care and help if the victim needs assistance.
- Mobilize community resources.

The rape patient, from the youngest child to the oldest adult, has survived an attack on her physical body. Most gynecologists are familiar with the legacy of these attacks (up to 75% of patients seen with CPP were physically or emotionally abused). The assaulted patient now needs reassurance from her surgeon and other health care workers that she will also survive the damage done to her psyche.

Hensley reported for National Public Radio that Naval researchers studied 800 soldiers who had been traumatized by atrocities like roadside bombs and gunshot wounds. While 61% of the soldiers who received morphine did develop PTSD, 79% of those who did not experience PTSD *also* received morphine. Dr. Matthew Friedman at the Department of Veteran Affairs National Center for PTSD writes that the findings add to the evidence already collected that “rapid pain reduction” after a traumatic injury may lower the risk of PTSD.

Could it also help the sexually assaulted if they received the morphine within hours of the trauma?

The Cancer Patient

In 2009, 84,155 women in the United States were diagnosed with gynecologic cancer. (This figure covers 90% of the population.) That same year, 27,813 women in the United States died from a gynecologic cancer. (This figure covers 100% of the population.)

Bloch cautions physicians that the manner in which the diagnosis of cancer is disclosed to the patient can determine whether the patient lives or dies. It is imperative to instill hope and the desire to fight the disease. A diagnosis of cancer by telephone can be devastating and is viewed by many physicians and patients as a form of cruelty.

In her book, *The Balance Within: The Science Connecting Health and Emotions*, Dr. Esther M. Sternberg presents evidence that relief from stress can make you less vulnerable to illness. The cancer patient shares the same fears common to all surgical patients. She may be psychologically attached to the body part that must be removed. She may fear anesthesia, disfigurement, the unknown, the hospital experience and staff, debility, loss of economic competence, and sexual dysfunction.

In addition to the normal realm of anxiety associated with surgery, a diagnosis of cancer brings special stresses to a woman's life. Schain describes universal concerns experienced by people diagnosed with cancer no matter

where in the body the cancer is located. These people fear death, postoperative adjuvant treatment, and recurrence.

The cancer patient is concerned about dying or being injured during the operation. Preoperative anxiety can manifest as anorexia, insomnia, tachycardia, fear, and panic. Acute depression is not uncommon and can lead to suicidal tendencies.

The patient is afraid of becoming unable to take care of her family members. Will she be sick for long? Who will raise her children if she dies? Who will care for her parents? Will her loved ones be supportive, or will they begin to back away from her? If the woman is alone, without mate or family, she fears becoming unable to care for herself.

The treating surgeon can ease some of the cancer patient's fear by free and open communication. Educate the patient

P.43

about exactly what to expect, and offer reassurance if possible. Explain the procedure she is about to undergo and the positive benefits that you both hope will result. Help her understand your commitment to her is long term. The best facilities have a team of helpers that include specialists as well as volunteers. The following study illustrates the results one group of patients obtained after a few lifestyle lessons.

Breast cancer patients ($n = 227$) who had undergone mastectomy and chemotherapy were randomized to a program of psychological intervention. They were trained in coping skills for stress, lifestyle changes, exercise, and advice on how to talk to their physicians.

A year later, these patients experienced better quality of life than did the controls. Psychological help at 4 months continued to yield positive results at 12. There was a reduction in symptoms and cancer treatment toxicities. Also, patients who exercised the most were able to receive significantly higher relative doses of taxane-based chemotherapy than did those patients who exercised some or not at all.

Surgery and cancer in the urogenital region can be consciously or unconsciously interpreted as mutilation. The possibility of some degree of postoperative sexual dysfunction can create a fear of abandonment by the sexual partner. If possible, assure both the patient and her partner that they will continue to be able to bring joy, pleasure, and comfort to each other.

The psychological effect of cancer on a woman is largely determined by whether the malignancy is primary, recurrent, or terminal. The surgeon is usually the patient's first big gun aimed at the cancer, as well as the patient's greatest hope for a complete cure. The surgeon is most likely the first physician to learn the stage of growth of the cancer, and the family will be waiting to hear the results of the surgical experience. How advanced is the cancer? What is the prognosis? What happens next?

If the news is good, the patient recovers and has routine checkups to monitor her health for the rest of her life. If the news is not good, the results should be revealed with as much sensitivity and hope as possible. Although no patient should ever be given an absolute death sentence, it is the surgeon's job to foster courage in the terminal patient.

The surgeon must wrestle with personal, ethical, and moral conflicts when the surgery for the cancer patient is palliative. Should procedures be performed that extend death and not life? If she is able, the patient herself must make the choice.

If the cancer patient elects to have a palliative procedure, her postoperative care may be shared by radiologists, chemotherapists, and others who specialize in cancer treatment. However, as her gynecologist, you should maintain contact and assist in trying to get the patient well or to at least enhance the quality of the remainder of her life. Meaningful psychosocial support should be based on established concepts of crisis intervention,

because cancer is a major life crisis. Counseling should be designed to support adaptive behaviors and feelings that reduce the psychological stress, restore and consolidate the patient's self-image, and normalize sexual functioning as quickly as possible.

The Suicidal Patient

The World Health Organization (WHO) reports that suicide rates have increased 60% worldwide in the last 45 years, with 870,000 annual deaths. Approximately 30,000 people commit suicide each year in the United States. Cooper, Rosa, and Daniel studied over 6,000 individuals and found that hopelessness ranked the highest of all symptoms associated with suicidal ideation in psychiatric patients and adolescents.

A surgeon probably will not know if a patient is contemplating suicide unless the patient admits to thinking about ending her life or unless a family member voices concern. Subtle warning signs include a chronic state of depression, lethargy, an inability to relate to others, weight loss or gain, lack of interest in life in general or the surgical procedure in question, a change in personal appearance, abnormal sleep patterns, or any strange behavior uncharacteristic of the particular patient. Many of these symptoms are normal for the presurgical and postsurgical patient, so it is easy to see how suicidal tendencies could hide within the maze.

To determine a patient's suicide potential, ask: Have you been troubled with thoughts of hurting yourself? Barbee advises physicians to ask directly: Have you ever thought of taking your own life? Do you feel like taking your life now? If the patient answers yes, the physician should find out if the patient has a simple, straightforward suicide plan that is likely to succeed.

A patient with low to moderate suicide potential is noticeably depressed but can identify some support system. There may be suicidal thoughts but no specific plan.

A patient with a high suicide potential feels profoundly helpless. Little or no support system seems to exist. Thoughts of suicide are frequent, and a plan exists that is likely to succeed.

The surgeon may be the first person to realize the patient is in emotional trouble, and he or she might be the only support system available if the patient has significantly withdrawn from others. Crisis therapy for the suicidal patient begins when the patient requests help or when someone recognizes her potential for self-destruction. By showing interest in her feelings and concern for her welfare, the surgeon initiates crisis intervention.

Rare Causes for Concern

Pelvic Injury from Traumatic Accident

In a review of high-impact pelvic fractures, Harvey-Kelly et al. found that 35.9% of men and 39.6% of women experience sexual dysfunction, and they believe the numbers may be underreported. Patient age, urogenital injuries in particular, and specific fracture types B with accompanying rotational instability, but vertical stability, and type C with double instability were the highest risk factors. In conclusion, they advised that sexual function in both sexes should be assessed no sooner than 1 year, and no more than 3 years after the injury using the International Index of Erectile Function and the Female Sexual Function Index.

Disorders of Sexual Development

The terminology of Disorders of Sexual Development (DSD) has changed in an effort to reflect a more accurate description of the pathophysiology ([Table 3.4](#)).

TABLE 3.4 Terminology of Disorders of Sexual Development

PREVIOUS

REVISED

Female pseudohermaphrodite	46,XX DSD
Male pseudohermaphrodite	46,XY DSD
True hermaphrodite	Ovotesticular DSD
XX Male	46,XX testicular DSD
XY Sex reversal	46,XY complete gonadal dysgenesis

P.44

Hutchinson et al. say that once children are diagnosed with ambiguous genitalia or other manifestations of DSD (ideally from birth), a team of specialists is required to counsel the parents and teach them how to deal with their specific set of circumstances. Interestingly, clinical and basic science research now shows gender identity development *begins* in utero.

Ocal lists four issues causing the current intense debates about how to manage intersexual patients:

- Etiologic diagnosis
- Assignment of gender
- Genital surgery indication and timing
- Disclosure of medical information to patient and parents

A government publication emphasizes that the psychologist chosen must have knowledge of sexual development, gender identity development, factors that influence sex role behavior, and sexuality; he or she must understand the trajectory of a DSD across the individual's life. Thus, the role of the psychologist as part of the individual's holistic team is routine, preemptive, and reactive as time passes and important issues arrive.

These children offer all of humanity a glimpse into how we came to be female or male. The contributions they make are without bounds.

Premature Ovarian Insufficiency

In Premature Ovarian Insufficiency (POI), a woman's ovaries cease to function properly before her 40th birthday. Symptoms are irregular or absent menstrual periods, hot flashes, night sweats, vaginal dryness, and decreased sexual desire. Infertility is common, though 5% to 10% of women with POI are able to conceive without medical intervention.

Because there are fewer than 200,000 cases in the United States, POI is classed as a “rare” disease, and 90% of the causes remain unknown, mysteries yet to be solved. Some guesses are genetic history, a woman's ovaries attacked by her own immune system, infection, chemotherapy and radiation cancer treatments, or something environmental.

DEALING WITH DEATH

Death is a taboo subject for most physicians. Many doctors go to great lengths to avoid discussing the eventuality, and most are uncomfortable dealing with the emotional consequences of the death of a patient. To many physicians, death is viewed as a personal failure. Regardless of any internal attitudes he or she may have,

the surgeon is responsible for communicating the facts of the death to the family and for being the first person to help them cope with the loss of their loved one.

When a patient dies, explain to the family, to the best of your ability, exactly what happened. Assure them that everything medically possible was done. Ufema suggests the following guidelines to make the death experience as bearable as possible for all concerned.

- Ask about donations for transplantation.
- Provide an area where the family members can say goodbye.
- If it is true, tell the family members how the patient affected you personally.
- Transfer your protective feelings for the patient to the family members.
- Begin the grief process by saying, "Jane's body is ready for the morgue now. Would you like to say a final goodbye?"
- If family members want a lock of hair, allow them to take it.
- Give family members the patient's belongings.
- Provide an escort for any family member who is alone.
- Help the hospital staff cope with the loss.

Remember that it is permissible for the physician to show emotion with the family if the emotion is genuine. Someone is gone and will never see tomorrow.

FUTURE TRENDS

The new millennium was heralded with great joy and celebration. Its predominant theme was one of hope, and nowhere is this more evident than in the field of medicine, especially women's health issues. The hand that rocks the cradle now rules important aspects of the research world. During the next 20 years, 45 million women will enter menopause and live onethird to one-half of their lives postmenopausally. Research into improving the quality of their lives and subsequently all those they touch has never been more important or timely.

Guidelines for Practice

Pelvic exams are a source of dread for most gynecologic patients. Many women will applaud new guidelines from the American College of Obstetrics and Gynecology that state no pelvic exam is necessary on healthy asymptomatic women under 21 years of age or over 21 years of age if they, too, are asymptomatic and have had the uterus removed, fallopian tubes removed for benign conditions, no history of cancer, and some forms of precancerous neoplasia; are neither HIV positive nor immunocompromised; and were not exposed to diethylstilbestrol in utero.

Common sense and patient wishes should dictate whether a pelvic exam is done on asymptomatic low-risk women, because no evidence supports or refutes benefits from the annual pelvic exam or speculum and biannual exam for this group of patients.

Some women, because of age and other health issues, choose not to seek treatment for conditions detected during the pelvic exam. Physicians may honor their wish to end the pelvic examinations.

As a multitude of women move through the life stages of maiden, mother, and crone, the health care they receive during one stage will be reflected in all those that follow. Baby boomer women, born between 1946 and 1964, will continue their legacy of reform by participating in medical clinical studies concerning endocrinology, gynecology, neurology, oncology, genetics, and finally, geriatrics. The daughters and sons they presented to the

world will advance reproductive technology in all its genetic and social ramifications.

Robotics

Robotic gynecologic surgery, a recent gift of the technologic world, is being performed routinely now. It is envisaged that most surgery in the future can and will be performed robotically. The systems currently in use are not intended to act independently from surgeons or to replace them. They provide a means for the skilled surgeon to complete complex and advanced procedures with increased precision and with a minimally invasive approach. Medical students will soon be able to perfect their surgical techniques using cyber scalpels, simulated lifelike patient bodies, three-dimensional models, and long-distance mentors. The space industry has also yielded a smart surgical probe that will be used for breast biopsies. The small disposable needle with multiple sensors will be able to distinguish normal tissue from tumor tissue and greatly reduce the 18,000 breast biopsies per week now performed on women with suspicious lesions. Originally conceived as a robotic tool to aid astronaut/physicians during long-duration space flights, it has already found a medical application in neurosurgery.

In 2005, the FDA approved the use of a robotic system (da Vinci built by Intuitive Inc.) for use in gynecology. While most

P.45

advanced gynecologic surgeries are still performed through an abdominal incision (teaching hospitals 82%, nonteaching hospitals 77%), laparoscopic surgeries have less blood loss, fewer complications, shorter hospital stays, and quicker recoveries than do abdominal or vaginal procedures. The da Vinci Robotic System allows less experienced laparoscopic surgeons to perform complex procedures.

Weinberg, Rao, and Escobar found that although there is widespread adoption of the robotic platform, there have been *no* randomized trials comparing its efficacy and safety with traditional surgical approaches. Their comprehensive work updates previous published reviews and focuses only on actual comparative observational studies. In conclusion, they believe, given the caveats of appropriate patient selection and proper physician training, robotic surgery could be advantageous, but they cautioned that until larger, well-designed observational studies or randomized control trials are completed with longterm outcomes, the superiority of robotic surgery over other methods cannot be determined.

Wright, like the former researchers, cautions against overexuberant use and rapid adoption of robotic-assisted surgery, also citing the absence of randomized trial evidence validating its use. In addition, higher costs are noted compared to conventional surgery for many of the procedures. There is marked concern that the sole manufacturer of the FDA-approved devices controls the market by regulating the product's cost, buying up the competition, and using unsubstantiated advertising claims.

Makary et al. at Johns Hopkins had similar concerns when they analyzed 400 randomly selected websites for US hospitals that had 200 beds or more. They found that 89% of them touted the clinical superiority of robotic surgery over conventional surgeries but failed to provide substantiation or to disclose any associated risks. Again, no randomized controlled studies to date show that patients benefit from robotic surgeries over any others. It is known that robotic surgeries take more time, keep patients under anesthesia longer, and cost more.

Makary believes hospitals are perceived as trusted advisers by the public and should have no conflicts of interest when recommending one service or product over the other. Hospital website use of manufacturer provided text and images was blatant.

Johns Hopkins forbids the use of industry-provided content on its websites.

The Old is the New New

Old sciences and contemporary science hold that optimal therapeutic results are obtained when the patient

actively participates in the healing process. The use of traditional or alternative therapies is not only popular among some patients but can also be effective.

Schiff, Gurgevich, and Caspi advocate for scientific studies to determine if hypnosis and acupuncture used concomitantly would work better than either works alone. Acupuncture is based on the principle that channels of energy in the body become blocked and result in disease or discomfort. Theta waves produced during hypnosis result in a heightened state of relaxation or a state of laser-focused attention.

During acupuncture, the patient lies still for 20 to 30 minutes. Listening to hypnotic suggestions (of the patient's choosing) during this time might double-prime the individual to expect and receive positive health results.

The possibilities for relief of chronic pain, chemotherapy-induced nausea, childbirth, and success making those vital lifestyle changes are just a few of the possibilities of combining the two modalities into what might be called hypnopuncture.

Psychosomatic Medicine

Psychosomatic medicine is a system of medicine that aims at discovering the exact nature of the relationship between the emotions and bodily function, affirming the principle that the mind and body are one.

Psychosomatic medicine is an idea whose time has come. The discipline is particularly useful for those mysterious symptoms that are experienced by 30% to 40% of all medical patients. Chronic illnesses account for the expenditure of 80% of health care dollars. These patients will never be cured, but the quality of their lives can be dramatically improved if areas other than the illness itself are explored.

Psychosomaticism tries to determine the character of the relationship between the body and the mind and what's going on between them to make or keep the patient ill. Is it an unresolved problem from the past? Is it recent trauma? Is it an unhealthy lifestyle? If hard, cold, biologic, diagnostic tests can't confirm or deny a causal agent, what is the culprit?

Fava et al.'s comprehensive review of psychosomatic literature elucidates the progress already made when an interdisciplinary approach of investigation is applied, with patient, physician, psychotherapists, nurses, other clinicians, and family members all working together in the best interest of the patient. Allostasis is the goal.

Allostasis means the ability of an organism to achieve stability through change. Productive positive change can only occur if the individual has the necessary coping mechanisms to deal with the destabilizing circumstances affecting the illness or the patient's quality of life.

Infertility

Wurn and Wurn et al. conducted original research to determine if noninvasive physical therapy could open completely blocked fallopian tubes in infertile women. Not only is this a major cause of infertility, both natural and in vitro, but of abdominopelvic pain and pain during intercourse.

For inclusion, the patients had to have a history indicative of abdominopelvic adhesions, with:

- Documented complete bilateral or unilateral (if one tube had already been surgically removed) tubal occlusion
- A history of meeting the US requirement for infertility by failing to achieve a natural intrauterine pregnancy after a minimum of 1 year of unprotected intercourse
- Documented radiologic, surgical, or pregnancy reports after treatment

All therapists had been specifically trained to treat pelvic adhesions. Fallopian tubes were accessed via external, internal, and bimanual manipulation of neighboring soft tissue structures. Truly occluded fallopian tubes are not known to spontaneously open. Confirmed patency or natural intrauterine pregnancy within a 2-year follow-up

was considered success.

Within that time frame, 9 (53%) of the 17 patients with confirmed patency reported a natural or intrauterine insemination.

Researchers concluded that, though the study was small, a noninvasive manual soft tissue physical therapy approach to reopen blocked fallopian tubes absolutely exists and is pregnant with possibility.

Depression

Jackson et al. ask the critical question of whether successful treatment of depression, a profound source of human suffering, can prevent the occurrence of other disease processes. Thus far, clinical trials have not shown this to be true, so there could be an unknown, yet-to-be-discovered factor that causes both depression and comorbid disease.

P.46

Scrutiny of body-mind interactions may soon spawn radical new approaches to the practice of Western medicine and spell the end of traditional separation of the two entities.

Those Stimulating Seniors

The next time you see senior citizens, you might want to thank them for your job.

The Census Bureau records that 10,000 baby boomers retire every day, and one American turns 65 every 13 seconds. By 2030, 70 million people will be seniors. Directly or indirectly, they will influence the creation of 20 million jobs, many in health care and others in the financial industry, real estate, the legal profession, and technology.

The Congressional Budget Office estimates that \$135 billion is spent every year just on long-term care for seniors. Of the most rapidly growing businesses in the United States, 10 out of 20 are in health care.

Jonathan Tilly told attendees at the North American Menopause Society 22nd Annual Meeting that a woman's ticking biologic clock may not be inevitable. Maybe the ovaries don't "fail"; maybe they just go into a state of suspended animation.

His study took half the ovary tissue from a mouse he had forced into menopause and grafted it into a young wild mouse. The dormant premeiotic germline stem cells became active again when exposed to the young mouse's ovaries. They produced oocytes.

Human oogonial stem cells will spontaneously generate what appear to be immature oocytes in vitro. To determine if this is possible in vivo, the researchers transplanted cells from a menopausal woman into immunodeficient mice. There was clear evidence of positive oocytes in the grafted tissue.

Tilly believes ovarian replacement therapy could improve the life course of women, and not just women who wish to reproduce. Will women be able to function better if the biologic clock is turned back?

Tilly and team compared a menopausal mouse to her nonmenopausal sisters. The sisters did not suffer the ravages of time such as loss of hair, wrinkly skin, or cancer, whereas the menopausal sister looked "ratty."

As surgeons, it will be your duty and privilege to witness, record, and practice the new knowledge and incorporate it with what is already known so that you can make a positive difference in the lives of women now living as well as those yet to be born.

CONCLUSION

Advanced technology cannot change the fact that women are emotional creatures by nature. Few

experiences give women more satisfaction than do sexuality and conception. Surgery on or near her reproductive tract is potentially fraught with emotional sequelae. The gynecologic surgeon's responsibility transcends a stunning technical performance in the surgical arena. The accomplished surgeon must considerably manage the patient's return to physical and psychological health. The most important thing a doctor will ever do is learn to listen, even in these, what will someday be known as, the halcyon days of technology.

Chapter 4

Risk Prevention, Risk Management, and Professional Liability

Gerald B. Hickson

Ilene N. Moore

DEFINITIONS

Adverse event (AE)—Undesired occurrence resulting from complication and/or error.

Adverse outcome (AO)—Undesired clinical outcome without implying cause. AOs may be due to: (a) the underlying pathologic disease process, (b) complication of treatment, (c) medical error, or (d) perception of a disappointing result.

Complication—A known risk of a specified procedure, operation, medication, therapy, or treatment plan.

Medical error—Failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim.

Near miss—Event or deviation from best practice that did not cause harm but may signal risk for other patients.

This chapter addresses the myths and realities surrounding “risk management.” The goals of the chapter are for the gynecologic surgeon to better understand:

- Health care's increasing focus on safety (**Introduction**)
- Incidence of AEs, which patients sue, why they sue, and whom they sue (**Section I: The Genesis of Malpractice Claims**)
- Best practices for professional self- and group-regulation and learning from near-misses and AEs in order to promote patient safety and reduce claims risk (**Section II: Professionalism and Risk Prevention**)
- Best practices for managing the aftermath of risk events (**Section III: Managing Risk Events**)
- Medical malpractice law, discovery, trial, settlement, alternative dispute resolution (ADR), and tort reform (**Section IV: Litigation**)

We begin with a case:

Ms. AJ is a 46-year-old G3P3Ab0 female with a 5-year history of uterine fibroids. She notes increasing menorrhagia and pelvic pressure over the past 2 years with an increase in uterine size to 20 weeks. Dr. GYN has treated her conservatively but now recommends a hysterectomy. He engages Ms. AJ in an informed consent discussion, covering treatment options and their potential risks and benefits. Ms. AJ agrees to a total abdominal hysterectomy (TAH), and surgery is scheduled.

On the day of the procedure, her husband waits in the surgical waiting room for word that his wife is out of the operating room. He inquires several times at the reception desk, always told, “Someone will come out to talk with you.” No one does before his wife is transported to her inpatient room.

On arrival to his wife's room, Mr. J meets the advanced practice nurse on Dr. GYN's team, Ms. NP. In response to Mr. J's questions, Ms. NP states, “You will have to ask Dr. GYN.”

Dr. GYN does not round on Ms. AJ until the following morning. Ms. AJ mentions that she expected to see him after surgery. Dr. GYN states, “I'm here now, so what do you want to know?” and proceeds to discuss in general terms that the surgery took a little longer than anticipated but overall the procedure went well. He checks her dressing, turns, and leaves the room.

On postoperative day (POD) 3, Ms. AJ tells Ms. NP that she is having low abdominal pain. Ms. NP states that pain is normal postoperatively, and she will prescribe some pills to take at home. She discharges Ms. AJ and instructs her to keep her post-op follow-up appointment with Dr. GYN, scheduled for 3 weeks hence.

INTRODUCTION

Health care delivery in the United States is evolving. Press coverage related to the Institute of Medicine (IOM)'s landmark studies, *To Err Is Human* and *Crossing the Quality Chasm*, accelerated public and industry recognition of patient harm caused by medical care. Most distressing was the IOM's estimate that 98,000 people die annually in the United States as a result of medical error, with countless more injured. Unfortunately, progress aimed at making health care safer has been slow despite more than a decade of increased awareness and investment in research and safety initiatives. A study of 10

P.49

North Carolina hospitals by Landrigan et al. illustrates this point. The hospitals' overall harm rate did not change between 2002 and 2007. Furthermore, two thirds of the harms were judged preventable. Despite the overall finding, a closer look at the data revealed a range of results among the study sites, suggesting that some appeared to have tackled risk issues more successfully than did others.

The fact is, safety and quality vary among, and even within, practices, hospitals, and health care systems. Some patients experience well-coordinated, timely, efficient, and effective service, while others receive fragmented, delayed, redundant, or inadequate care. As society becomes less tolerant of unsafe conditions and avoidable AEs, the focus on claims management must shift to an emphasis on risk prevention.

Utilizing evidence-based best practices, professionals must move patients out of harm's way through risk surveillance, apply analytic methodologies to identify factors that contribute to AEs, fix defective systems, and hold professionals accountable. Furthermore, professionals must treat patients, their families, and each other with respect. Private and public payors are leveraging their market power to encourage practices that promote safety, improve outcomes, and manage costs. The Centers for Medicare and Medicaid Services (CMS), for example, uses a payment withholding and reward system to incentivize professionals and hospitals to achieve lower hospital-acquired infections rates, reduced need for hospital readmissions, and integration of patient perceptions of care into quality standards. Payors also deny reimbursement for the extra care needed to treat outcomes they deem avoidable or place liens for reimbursement against patient claimants' jury awards and settlements.

SECTION I: THE GENESIS OF MALPRACTICE CLAIMS

KEY POINTS: GENESIS OF CLAIMS

- Many patients with valid potential claims do not sue.
- Noneconomic factors play a significant role in patients' and families' decisions to sue.
- Claims are nonrandomly distributed.
- 3% to 8% of physicians by specialty account for over half of all risk management expenses.
- Risk status appears constant over time.

- Unsolicited patient complaints are related to malpractice claims risk.
 - Intervention with high-complaint physicians can lower claims risk.
-

Incidence of AEs

Responding to the malpractice insurance crisis of the 1970s, the California Hospital Association organized a study in which 21,000 medical charts from all 1974 hospitalizations at 23 California hospitals were reviewed. Mills reported that the study found almost 5% of inpatients (7% if over 65) experienced AEs. Nearly one fifth of the AEs were further classified as injuries for which the professional staff and/or hospital would likely be liable, that is, due in whole or in part to medical negligence.

The Harvard Medical Practice Study I (HMPS I) reported similar findings from a review of 30,000 New York State hospital records from the year 1984. The overall AE rate was 3.7%; for those over 65, the AE rate was 5%. Twenty-eight percent of the AEs involved negligence ([Fig. 4.1](#)). Replicating the study in Colorado and Utah, the researchers found essentially the same results.

Other studies, including some from the international community, also confirm that the majority of AEs do not involve negligence.

Who Sues?

Or, to rephrase, who are the claimants in medical malpractice cases?

Danzon reported that in the 1970s no more than one out of 10 patients injured by care filed suit. In the HMPS III, Localio and colleagues found an even lower claims rate among injured patients. HMPS III matched 47 malpractice cases to the 30,000 1984 HMPS I hospitalizations. In only eight of the 47 cases did medical record review demonstrate evidence of negligence. However, these eight cases represented only two percent of the patients with AEs attributable to medical negligence. The majority of claims were instead filed by patients whose AE did not result from negligence; for every suit with an AE attributed to negligence, five to six suits lacked such evidence. The results were consistent with Mills' earlier observation that "most patients who file lawsuits for medically caused disabilities do so without real knowledge about presence or absence of legal fault as the cause of their disability". HMPS III remains an important study for its insight into the fact that much of the legal activity involving allegations of medical malpractice represents circumstances where care was appropriate, but the patient or family do not appear to understand or accept.

A later study of 1,452 medical malpractice cases conducted by Studdert et al. found that, in comparison to HMPS III, three out of five claims are legally justifiable. What might account for the higher proportion of cases deemed valid? We suggest

P.50

four potential factors: (a) study methodology, (b) threshold for finding preventable harm, (c) evolving error disclosure practices, and (d) case selection.

FIGURE 4.1 Adverse events versus negligent injuries. Adapted from Bovbjerg RR. *Medical malpractice: problems & reforms— a policy-maker's guide to issues and information*. Washington, DC: The Intergovernmental Health Policy Project, George Washington University, 1995; Mills DH. Whither malpractice regulation? *West J Med* 1988;149:611; deVries EN, Ramrattan MA, Smorenburg SM, et al. The incidence and nature of in-hospital adverse events: a systematic review. *Qual Saf Health Care* 2008;17:216; Brennan TA, Leape LL, Laird NM, et al. Incidence of adverse events and negligence in hospitalized patients: results of the Harvard Medical Practice Study I. *N Engl J Med* 1991;324:371.

The study methodologies differed in that HMPS III reviewed patients' medical records for evidence of AEs and negligence, while Studdert reviewed insurers' closed claims. Documentation in medical records can be incomplete or absent. In contrast, insurers' files contain deposition transcripts and/or witness interviews that may reveal evidence of negligent events not found in medical records.

Second, because of our evolving understanding of how faulty systems and human factors intersect to cause error, some of the “no negligence” AEs in HMPS III might be characterized today as avoidable error-based AEs. The IOM definition of error (“the failure of a planned action to be completed as intended or the use of wrong plan to achieve an aim”) captures the notion that occurrence of an unintended outcome itself signals likelihood that faulty systems and/or human decisionmaking contributed. Reassignment of some of the 47 HMPS III cases would likely have brought HMPS III's valid:invalid ratio closer to Studdert's.

The third potential reason for Studdert finding a higher percentage of justifiable claims may relate to increasing error disclosure. Some patients who might otherwise never realize medical error caused them harm may sue once this information is disclosed. However, the data so far suggest that disclosure does not lead to more suits nor an increase in overall liability costs; rather, disclosure may reduce suit and claims rates, time to resolution, average payouts, and legal costs.

A fourth factor is that plaintiff's attorneys today are likely more selective about which cases they accept. Attorneys take malpractice cases on a contingency (rather than hourly pay) basis and are not paid if they lose. Thus, accepted cases must potentially yield a recovery large enough to cover attorney fees and upfront costs, including experts' travel expenses and billings for time spent reviewing cases, executing certificates of merit (in states where required), and testifying.

Rice reports: “Experienced malpractice attorneys say they tend to be very judicious about what they pursue.”

Shepherd reports that “Over 75 percent of the attorneys... survey[ed] indicate[d] that they reject more than 90 percent of the cases that they screen...over half...responded that, even for a case they are almost certain to win on the merits, they will not accept the case

unless expected damages are at least \$250,000.”

In sum, it is important to recognize that there are patients who are injured by medical care, and a significant proportion of injury is due to avoidable error. However, most patients with valid claims do not pursue litigation. Although many claims are valid, there still remain patients who file claims despite little or no evidence of bad care. We now examine what motivates patients and families to contact an attorney.

Why Do Patients Sue?

Some professionals assert it is all about “ambulance-chasing lawyers” and plaintiffs' desire for money; however, the evidence suggests that decisions to sue are more complex. In one study where families were asked why they had sued their obstetrician, many offered more than one reason. Money was mentioned as a reason for contacting an attorney by a quarter of the families, but most identified a host of noneconomic reasons: wanting to “make sure this doesn't happen to anyone else” (19%), needing information (20%), feeling their loved one would have no future (20%), believing there was a cover-up (24%), and advice from an “influential other” (33%). Only one respondent indicated that she had been solicited by an attorney. In the United Kingdom, Vincent et al. also found noneconomic factors more prominent in patients' decisions to sue than the need for financial compensation.

While some factors are outside a professional's control, how and what information a professional provides to the patient is not. As gynecologic surgeons reflect about their personal risk prevention strategies, it is beneficial to examine the types of informational issues families cited as reasons for filing: no one would tell them what was wrong, their physician would not answer questions, and no one warned them that the problems might be permanent. The need to understand is normal. Patients want answers if only to help dispel fears that somehow something they did contributed to the AO.

If patients do not raise questions, do not assume they have none. Make clear through your verbal and nonverbal communications that you want to address their questions. If you are asked questions, say what you know but be careful about speculation. If you do not know the answer, say so. Specify when you expect to be able to follow up with more answers, and make certain that you *do* follow up.

Patients and families may claim they did not receive clear explanations of what happened even when the professional tried. When you provide answers, seek to confirm that they understood utilizing “teach-back” methods; do not equate a head nod with comprehension.

Ineffective communication may also lead to allegations of cover-up or incompetence, especially if other professionals provide conflicting information or “joust” (criticize the treating professional, practice, or health care institution). For the one third of families in the study who decided to file suit based on the “advice” of an “influential other,” most often it was a health care professional who told them the bad outcome was a result of poor care and/or that they should sue. The following represent examples of reported communications:

“The nurse practitioner told me, “They gave you the wrong medication when they discharged you. That's why you're having this problem.”

“After talking to the anesthesiologist, I realized it clearly was the surgeon's fault. I had no idea that the bad outcome was related to Dr. XX's care until he suggested....”

“Influential others” fill gaps when patients have unanswered questions, residual concerns, lack of trust in the professional, or worries about the future. Healthcare professionals should remain alert to the possibility of error by others. However, by jousting and offering gratuitous negative comments, they bear some responsibility for inflaming and undermining colleagues' relationships with their patients, which can contribute to unnecessary

litigation. Thus, professionals should ask themselves a set of questions before commenting about care delivered by others:

- Do I have all the data?
- Am I certain the history provided by the patient is accurate?
- Do I have the expertise, or am I making a judgment about someone who practices in another field?

Whenever possible, professionals should seek direct clarification of the facts of the case from colleagues who provided care to the patient. If direct contact is not possible, reviewing the medical records may shed light.

If needed information is not available or what is learned does not reassure, then reporting through appropriate channels is professional. In the group setting, the reporter can make

P.51

practice leaders aware. In the hospital setting, one should utilize an online reporting system (if available) and/or directly contact designated personnel such as risk managers and/or safety and quality officers. In other words, commitment to safety means that colleagues and team members raise questions with the involved parties, route concerns for objective review, and if information emerges that impacts the patient, share it with him/her in a professional manner. Arguing at the patient's bedside or rushing to tell a patient or to comment in the medical record that a previously treating professional "messed up" is not consistent with principles of professional disclosure.

Inflammation and communication failures can trigger unnecessary claims. Examples of such circumstances include the following: (a) The AO is not due to medical mishap, but the patient believes it is; (b) a medical error did not result in harm, but the patient believes it to be the cause of his/her outcome; and (c) medical error caused harm, but failed opportunities to address the patient's and family's needs spurred their decision to pursue legal action and/or to make unreasonable demands. Understanding the reasons families sue can help professionals reflect and act in ways to prevent claims that might be avoided.

Who Gets Sued?

Many physicians assert there is little they can do to prevent malpractice claims, citing as "fact" that "everyone in my specialty gets sued." It is true that overall claims rates vary by specialty. Jena et al. and Kane found neurosurgeons and cardiothoracic surgeons to share claims rates of 19% per annum; general surgeons, 15%; and obstetrician-gynecologists, 12%. (Obstetrician-gynecologists also account for the highest number of indemnity payments of over one million dollars.) In comparison, psychiatrists, family physicians, and pediatricians experience overall rates of 3% to 5%.

Such aggregate statistics suggest that claims are common and likely inevitable over the course of a career. They do not tell the whole story, however, for claims rates do not address the distribution of claims among physicians. In fact, claims are nonrandomly distributed, and a small subset of physicians within any specialty accounts for a disproportionate share of claims and payouts. Studying physicians in Florida, Sloan and colleagues reported that, depending on the specialty, 3% to 8% of physicians account for 75% to 85% of all indemnity payouts within their specialty: 8% of surgical subspecialists, 6% of obstetrician-gynecologists, and 3% of medical specialists.

Other studies have confirmed nonrandom distribution of claims and payouts within multi-specialty groups. Furthermore, the propensity to attract claims persists over time; physicians with high numbers of past claims appear to continue this pattern into the future.

Is there something different about physicians who experience multiple claims compared with peers who are seldom or never sued, or are they just unlucky? Four likely hypotheses are that high suit physicians: (a) care for a more litigious population, (b) care for the sickest patients, (c) are less technically or clinically competent than

low-suit colleagues, and/or (d) do not “connect” as well with patients.

Well-educated, higher income patients are more likely to sue than are those who are elderly, poor, or uninsured. However, Entman and colleagues found no difference in practice demographics for obstetrician-gynecologists with a history of multiple claims when compared with peers in their community with few or no claims.

Review of patient medical charts from the practices of high versus low claims obstetrician-gynecologists also revealed no significant differences in patient mix, acuity, documentation practices, or evidence of marginal care. The area in which high claims physicians did differ, however, was in how they were perceived by patients. The researchers asked open-ended questions of the patients (none of whom had filed suit against their physician) whether any aspects of care failed to meet or exceed their expectations. Their responses could be sorted into concerns about their physician's communication skills, care and treatment, access and availability, and “humaneness” during labor and delivery. The following are sample patient comments from the interviews:

“He did a very poor job of communicating... discounted everything that we said.”

“Dr. X offered no information. I felt he was hiding information.”

“...never gives me more than 5 minutes.”

“He was terrible with this pregnancy and was even worse with the next one, but the HMO said I had to stay with him. I kept hoping to get his partner, but never lucked out. I'm not getting pregnant anymore because of him.”

Patients whose obstetricians had a history of multiple lawsuits voiced three times more complaints about their care than did patients of low-suit physicians. In other words, the same small group of physicians responsible for high numbers of malpractice cases was also associated with higher numbers of patient complaints and dissatisfaction.

Identifying Professionals at High Risk of Claims

If physicians with high numbers of malpractice cases have significantly higher complaint rates than do their peers with few or no claims, is the converse also true? Do patient complaints identify physicians at high risk for claims? If they do, perhaps it is possible to identify high-risk physicians by a method other than waiting for lawsuits.

Unsolicited “patient complaints” are the stories patients and families share with practice and hospital representatives about their care experiences:

“The GYN... didn't listen... just cut me off... made me worry about the treatment plan.”

“[Patient] described the exam as torture... Dr. XX was yanking and shoving the speculum... it hurt worse than her surgery.”

“They left me sitting in the stirrups... then Dr. XX made a very inappropriate remark and left the room... I felt humiliated.”

Capturing patient complaints allows opportunities for “service recovery,” that is to say, helping to “make right” what patients and families perceive as wrong. Hickson and colleagues hypothesized that coding and aggregating unsolicited patient complaints over time would reveal risk patterns. Studying unsolicited patient complaints at an academic medical center Hickson et al. and Moore et al. found:

- Most physicians were associated with few or no unsolicited patient complaints over a 6-year audit period. Five percent of physicians were associated with nearly one third of all patient complaints ([Fig. 4.2](#)).

- Risk management activity was associated with three characteristics of physician practice: unsolicited complaint numbers, specialty, and productivity as measured by relative value units (RVUs) by discipline. Logistic regression analysis revealed, however, that of the three predictors of risk,

P.52

unsolicited complaints and risk management activity were most closely linked.

- Association of physician productivity with lawsuit risk was minor when compared with patient complaints and disappeared for physicians with multiple lawsuits. In other words, the unique ability of a physician and his/her practice to create dissatisfaction among patients overwhelmed productivity as a predictor of high claims experience.
- Nine percent of physicians, as a group, were associated with the highest numbers of unsolicited complaints and 50% of all risk management expenditures and payouts.

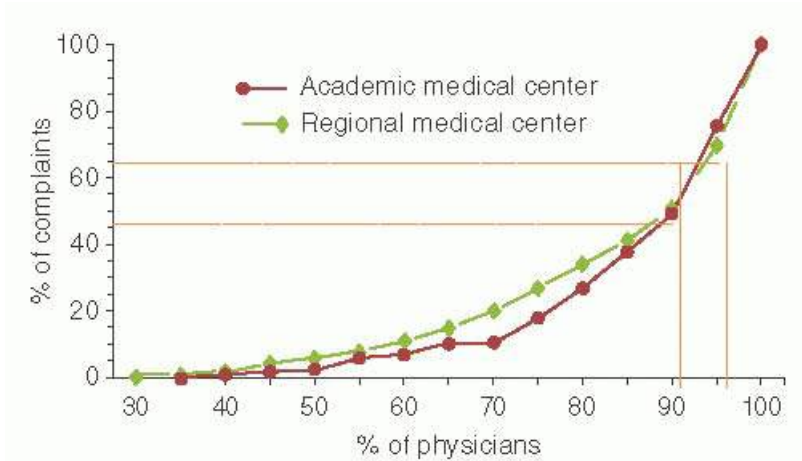

FIGURE 4.2 Distribution of patient complaints. Adapted from Hickson GB, Pichert JW. Identifying and intervening with high-malpractice-risk physicians to reduce claims. *Physician Insurer* 2007: 29. Adapted with permission from the Fourth Quarter 2007 issue of *Physician Insurer Magazine*, Physician Insurers Association of America. Copyright © 2007.

A follow-up study at a regional medical center affirmed the results ([Fig. 4.2](#)).

Stelfox et al., Fullam et al., Cydulka et al., and Levtzion-Korach et al. have confirmed the relationship between patient complaints and claims experience. Furthermore, any relationship between patient satisfaction survey data and risk management activity disappears once patient complaints are entered into the model. Complaint distribution patterns similar to those from the multispecialty group studies are also seen for single physician specialty groups including trauma, urology, and cardiothoracic surgeons and can support targeted interventions to help reduce unnecessary risk.

In sum, the empirical data demonstrate that professionals' own behaviors and practices are primarily responsible for inspiring claims rather than external factors. Malpractice claims should not be viewed as just an expected "cost of doing business." Rather, AOs are more likely to lead to claims when patients are dissatisfied with their physician's practice and/or interpersonal behaviors. Unless high-risk professionals are willing and able to address sources of patient dissatisfaction, their malpractice costs will continue to exceed those of their low-risk colleagues.

SECTION II: PROFESSIONALISM AND RISK PREVENTION

Traditional risk management programs focus primarily on managing claims. Skillful management of potential claims is, of course, important to gynecologic surgeons when their patients are unhappy about outcomes of care.

Modern risk prevention programs, however, also proactively identify sources of risk through surveillance and monitoring, utilize methodologies that elucidate “sharp end” (obvious) and “blunt end” (less obvious) contributors to AEs, and take corrective action to fix defective systems and remedy deficient human performance and behavior. Both risk mitigation and proactive management of potential claims (Section III) reduce medicolegal costs.

Organizations with a knowledgeable risk prevention/management department and stakeholders with aligned interests can help reduce risk of patient harm and individual professionals' risk for claims. One way to lessen your own risk is to practice in a setting with a good, integrated, aligned risk prevention program.

KEY POINTS: BEST PRACTICES FOR RISK PREVENTION

- Promoting professional behaviors to support teamwork
 - Early reporting and timely review of unexpected AOs, suspected errors, and near misses
 - Event analysis methodologies to understand “how and why” the risk event occurred and a process for fixing system defects
 - Remediation of human performance and behaviors that threaten patient safety and increase risk of medical malpractice claims
-

Professionalism

Professionalism is the fundamental human force behind the goal of making medicine safer and kinder. Professionalism requires more than clinical knowledge. Beyond the need for cognitive and technical competence are the essential behavioral dimensions: modeling respect, communicating effectively, being available, and demonstrating willingness to give and receive feedback. The Joint Commission's requirement for Ongoing Professional Practice Evaluations reflects growing recognition that the ability to deliver safe, high-quality patient care requires competency in this complex skill set.

Professionalism promotes teamwork; unprofessional behavior creates team dysfunction. Rosenstein and O'Daniel's survey of perioperative personnel found disruptive behaviors to be common. Study participants linked unprofessional behaviors with communication failures as well as distractions leading to momentary lapse of attention, well documented by others as contributors to errors and AEs. Sample comments from study participants included:

“Some surgeons seem to believe that they have the right to be rude...and disrespectful to non-physicians. It makes it very difficult to perform at a high level when one is constantly in fear of being screamed at.”

“We have some... team-oriented surgeons... but the ones who are disruptive make it so intensely difficult that it is overwhelming. Unfortunately, as good as the good ones are, they can't outweigh how bad the bad ones are.”

Professionals are committed to self-assessment of their performance and continually seek ways to improve. Professionals are also committed to group regulation. Risk prevention, therefore, includes methodologies to

identify and address unprofessional interpersonal and practice behaviors that threaten safety. Professionals' commitment to group regulation is

P.53

evidenced by their participation in related activities, including peer review. Professionals further assume personal responsibility for identifying faulty systems within the environment, work to "fix" systems thus identified, and disseminate information about best practices.

Reporting and Timely Review

How do professionals learn about threats to safety within their practice, group, or health care institution? Active reporting is a critical component of a risk prevention program. Professionals, support staff, patients, and families are all observers, and by lowering barriers to reporting, they help identify threats to safety and quality.

Information on how to report should be disseminated so that all potential reporters, including patients, know how to report within the practice or health system (e.g., by phone, written contact, face-to-face, and/or electronic reporting) and to whom they should report (e.g., patient relations personnel, practice leaders, or a risk manager).

Practices, health care organizations, and malpractice insurance carriers should make clear in their policies what types of events health care professionals and personnel are to report. These should include sentinel events, errors or suspected errors with consequences (e.g., lengthened hospital stay, temporary or permanent disability, death), near misses, coworker concerns about performance or conduct, information about unsafe conditions or faulty equipment, and patient/family complaints of which they are aware.

Early reporting of suspected risk events, near misses, or patient injury to the professional's risk manager or malpractice carrier is always good. Reporting permits timely review and optimal management of a potential claim. Designated personnel must promptly address each report, review the asserted issues, and assemble a response and action plan. Reports should also be entered into a database for tracking, trending, and identifying patterns.

Early reporting also allows an opportunity to quickly address patient and family concerns and rebuild trust. In particular, when avoidable error with harm is identified, disclosure with apology may reduce inflammation and therefore risk of a lawsuit. Emerging evidence suggests that honesty and proactive risk prevention strategies help avert litigation and reduce claims costs.

Despite its critical importance, professionals sometimes hesitate to report. Possible reasons include lack of clarity about the mechanism for reporting and loyalty to the professionals involved in the incident. Because of concerns that even anonymous reporting will invite retribution from those who are the subject of the report, explicit nonretaliation language should be a part of the reporting policy to protect reporters and must be enforced.

Ultimately, failure to report is not consistent with being a professional. Reporting is part of one's commitment to self and group-regulation. Success of surveillance relies on team members recognizing the value of reporting safety risks, understanding it is an expectation and part of their professionalism, and making it psychologically safe for all to speak up when they observe practices that appear unsafe.

Event Analysis Methodologies

If harm or the potential for harm is suggested by a report, professionals try to understand what happened and why. Event analysis methodologies represent best practices in seeking to understand how errors occur and how to prevent them. Practices, health care organizations, and medical malpractice insurance carriers should endorse utilization of event analysis in order to identify and address faulty systems and individuals.

Common event analysis techniques include: (a) risk management file review (b) root cause analysis (RCA), also termed event analysis, or multicausal analysis and (c) multidisciplinary morbidity, mortality, and improvement (MMM&I) conference. The tools support a balanced focus on systems and individual accountability, and the

information uncovered by the analyses is what drives risk prevention efforts.

Protecting event analysis activities from discovery may vary by state, and you will want to seek legal advice to set up these processes. Even in states where legal protection of such activities is untested, professionals' commitment to continual learning and improvement can help them work through how best to achieve what is right for patients and their care.

Risk Management File Review

Risk management file review is the foundation for evaluating all claims and potential claims, whether the insurer is a carrier or a self-insured entity. The case is assessed for potential liability by reviewing, for example, medical records, witness interviews, and consultant/expert reports. Reviewers seek to identify strengths and weaknesses in individual cases, including medical conditions likely to have led to the same outcome in the absence of medical or nursing error, and patient actions that may have contributed.

The risk prevention lens, in contrast, views cases as opportunities to learn about modifiable contributory factors that can prevent future occurrences. For example, a traditional risk manager may focus on poor documentation that represents a weakness in a case and suggest better documentation in the future to make cases more defensible. A risk prevention lens would disseminate the notion that poor documentation impairs team communication and therefore the ability of the team to achieve intended outcomes. Exhorting improved documentation practices through the latter lens serves to increase patient safety in a broader sense.

Although the traditional risk management model cautions against sharing results of a review for fear the opposing litigant could gain access to that information during discovery, modern risk prevention recognizes that waiting years for a case to close before disseminating lessons learned inhibits professionals' ability to improve care. Coded and aggregated medicolegal data can be used to identify recurring safety themes and individual and group patterns, and when consolidated with claims files data within larger consortia (e.g., the Harvard-based CRICO/RMF), allow identification of common areas of risk. Larger databases can help prioritize areas in which best practice standards should be developed, disseminated and implemented. For example, the American Society of Anesthesiologists (ASA)'s review of over 5,000 closed claims dating from the 1970s through 1994 transformed a medical discipline's safety record. Practice changes such as use of end-tidal CO₂ monitoring and intraoperative pulse oximetry, virtually eliminated claims for undetected esophageal intubation and inadequate ventilation.

Root Cause Analysis

RCA is a tool for drilling down and understanding what caused an AE. RCAs are designed to explore AEs for factors that represent variation in performance by systematically teasing out both sharp and blunt end contributors to AEs. RCAs

P.54

attempt to answer three questions: What happened? Why did it occur? ("Ask five times.") What can be done to prevent recurrence? Follow-up should occur and the action plan assessed for effectiveness.

In smaller practices, a designated group can develop expertise in RCAs. In larger settings, participants in RCAs generally include a trained facilitator, team members, managers of involved service areas, risk managers, and quality and safety officers. Causative factors are coded, action plans developed, and professionals and staff educated. Percarpio and Watt's recent study of Veterans Affairs medical centers suggests that committing resources to RCAs results in safety improvements such as lower postoperative complication rates.

Multidisciplinary Morbidity, Mortality, and Improvement Conference

The MMM&I conference is an educational forum, open to a broader range of individuals than attend an RCA.

MMM&I attendees include professional, clinical, administrative, and clerical staff. In the hospital setting, attendees likely also include pharmacists and learners. The conference is designed to help attendees feel comfortable speaking up about circumstances and behaviors that contributed to an AE (psychological safety) and to lessen the inhibitory effect of the hierarchy. In addition, by reminding everyone that errors occur, the MMM&I can help start the healing process for professionals involved in the case.

In contrast to traditional M&M (morbidity and mortality) conferences, which tend to focus on individual performance (sometimes perceived as “shame and blame”), MMM&I conferences review a case within a framework of factors known as common contributors to failures or errors resulting in AEs. In one model, six domains (policies, environment, equipment, communication, procedures, and people) are set up as a “fishbone” or cause-and-effect Ishikawa diagram to identify all factors that contributed to failures. The “I” (Improvement) of the MMM&I results when a work group prioritizes identified issues and develops a follow-up action plan and assigned team members complete tasks and provide feedback.

Aggregating analyses from MMM&I conferences can identify recurring factors that underlie failures and help focus efforts on highest-yield projects. For example, one department of obstetrics-gynecology aggregated analyses of inpatient women's health cases and identified contributory factors such as jousting, ineffective communications, lost and overlooked documents, inadequate supervision, failure to follow policies, and equipment issues. Patterns suggested that improved systems for alerting key professionals for emergencies and facilitating intercaregiver communication would help remedy these issues. As a result, the department established a team to identify best practices and trained all clinical personnel.

Remediating Human Performance and Behavior

Unsolicited patient complaints support risk prevention efforts. Complaints help identify opportunities for service recovery, learning about threats to safety, and supporting interventions for professionals at high risk for claims.

Only a fraction of the patients who are unhappy with their care complain. For each patient who voices a complaint, many dissatisfied patients do not (estimated ratios range from one out of three to fewer than one in fifty). Patients who do not share their concerns with you or your group may instead tell family, friends, neighbors, and, increasingly, the general public via social media. Professionals should therefore make every effort to narrow the gap between voiced and unvoiced dissatisfaction by making it easy for patients to file complaints and responding professionally to those complaints by providing service recovery.

Patients and families also serve as the “canary in the mine.” Murff found, for example, that admissions with surgical complications generate more complaints than surgical admissions without complications. Unsolicited complaints at times are the first (and sometimes only) notice of errors and sentinel events:

“I had a cystocele and a rectocele... After surgery I went for my checkup and she explained that it was my rectocele falling and now I had an enterocoele... she never repaired the rectocele during my first surgery... because she thought if she pulled everything up tight, it would take care of it... I am now faced with a third surgery for same problem.”

Additionally and as previously discussed, patient complaints may be used to identify and address professionals with a disproportionate share of complaints and at high malpractice claims risk. Vanderbilt's Patient Advocacy Reporting System is a risk prevention tool that utilizes a reliable process to collect and code complaints and aggregate and analyze the data. The tool supports a risk prevention program in which professionals are made aware of their high numbers of complaints and associated high-risk status through a committee organized in accordance with the requirements of their state's peer-review statutes.

Volunteer peer “messengers” are trained to conduct nondirective, nonjudgmental interventions with identified professionals and share individualized and local and national comparative data. The messenger asks his/her colleague to reflect on why he or she appears to stand out. The majority of professionals respond to peer-based intervention by reducing complaint numbers and claims risk.

Follow-up data are provided at intervals to help professionals evaluate the effectiveness of self-directed changes in their practice or interactive style. As illustrated by the Promoting Professionalism Pyramid model (**Fig. 4.3**), if complaints continue after peer-based interventions, the professional is escalated to the next tier. An appropriate “authority figure” then develops a specific accountability action plan designed to assist the professional. The plan may include coaching, relevant continuing education, a practice review and redesign, and/or medical evaluation to rule out conditions that require further attention, such as substance abuse, psychiatric disorder, or cognitive impairment.

The Role of the Insurance Carrier and Risk Manager

As a gynecologic surgeon, reflect on your relationship with your malpractice carrier (or self-insured health system), risk manager, and any personal experience you may have had with claims. Identifying patterns and threats to safety helps professionals focus on education and resources where they can most favorably impact patient care and risk prevention.

Do your carrier and risk manager:

- Encourage and make early reporting accessible?
- Support risk management file review, RCAs, and MMM&Is?
- Promote patient complaint collection, analysis, and intervention with high-risk individuals?

P.55

- Offer on-site practice review to identify risk issues?
- Incentivize you to adopt risk prevention procedures and participate in safety initiatives?

SECTION III: MANAGING A RISK EVENT

In spite of the best risk prevention strategies, some confluence of the human condition and systems failures

interact in ways to create a risk event. Even so, it may be possible to identify early and respond in a way to avert the level of anger that can make managing risk more challenging.

The genesis of a potential lawsuit may begin before an AE occurs or is recognized. From the time a patient first calls a physician's office for an appointment, or tries to find a parking space, the practice is either building credit or is creating debt with the patient:

In Ms. AJ's case, Dr. GYN seemed professional at their first meeting, providing an explanation of her procedure and answering questions. Her postoperative experience created concern. Postdischarge, Ms. AJ's frustration mounted.

At home (POD 4), Ms. AJ continues to have low abdominal discomfort. She feels her abdomen is swollen and experiences persistent back pain. Ms. AJ calls Dr. GYN's office and asks to speak with him. Ms. NP returns the call. Ms. NP states she doubts symptoms are related to surgery. She promises to get back to Ms. AJ as soon as she has a chance to talk with Dr. GYN. Ms. AJ does not receive a callback that day. The next morning (POD 5), Ms. AJ leaves a voice mail as prompted by the office messaging system, asking if she can be checked by Dr. GYN because she is feeling "really bad."

Ms. AJ does not hear back. That afternoon, Ms. AJ calls her primary care physician who suggests she go to the emergency department for evaluation. Dr. ED orders an abdominal CT scan with contrast. The study reveals extravasation of dye into the abdominopelvic region. An intravenous pyelogram (IVP) confirms leaking dye from the left ureter. Dr. ED calls Dr. GYN's answering service. Dr. GYN's partner calls back and asks Dr. ED to call a urologist to admit Ms. AJ because Dr. GYN is out of town and the patient will need a urologic procedure.

Ms. AJ is admitted. Dr. GYN is informed the next morning.

Once a professional realizes that his/her patient has experienced an AE, some thoughts may come to mind:

- This is a recognized complication, right? (It was covered in the informed consent process....)
- What do I say to my patient?
- Should I report this to my practice leaders, risk manager, or malpractice carrier?
- Do I have liability exposure? Will I be sued?
- I wonder what Dr. ED and Dr. Urology are saying to my patient....
- Could the "complication" have been identified sooner?

Knowing that the practice and/or health care organization is principled, "aims to do right" by patients and families, has the right tools to manage the situation, and offers guidance to team members, can help make an uncomfortable situation more tolerable for professionals. If your carrier or hospital does not offer information about a comprehensive approach to risk management after an event, you should ask what they do.

Dr. GYN goes to see Ms. AJ. She appears upset. Ms. AJ tells Dr. GYN that no one in his office listened when she reported continued discomfort, and she feels she should not have had to contact her primary care physician to get help; Dr. GYN did the surgery so he should have responded. She fears that the delay has led to a more serious problem. Ms.

AJ also mentions that the urologist kept shaking his head when she told him how no one in Dr. GYN's office seemed to take her seriously.

At the time an AE is recognized, the cause—*complication? error? combination?*—is often not clear. In some cases, objective review never fully elucidates the answer. Even if a professional is confident that what the patient is experiencing is a complication that happens under even the best of circumstances, patients and their families may still wonder if extra care might not have prevented the event. So, too, should the involved professional.

KEY POINTS: BEST PRACTICES FOR RISK MANAGEMENT AFTER AN AE

- Coordinate care for the patient's medical and emotional needs
 - Support emotional needs of involved team members
 - Notify your carrier or group or hospital risk manager if an error is identified, suspected, or unclear
 - If appropriate, dispatch trained individuals within the practice, group, or hospital to meet with the patient and family to assist with service recovery
 - Engage in a process of disclosure with the patient and offer an apology if error is identified. "Patient" includes family members or other parties authorized by the patient or legal guardians
 - Consider reimbursement of out-of-pocket expenses and early settlement offers. (This is done by risk management professionals.)
-

Coordinating Care for the Patient's Medical Needs

After an AE, a professional should not delay care for his/her patient but does need to ask, "Do I need help in caring for the patient?" "Do I have the expertise to address the adverse outcome?" Do not be tempted to deliver care outside your usual scope of practice; arrange appropriate consultations from other professionals.

Furthermore, irrespective of whether you or another specialist manages the patient's current medical needs, it is important that you do not abandon your patient. Continue to visit

P.56

and follow the patient. If patients do not see their physician, especially after an AE with error, patients may believe you are avoiding them for one of two reasons: either you don't care or you feel guilty.

After an event, physicians and nursing professionals set the tone for the patient and family's ongoing relationship with the health care team and the ability to move forward. Because the patient and family are likely experiencing feelings of loss, guilt, anger, and fear (whether or not expressed), professionals should engage without defensiveness.

Supporting the Emotional Needs of Involved Team Members

Situational stress poses risk. Professionals should be cautioned when error is suspected or confirmed that they may experience intense emotions of fear, guilt, or anger (often about other team members' performance) and/or disorientation due to an altered sense of one's abilities. Such feelings cloud judgment. When appropriate, team members should be encouraged to obtain professional help for themselves during a crisis.

Notifying Risk Management or Insurer

Risk managers and insurers want to hear about AEs as soon as possible. Make them aware of any outcome that has the potential to result in a claim, *even* if you believe you have no liability and *even* if you believe you have such a great relationship that “she would never sue me.” Treat each potential risk event the same way.

Risk managers who learn about risk events can facilitate timely review, help team members prepare for disclosure to the patient and family, and sequester defective equipment (e.g., an IV pump that dispensed heparin 10 times faster than programmed) in accordance with federal regulatory requirements. Furthermore, evidence demonstrates that professional and prompt engagement with the patient decreases overall malpractice costs.

Engaging in Service Recovery

Trained patient relations personnel in a practice, group, or hospital setting are a valuable resource in managing the aftermath of an AE by focusing on the needs of the patient. Service recovery aims to facilitate communication among the patient, family, and health care professionals and to identify ways to assist the patient and family. They can also help defuse situations in which professionals come under verbal assault from angry family members.

Commencing Disclosure

Dr. GYN is aware of the results of the imaging studies that show a ureteral transection, almost certainly related to Ms. AJ's TAH. Dr. GYN is confident that the laceration did not result from carelessness but rather the challenges of the procedure. Before surgery, Dr. GYN discussed possible complications with Ms. AJ. He recognizes he needs to talk with Ms. AJ.

Dr. GYN promptly notifies his insurer and risk manager about the AE and discusses a disclosure plan. They agree that Dr. GYN proceed with speaking with Ms. AJ and her husband, but not speculate on the cause of the injury until the review is completed.

The move toward disclosure of AOs and errors is fairly recent. Not that long ago, some malpractice carriers recommended against disclosing to patients and families the fact that a poor outcome was due to problems with care, or policy language prohibited admissions of liability.

Such policies appear counterproductive. Prohibiting direct admission of error or fault can create ethical dilemmas for professionals who believe they should be honest with their patients, consistent with principles long embedded within professional codes of ethics. Such policies also create risk; patients may find other professionals who reinforce their concerns, leading to the belief that litigation is the only option to compel truthful answers.

Insurers or risk managers who encourage nondisclosure may do so because they believe that admission of fault increases likelihood of lawsuits or makes cases harder to defend. A growing body of evidence suggests, however, that a more transparent model lessens the risk of suits and moderates payouts. In such a model, specific information about AEs is shared with the affected patient and sincere and specific apology offered for error that caused or contributed to the outcome. Progressive risk prevention/management programs now encourage training in disclosure for professionals so they know how and when to share information related to AEs with patients and families. Training reinforces that respect for the patient is paramount.

Specific skills sets are required for effective communication; disclosure is no different. Disclosure, if done appropriately, can promote understanding and builds trust. Done poorly, it increases anxiety and destroys trust. Gynecologic surgeons would be prudent to ask their insurance carrier and any health care institution in which

they care for patients about their disclosure policy and relevant training programs.

Training helps professionals prepare for the skills needed to manage four key disclosure scenarios:

1. AO is recognized, but the “why” (disease process? complication? error?) is uncertain at the moment.
2. Obvious error has occurred with obvious consequences.
3. The professional suspects error by another professional.
4. The patient believes that error caused the AO despite a review that finds no supporting evidence.

Disclosure is a process that takes place over time. The team leader for the patient's care, usually the physician, has primary responsibility for communicating with the patient after an event and managing disclosure. The professional needs to recognize what he or she knows (really) about the event and when. Share with the patient and family the known *facts*, if only to say, “I do not yet know the cause, but these are our observations so far....” Speculating or saying nothing may be equally destructive and increase probability of misunderstanding with the patient (especially if he or she asks others what they think).

If medical error is identified and confirmed to have caused harm or potential future consequences for the patient's care, professionals should disclose and offer an apology. Disclosure training should prepare professionals to anticipate questions patients might ask and to deal with a range of reactions from the family, such as shock, hostility, rage, or emotional breakdown.

How might one categorize the type of disclosure scenario Dr. GYN initially faces? At the time Dr. GYN first engages with Ms. AJ after identification of the ureteral leak, what he knows is that there is a tear in the ureter and that the patient's ultimate outcome is unclear at this time. He believes he conducted the procedure correctly, but may wonder whether he or others within his practice might have identified Ms. AJ's “complication” sooner. Dr. GYN decides that this case contains uncertainty.

P.57

Disclosure: Uncertainty as to the Cause of the AO

When a patient suffers an AO, it is important that professionals not jump to the conclusion that someone did something wrong nor summarily dismiss the possibility. Professionals should refrain from becoming confessional or defensive. In an “uncertainty” scenario, the team must quickly discern the facts that are known and what information is not yet clear. Professionals should not speculate, even when asked by patients or family, but instead affirm their commitment to the review process.

Conversation in the face of an AE should always contain an expression of human concern. An expression of human concern should not be confused with apology. Apology is offered when the injury resulted from error.

Dr. GYN meets with his patient. “Ms. AJ, as you recall, because of your symptomatic fibroids, we discussed treatment options and then scheduled you for a total abdominal hysterectomy. I know you've not felt well since leaving the hospital. Because of your symptoms, the emergency medicine physician ordered a CT scan and IVP, and as you are aware, the tests confirmed a leak from your left ureter, and fluid is collecting in your pelvis and abdomen. I am sorry that you have experienced a ureteral tear. You are in good hands with Dr. URO.”

Ms. AJ asks Dr. GYN why this happened. He tells her that he requested a review of the case; there are several potential causes, and he does not want to speculate. He promises Ms. AJ he will share what is learned. Dr. GYN states he realizes it must be hard for her to go through additional surgery and the hospitalization. He offers to continue to follow her

progress, if she will permit, as the urology team provides care.

Disclosure: Obvious Error, Obvious Consequences

“Obvious-obvious” refers to those circumstances where error has occurred with clear clinical consequences. If certain that an error occurred—for example, retained foreign body, wrong procedure, wrong patient, wrong plan, failure to follow up on an abnormal test, or failure to get the patient in sooner—the professional with primary responsibility for the patient shares the information with the patient. The professional should:

- Review “how we got here.” Summarize the medical condition for which the patient was treated, the treatment provided, and the patient's current clinical status.
- Specify what happened: what the error was, when and where it occurred, and its cause (if known).
- Offer an apology.
- Describe actions taken so far to reduce the gravity of the harm, and additional actions needed.
- Convey who will manage ongoing care (you or someone else? what is the patient's preference?).
- Provide contact information for ongoing communications.
- Assess the need for counseling or other support, and if indicated, make an appropriate referral.

When offering an apology for error with harm, acknowledge the specific nature of the error and the resulting impact on the patient. The apology must be sincere in both words and body language. Remember that patients may conditionally accept an apology; they will wait and see if you follow through on promises they heard during disclosure or reserve judgment until they see how you care for them subsequently.

If the patient believes you promised something, be sure you do it. Failure to follow up may inflame.

If review reveals that the care, including follow-up, was appropriate and the AE was due to an unavoidable complication, apology is neither necessary nor appropriate. Nonetheless, we hope that professionals would still regret that their patient experienced a complication.

A review of Ms. AJ's case determines that Dr. GYN made reasonable efforts to identify the ureter at the time of surgery, but despite these efforts, ureteral injury occurred, likely due to complex anatomy. There was no evidence Dr. GYN's intraoperative technique deviated from best practices. Notwithstanding this conclusion, a team is assigned to review the literature to see if postoperative cystoscopy with indigo carmine flush is emerging as a best practice. If so, it can be considered for future patients.

The review also finds that Ms. AJ was placed at increased risk by the challenges seeking care after discharge. The reviewers agree that Ms. AJ's best chance for restoration of ureteral function would have been recognition of the transection at the time of the TAH. However, once discharged, the additional 2 days' delay in making the diagnosis did not otherwise affect her prognosis for success of the repair procedure.

Dr. GYN returns to speak with Ms. AJ. He expresses his regret that Ms. AJ experienced the complication and apologizes for the failure of his office to afford her access to be seen more timely. In fact, he is distressed that Ms. AJ had difficulty being seen, voice messages were not checked, and his partner did not call him but instead asked the emergency department to have Urology admit his patient. Dr. GYN, however, does not feel an apology

is appropriate for the ureteral injury, as he does not believe he was negligent. Dr. GYN shares with Ms. AJ:

“The results of the review confirm that the initial surgery was performed appropriately, and your ureteral injury was a recognized complication. The intent is never to cut the ureter. I am sorry you have had this complication and that you needed a second hospitalization and surgery.

The review also concluded that we did not get you back into our office quickly enough when you tried to let us know things were not going well. I apologize to you about the problems you experienced gaining access to my office and the resulting delay in making the diagnosis. I know you spent extra days in pain and were worried about what was going on.”

It is important to recognize that a sincerely felt and expressed apology is good, but some apologies are not offered or not received well. Remember that an apology is delivered within an existing relationship and that related and previous events may increase or decrease the probability it is accepted. If previous interactions have created trust, this is helpful. If events unfold in a way that create doubt, then the apology is less likely to be accepted. Patients and families also are impacted by nonverbal communication: How do you look? Do you appear distracted? Are you sitting or standing? Does your communication device go off?

Be aware also of the apology that inflames:

- The nonapology apology: “I’m sorry you feel that way.”
- Blaming the victim: “I’m sorry it happened, but you should have been more insistent when you called.”
- Blaming colleagues: “I’m sorry for my [sorry] APN who clearly should have made sure I saw you right away.”
- Narcissistic: “I am so sorry but this has never happened to *me* before... affects my reputation in the community.”

Dr. GYN continues:

Because of your case, our office manager and I have reviewed our policies and procedures for postoperative patients. We have made some changes to make sure future patients have a different experience.

P.58

Ms. AJ thanks Dr. GYN for the information and tells him she appreciates his candor. Then she states, “There are going to be costs, and I’m going to miss more work than anticipated. Who is going to pay the bill for the second surgery, antibiotics, and hospitalization? And who is going to compensate me for my lost income? I’m not going to be able to teach my fall course now; that is going to impose a big loss.”

Many professionals may want to reassure a patient asking “Who is going to pay?” and tell them, “Don’t worry, it will be taken care of.” But what does that mean, really? In most cases, treating professionals do not have the authority to make promises to waive bills (except perhaps their own) or to provide compensation. Practices and organizations should have a designated group and process for conducting a review and determining what should be done about associated costs. Professionals should also keep in mind that CMS and, increasingly, other payors are denying coverage for “never” events and outcomes deemed avoidable.

Expenses Reimbursement and Early Settlement

Humane gestures can create goodwill and reduce risk of litigation. Some risk managers and insurers are finding ways to help support families of patients with AEs through hospitalization and beyond. For instance, COPIC, a Colorado insurer, offers a program to reimburse out-of-pocket medical and recovery time expenses without requiring a determination of negligence or waiver of the right to sue. Over a 10-year period, 2,000 patients received an average payment of \$5,000. Only 3.4% of these patients sued; 0.6% received indemnity payment through the tort system.

Other options include offering patients a pre-suit mediation process and/or early settlement in appropriate cases. Early settlement can help the patient and family move forward emotionally and provides them with money when they have the most need for it. Note, however, that once the patient hires an attorney, the opportunity to directly engage with the patient is foreclosed; all communication related to the case thereafter must be handled attorney to attorney.

Unfortunately, not all carriers and health systems know the literature or support disclosure and early offer. Those that do understand these principles, however, realize that the goal is to do the right and professional thing for the patient.

Special Cautionary Circumstances

- If you are asked by a patient for permission to record a conversation, or suddenly realizes a conversation is being recorded, you should remain calm and ask the patient (without anger or defensiveness) why. If the reason does not seem to have a legitimate clinical basis or the purpose appears adversarial, explain that recording is potentially counterproductive to the relationship. Politely ask the patient to stop recording. If the patient refuses, then you should end the visit and offer to reschedule if the patient will agree to a visit without recording devices. You should also contact your insurer (or risk manager) to inform them of the encounter.
- If you receive a call or written query from a plaintiff's attorney regarding a patient you have treated (and even if the attorney assures you that the patient has no intention of suing you but just has questions about care received from others), respond by referring the attorney to your medical malpractice insurance carrier or risk manager.
- If you receive a request for records from a plaintiff's attorney, contact your insurer or risk manager, confirm that the request is accompanied by a valid release from the patient or legal representative (e.g., court-appointed conservator or parent for minor patient) authorizing release to that attorney, and release only those records specifically authorized by the patient or representative. Collect reasonable charges for duplication and preparation of records.

SECTION IV: LITIGATION

Sometimes, in spite of efforts to avoid or defuse potential claims, patients file suit. When the health care professional is sued, he or she enters a different world filled with unfamiliar rules, strange standards of proof, and, at times, confusing outcomes. Furthermore, the plaintiff's attorney represents an opponent whose methods of inquiry may feel manipulative or accusatory. Health care professionals should recognize the differences between the health care and legal worlds and respect them.

This section discusses common concepts of the legal process and provides a simplified overview of how medical malpractice cases progress. It will not make you an expert. If you are sued or need legal advice, consult a licensed and experienced attorney.

KEY POINTS: WHAT TO REMEMBER IF YOU ARE SUED

- Errors occur, and some patients are injured by negligent care.
- Patients have a right in our society to dispute.
- Notify and consult your malpractice insurance carrier and hospital risk manager.
- Discuss what you know about the case with your attorney; do not discuss details of the case with others except in venues your attorney deems protected from discovery under state law.

Do not alter health care records or destroy equipment related to the suit.

- Being sued can threaten one's sense of well-being. If stressed or depressed, seek professional help.

The Start of Litigation

Eleven months after Ms. AJ's ureteral repair surgery, she files a medical malpractice lawsuit against Dr. GYN. The summons is delivered to Dr. GYN in the office in the middle of a busy day. He immediately contacts his carrier.

Law is traditionally divided into two major categories, civil and criminal. Medical malpractice actions belong to that branch of civil law called tort (as opposed to contract). A tort is a breach of an existing legal duty that impairs a person's legal right or causes damage to his person or property; tort law seeks to redress these violations of conduct (Prosser, 1971).

Medical malpractice is a subtype of tort law called negligence. Negligence can be defined as failing to take the appropriate level of care. The difference between medical malpractice and simple negligence is that the legal duties health care professionals owe to their patients are established by norms of the profession. To prove a case of medical negligence to a lay jury

P.59

requires expert testimony to describe the applicable norms in the case at hand, demonstrate how the defendant failed to meet those norms, and show linkage between that failure and the claimant's injury (Prosser, 1971).

The plaintiff initiates a lawsuit by filing a "complaint" alleging the medical malpractice cause of action. A cause of action is a claim on which a court can grant relief. The complaint must be filed before the statute of limitations expires or the plaintiff will be barred from filing. In most jurisdictions, the limitation is 1 to 2 years and begins to run when a plaintiff knows, or should have known, that his/her injuries may have been caused by negligent medical care. In some states, the limitation period is longer for minors. Some states require plaintiffs to give "notice of intent to file" to defendants prior to filing a suit. Other jurisdictions require plaintiffs to obtain a certificate or affidavit of merit, or to present the proposed medical malpractice case to a panel for a determination of merit.

After the suit is filed, a defendant is served with a "summons," a notification that he or she is being sued. Defendants have a limited period in which to "answer," either admitting or denying the allegations (Garner, 2009). If you receive a summons, do not let it sit on your desk. Notify your carrier or risk manager immediately; an attorney will need to file the answer on your behalf. Failure to respond within the required timeframe may result in a default judgment against you; in other words, you may lose without a chance to defend (Garner, 2009).

Discovery

Once the answer is filed, the case moves on to “discovery.” The purpose of discovery is to obtain information that may lead to admissible evidence. Each party is able to subpoena (compel) production of records, written answers to interrogatories (a set of questions), and witness deposition (the taking of testimony under oath outside of court) (Garner, 2009). Today, parties also commonly subpoena each other to produce any e-mail communications, images on smartphones, text messages, or social media pages that could lead to admissible evidence Fed. R. Civ. P. 26(a)(1)(A). Either party may file a “motion to quash” (ask the court to deny or nullify) a discovery request, which the court will then adjudicate; the presumption, however, is strongly in favor of discovery Fed. R. Civ. P. 45(a)(3).

Deposition is an important part of discovery. During deposition, each side has an opportunity to learn what evidence might be presented to the jury by the other side and, therefore, learn the strength of the other's case. Further, each side has an opportunity to observe the demeanor and “likeability” of their own and the opposing side's witnesses. Deposition transcripts also serve an important role at trial; parties attempt to impeach witnesses' credibility by showing the jury discrepancies between their recorded deposition and testimony in court.

Health care professionals should never go to a deposition without their lawyer. Equally important is that defense counsel must adequately prepare clients for deposition in advance. The deponent (person being deposed) should guard against volunteering information beyond what is asked for by opposing counsel; saying more than necessary is disadvantageous in a litigation context, for plaintiff's attorneys can use the defendant's words against him/her at trial or in settlement negotiations. Deponents should listen carefully to each question, wait to see if his/her attorney objects, then provide a succinct and narrow response. If one does not understand the question, or the question has several parts, ask for it to be rephrased. If the deponent does not have an actual recollection or is not certain, he or she should state so.

A defendant deponent's role at deposition is as a witness, not an expert. Experts can offer opinions, but defendants should only state the facts as they know them. Thus, if a defendant is asked his/her opinion about a hypothetical case, he or she might reply, “I am not here as an expert witness. I have no opinion.” If asked about something that happened in the patient-plaintiff's case, they should refer to the relevant note in the medical record.

Defendants are allowed to testify during deposition (and trial) as to their “habit and custom” if information is not documented in the chart and they do not have a specific recollection (Garner, 2009). As an example, if the medical record contains a notation that an informed consent discussion took place but no further detail is documented, the health care professional would likely not have a *specific* recollection of having informed *this* patient about a particular risk such as a transected ureter. However, he or she could testify (of course *only if true*) that “it would be my habit and custom to include that risk in any informed consent discussion for this procedure.” It is far better to have the documentation of what was discussed.

Ms. AJ's attorney deposes Dr. GYN. Dr. GYN does well explaining the indications for the procedure, the findings at surgery, and the procedure itself. He states he was unaware that Ms. AJ had called the office and spoken with Ms. NP.

Ms. NP is also deposed. She states that she mentioned to Dr. GYN that Ms. AJ had called and told him about their conversation. Upon being pressed by Ms. AJ's attorney, Ms. NP states that Dr. GYN was busy when she spoke with him; he nodded but did not suggest anything else. Ms. NP states she called Ms. AJ back. When asked how she knows she called, Ms. NP asks to look at the medical record and states, “I didn't write it down, but it

would have been my habit to call; I am good about calling patients back.”

Trial

The Standard of Proof

The “trier of fact” in malpractice cases may be a jury, single arbitrator, arbitration panel, or judge (“bench trial”). Their role is to hear and evaluate the evidence to determine if the plaintiff satisfied his “burden of proof” (Prosser, 1971). The evidence presented must demonstrate that each of the four elements of the medical malpractice case is “more likely than not” to be true or, in other words, to have a greater than a 50% (a “feather’s weight”) likelihood of being true. These elements are:

1. The defendant owed a duty of care to the plaintiff.
2. There occurred a breach in the standard of care, that is to say, the defendant failed to exercise “that degree of care and skill which is expected of a reasonably competent practitioner in the same class to which (s)he belongs, acting in the same or similar circumstances”.
3. Damages were proximately caused by a breach of the standard of care (in other words, without the defendant’s acts, the damages would not have occurred).
4. Actual damages resulted.

Prior to trial or arbitration, parties may “stipulate” agreement as to certain facts or elements of the case; these facts or elements are then no longer in dispute. There usually is no controversy over whether the defendant owed a duty of

P.60

care to the plaintiff except in those rare cases where the parties litigate as a threshold issue whether a physician-patient relationship existed. Sometimes, defendants agree pretrial to stipulate to liability, that is, admit that the standard of care was breached and caused the plaintiff injury, because the real issue is the disagreement over amount of damages; in this circumstance, the damages dispute becomes the sole issue at trial or arbitration.

The Defendant

During the trial, plaintiffs and defendants call witnesses and usually testify themselves. As in your deposition, remember that your role as a defendant is to state the facts within your personal knowledge and to not opine; your experts will do that on your behalf. The plaintiff’s attorney may use any of your court testimony that differs from your deposition to attempt to impeach your credibility. If your recall of any fact now differs from what you testified to on deposition, discuss with your attorney who will then advise. You must do your best to remain calm and professional. You do not want to alienate a jury.

“Likeability,” in particular, is important for defendants. If the jury interprets the professional’s demeanor as arrogant or “clueless,” they may infer that this is how he or she acted at the time of the event in question. Attorneys are generally able to assess in advance if one of their clients will not make a good witness, an observation that may enter into a recommendation to settle pretrial (Peters, 2007b). If a client or other party witness does not do a good job when testifying at trial, the attorney may attempt to settle the case before the case goes to the jury.

Missing records or evidence of an improper attempt to alter a medical record entry can hurt a defendant’s credibility. Paper records can be analyzed for discrepancy between asserted timing of a written entry and actual entry. Entries are all timed in electronic medical records, so timeline discrepancies can be fatal to cases.

Expert Witnesses

As noted, medical malpractice cases depend heavily on expert testimony when jury members are laypersons without medical training. In a typical case, both sides will present experts to testify as to the standard of care under the facts of the case and whether the defendant met that standard, whether the plaintiff's damages were caused by a breach of that standard, and the quantum of damages that resulted from the events in question.

One of the reasons why going before a jury can be risky is illustrated by the fact that after review of the same records, experts often reach different conclusions about the standard of care and whether the care provided caused the plaintiff's outcome. In other words, the legal system uses indistinct borders to separate AEs with negligence from those without negligence. A more skeptical view is the consideration that because experts are not court appointed but instead hired by the plaintiff or defense attorney, their opinion may be influenced by that affiliation, whether intentional or not.

If a party asks you to review and consult on a case of possible medical malpractice, keep in mind that if your opinion supports their position, they may also ask you to testify as an expert witness. Before and during the review, ask yourself the following questions:

1. Do I (really) have the expertise related to the medical practice in question?
2. Am I current? After all, medical practice evolves quickly.
3. Am I biased in a way that will impact my review, for example, am I against all plaintiffs or against doctors who don't practice the way I do?
4. Is the money the party is paying me affecting my opinion? (Dollars influence in very subtle ways.)
5. *Can I serve a professional role?*

The Jury: Verdict and Damages Awards

The judge provides "jury instructions" that explain applicable law and instructs the jury to apply the law to the facts presented to decide the case. The jury determines if the defendant is liable and, if so, what the damages award for the plaintiff should be.

One of the goals of medical malpractice law is to compensate those negligently injured by care and make them "whole" for their loss. Damages are intended to make up for the difference between how the person was prior to the injury—including what they would have been projected to earn and the type of life they would likely have had if not for the injury—and their "new normal" (Restatement of Torts, 1979). Two types of damages are awarded in malpractice cases: special damages and general damages.

"Special" or "economic" damages refer to the plaintiff's monetary losses and expense burdens resulting from the injury. Special damages include replacement of lost past and future earnings as well the cost of care necessary to restore or optimize the injured party's physical and emotional health over the length of time care will be needed. With serious, permanent injury, the care plan may be lifelong.

"General" or "noneconomic" damages (also referred to as "pain and suffering") are awarded to compensate for intangible losses related to mental anguish, pain, loss of enjoyment of life, loss of consortium (i.e., loss of normal marital relations and companionship), and disfigurement. Juries place dollar values on pain and suffering. The valuation often represents a significant percentage of the total damages award and may exceed the amount granted for special damages.

"Punitive" damages, intended to "teach the defendant a lesson," are rare in medical malpractice cases. Some states prohibit punitive damages or allow only for fraud, malice, or gross negligence. Plaintiffs who successfully prove battery (an intentional tort) may also receive punitive damages.

It is often asserted that juries are predisposed to find liability for a "sympathetic plaintiff." Vidmar found jurors to

be careful listeners, alert to plaintiffs who contribute to their poor outcome, and disinclined to punish doctors for imperfect human decision making. Furthermore, juries do not grant large awards because they view physicians or corporate defendants as able to pay. Rather, juries award substantial damages when they believe there is negligent care and award higher damages to more severely injured plaintiffs.

Even when jurors keep an open mind and listen carefully to the evidence, in the end, they are human; a host of factors may impinge on their deliberations. These factors influence the jury's view of each witness' credibility, acceptance of one expert's theory over another, or their evaluation of an appropriate award.

Settlement and Alternative Dispute Resolution

At the start of a lawsuit, a defendant may believe he or she “did nothing wrong” and the plaintiff may feel that no amount could sufficiently compensate their suffering and loss. External review and discovery can impact some of this confidence. Settlement allows parties to weigh the relative risks and costs of going to trial against allowing some monetary transfer from defendant to plaintiff. Settlement remains an option at every

P.61

stage of litigation. For example, a party that becomes aware of a significant weakness in its case will try to settle before spending more money. On the other end, parties may settle on the eve of trial, during jury deliberation, or after a verdict if the losing party makes clear it will appeal.

Dr. GYN has refused to settle and wants his carrier to defend the case. His attorney explains his concerns about aspects of the case that might not sit well with a jury and could lead to a generous award. Counsel reminds Dr. GYN that his office's telephone records confirm that the patient called several times. There is, however, no documentation that Dr. GYN called her back. Counsel agrees that it was not unreasonable for Ms. NP to field the request; unfortunately, however, Ms. NP gave the patient advice that proved to be inadequate, and the evidence suggests she did not follow up with the patient as promised.

Dr. GYN's attorney further shares that plaintiff's expert will testify that the standard of care required cystoscopy with intravenous indigo carmine dye contrast to look for ureteral injury at the end of the procedure. The defense attorney assures Dr. GYN that their own expert will dispute this assertion; it will be up to the jury to weigh the two testimonies.

Dr. GYN's defense attorney makes a recommendation to Dr. GYN to settle the case.

Throughout a lawsuit, plaintiff and defense attorneys assess their strategy for achieving an optimal result for their client (and themselves). Attorneys weigh the facts of the case that emerge from record review, interviews with witnesses and experts, and discovery. They observe performance at deposition to anticipate how witnesses and experts will do at trial. Trial attorneys also remain sensitive to the fact that cases can turn on a single weakness. For example, a key defense witness who no longer works for the practice or organization may not wish to cooperate, or a medical chart entry by a team member appears to criticize the patient's care.

Client motivations, too, play a role in settlement decisions. A defendant may wish to avoid publicity or have concern that a jury will not fully understand a subtle defense. (Imagine a case with a serious error, a patient with a bad outcome, but no likely causal connection between the two.) A plaintiff may fear exposure of embarrassing information at trial or, in need of cash, decide to accept less than to wait years for trial without guarantee of a larger jury award.

Ultimately, the decision to settle is a microeconomic assessment. Each side calculates the damages at stake discounted by the probability that the plaintiff will win in comparison to the cost of continued litigation. If the two sides' valuations are similar, they are likely to settle. Parties have trouble settling when both perceive their own

case as strong, the plaintiff overestimates the chance that it will win and the defendant underestimates, or they are unable to assign a realistic valuation because previous jury awards for similar injuries vary widely (especially for pain and suffering awards).

Mediation, a form of alternative dispute resolution (ADR), can help the settlement process. The mediators' role is to facilitate information sharing, finding areas of agreement, and negotiating based on mutual benefit. Mediation is particularly helpful when parties enter with a realistic idea of the settlement value of their case.

Arbitration, another ADR format, differs from mediation in that a third party makes a decision on the merits of the case. In other words, arbitration declares a winner and a loser. Arbitrators tend to have experience in the field (e.g., practice as a medical malpractice litigator), and so can assess each side's position on the basis of previous cases within the jurisdiction.

With nonbinding arbitration, parties are free to reject the arbitration decision and proceed to trial. Binding arbitration, on the other hand, is based on an existing contract in which the patient-plaintiff agrees to waive the right to go to court to adjudicate disputes and accepts binding arbitration as his/her sole venue for recourse. Courts generally uphold binding arbitration agreements as long as the agreements conform to state statutory requirements.

Ms. AJ and Dr. GYN agree to mediate. At mediation, Ms. AJ's attorney puts forth a demand far in excess of a million dollars. Dr. GYN's team counters with a significantly smaller offer, explaining the ureteral injury was not the result of negligence but a known complication, mentioned in the informed consent discussion and consent form (which Ms. AJ signed). The defense acknowledges that it took longer than it might for the diagnosis to be made, but this did not affect Ms. AJ's outcome.

The mediator urges the parties to make a realistic assessment of their cases and provide numbers that are closer to what they would be willing to settle for.

Dr. GYN tells his attorney that he still believes he did not do anything wrong and is unhappy with the idea of settling the case. However, the suit has created enormous stress, and he just wants the case to "go away."

Over the course of the next 6 hours, with some back and forth, the parties agree to a settlement amount. The parties agree that the amount will be kept confidential.

In sum, parties to a medical malpractice case must recognize that whether the care was negligent is not necessarily dispositive of the case. Other factors influence the outcome and the decision to settle. While settlement or verdict decisions may not seem fair to health care professionals accustomed to rigorous standards of proof, attorneys and medical malpractice insurance carriers understand the risks and advise settlement or defense strategies accordingly.

Does the Medical Malpractice Legal System Achieve its Goals?

Although variation among cases and wide ranges of awards for similar categories of injuries create an impression of randomness, data suggest that the US legal system does a reasonable job sorting filed claims. Compared with meritorious suits, nonvalid suits result in more case withdrawals, trial loss, or lower settlement payments. Sixty to sixty-five percent (60-65%) of claims are dropped or dismissed without payment, and about one fourth to one third of cases settle. Five to fifteen percent of cases proceed to trial. In 80-90% of trials, there is a verdict for the defense (physician).

Unfortunately, a gynecologic surgeon who believes the legal outcome in his/her particular case was wrong

probably does not feel any better if told the system usually gets it right. As someone trained to understand scientific probabilities, awarding a plaintiff a lot of money on only a 51% level of certainty feels different from the 95% probability medical professionals demand before they are persuaded the effect is real and not due to chance. Furthermore, awareness that weaker claims are sometimes paid because trial costs will likely exceed the settlement amount also may seem unfair. In any event, even legal vindication at trial does not erase incurred defense costs or the emotional burden of a suit.

Despite outcomes that are not perfect in all cases, it is reasonable to consider if, overall, medical malpractice tort law achieves its goals. These goals are: (a) compensation of injured patients, (b) vindication of the injured plaintiff's sense of justice, (c) deterrence of undesirable (negligent) behavior, and (d) structural improvement of the medical care system to reduce risk of patient harm in the future.

P.62

Compensation

Some injured patients are made whole by the system, but overall only a fraction of injured patients are ever compensated. As discussed earlier, only a small percentage of patients harmed by negligent care actually sue. Some patients forgive. Others resign themselves to the outcome. Also, as we have seen, patients are commonly thwarted in their efforts to sue by lawyers' selectivity of cases. Attorneys' selectivity of cases also means many injured patients are unable to receive compensation. Finally, in the absence of express disclosure, it is likely that a large group of patients never learn that the harm they suffered was avoidable.

For patients who win their cases, the award may not sufficiently cover their financial needs once attorney fees and costs are deducted. Tort reform such as caps on noneconomic damages (see below) also contributes to undercompensation, especially in cases of severe injury. Furthermore, lags of up to four years to resolve litigated cases mean that many patients lack current funds to pay for needed medical care or support for their families.

Some states are attempting to shift resources to serve more people. Lower-cost arbitration in some states is linked to increased claims frequency, suggesting that more claimants are gaining access to compensation. In addition, some states have enacted no-fault administrative systems for certain conditions, such as birth-related injury, in order to remove the unpredictability of the tort system, lower its cost, and accelerate payment.

Vindication

Litigation affords the ability to, according to Bovbjerg, “command more attention from providers”, which can help achieve closure for many plaintiffs, especially in cases where they sued to find out what happened. The need for accountability is one of the deficits of a no-fault compensation system for medical injury.

Public exposure of a health care professional's claims also can provide a sense of vindication for plaintiffs. Information about filed lawsuits and named physicians are increasingly available on public databases in many jurisdictions. One can identify physicians who are sued (and those sued repeatedly). However, not all states and counties provide claims information, and others require a “per query” payment.

The Healthcare Quality Improvement Act of 1986 established the National Practitioner Data Bank (NPDB) as a federal repository for information regarding health care professionals' malpractice payments and disciplinary actions. Individual consumers cannot query the database. However, Public Citizen Congress Watch, a consumer watch group, reports that 16 years of cumulative NPDB data show 6% of physicians responsible for 58% of all malpractice payments, 2% account for 33% of all payments, and 1% for 20% of payments. The nonrandom distribution of medical malpractice payouts in the NPDB database is consistent with Sloan's conclusions of twenty-plus years ago that lawsuits are nonrandomly distributed.

Deterrence

Medical malpractice tort law aims to deter future conduct of the type that led to the patient's injury. Litigation achieves this goal when health care professionals understand that different actions likely would have prevented injury, and then act with greater caution in the future.

The tort system leads to other incentives for change. For example, medical malpractice actions may deter if they raise medical malpractice insurance costs. With enough claims, carriers may drop insureds from coverage. The risk that one will be uninsurable or shifted into a high-risk pool with very high premiums may motivate some individuals to take extra precautions to avoid patient injury. Others find the experience of being deposed and cross-examined, perceived or real reputational effects, and the anxiety associated with being involved in a lawsuit incentive enough to change behaviors and practices in ways that lower risk.

Unfortunately, litigation may not deter when physicians sued repeatedly continue to see claims as random events, a cost of doing business, and a nuisance that one simply cannot do anything to prevent. Fatalistic “acceptance” of claims suggests lack of awareness that suits are nonrandomly distributed. Thus, other means of professional regulation besides tort law, such as identifying and intervening with high risk physicians as discussed in Section II, are needed to change behavior.

The malpractice tort system has also led to “overdeterrence” or the practice of “defensive medicine.” Defensive medicine is a self-focused reaction to the malpractice tort system in which unnecessary tests and imaging studies are ordered in an effort to protect from suits. Refusing to see patients with complex problems or terminating “difficult” patients in the name of lowering risk increases patient risk in other ways.

Structural Change

Another goal of medical malpractice tort law is to induce movement toward structural change in the health care system in order to protect future patients. Certain liability rules such as joint and several liability and enterprise liability for malpractice can encourage such movement.

Joint and several liability makes full compensation for injured plaintiffs a higher priority than limiting codefendants' liability for damages to their proportional contribution to the injury. Specifically, defendants who co-contribute to injury are liable not only for their own apportioned share of the damages but also for the share of any co-defendant who does not pay (Wright, 1988). Such cross-subsidization should incentivize “deep pocket” defendants to therefore more carefully choose and monitor those with whom they share patients.

The doctrine of enterprise liability for malpractice holds health care organizations responsible for medical liability in place of, or in addition to, individuals. Enterprise liability encourages integration of professionals, systems, services, and practices into a system that can exert more uniform control and supervision over processes, behavior, and performance. Emerging data suggest that such integration results in lower defense costs than in less integrated settings.

Despite the tort system's partial ability to increase structural accountability, it alone cannot achieve safer care for reasons that include its retrospective nature, high transaction costs, and failure to draw on our increasing knowledge of risk prevention best practices. The retrospective quality of litigation allows injuries to keep occurring, for it focuses primarily on compensation rather than prevention. Going forward, defendants may fix systems and remediate individuals, but they are always playing catch-up.

The system's excessively high transaction costs represent wasted resources that could be used to compensate more patients who suffer harm from care. Fifty-four cents of every dollar spent goes toward administrative, attorney, and expert costs. Defensive medicine, too, adds to the unnecessary costs stimulated by the litigation system, wasting billions of national health care dollars.

In sum, the medical malpractice tort system cannot act as a primary corrective agent. Rather, in order to prevent patient injury, we must use risk prevention best practices to reliably

and promptly identify risk (monitoring and reporting), review for contributors to AEs (risk management file reviews, RCAs, MMM&Is), and address behaviors and systems that undermine safety and performance.

Tort Reform

Over the past four decades, varying medical malpractice tort reforms have been implemented throughout the United States. The earliest enactments were spurred by escalating liability costs that threatened the ongoing availability of medical malpractice insurance. Medical malpractice insurance costs have since stabilized, but the tort reform debate continues. Although a lengthy discussion on tort reform is outside the scope of this chapter, we present a brief overview of some common types of tort reform.

Some reforms primarily affect the litigation process. These include (a) screening cases for legitimacy prior to filing suit (e.g., mandatory panel review, medical reviewer affidavits or certificates of merit), (b) imposing a shorter statute of limitations (e.g., reducing the statute of limitations to 1 year), and (c) placing stricter criteria for expert witness eligibility (e.g., requiring that an expert is in active practice within the same specialty as the defendant).

Reforms that impact damage awards include (a) collateral source rule modifications in which any compensation plaintiff receives from another ("collateral") source such as auto or worker's compensation insurance is subtracted from the damages award ("offset"), (b) caps that place an upper limit on the plaintiff's noneconomic damages award, and (c) tiered contingency fee rates that direct more of the award toward the seriously injured plaintiff than would result from standard contingency fee agreements. California's Medical Injury Compensation Reform Act of 1975 or MICRA is a wellknown example of tort reform. The statute provides for various reforms that include collateral source rule modification, a \$250,000 cap on noneconomic damages, and limits on attorney fees to 40% of the first \$50,000 awarded, 33% of the next \$50,000, 25% of the next \$500,000, and 15% of any amount over \$600,000.

Of the tort reform features discussed, only noneconomic damages caps are consistently shown to lower the payout per claim and numbers of paid claims.

CONCLUSION

Health care professionals want to deliver exemplary care and reduce risk of patient injury. To achieve these goals, they must be willing to regulate their own and group members' performance and behavior.

Professionalism is essential for effective teamwork and achieving intended outcomes.

Professionals should utilize risk prevention tools to identify and address variation from best practices. When errors negatively impact clinical outcomes, professionals share information with the patient and remain engaged.

Understanding why patients sue and best practices for managing potential claims can help professionals avoid claims. Still, patients sometimes sue. Therefore, health professionals should gain familiarity with the medical malpractice tort law process and rely on trusted legal professionals for guidance.

Chapter 5

The Changing Environment in Which We Practice Gynecologic Surgery

Eric J. Bieber

DEFINITIONS

Accountable Care Organization (ACO)—An organization of health care providers (hospitals, providers, and others) that agrees to be accountable for the quality, cost, and overall care of the beneficiaries.

Hospitalist/laborist—Physician/providers who dedicate all or part of their practices to providing care specifically to patients within the hospital.

Institute for Healthcare Improvement (IHI)—A not-for-profit organization founded in 1991 and dedicated to improving health care throughout the globe. Initiated the 100,000 lives campaign (www.ihl.com).

Institute of Medicine (IOM)—Not-for-profit organization chartered in 1970 as part of the National Academy of Sciences to provide unbiased, evidence-based guidance to improve health in the United States (www.iom.com).

Patient Protection and Affordable Care Act (PPACA)—A federal statute approved in 2010 by President Obama and upheld by the Supreme Court in June 2012. The act aims to increase the health insurance coverage for Americans via mandates, subsidies, and tax credits.

Pay for performance (P4P)—A broad construct that attempts to pay providers or health care organizations for achieving predetermined quality thresholds.

Value-based purchasing—Authorized by PPACA, this is a payment method for rewarding quality of care through financial incentives.

As gynecologic surgeons and care providers of women, we have witnessed major changes in our practices over the years. When we think back to our days as medical students and residents, even the youngest of us is able to appreciate the palpable differences that exist today: from how we manage our offices to how we approach diagnostic testing and treatment. Most recently, the passage of the PPACA, the advent of Accountable Care Organizations, and the focus on value and value-based purchasing have begun to rapidly change our external environment.

The cornerstone of the modern practice of medicine continues to be the resounding theme of evidence-based medicine. Quality initiatives from the IHI recommendations, National Committee for Quality Assurance (NCQA), and more recently the efforts of many organizations with the Partnership for Patients as well as many other initiatives have made attempts to promote the safest, most effective care of our patients. Pay for performance and adherence to quality metrics and benchmarks are becoming commonplace. Hospitals have their patient satisfaction scores transparently available for patients to evaluate, and we expect doctor scores to similarly

P.68

be available in the coming years. We are also being challenged to move from a time when surgical and other treatments were the mainstay of our practice to a new time of screening, prevention, wellness, and the ultimate promise of genomics.

Few of us appreciated how profound a role the computer would play in our daily practice or how this tool might empower us to provide the best possible care in each encounter. The electronic health record (EHR), its implementation and daily use, and its significant benefits and pitfalls will be reviewed in part. We also

review the changes that are occurring in medical education from residency to postgraduate training.

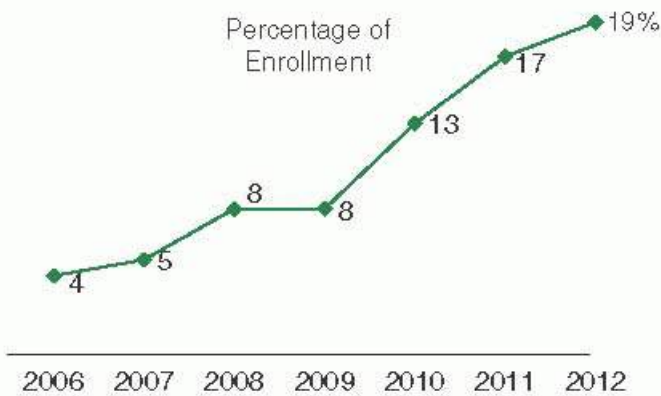

We discuss one of the latest trends: a move for at least some physicians, including obstetrician-gynecologists, to choose to function as hospital-based providers or hospitalists. Finally, we review the importance of evaluating evidence-based methodologies for rating our literature.

HEALTH CARE REFORM

The PPACA has profoundly changed the landscape of medicine in the United States. Signed into law in 2010 and upheld by the Supreme Court in 2012, this large body of legislation will continue to impact all care providers for decades to come. Undoubtedly, there will be alteration to the original, but the main tenets of the law are likely to be enacted over the next few years.

Accountable Care Organizations or ACOs had been proposed and piloted in the late 2000s. They are called out specifically within the PPACA, and by law, pilots had to be started. The Centers for Medicare & Medicaid Services (CMS) is the responsible party for overseeing the Medicare Shared Savings Program (MSSP). The Center for Medicare & Medicaid Innovation (CMMI) launched the initial Pioneer ACO program composed of 32 initial ACOs. Since this time, there has been a proliferation of both Medicare ACOs and more recently of commercial ACOs. The main tenet of an ACO is patient-centered care with a view to optimizing care over the continuum including wellness and preventative care. Don Berwick's triple aims of improving the health of the population, enhancing patient experience, and decreasing cost or improving efficiency are core to ACOs mission. In addition, the MSSP calls out 33 key quality metrics that must be met to share in savings. These metrics are in the four core areas of patient/caregiver experience, care coordination/patient safety, preventative health, and care of at-risk populations. A different variation on patientcentric care is the advent of the patient-centered medical home (PCMH). NCQA has defined the PCMH as a "health care setting that facilitates partnerships between individual patients, and their personal physicians, and when appropriate, the patient's family. Care is facilitated by registries, information technology, health information exchange (HIE), and other means to assure that patients get the indicated care when and where they need and want it in a culturally and linguistically appropriate manner."

Additional changes brought about through PPACA include the introduction of "value-based purchasing" where providers are either rewarded or penalized for their efforts relative to quality and efficiency. Discussed in more detail later, this is a true pay-for-performance program. Bundled payment demonstrations are also called out in the legislation and aim to better align providers, hospitals, and others to work together to optimize care over the continuum by providing a single payment for an entire episode of care. The issue of readmissions has also been brought to the forefront with penalties now beginning for many hospitals. Also, key to the PPACA is the expansion of Medicaid by many states and the formation of health care exchanges with the goal of providing health care coverage to the majority of the citizens of the United States. The details of many of these issues remain to be worked out as of the time of this writing and are outside the scope of this chapter. Indeed, many states have chosen to opt out of Medicaid expansion in 2015, and health exchanges have largely only been attempted in Utah and Massachusetts. The true impact on health care at an individual level as well as a population level remains to be seen. Other issues such as the physician and nursing workforce required to care for the additional millions of individuals who will now have health care coverage continue to be hotly debated topics.

Studies: High Deductible Plans can Reduce Utilization up to 25%

FIGURE 5.1 Increasing enrollment in high-deductible health plans. Data from Towers Watson. *2012 health care changes ahead survey report*. <http://www.towerswatson.com/DownloadMedia.aspx?media={24F68B2F-90F6-48C9-ADF3-CA61A378300A}>. Published on October 2012.

Another evolving area is the increase in high-deductible or consumer-driven health plans (Fig. 5.1 and Table 5.1). Because of the ever-increasing cost of health care premiums, many

P.69

companies and employees have chosen to accept the potential of greater out-of-pocket expense for the concomitant reduction in health insurance premiums. The outcome of patients having to pay these “first dollar amounts” to providers is more and more patients asking about the cost of visits, surgeries, and radiologic studies. Given the complexities of charges and billings, this may be challenging for many organizations. This advent of consumerism in health care is consistent with the government's desire to increase transparency of both quality and pricing in an effort to increase the value for patients. With the significant increase in the number of these plans across the country, the issues of cost, access, and transparency of information are likely to become of even greater interest for patients.

TABLE 5.1 High-Deductible Health Plan: National Enrollment

2012 DATA BY STATE	TOTAL ENROLLMENT IN HIGH-DEDUCTIBLE HEALTH PLANS
California	1,002,000
Texas	755,000
Illinois	717,000
Ohio	663,000
Florida	540,000
New York	495,000
Minnesota	487,000

QUALITY INITIATIVES

In 2010, Daniel Levinson of the Office of the Inspector General of the Department of Health and Human Services released a report on safety issues for Medicare beneficiaries. After evaluation of numerous patient records, including review by multiple physicians, the report concluded that 13.5% of hospitalized Medicare patients experience at least one adverse event during a hospitalization. An additional 13.5% of all patients experienced an event that led to temporary harm. In the subsequent review by physicians, they noted that 44% of these events were preventable. The total yearly cost estimate appeared to be close to \$4.4 billion.

Few clinicians would argue that quality is the most important parameter in health care today. Yet, it is becoming ever more evident that many patients do not receive state-of-the-art health care. In a landmark article published in 2006, Asch et al. from the Rand Health group evaluated 30 chronic and acute conditions and used 439 indicators of quality to assess if patients had received appropriate care. Unfortunately, overall, only 54.9% of patients received what would be considered recommended care. Some sociodemographic differences existed: Women received 56.6% of care versus men at 52.3%, and those with annual household income greater than \$50,000 received 56.6% versus those less than \$15,000 at 53.1%. However, what is striking is the low level of achieving recommended care for all the groups studied regardless of the sociodemographic differences.

In 1999, the IOM released a report suggesting that 98,000 patients per year die secondary to inadequate care being rendered. Many subsequent debates ensued regarding the methodologies used to attain these numbers. However, this report created a call to arms, challenging those individuals and organizations who provide care to improve the quality of care delivered to all patients. Furthermore, it has caused a number of initiatives from a broad base of organizations. In December 2004, the IHI, at its 16th Annual National Forum on Quality Improvement in Health Care, announced a goal to save 100,000 lives by June 2006. The campaign invited all US hospitals to join in implementing six broad initiatives that have demonstrated efficacy in well-performed clinical trials. These include

1. Prevention of surgical site infections
2. Prevention of ventilator-associated pneumonia
3. Prevention of central line infections
4. Prevention of adverse drug events (ADEs) through medication reconciliation
5. Deployment of rapid response teams
3. Delivery of evidence-based care for acute myocardial infarction

What is particularly impressive about the IHI campaign is the extent of support across a broad range of disparate federal, state, political, and private organizations, including—but not limited to—the CMS, Veterans Health Administration, American Medical Association, American Nurses Association, Centers for Disease Control and Prevention, Joint Commission on Accreditation of Healthcare Organizations, the Leapfrog Group, and multiple others.

Ultimately, the IHI released information suggesting that these initiatives were able to save 122,300 patients. This

was good news and suggested that progress was indeed being made. Unfortunately, a more recent publication reviewed hospital admissions from 2002 to 2007 in North Carolina hospitals. The authors found a rate of 25.1 harms per 100 admissions with no statistical change over the 5 years of the study. The challenge to implement the IHI recommendations as well as multiple other quality initiatives has caused a number of hospitals and large organizations to create chief quality officer positions that are largely responsible for implementing and monitoring compliance to these programs. In essence, this may be the confluence of patient safety, performance improvement, utilization review, and other previous orphan committees.

Consistent with the IHI initiatives, other initiatives have come from CMS, including recommendations for optimization of diabetic patients. These include bundles of care much like the IHI central line bundle, in which appropriate care consists of all elements being appropriately performed or delivered within the correct time frame. Unfortunately, as the bundles become more complicated, it becomes more and more difficult for the provider to remember what has or has not been done. This may be yet another opportunity for the EHR to allow both the clinician and the patient to know what tests or interventions need to be performed, thus optimizing the encounter. The Joint Commission has also continued to evolve its recommendations, including core measure sets for venous thromboembolism, the surgical care improvement project, and most recently a core measure set for perinatal care. In addition, there continue to be updates and new releases of National Patient Safety Goals (Table 5.2). We expect that with increasing evidence-based knowledge, many additional quality-driven initiatives will come forward.

Another key safety initiative is the Partnership for Patients, a public-private partnership that aims to improve quality, safety, and affordability. An amazing 3,700 hospitals have signed on to portions of this program whose two primary goals are the reduction of hospital-acquired infections by 40% by the end of 2013 (as compared to 2010) and reducing complications using care transitions to effect a 20% reduction in hospital readmissions. Twenty-six hospital engagement networks were awarded \$218 million to lead these efforts. The patient safety areas of focus include (but are not limited to) the following (many of which an obstetrician-gynecologist may encounter):

1. Adverse drug events
2. Catheter-associated urinary tract infections
3. Central line-associated bloodstream infections
4. Injuries from falls and immobility
5. Obstetrical adverse events
6. Pressure ulcers
7. Surgical site infections
8. Venous thromboembolism
9. Ventilator-associated pneumonia
10. Readmissions

TABLE 5.2 2013 Hospital National Patient Safety Goals

Identify patients correctly

NPSG.01.01.01	Use at least two ways to identify patients. For example, use the patient's name and date of birth. This is done to make sure that each patient gets the correct medicine and treatment.
NPSG.01.03.01	Make sure that the correct patient gets the correct blood when they get a blood transfusion.

Improve staff communication

NPSG.02.03.01	Get important test results to the right staff person on time.
---------------	---

Use medicines safely

NPSG.03.04.01	Before a procedure, label medicines that are not labeled, for example, medicines in syringes, cups, and basins. Do this in the area where medicines and supplies are set up.
NPSG.03.05.01	Take extra care with patients who take medicines to thin their blood.
NPSG.03.06.01	Record and pass along correct information about a patient's medicines. Find out what medicines the patient is taking. Compare those medicines to new medicines given to the patient. Make sure the patient knows which medicines to take when they are at home. Tell the patient it is important to bring their up-to-date list of medicines every time they visit a doctor.

Prevent infection

NPSG.07.01.01	Use the hand cleaning guidelines from the Centers for Disease Control and Prevention or the World Health Organization. Set goals for improving hand cleaning. Use the goals to improve hand cleaning.
NPSG.07.03.01	Use proven guidelines to prevent infections that are difficult to treat.
NPSG.07.04.01	Use proven guidelines to prevent infection of the blood from central lines.
NPSG.07.05.01	Use proven guidelines to prevent infection after surgery.
NPSG.07.06.01	Use proven guidelines to prevent infections of the urinary tract that are caused by catheters.

Identify patient safety risks

NPSG.15.01.01	Find out which patients are most likely to try to commit suicide.
---------------	---

Prevent mistakes in surgery

UP.01.01.01	Make sure that the correct surgery is done on the correct patient and at the correct place on the patient's body.
UP.01.02.01	Mark the correct place on the patient's body where the surgery is to be done.
UP.01.03.01	Pause before the surgery to make sure that a mistake is not being made.

The purpose of the National Patient Safety Goals is to improve patient safety. The goals focus on problems in health care safety and how to solve them.

This is an easy-to-read document. It has been created for the public. The exact language of the goals can be found at www.jointcommission.org. Copyright © The Joint Commission, 2013. Reprinted with permission.

Because of the breadth of the Partnership for Patients effort and the collaborative nature of the learning, there is real hope that sustainable change may be able to be accomplished.

It was previously believed that organizations with higher caseloads of a particular disease might be better positioned to deliver recommended care. Lindenauer et al. studied this tenet as it relates to pneumonia in the acute care setting. Surprisingly, they found both hospitals and physicians who had a higher caseload of pneumonia patients actually had reduced adherence to recommended guidelines—such as influenza and pneumococcal vaccine administration or early antibiotic administration—and had no better outcomes.

Quality initiatives are currently being led by a number of organizations, including some physician groups. For example, in Washington State, a physician-led group has brought all hospitals to the table to evaluate discrete performance measures regarding cardiac revascularization. Similarly, the California Perinatal Quality Care Collaborative in 1998 targeted improving antenatal steroid use as an initiative. They accumulated baseline data, developed educational materials, and broadly disseminated this information. They concluded that regional collaboration allowed an improvement from a baseline rate of administration of 76% to 86% post implementation. Callcut and Breslin discuss how private groups, such as the Leapfrog Group, are playing an important role in moving the private regulatory movement forward and suggest that surgeons need to become more active participants in this process of reshaping and redefining our future.

How to best implement quality improvement programs in a given setting is also continuing to be investigated. A recent evaluation of hospital quality improvement implementation and subsequent impact on discrete patient-safety metrics suggested that involvement by multiple units within a hospital might have a negative impact on results. Alternatively, having a higher percentage of physicians involved was associated with better scores on at least two of the four safety indicators. Interestingly, having a higher percentage of hospital staff or senior management involved had no impact on any of the indicators.

P.71

TABLE 5.3 Key Steps for Initiating, Improving, Evaluating, and Sustaining a Quality Improvement Program

Initiating or improving a quality improvement program

1. Do background work: Identify motivation, support teamwork, and develop strong leadership.

2. Prioritize potential projects and choose the projects to begin.
3. Prepare for the project by operationalizing the measures, building support for the project, and developing a business plan.
4. Do an environmental scan to understand the current situation (structure, process, or outcome), the potential barriers, opportunities, and resources for the project.
5. Create a data collection system to provide accurate baseline data and document improvement.
6. Create a data reporting system that will allow clinicians and other stakeholders to see and understand the problem and the improvement.
7. Introduce strategies to change clinician behavior and create the change that will produce improvement.

Evaluating and sustaining a quality improvement program

1. Determine whether the target is changing with ongoing observation, periodic data collection, and interpretation.
2. Modify behavior change strategies to improve, regain, or sustain improvements.
3. Focus on sustaining interdisciplinary leadership and collaboration for the quality improvement program.
4. Develop and sustain support from the hospital leadership.

From Curtis JR, Cook DJ, Wall RJ, et al. Intensive care unit quality improvement: a “how-to” guide for the interdisciplinary team. *Crit Care Med* 2006;34:211, with permission. Copyright © 2006 by the Society of Critical Care Medicine and Lippincott Williams.

Most clinicians have not been trained in how to develop and implement quality improvement programs. Curtis et al. have published a how-to paper that came out of an outcomes task force of the Society of Critical Care Medicine but has wide applicability to many areas of medicine ([Table 5.3](#)). The generalized lack of education and training in quality may explain some of the lethargy that Leape and Berwick allude to in their article “Five Years after *To Err Is Human*: What Have We Learned?” They suggest that extraordinary quality improvements have been achieved by implementing discrete strategies in specific environments. If each of our organizations could fractionally achieve similar success, the impact on patient care might be quite remarkable.

PAY FOR PERFORMANCE

In many settings, multiple quality measures are being subjected to pay for performance, with groups achieving higher levels of patient compliance being awarded higher levels of reimbursement. This is a marked change from being paid for delivery of units of health care or procedures in which disease states are being managed. As of 2013, 100s of pay-for-performance initiatives have been started by a wide variety of sponsors, ranging from employers to the federal government. The most important current pay-for-performance effort is the value-based

purchasing program sponsored by CMS. In this program, up to 2.0% of a hospital's base-operating diagnosis related group (DRG) payments will be at risk (Table 5.4). CMS calculates the incentive adjustment based on a total performance score achieved by the hospital. The program is structured to allow a continual evolution with measures and weighting changing each year. Because almost \$1 billion dollars is at risk, many organizations have highly focused efforts around the measures. As can be seen, CMS is moving from a time when surrogate measures, such as core measures, were the key drivers to outcomes and efficiency metrics (Fig. 5.2 and Table 5.5). The PPACA also required a Hospital-Acquired Condition (HAC) Reduction Program with another potential 1% payment reduction if performance thresholds are not met. Currently, there are eight measures in two domains, but these will likely increase over time (Table 5.6). In addition, many of these measures have applicability for obstetrician-gynecologists. The final major pay-for-performance program is aimed at reducing readmissions. In this program, payments are again reduced (1% in 2013, 2% in 2013, and 3% in 2015 and beyond) if readmission rates exceed the expected level. While the initial disease states being evaluated are acute myocardial infarction, pneumonia, and heart failure, all Medicare discharges are penalized. Reviewing Figure 5.3 demonstrates the significant potential for hospital revenue reductions as all of these programs are phased in.

TABLE 5.4 Amount Available Each Year Controlled by Statute	
2013	1.00% of base-operating DRG payments
2014	1.25%
2015	1.50%
2016	1.75%
2017	2.00%

In an early article on the subject of paying for high-quality care, Epstein et al. called for several significant changes to facilitate adoption of pay-for-performance initiatives. These recommendations included an expansion in the scope of the efforts, as well as the amount of incentive available to the clinician or group; the importance of large groups such as CMS becoming involved; an expansion from the current small cadre of clinical indicators; an improvement in our ability to establish reliable metrics for evaluation of quality; and, finally, a call for investment in electronic infrastructure to facilitate all of the above.

A Cochrane systematic review of the subject of targeted payments to affect outcomes in primary care was unable to reach a conclusion because of limitations in prior study quality and power. Kouides et al. evaluated the use of financial incentives to increase rates of influenza vaccine administration and found that modest incentive increased an already high baseline administration rate. In another study on immunizations, Fairbrother et al. evaluated use of cash bonus, enhanced fee for service, and feedback for improving baseline vaccination rates. They found only the bonus group statistically improved (increased by 25.3%), although they believed much of this effect was due to better documentation versus actual increased administration of vaccine. Roski et al. noted that in incentivized groups, documentation of tobacco use was markedly increased, as was accession to counseling programs.

Unfortunately, other important clinical end points showed no difference.

FIGURE 5.2 Evolution of value based purchasing from 2013 to 2017.

A more recent investigation evaluated a pay-for-performance initiative by PacifiCare Health Systems. Three quality measures were evaluated: cervical cancer screening, mammography, and HgbA1c. Unfortunately, only in the cervical cancer screening group was there an improvement after the intervention, and in spite of \$3.4 million paid in pay-for-performance incentives, only nominal gains were made. Also, physicians with the highest initial baseline performance had the least improvement but were the recipients of the greatest portion of the paid bonus. This trial demonstrates the potential limitation of identifying discrete end points to reward heterogeneous groups of providers, all of whom start from different baseline levels of efficacy. Dudley has suggested that how an incentive is offered (i.e., reward or penalty) and factors such as what percentage of patients in a provider's panel incentives are applicable to may affect the success of these programs. Rosenthal et al., in evaluating multiple trials and multiple industries in which pay for performance has applicability, found little evidence that paying for quality is effective. They noted that even in other industries, results are inconsistent. They raise the concern that incentives may be too low, with limited penetrance within a given provider's or group's practice panel. An additional concern is making the target for incentive so much higher than baseline that the providers feel it is unachievable and therefore do not try. This is consistent with data from Beckman et al., who interviewed providers in a pay-for-performance program. Interestingly, providers reviewed their personal profiles but did not always change their functional behaviors in response to the data.

TABLE 5.5 Outcome Measures

MEASURE DESCRIPTION	2014	2015	2016 (PROPOSED)
Acute myocardial infarction mortality rate	X	X	X

Heart failure mortality rate	X	X	X
Composite patient safety indicators		X	X
Central line-associated bloodstream infection (CLABSI)		X	X
Catheter-associated urinary tract infection			X
Surgical site infections			X

Bundled payments are a variation on pay for performance where all the providers are paid for the entire care episode and certain outcomes are achieved. In January 2013, CMS announced that a number of organizations had been selected to become part of the Bundled Payments for Care Improvement Initiative. In the program, organizations and providers enter into payment programs that generally include financial and quality performance metrics. For the CMS program, participants could pick from a menu of 48 different episodes of care to bundle. The hope is that by aligning all providers across the continuum that coordination of care and thus quality and cost will be improved. These types of programs may have had the greatest initial application in the area of cardiovascular surgery, for which outcome metrics of individual surgeons and hospitals have been reported for several years. In addition, there are well-defined clinical algorithms regarding “best practice.” This may have driven the American Heart Association's Reimbursement, Coverage, and Access Policy Development Workgroup to publish a statement on pay for performance. More recently,

P.73

the American Hospital Association has evaluated bundled payments and asked the following eight questions:

1. To which conditions should bundled payments be applied?
2. What providers and services should be included in the bundled payment?
3. How can provider accountability be determined?
4. What should be the time frame of a bundled payment?
5. What capabilities are needed for organizations to administer a bundled payment?
3. How should payments be set?
7. How should the bundled payment be risk adjusted?
3. What data are needed to support bundled payment?

FIGURE 5.3 Total hospital revenue at risk from major Medicare quality programs.

TABLE 5.6 Proposed Measures for the HAC Reduction Program

MEASURE DESCRIPTION	FY 2015	FY 2016	FY 2017
Domain 1: AHRQ patient safety indicators			
Pressure ulcer rate	X	X	X
Foreign object left in the body	X	X	X
Iatrogenic pneumothorax rate	X	X	X
Postoperative physiologic and metabolic derangement rate	X	X	X
Postoperative pulmonary embolus (PE)/deep vein thrombosis (DVT) rate	X	X	X
Surgery patients with recommended venous thromboembolism prophylaxis ordered	X	X	X
Accidental puncture and laceration rate	X	X	X
Domain 2: CDC Hospital acquired infection (HAI) measures			
Central line-associated bloodstream infection (CLABSI)	X	X	X

Catheter-associated urinary tract infection	X	X	X
Surgical site infection (SSI):		X	X
SSI following colon surgery			
SSI following abdominal hysterectomy			
<i>Methicillin-resistant Staphylococcus aureus (MRSA)</i>			X
<i>Clostridium difficile</i>			X

It is believed that the results from the demo project will provide clarity around many of these issues, although one

P.74

could argue that obstetrician-gynecologists have been doing bundled payments for obstetric care for many years.

In addition to the previously noted problems with payfor-performance programs, another limitation is that most programs to date have focused on single disease states or outcomes (such as immunization or Pap test or mammogram compliance). In reality, many patients aged 65 or older have multiple medical problems and treating single disease states in isolation may not lead to overall improved outcomes and enhanced quality. It is not surprising that 89% of Medicare's annual budget is consumed by patients with three or more chronic conditions. Boyd et al. evaluated current clinical practice guidelines (CPGs), which are often used in pay-for-performance programs, but which also focus on single disease states. In a hypothetical 79-year-old female patient with the common comorbidities of chronic obstructive pulmonary disease, diabetes, osteoporosis, hypertension, and osteoarthritis, they found that following each CPG would lead to 12 prescribed medications and a potential outlay of \$406 per month. There were also significant issues with the potential for drugdrug interactions if this “optimal” regimen was followed. They concluded that pay for performance based on CPGs for single disease states may create “perverse incentives” and actually decrease quality of care and that significant effort should be placed on effectively treating the multiple chronic conditions that many of our patients have.

While these initiatives are only still beginning, there will likely be future pressures both at the state and federal level to achieve an ever-higher level of quality. In addition, pay for performance needs to evolve to incorporate these early findings into rationale paradigms for physicians, which align the needs of our patients, payers, and providers. It may also become quite difficult for groups and practices that do not have access to electronic data to be able to participate in such projects.

ELECTRONIC HEALTH RECORD

The advent of the EHR has changed forever how medicine will be practiced. Many of us were trained in a time where orders and notes were handwritten and charts were sent to a large repository (i.e., medical records). Many notes written by our colleagues were difficult to read or were unable to be located. Certainly, these were not often available in real time, across specialties or from home. Authentication of results was performed by hand and had to be reassociated with the correct chart, wasting significant time and resources that might be better directed. Prescriptions were written and handed to patients who then delivered them to a pharmacy. In a bestcase scenario, writing was legible, charts were placed in their appropriate position within the repository, and the pharmacist could read the prescription. Unfortunately, often this was not the case.

- CMS established 3 stages of meaningful use
- Stage 1 and 2 requirements final
- Stage 3 to follow

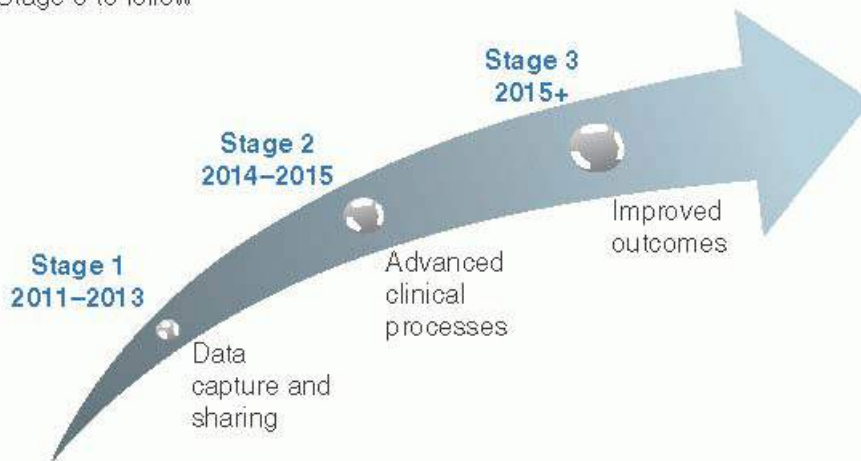

FIGURE 5.4 Meaningful use roadmap.

In many areas of the United States, much of this has changed. Numerous opportunities exist with the EHR to overcome many of the technical issues associated with handwriting, but the opportunities go well beyond legibility. In addition, groups like the American Medical Informatics Association's College of Medical Informatics has called for integration of the EHR and personal health records (PHR) to provide the greatest value for our patients. Much of the current focus on EMR implementation is being driven by the billions of dollars available to providers who can attest to "meaningful use." The American Recovery and Reinvestment Act (ARRA), which was enacted in 2009, includes the Health Information Technology for Economic and Clinical Health (HITECH) Act, wherein meaningful use in three separate stages is called out ([Fig. 5.4](#)). Incentive payments range from \$44,000 over 5 years or \$63,750 over 6 years to providers attesting to Medicare or Medicaid, respectively ([Fig. 5.5](#)). Importantly, if providers fail to attest by the designated time, not only do they lose the meaningful use dollars, there will also be a negative adjustment to their Medicare/Medicaid fees.

Multiple studies have suggested the potential positive consequences of an EHR implementation. The Kaiser group reported that with an implementation of an EHR in the northwest United States, age-adjusted outpatient visits dropped by 9%, with only a slight increase in phone calls from patients but no change or a slight improvement in quality metrics. Embi et al. found that by using EHR data to define patient eligibility into a clinical trial and then causing an electronic prompt to let the provider know of patient eligibility, they were able to double study enrollment as well as improve physician referrals to their study. In an obstetric EMR study, Klatt and Hopp demonstrated that through the use of best practice alerts in the EMR, they were able to significantly improve influenza documentation rates in pregnant women. The alert fired at each prenatal visit if the patient was either unvaccinated or didn't have documentation regarding refusal. Such alerts can be configured for a number of different clinical issues. However, a key to success is not creating "alert" fatigue and limiting the number of hard stops requiring active clinician input. The EMR is also only as good the data within it. We are aware that patients with gestational diabetes (GDM) are at increased risk for type 2 diabetes. Stuebe evaluated documentation of GDM in the EMR of a large health system. They found that only

P.75

45.8% of patients had the GDM history documented in the electronic problem list. This lack of documentation could lead to poor communication to the patient's primary care physician and the potential risk that the patient will not be screened when not pregnant.

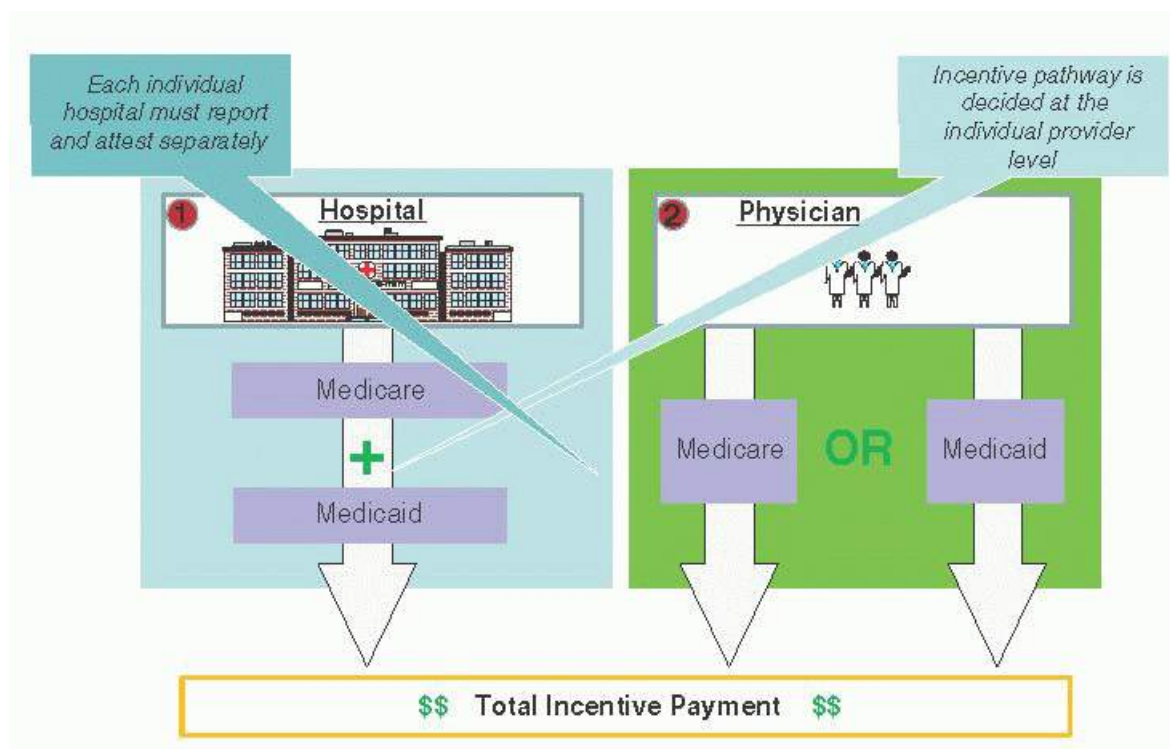

FIGURE 5.5 Meaningful use incentive roadmap.

There are multiple factors that have made the adoption of the EHR difficult for some providers and groups. Likely highest among these is the cost to implement as well as maintain the EHR. Multiple third-party vendors exist that have various EHR platforms. These range from simple documentation and chart programs to software and hardware that integrate patient care across both inpatient and ambulatory platforms and the PHR. There are currently efforts to standardize EHR language, but many of these efforts are in their infancy. It will become critical as we evolve to an all digital-based health record that these systems are able to communicate with one another, allowing patients to have their records available anywhere and anytime. Ford et al. evaluated EHR adoption rates in small physician groups of 10 or fewer partners. Using models, they projected the potential for broad adoption of EHR into the future. They suggest that it may take until 2024 for small groups to fully implement EHRs, which is much longer than is currently being called for by agencies interested in quality initiatives and cost containment. Unfortunately, the health digital information superhighway continues to have a long way to go to be completed.

Baron et al. detail their personal experience as a small group of internists (four members) with implementing an EHR. They described alterations in work flow and the initial deterioration in their office environment for staff, patients, and physicians alike. However, they also state that in spite of the various limitations, "...none of us would go back to paper health records." They identified five key issues that are likely relevant for both small and large groups involved with implementing an EHR:

1. Financing of the EHR
2. Interoperability, standardization, and connectivity
3. Work-flow redesign issues
4. Technical support
5. Issues of change management

More recently, there have been questions regarding whether the EHR is really the panacea for moving medicine to Six-Sigma quality. Computerized physician order entry (CPOE) has been suggested as a key element in

decreasing errors and improving quality. Several papers have recently addressed this issue with different conclusions. Upperman et al. evaluated the rates of ADEs pre- and post-CPOE implementation. They noted an improvement in verbal order regulatory compliance, as well as an elimination of transcription errors after implementation. They also noted a statistical decrease in harmful ADEs and suggested that this improvement would result in one less harmful ADE for every 64 patient days. Han et al. noted a different experience when implementing a CPOE system in an academic tertiary care children's hospital. Surprisingly, they noted that the mortality rate increased from 2.8% before CPOE implementation to 6.57% after, an increase that remained significant even after multivariate analysis. It is noteworthy that in this paper, the authors document that the CPOE training was given 3 months before implementation. They also note that the implementation itself occurred over a period of only 6 days for the entire pediatric hospital. This may be too long an interval from training and too short a period for implementation. It is interesting that two papers, both published from the same institution, could have such different conclusions.

Ash et al. have suggested that the mere implementation of an EHR is not in and of itself enough to insure that unexpected errors won't occur. They suggest that these errors fall into two broad categories: "those in the process of entering and retrieving information and those in the communication and coordination process that the patient care information system is supposed to support." The key for powering the CPOE and the EHR is likely through well-thought-out algorithms that allow us to take advantage of the computer's ability to maintain data while attempting to best understand what a particular patient needs and while limiting changes in underlying clinical functionality, unless that change actually improves functionality.

There has also been a push to allow patients to have access to their records. This may enhance patient engagement and activation by facilitating the patients' ability to participate in their own care in a way not previously thought possible. Patients are able to view data within the EHR for accuracy, reviewing current or prior medications, allergies, etc. They could also be made aware of when lab test or studies are due or overdue, helping to improve compliance and screening. An even more novel concept that has been introduced by several groups is the ability of the patient to communicate with her

P.76

care providers through Web-based messaging. Initially, providers were concerned regarding the potential for overuse, but little evidence demonstrates this type of abuse. Indeed, in a time when it may be quite difficult to locate your patient during the course of a business day, dyssynchronous communication may be a preferable manner to communicate nonemergent information with patients. In addition, these data may be appropriately security encrypted at 128 bits and easily made part of the health record.

HIE are currently being pursued by a number of organizations and states. The hope would be true interconnectivity so that patient data could be viewed regardless of the point of presentation. Numerous technologic barriers exist to limit this functionality at present, but the hope of multidirectional data flow with immediate access to this vital information promises improved care for our patients.

CHANGES IN EDUCATION

One of the most significant changes in medical education has been the limitation of resident duty hours. Such regulation of work hours has been common in industries such as aviation, in which pilots and other crew are limited both in the number of hours worked and requirements for time off between work episodes. Although many gynecologists were trained in a time of every second- or third-night call, this is no longer acceptable or allowable. New York led the way in creating legal mandates, but the Accreditation Council for Graduate Medical Education (ACGME) and the various specialty resident review committees have quickly followed. In July 2003, the ACGME put into effect new requirements and regulations (www.acgme.org). These regulations limited total duty hours to 80 hours per week when averaged over 4 weeks, limited in-house call to no more than every third night with 1

day off in 7, and limited continuous patient care hours to 30, with the last 6 hours to patient handoffs and educational activities, such as grand rounds. In addition, there had to be 10 hours between shifts worked. In 2009, the IOM opined that based on fatigue-related errors noted in other industries, residents should have a period of protected sleep of no less than 5 hours during any shift of more than 16 hours. In July of 2011, the ACGME further revised the standards mandating that duty hours for interns not exceed 16 hours. Second-year residents and above may work up to 24 hours of continuous duty, but there is a recommendation for “strategic napping.” These changes represent a paradigm shift that is a dramatic departure from times past. While recent data have suggested that decision-making as well as technical skills may suffer with sleep deprivation, it is much less clear how these changes have affected patient care, safety and quality, as well as overall resident experience.

Hutter in 2006 evaluated the impact of changing to the 80-hour workweek on surgical residents in Boston. They noted that after implementation of the 80-hour workweek, residents had lower burnout scores and less emotional exhaustion, whereas sleep and motivation to work were improved. Objective quantitative measurement demonstrated no differences in the quality of patient care. In contrast, another pre- and post-duty-hour implementation study from the surgery department of University of California, Irvine, did not show changes in measures of burnout. They did note a decrease in weekly work hours from 100.7 to 82.6 after implementation and found a significant decrease in formal educational time. Of interest, time in the operating room, on clinical rounds, and in the clinic was not significantly different.

In contrast to previous publications, a report from University of California, San Francisco, internal medicine residency did not demonstrate improvement in educational satisfaction with the onset of the new duty-hour regulations. Similarly, another obstetric and gynecologic survey pre- and postimplementation of duty hours at the University of Colorado demonstrated no differences in overall satisfaction with the residency. However, some key elements were found to be statistically elevated after implementation, including reading, reviewing literature, doing research, and some clinical aspects of training.

More recently, Volpp reported on protected sleep for interns. Their prospective trial suggested that implementation of a “protected sleep period” did have a significant impact on the amount of sleep but also improved alertness the following morning as assessed by a sleepiness scale.

Two pivotal papers were published in 2013 on a number of these issues. Desai et al. from Johns Hopkins compared the effects of the 2003 duty-hour regulation with the changes the ACGME put in place in 2011. Using a crossover study design, they randomly assigned interns to a model that was compliant to the 2003 regulations or to two different models compliant with the 2011 recommendations. Both 2011-compliant models increased sleep duration while on call; however, handoffs were more than doubled, educational time was decreased, and there was a perception by residents and nurses that quality was negatively impacted. In the same journal, Sen et al. reported on results from the Intern Health Study, a prospective longitudinal cohort. They evaluated interns from before the 2011 change (2009 and 2010) and after the change with 51 residencies at 14 academic and community training programs represented. In studying the 2,300 interns, they noted a decrease in duty hours (67.0 to 64.3) with no significant impact on total sleep hours, depressive symptoms, or sense of well-being. Of concern, the number of interns self-reporting an error that caused harm to a patient increased from 19.9% prior to the rule change in 2011 to 23.3% after.

Obstetric residencies have responded to these directives and made significant changes in underlying residency structure. Nuthalapaty et al., in querying obstetric residency programs, found that 98% reported changing their programs in response to the new regulations, 94% changed their on-call structure, 85% changed distribution of responsibility, and 80% modified how residents participate in rendering care to patients.

Outside this country, even more stringent regulations exist. For example, in Brazil, the Brazilian National

Committee on Medical Residency created requirements in 1981 that limit maximum weekly work hours to 60, with 30 consecutive days of vacation each year and 10% of total hours mandated to be dedicated to education. Importantly, Brazil is not the most aggressive country to implement these changes; multiple countries around the globe have decreased duty hours to 48 to 56 hours per week. It is reasonable to ask the question: Have we seen the full evolution of these changes in the United States?

It has also been noted that in some cases, residents may work fewer hours than what might be seen in a private setting, in which every-other-night call may be commonplace. One article that questioned residents in internal medicine noted that at least half of residents believed sleep deprivation was a necessary foundation in residency training. A question for the future is whether regulations such as those that have been put in place for residents may also come to exist for all physicians. Certainly, given the potential for significant manpower limitations in some specialties, as well as a trend away from rural- and toward hospitalist-type practices, this would be especially problematic and require significant redistribution of resources. There are additional issues with the duty-hour limitations, including the need to transition patient care from

P.77

the previous on-call residents and the likelihood that some cases that are seen during the resident's call (especially from the emergency room) may come under the care of a different resident and result in a loss of continuity for both the resident and the patient. Whether such handoffs and the decrease in continuity are responsible for some of the results noted earlier is still in question. Although such changes have caused us to rethink classic patient flow in training programs, there is a need to learn how to appropriately transition care from one service to another. This will be critical as residents become attending physicians. One methodology for training teams to work together and communicate better is called TeamSTEPPS (team strategies and tools to enhance performance and patient safety). The tool has been developed by the Department of Defense and the Agency for Healthcare Research and Quality (<http://teamstepps.ahrq.gov/index.htm>). Regardless of the tool used, optimized communication and team function remain critical as there will continue to be pressure to decrease worked hours and concomitant increases in handoffs among care providers.

In recent residency matches, both general surgical and obstetric and gynecology slots have been filled at much higher percentages than in the years immediately prior to the institution of work hour limitations. Whether this is consistent with senior medical students sensing a change after the decrease in duty hours, thus creating a new perception of these “difficult” specialties, remains to be seen.

Less investigation has been performed on the impact of the duty-hour changes to medical students and how this might affect their learning. Brasher et al. used completed end-of-rotation evaluations pre- and postimplementation and found more negative comments after implementation, including decreased scores of residents as supervisors and teachers, and in teaching activities. What is less clear is this: As programs and residents have acclimated to these new standards, will there be adaptation as we get farther out from the change?

There remains limited information regarding real change in the quality of care rendered in this new paradigm. Indeed, the proponents for change would suggest the opposite: that a fresh team will deliver better care.

POSTGRADUATE TRAINING

Questions continue regarding how best to train clinicians in the postgraduate environment. Most find learning easy while in residency, with time often dedicated to didactic lectures. Few practicing physicians are afforded similar luxury, and yet, significant technologic and medical advances continue throughout our careers. Given the limitations that state-by-state licensure imposes, as well as malpractice constraints, it is also difficult for physicians to cross state boundaries to learn novel surgical procedures and be tutored. Fortunately, there have also been advances in our ability to educate with Web-based or computer technology. The classic forum of the

in-person lecture remains the gold standard for education. However, some institutions have moved to Web-based programs to allow transmission of grand rounds or other educational forums in real time. This allows attendees to log on and participate regardless of their location, be it at home, in the office, or in the hospital. It also allows for lecturers to limit their time away from work as they may deliver their lecture from afar with remote transmission to multiple sites. In a time of shrinking grand-round budgets and limited external support for lectures, this may be one methodology for continuing to deliver state-of-the-art education to a diverse, ever-changing audience.

As we continue our transition from open surgery to minimal invasive surgery and now to robotic surgery, there continue to be questions regarding how to best credential surgeons on new technology. The issues discussed previously regarding limitations in postgraduate opportunities to mentor and train are the origin of some of these problems. How many preceptor cases are adequate for an individual surgeon to be able to demonstrate mastery? Unfortunately, most of us as educators realize there are profound differences between cases and surgeons. What one surgeon is able to master in 20 cases, another may be able to conquer in five or fewer. At the writing of this chapter, most residents will garner adequate experience with minimal invasive techniques during their training, but less will master robotics during this time.

Previously, many gynecologic services existed in a silo, consulting other services only when specific situations existed. In the new practice of medicine, we are being faced with many multidisciplinary procedures requiring seamless transition between multiple providers and specialties to assure the best outcome. Uterine artery embolization would be one such example. Generally, gynecologists see the patient with symptomatic myomata, but on occasion, patients will self-refer to an interventional radiologist. In most cases, the interventionalist performs the procedure, but often, this individual does not have admitting privileges. If the patient requires admission for pain management, the gynecologic service may be asked to admit and manage the patient. In addition, appropriate preoperative evaluation will need to be performed to decrease the risk of a failed or inappropriate procedure. Generally, all of the above are best accomplished in a setting where excellent communication exists between the services, and the patient seamlessly transitions through the treatment and is not held hostage to political or other logistic issues that often exist in the complicated systems we work within. This requires physicians and surgeons from multiple specialties to decide in advance how such programs should work and what each individual team member is responsible for providing. This often requires identification of specific team leaders (physician and nursing) from each discipline, as well as a specific leader who will have proximate authority to resolve issues that will predictably arise in such complex interactions. When services work in this manner, functioning at a high level, patient care is optimized. Because of the need to act across disciplines and in a team-like manner, resident and even medical student curriculums have begun to emphasize the need to work as teams—a concept adopted long ago in the business world but adopted much more slowly in the world of independent thinking and functioning within medicine. In fact, team-building retreats are becoming departmental norms in many training programs around the country.

HOSPITALISTS/LABORISTS

In the last decade, there has been a move toward some practitioners working solely within the hospital setting to care for inpatients, a practice common outside the United States for decades. This started when data suggested that in some cases, patient care might be optimized and length of stay (LOS) reduced by having a single individual responsible for overseeing a patient's stay in the hospital. Emergency department physicians have performed shift work for decades, but the change was most dramatic for hospitalists who are generally internists or family practitioners—fields that were more typically associated with primary care. With the advent of the resident 80-hour workweek, some services have been unable to be covered by residents, and again, the utility of a hospitalist coverage arrangement began to make sense.

Wachter and Goldman reviewed published studies and abstracts regarding hospitalist services and noted only 2 of 19 studies didn't demonstrate decreased LOS. The range of LOS reductions was 7% to 27%, which even on the lower end often translate into significant savings to health care organizations. Several variations on the hospitalist model exist, including use of combinations of private staff, academic staff, and house staff. One study evaluated differences between community physicians, a private hospitalist service, and an academic hospitalist group within the same tertiary care hospital and found a 20% LOS and 10% cost reduction on the academic service versus 8% and 6% reductions for the private hospitalists and the community physicians, respectively. They did not note differences in mortality rates (either inpatient or 30-day) or readmission rates between the three groups. Another variation is to use the hospitalist to cover patients typically covered by surgical services. One trial evaluated use of a hospitalist in managing elderly hip fracture patients along with orthopedic surgeons. They noted decreased time to get patients to surgery, decreased length of hospitalization after surgery, and overall decreased LOS with no adverse impact on mortality or readmission. Another area of question has been how a hospitalist service might affect teaching and education for students and residents. Hauer et al. analyzed 1,587 house staff and student evaluations on internal medicine rotations during a 2-year period. They scored the hospitalist group (vs. traditional attending physicians) higher in teaching effectiveness, knowledge, and feedback. More recently, the hospitalist trend in internal medicine and family practice has carried over to pediatric hospitals that have now created pediatric hospitalist services. Dwight et al. describe that with manpower reductions and limitations in house staff, among other issues, some Canadian hospitals have begun to successfully use a non-house staff-based model effectively. Landrigan et al. performed a systematic review of the pediatric hospitalist literature, and consistent with nonpediatric hospitalist studies, these programs had an average LOS and cost decrease of 10%. They do note that many of the programs themselves do not generate adequate revenue to not lose money. An interesting article on keys to success for creating a pediatric hospitalist program suggests six key principles that may have broad applicability to establishment of similar programs in obstetrics and gynecology (Table 5.7).

Over the last 10 years, this trend has carried over into obstetrics and gynecology. Weinstein first introduced the concept of the laborist in 2003. Since that time, a number of hospitals have moved forward with establishing programs. In a time when clinicians have become highly interested in balancing lifestyle and workplace activities, it is understandable why this concept may become more prevalent. Funk

surveyed obstetrician-gynecologists and noted that laborists were slightly younger and had a high rate of career satisfaction. More recently, the American Congress of Obstetricians and Gynecology has released a committee opinion supporting the concept.

TABLE 5.7 Six Principles to Establish a Successful Pediatric Hospitalist Practice

1. Voluntary referrals
2. Local design
3. Minimum physician-training requirements
4. Arrangement for appropriate follow-up
5. Communication among primary care physicians, subspecialists, and hospitalists
6. Data collection and outcome measures

TABLE 5.8 Classification of References and Recommendations According to the U.S. Preventive Services Task Force

REFERENCES	
Level I	Evidence obtained from at least one properly conducted randomized clinical trial
Level II-1	Evidence obtained from welldesigned controlled study without randomization
Level II-2	Evidence from well-designed cohort or case-control studies, preferably from more than one center or research group
Level II-3	Evidence obtained from multiple time series with or without intervention
Level III	Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees
Meta-analysis	A systematic structured process that is more than a literature review
Decision analysis	Use of mathematical models of sequences of several strategies to determine which is optimal
Cost-efficient analysis	Comparison of health care practice or techniques in terms of the relative economic efficiencies in providing health benefits
RECOMMENDATIONS	
Level A	Based on good and consistent scientific evidence
Level B	Based on limited or inconsistent scientific evidence
Level C	Based primarily on consensus and expert opinion
Level D	Fair evidence against the recommendation
Level E	Evidence against the recommendation

Adapted from American College of Obstetricians and Gynecologists. *Reading the medical literature: applying evidence to practice*. Washington, DC: American College of Obstetricians and Gynecologists, 1998.

TABLE 5.9 New U.S. Preventive Services Task Force Grade Definitions After July 2012

GRADE	DEFINITION	SUGGESTIONS FOR PRACTICE
A	The USPSTF recommends the service. There is high certainty that the net benefit is substantial.	Offer or provide this service.
B	The USPSTF recommends the service. There is high certainty that the net benefit is moderate, or there is moderate certainty that the net benefit is moderate to substantial.	Offer or provide this service.
C	The USPSTF recommends selectively offering or providing this service to individual patients based on professional judgment and patient preferences. There is at least moderate certainty that the net benefit is small.	Offer or provide this service for selected patients depending on individual circumstances.
D	The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.	Discourage the use of this service.
I statement	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.	Read the clinical considerations section of USPSTF Recommendation Statement. If the service is offered, patients should understand the uncertainty about the balance of benefits and harms.

Srinivas reported that 40% of National Perinatal Information Center/Quality Analytic Services member hospitals were using laborists in 2010. They noted an association with delivery volume but not geography or presence of residents. Unfortunately, while the laborist movement is growing quickly, there are presently few data regarding improved maternal or neonatal outcomes, enhanced patient experience, or the impact on resident education. Undoubtedly, we will begin to see some of this data in the literature, similar to that published and previously mentioned in medicine and pediatrics.

RATING SCIENTIFIC EVIDENCE

It has become increasingly important for physicians to evaluate the adequacy of data to which we are constantly exposed. There has been a transition in articles published in the peer-reviewed literature over the last 10 to 15 years with a significant effort toward asking and answering questions in the most rigorous manner possible. Numerous methodologies exist for evaluating these trials, which place differing values on the quality, quantity, and consistency domains expressed within each report. Given the subtleties of these differing methodologies, a paper may be deemed to be stronger or weaker. The Agency for Healthcare Research and Quality (AHRQ) has reported on an evaluation of these various systems and describes the differences relative to the type of trial

being evaluated (e.g., randomized control trial vs. observational).

The most commonly used systems are seen in [Tables 5.8](#) and [5.9](#) as described by the U.S. Preventive Services Task Force (USPSTF). These methods describe the type of trial and give a recommendation regarding the strength of the conclusion. It is relevant for us as practicing surgeons to be able to differentiate between data and reports that are merely interesting and those that should cause us to reevaluate our practice patterns. It is also important to understand not only what the grading system means but how the conclusions are reached for each of these unique systems. Because there are presently a number of systems and no one is universally used in journals or textbooks, this is an even greater challenge.

In a review of 55 American Congress of Obstetricians and Gynecologists practice bulletins, Chauhan et al. found that only 29% of 438 recommendations were level A (good and consistent evidence), whereas 33% of recommendations were level B (limited or inconsistent evidence) and 38% were level C (consensus and expert opinion). This is the quandary in medicine today: Evidence-based medicine is how all of us would like to practice, but unfortunately, all questions have not been answered to the extent needed. Because of this, panels of experts may by necessity have to revert to the best available data, which may be less than optimal. However, even in the field of medical ethics, there is an effort toward moving to formal tools for evaluating the validity of discussions and data. If the last 10 years is any indication to what will happen in the future, there will be an increasing number of randomized controlled trials that are well thought out and executed to aid us in determining how to best counsel our patients.

CONCLUSION

The examples illustrated in this chapter are but a small sampling of the numerous ongoing changes occurring daily. Many of these changes will likely affect our lives and practices—some more than others—but all are a radical departure from times not too distant. It will be interesting to evaluate how these changes evolve over editions of this textbook. Changes underscore the importance of lifelong education, not only in the functional practice of medicine but also in the art of the practice of medicine. It certainly makes our profession an exciting place to be—stay tuned!

P.80

BEST SURGICAL PRACTICES

- Resident education has been transformed to being less service oriented and more competency based. The 80-hour workweek has effected revolutionary changes in the mindsets of today's trainees and the people who train them.
- Quality has always been important to physicians in theory, but new initiatives, such as the Partnership for Patients program, are making evidence-based practice a reality.
- The EHR continues to evolve. This modality will alter every aspect of care delivered by physicians and effect communication between providers and their patients.
- By being dedicated providers for inpatients, hospitalists will render more efficient and timely care and therefore more effectively manage patients, with an eye to improving quality and decreasing error.
- Pay for performance is being used by both governmental and third-party payors as a means to reward providers and health care organizations for optimizing predefined outcomes and quality metrics.

Training the Gynecologic Surgeon: Maintaining and Improving Surgical Skills

Tola B. Fashokun

Victoria L. Handa

DEFINITIONS

Assessment—The process of measuring a trainee's knowledge skills, judgment, or professional behavior against defined standards.

Deliberate practice—A highly structured form of training that consists of focused, repetitive practice in which the subject continuously monitors his or her performance and subsequently corrects, experiments, and reacts to immediate and constant feedback, with the aim of steady and consistent improvement.

Global Rating Index for Technical Skills (GRITS)—A validated assessment tool used for evaluation of intraoperative performance.

Learning style—The process by which a person understands and retains information, thereby gaining knowledge or skill.

Learning theories—Conceptual frameworks and principles that attempt to explain the learning process.

Mental imagery (mental practice)—The cognitive rehearsal of a task with or without physical movement. It can be used to enhance the acquisition of new technical skills.

Objective Structured Assessment of Technical Skills (OSATS)—A valid and reliable examination in which subjects perform standardized surgical procedures while being evaluated by an expert surgeon.

Simulation—The act of reproducing or imitating a real-life event, process, or procedure. It can be utilized both as an effective training technique and assessment tool.

Vaginal Surgical Skills Index (VSSI)—A validated procedure-specific assessment tool used for intraoperative evaluation of vaginal surgical skills.

*"It would take me one year to teach a trainee **how** to do an operation, five years to teach them **when** to do the operation, but a lifetime to teach them **when not** to do an operation."*

Lord Smith, past President of The Royal College of Surgeons of England

HISTORY OF SURGICAL EDUCATION

For more than a century, the surgical teaching model introduced to Johns Hopkins Hospital in 1889 by Dr. William Halsted has been the standard approach for training surgeons. Under this apprenticeship model, the surgeon trainee experiences "...the orderly exposure to graduated clinical experience in the operating room during several years of residency under the close tutelage of dedicated senior attending surgeons...." This widely accepted and historically successful model traditional paradigm "to see one, do one, teach one" led to the declaration that "the operating room is the surgeon's classroom."

P.82

However, there are limitations to this surgical education model. Variability in the number and type of surgical cases and duration of apprenticeship will impact training. Second, this model does not provide for remediation. Even Dr. Halsted recognized this limitation. Halsted observed, "experience can mean doing the same thing wrong over and over again." Finally, this traditional method of training may not be practical given the current pressures of residency work hour restrictions, increasing numbers and complexity of surgical procedures, and financial and ethical constraints of teaching surgical skills in the operating room.

EDUCATIONAL THEORIES: HOW DO ADULTS LEARN?

A contemporary approach to surgical training requires consideration of not only *what* the trainee is learning but *how* they learn. Advances in educational research have identified principles of adult learning, and accumulating evidence suggests that surgical trainees have specific learning styles. The three basic types of learning styles are visual, auditory, and tactile. To learn, we depend on our senses to process the information around us. Most people tend to use one of their senses more than the others; however, it is not unusual to use a different style to learn a particular skill. For example, some novice surgeons may find it difficult

to hear and then duplicate instruction on how to correctly apply a clamp; they may learn best by first observing and then performing the illustrated task. The latter method might have a direct impact on the efficiency of intraoperative teaching. This does not imply that one style is better than the other, but one style may be more preferable given the learning environment, and the trainee may need to make adjustments to minimize any obstacles to effective learning.

A better understanding of the factors that impact the process of learning new surgical skills will hopefully lead to a more effective and efficient educational model for surgical educators and novice surgeons. Dr. Reznick et al. have suggested that “adult learning is enhanced by an approach that is self-directed and centers on the learner rather than the teacher. Adult learning is facilitated by focusing on a problem or task. Abstract, subject-centered learning is less effective as a motivator. Adults also come to an educational activity, such as learning operative skills, with a vast amount of past experience that must be recognized and utilized.” Because the development of surgical skills is an active learning process, a surgeon’s optimal surgical education should be based on learning theory.

One learning model relates to the psychological states involved in the process of progressing from incompetence to competence in a skill (Table 6.1). This theory outlines four stages. The first stage is “Unconscious Incompetence”: You don’t know that you don’t know something. The second stage is “Conscious Incompetence”: You are now aware that you are incompetent at something. Next is stage 3, “Conscious Competence”: You develop a skill in that area but have to think about it. In the final stage is “Unconscious Competence”: You are now so good at it, and it now comes naturally. Obviously, most surgeons would agree that their goal is to achieve the final stage when a particular surgical skill becomes “second nature”; however, this may have a direct impact on one’s ability to teach this skill or procedure. Surgical educators are most effective when they are able to “break down” a complex procedure to its basic elements, which can be challenging if they are not “conscious” about the process.

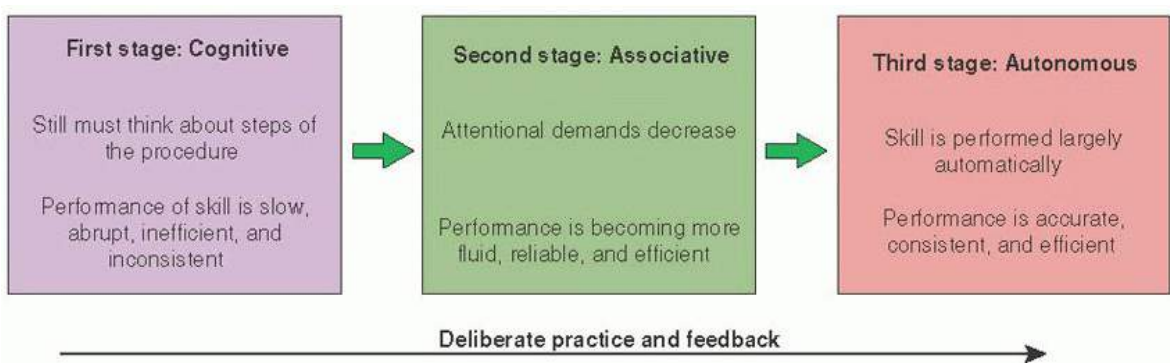

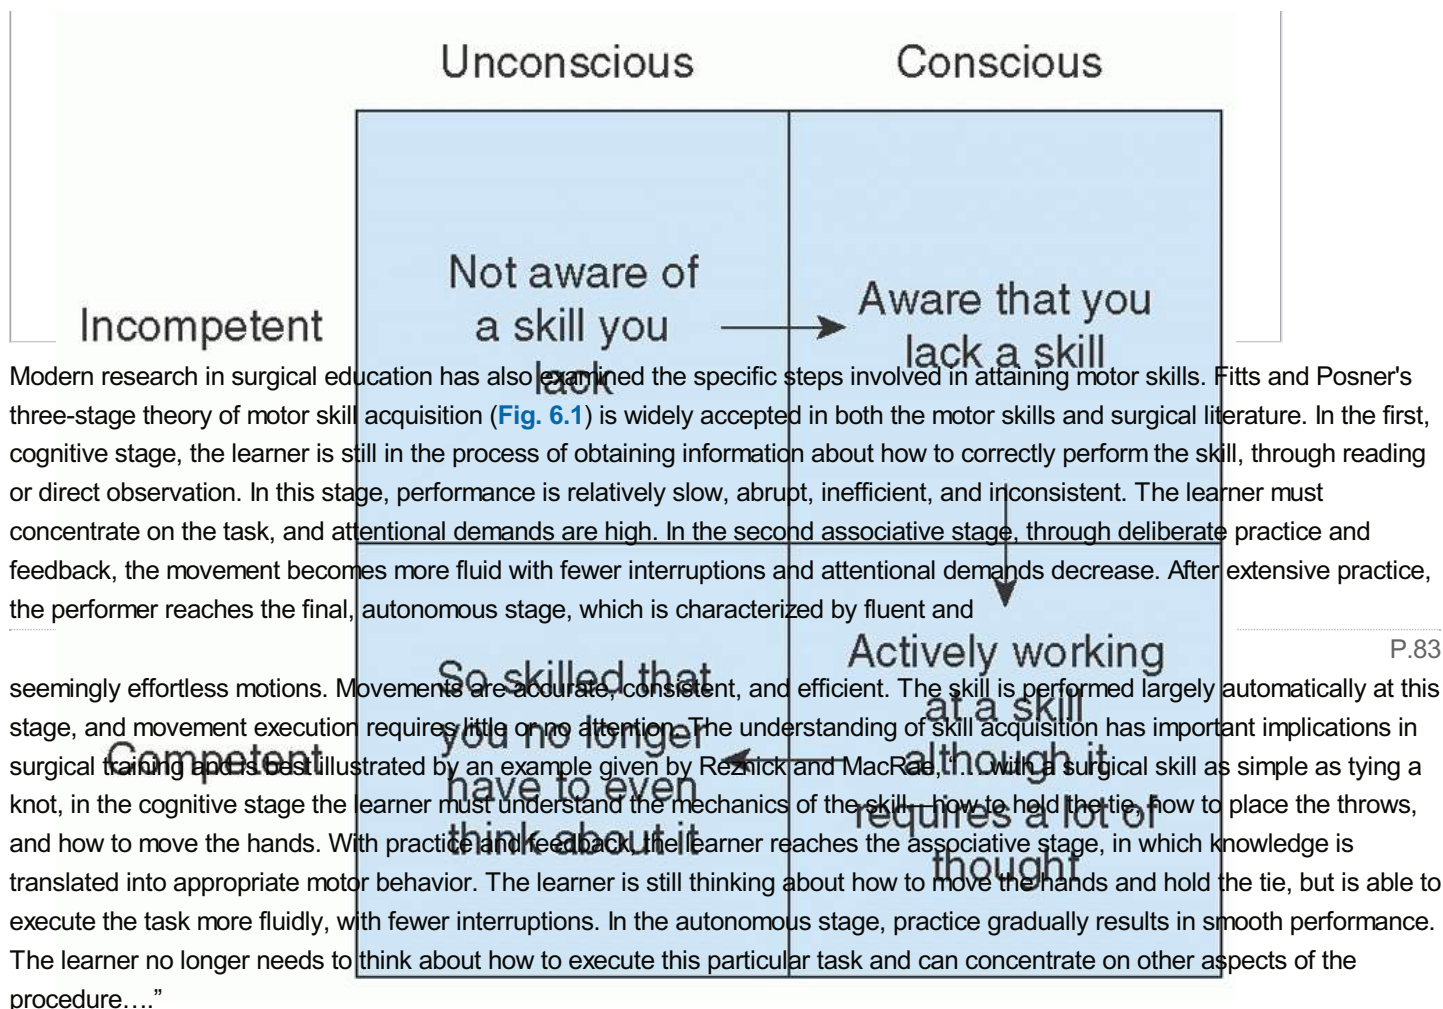

FIGURE 6.1 Fitts and Posner's three-stage theory of motor skill acquisition.

TABLE 6.1 The Four Stages of Learning

P.83

Surgical trainees must have a firm understanding of basic skills first before they can progress to more complex and elaborate tasks, and the quality of performance requires assessment at every stage. Therefore, the earlier stages of teaching fundamental technical skills should take place outside the operating room; practice with constructive feedback is the rule until automaticity in basic skills is achieved. The mastery of basic skills allows trainees to focus on more complex tasks in the operating room.

OUT OF OPERATING ROOM LEARNING EXPERIENCES

Simulation

The advent of surgical simulation has resulted in significant and dynamic changes to surgical education. The use of simulation has been adopted from other disciplines, most notably the aviation industry. An obvious advantage of simulation training is that core skills can be learned prior to application in the operating room, theoretically improving safety and efficiency. Also, with a simulation curriculum, training opportunities are not constrained by the available clinical experience. Simulation offers the opportunity for repeated practice in a safe and controlled environment, focusing on trainees and tailored to their needs. Most surgical educators would agree that fundamental surgical principles and technical skills should be taught outside the operating room. Although some training programs include surgical training models in their surgical curricula, no simulation model has gained sufficient acceptance to be considered a gold standard. Simulation practices vary widely across and within residency programs. Several research studies have confirmed the positive impact on surgical skill of practice outside the operating room using surgical simulators. Trainees whose initial learning occurs in a simulated environment make fewer errors and complete the “real” operation faster than those without such training. In essence, better skills translate into better surgery.

TABLE 6.2 Simulation Methods

SIMULATION	DESCRIPTION/COST	PROS	CONS
Bench models	Suture boards and foam models Low to mid cost	Inexpensive, safe, generally reusable; can perform basic tasks	Decreased realism; not able to perform more complex tasks

Mannequin	May be entire anatomy or pelvis Mid to high costs	Multiple use; can perform basic or more complex procedures, patient specific Team training	Limited realism, not “exact” anatomy, limited applications
Computer/virtual reality surgical simulators	Virtual software, computer visual-haptics Can practice basic laparoscopic skills High cost	Multiple use, data capture, minimal setup time; provide performance feedback, can make patient-specific	Cost, maintenance, and down time; realism varies
Live animals	Primate, sheep, pig, rabbits High cost	Closer to human anatomy; can perform entire operation or complex procedures	Expensive, differences in anatomy, single use; requires special facilities and personnel, tissue compliance, infection risks, ethical concerns
Cadavers	Entire anatomy, best used for continuing medical education High cost	Accurate anatomy; can perform the entire operation	Expensive limited availability, single use, compliance of tissue, infection risks, and ethical concerns

There are a variety of types of surgical training models, including bench models, virtual reality trainers (computer-generated models), surgical simulation in live animal models, and surgical simulation in human cadavers ([Table 6.2](#)). These various simulators have advantages and disadvantages. All are believed to result in improved trainee performance that is transferable to the operating room.

However, it is unclear which type of trainer is superior. A number of studies have reached differing conclusions. For example, a Cochrane Database Systematic Review of the effectiveness of virtual reality training compared with physical reality simulators concluded that these two training methods result in similar laparoscopic skill acquisition, but that the virtual reality trainers may result in better transferability of skills into the operating room (especially for more complex tasks). In contrast, Denadai et al. demonstrated that the acquisition of suture skills was similar on a low- and high-fidelity bench model. Practice on either model was shown to improve

P.84

performance compared to training with only didactic materials. However, another systematic review (performed by Sutherland et al.) of 30 randomized controlled trials concluded that simulation training was superior to no training but was not consistently superior to traditional training methods. Most investigators would agree that the effective use of surgical training models requires standardization of instruction, feedback, and evaluation.

Ultimately, the role of simulation in teaching surgical skills is to facilitate practice of technical skills. Ericsson et al. showed that becoming an expert takes about 10,000 hours of *deliberate* and *distributed* practice, regardless of whether the goal is to become a competent surgeon, a chess master, or a professional musician. Deliberate practice is defined as a “highly structured activity, the explicit goal of which is to improve performance.” In other words, time spent practicing a new surgical skill is most useful if the learner reflects on or receives feedback on performance (either self-evaluation or through formal assessment) and has numerous sessions distributed over time (e.g., throughout residency or fellowship), rather than the same number of hours compressed into a single training session. This confirms what other educators have suggested that “practice does not make perfect; perfect practice makes perfect.”

Simulation may also facilitate the evaluation of surgical skills. However, for simulation to provide a robust and valid assessment tool, the simulation exercise must be highly standardized, widely available, and focused on the critical aspects of performance. It is important that simulation is incorporated as part of a standard surgical curriculum, with well-defined learning goals and objectives that should be completed at specific time intervals.

MENTAL IMAGERY (MENTAL PRACTICE)

Mental imagery, also called visualization and mental imagery rehearsal, is “the cognitive rehearsal of a task with or without

physical movement.” It can be used to enhance the acquisition of new technical skills and increase emotional preparedness to perform in stressful situation, both qualities applicable to the training of novice surgeons.

Educational researchers have examined whether the experience of mental imagery affects the degree of learning. For example, imagining playing a 5-finger piano exercise (mental practice) resulted in a significant improvement in performance over no mental practice—though not as great an improvement as that produced by physical practice. Mental practice alone seems to be sufficient to promote the modulation of neural circuits involved in the early stages of motor skill learning.

So how does this translate to the use of mental practice to teach surgical skills? Several studies support the use of this training tool to teach surgical skills. In a multicenter randomized controlled trial, gynecology residents who had performed three or fewer cystoscopies were randomized to preoperative mental imagery sessions or reading a book chapter describing cystoscopy. The imagery group's surgical performance assessment was 15.9% significantly higher than controls ($p = 0.03$). In addition, residents considered mental imagery to be a more useful preoperative preparation. Two additional studies using mental imagery to teach medical students demonstrated similar results. Medical students who used mental imagery techniques had at least equivalent and sometimes superior results when compared to traditional methods of learning new skills.

Despite evidence to support its usefulness, the exact role of mental imagery in surgical training has yet to be clearly defined, and there is no ideal way to use this technique. Based on prior research, mental practice is most effective when the learner is familiar with the task and the actual performance immediately follows the imagery session. Novice surgeons could use this technique in preparation for an “actual” surgery by reviewing details of an entire surgical procedure with the appropriate hand movements for the operation. Thus, this approach may offer a less expensive, efficient, and ethical way for a surgeon to acquire a new skill before operating on a “live” patient.

WEB-BASED LEARNING

In recent years, Web-based learning has become an emerging technology for learning and teaching surgical skills. This online learning environment includes access to videos as well as live surgeries viewed remotely. These resources support the learner-centered teaching approach, facilitating interactions with experts and with other learners. The availability of online surgical videos provides a useful resource that complements the more traditional options, including textbooks and case observation. However, the quality of materials available on the Internet is variable, and the materials available are typically not subject to peer review. Despite these limitations, Webbased learning may be a valuable resource for more seasoned surgeons interested in obtaining knowledge about a newer procedure or technique. In fact, most webcasts are created for surgeons already familiar with certain aspects of a surgical procedure or basic technical skills; surgical webinars provide an opportunity for these surgeons to interact live with an expert surgeon and may be the catalyst for a surgeon to seek more formal training.

TEACHING IN THE OPERATING ROOM

Simulation training and other surgical educational opportunities only complement traditional surgical educational experience (in operating room learning) but cannot replace it. The operating room is obviously a unique educational setting for several key reasons; first it can be a very high-stress environment for surgical educators and learners alike given the concern for providing an optimal surgical outcome in a safe, controlled, and efficient manner. In addition, it provides the teacher and learner with uninterrupted time together, and this time can and should be used for clinical teaching and learning. Operating room teaching should be similar to other structured learning activities in which key learning objectives and goals for the learner are reviewed prior to case. It is not acceptable or ethical for novice surgeon to learn a “new” technical skill without supervision. Dr. Roberts et al. emphasized the importance of deliberate and guided instruction in the operating room. The authors refer to this teaching method as “briefing, intraoperative teaching, and debriefing” or BID. The educational framework for this teaching begins with the “briefing” component before the surgery at the scrub sink; with a short interaction between the surgical educator and the learner assessing the needs of the learner and identifying mutual learning objectives. It is important that the learner is active in this process because it encourages the learner to reflect on areas that may need improvement (from previous surgeries) and formulate needs to be addressed in the current surgery. The “intraoperative teaching” should involve coaching and guiding the learner through the surgery, but the didactics or “teaching script” used during the operation should focus on the preestablished learning objectives. This more tailored approach is to avoid overloading the learner with too much information, which then becomes difficult to apply to future practice. The “debriefing” should occur at the end of the procedure and concentrate on

P.85

four areas of discussion: reflection, rules, reinforcement, and correction. Details about this process are discussed later in the chapter.

Surgical educational researchers have consistently identified certain principles of effective intraoperative teaching: They include

explaining reasons behind decisions, providing clear answers to questions, involving learners (letting them “actually operate”) with direct supervision, and providing feedback without belittling.

SURGICAL SKILLS ASSESSMENTS

Assessment is the process of measuring a trainee's knowledge, skills, judgment, or professional behavior against defined standards. Ideally, the assessment tool should be objective, reliable, and reproducible. Assessment can have different and multiple purposes, including aiding learning through constructive feedback, measuring progress over time, and/or determining a level of competence.

There are distinct differences between constructive feedback and evaluation of surgical skills. Ideally, in order for feedback to be most effective, it should be performed in a timely fashion; however, this can be a challenge for “in operating room” learning experiences. If time permits, the feedback should be given immediately after the surgical case or at the conclusion of the surgery day through a “debriefing process.” This is a systematic process of providing constructive feedback with the focus on changing or reinforcing surgical techniques, motivating the learner, and encouraging self-assessment. The feedback is direct and specific and gives the learner direction for improvement. Some of the initial questions asked of the learner such as “How do you think you did performing the vaginal hysterectomy?” “What part of the case went well?” and “What part of the case could have gone better?” can help facilitate the discussion. More specific questions about certain steps of a procedure, for example, “How do you think you did entering the posterior culde-sac?,” may help the learner identify a particular deficiency and methods to improve their skills. It is through this process that novice surgeons become more comfortable with selfassessment. Self-evaluation can be difficult because it requires surgeons to admit to knowledge or skill deficits. However, an objective critique of one's own surgical performance is beneficial to both novice and experienced surgeons and is the first key step in learning from past mistakes to advance as a surgeon.

When providing constructive feedback, “how” something is said is often just as important as “what” is said; Fenner encourages surgical educators to adhere to some basic rules when giving feedback. Some of the dos and don'ts that we follow at our institution are listed in [Table 6.3](#).

TABLE 6.3 The “Dos” and “Don'ts” of Feedback

DOS	DON'TS
Be descriptive, rather than elusive	Embarrass the learner
Be specific, rather than general	Give too much feedback at one time
Focus on behavior, rather than personality	Create a negative environment
Focus on modifiable issues	
Time the interaction	
Listen to the learner	
Follow up	

It should be the goal of both surgical educators and learners to foster an environment of constructive feedback, which means that giving feedback should be routinely performed and unsolicited. However, if it is not routine practice for the surgical educator to provide this constructive assessment, then it becomes the responsibility of the learner to seek this feedback.

Traditionally, formal evaluation of surgical skills is performed in the operating room with direct observation of a trainee's surgical performance by the supervising attending. Although this has been the standard evaluation process, studies have shown that an unstructured assessment using direct observation has limited reliability as an assessment method. In fact, one of the major issues with this approach is that the observation itself is not wholly successful and may be based on indirect observation or incomplete direct observation. In addition, this strategy is subjective and may be biased by factors such as the evaluator's prior knowledge of

the trainee and the outcome of the surgery. Recognition of these limitations has led to a search for more valid methods of evaluating surgical skills.

The Objective Structured Assessment of Technical Skills (OSATS) is an examination in which subjects perform standardized surgical procedures while being evaluated by an expert surgeon. The assessment is based on a task-specific checklist in which all important steps of a procedure are identified and a mark is assigned for every step the candidate completes correctly. Using a 10-point scale, it grades the trainee on seven important elements of any operation, concerning a combination of skill-based, rule-based, and knowledge-based behaviors: (a) respect for tissue, (b) time and motion, (c) instrument handling, (d) knowledge of instruments, (e) use of assistants, (f) flow of operation, and (g) knowledge of the procedure. Studies have repeatedly demonstrated the reliability and validity of this assessment tool. Through the use of specialty-specific OSATS in an obstetrics and gynecology residency program, researchers have also determined that evaluators could assess their own residents as reliably as an evaluator who did not know the resident. An OSATS can also be used to evaluate a specific curriculum.

An alternative to the evaluation of the explicit steps of the procedure is the rating of general technical skill. The Global Rating Index for Technical Skills (GRITS) (Table 6.4) is a valid and reliable assessment tool, created to provide a defensible and practical evaluation of resident's surgical skills. The GRITS was based on Global Rating Scales (GRS) previously validated in the setting of OSATS and the Global Operative Assessment of Laparoscopic Skills. The GRITS consists of 9 items, each scored from 1 to 5. These items were selected to be general markers of technical skill, rather than procedure-specific steps. Therefore, the GRITS tool could be applied to a wide variety of procedures without modification. Two items applied only to laparoscopic cases.

More recently, procedure-specific assessment tools have been created for gynecology. For example, the Vaginal Surgical Skills Index (VSSI) (Table 6.5) is a reliable and valid instrument to assess vaginal surgical skills. In a study conducted at two academic medical centers, trainees were directly assessed in the operating room by supervising surgeons while performing a vaginal hysterectomy. Assessment tools for this research included the VSSI, a GRS, and a visual analogue scale used to measure the trainees' overall surgical performance. Trainees were assessed again by the same surgeons 4 weeks after the live surgery and by a blinded outside reviewer using a videotape of the case. The researchers determined that VSSI scores correlated with global rating score and visual analogue scale scores. A higher VSSI score indicates better performance, and increasing VSSI scores significantly correlated with year of training and surgical volume (with an estimated increase in score of 0.3 per hysterectomy performed).

TABLE 6.4 Modified Global Rating Index for Technical Skills

1. Respect for tissue:				
1	2	3	4	5
(Novice) Frequently used unnecessary force on tissue or caused damage by inappropriate use of instruments		(Competent) Careful handling of tissue but occasionally caused inadvertent damage		(Fully independent) Consistently handled tissues appropriately with minimal damage
2. Time and motion:				
1	2	3	4	5
Many unnecessary moves		Efficient time/motion but some unnecessary moves		Clear economy of movement and maximum efficiency
3. Instrument handling:				
1	2	3	4	5

Repeatedly makes tentative or awkward moves with instruments by inappropriate use of instruments		Competent use of instruments but occasionally appeared stiff or awkward		Fluid moves with instruments and no awkwardness
<i>4. Knowledge of instrument:</i>				
1	2	3	4	5
Frequently asked for wrong instrument or used inappropriate instrument		Knew names of most instruments and used appropriate instrument		Obviously familiar with the instruments and their names
<i>5. Flow of operation:</i>				
1	2	3	4	5
Frequently stopped operating and seemed unsure of next move		Demonstrated some forward planning with reasonable progression of procedure		Obviously planned course of operating with effortless flow from one move to the next
<i>6. Use of assistants:</i>				
1	2	3	4	5
Consistently placed assistants poorly or failed to use assistants		Appropriate use of assistants most of the time		Strategically used assistants to the best advantage at all times
<i>7. Knowledge of specific procedure:</i>				
1	2	3	4	5
Deficient knowledge. Needed specific instructions at most steps		Knew all important steps of operation		Demonstrated familiarity with all aspects of operation
<i>8. Depth perception</i>				
1	2	3	4	5
Constantly overshoot, swings wide, slow correction		Some overshooting but quick to correct		Accurately directs instruments in correct plane
<i>9. Bimanual dexterity</i>				
1	2	3	4	5
Uses only one hand, poor coordination between hands		Uses both hands but does not optimize their interaction		Expertly uses both hands to provide optimal exposure

10. Does the trainee demonstrate competency to perform this procedure independently? (circle one)	Yes	No			
11. Overall, how prepared do you think you were for this procedure? (circle one):					
1	2	3	4	5	
Not at all prepared	Somewhat prepared	Adequately prepared	Very well prepared	Extremely prepared

TABLE 6.5 Vaginal Surgical Skills Index

Trainee's Name:		Date of Operation:				
Procedure(s) the trainee performed:		Proportion of the procedure(s) that the trainee performed:				
1. _____		≤50% or 50%				
2. _____		≤50% or 50%				
3. _____		≤50% or 50%				
Please evaluate each trainee according to the criteria below and check the box that most corresponds to his or her performance.						
1. Initial inspection (check one)	0	1	2	3	4	Not observed
	Incomplete and unsystematic inspection of relevant pelvic and vaginal structures	Partially complete and unsystematic inspection of relevant pelvic and vaginal structures	Complete but unsystematic inspection of relevant pelvic and vaginal structures	Complete and somewhat systematic inspection of relevant pelvic and vaginal structures	Systematic and complete assessment of relevant pelvic and vaginal structures	
2. Incision (check one)	0	1	2	3	4	Not observed
	Does not perform appropriate incision(s)	Incompletely performs appropriate incision(s)	Performs appropriate incision(s) safely but	Performs appropriate incision(s) safely and	Performs appropriate incision(s) safely and	

	safely and does not use incision(s) effectively ensuring optimal exposure	safely and does not use incision(s) effectively ensuring optimal exposure	does not use incision(s) effectively ensuring optimal exposure	partially uses incision(s) effectively ensuring optimal exposure	uses incision(s) effectively ensuring optimal exposure	
3. Maintenance of visibility (check one)	0	1	2	3	4	Not observed
	Almost never or never obtains appropriate exposure	A few times (less than half the time) obtains appropriate exposure	Sometimes (about half the time) obtains appropriate exposure	Most time (more than half the time) obtains appropriate exposure	Almost always or always obtains appropriate exposure	
4. Use of assistants (check one)	0	1	2	3	4	Not observed
	Almost never or never strategically used assistant(s) to the best advantage	A few times (less than half the time) strategically uses assistant(s) to the best advantage	Sometimes (about half the time) strategically uses assistant(s) to the best advantage	Most time (more than half the time) strategically uses assistant(s) to the best advantage	Almost always or always strategically uses assistant(s) to the best advantage at all times	
5. Knowledge of instruments (check one)	0	1	2	3	4	Not observed
	Almost never or never uses and is familiar with correct instruments	A few times (less than half the time) uses and is familiar with correct instruments	Sometimes (about half the time) uses and is familiar with correct instruments	Most time (more than half the time) uses and is familiar with correct instruments	Almost always or always uses and is familiar with correct instruments	
6. Tissue and instrument handling (check one)	0	1	2	3	4	Not observed
	Almost never or never appropriately handles tissue and instruments	A few times (less than half the time) appropriately handles tissue and	Sometimes (about half the time) handles tissue and instruments	Most time (more than half the time) handles tissue and instruments	Almost always or always handles tissue and instruments appropriately	

		instruments	appropriately	appropriately		
7. Electrosurgery (check one)	0	1	2	3	4	Not observed
	Almost never or never uses electrosurgery safely and efficiently	A few times (less than half the time) uses electrosurgery safely and efficiently	Sometimes (about half the time) uses electrosurgery safely and efficiently	Most time (more than half the time) uses electrosurgery safely and efficiently	Almost always or always uses electrosurgery safely and efficiently	
8. Knot tying/ligation (check one)	0	1	2	3	4	Not observed
	Almost never or never quickly and correctly performs suture ligation and knot tying	A few times (less than half the time) quickly and correctly performs suture ligation and knot tying	Sometimes (about half the time) quickly and correctly performs suture ligation and knot tying	Most time (more than half the time) quickly and correctly performs suture ligation and knot tying	Almost always or always quickly and correctly performs suture ligation and knot tying	
9. Hemostasis (check one)	0	1	2	3	4	Not observed
	Almost never or never exposes bleeders and uses correct technique to obtain hemostasis safely and effectively	A few times (less than half the time) exposes bleeders and uses correct technique to obtain hemostasis safely and effectively	Sometimes (about half the time) exposes bleeders and uses correct technique to obtain hemostasis safely and effectively	Most time (more than half the time) exposes bleeders and uses correct technique to obtain hemostasis safely and effectively	Almost always or always exposes bleeders and uses correct technique to obtain hemostasis safely and effectively	
10. Procedure completion (check one)	0	1	2	3	4	Not observed
	Almost never or never completely removes fluid and debris and thoroughly inspects for bleeding	A few times (less than half the time) completely removes fluid and debris and thoroughly inspects for bleeding	Sometimes (about half the time) completely removes fluid and debris and thoroughly inspects for bleeding	Most times (more than half the time) completely removes fluid and debris and thoroughly inspects for bleeding	Almost always or always completely removes fluid and debris and thoroughly inspects for bleeding	

11. Time and motion (<i>check one</i>)	0	1	2	3	4	Not observed
	Almost never or never efficiently performs movements with no awkward or unnecessary moves	A few times (less than half the time) efficiently performs movements with no awkward or unnecessary moves	Sometimes (about half the time) efficiently performs movements with no awkward or unnecessary moves	Most time (more than half the time) efficiently performs movements with no awkward or unnecessary moves	Almost always or always efficiently performs movements with no awkward or unnecessary moves	
12. Flow of operation and forward planning (<i>check one</i>)	0	1	2	3	4	Not observed
	Almost never or never demonstrates forward planning allowing for proper flow of the procedure	A few times (less than half the time) demonstrates forward planning allowing for proper flow of the procedure	Sometimes (about half the time) demonstrates forward planning allowing for proper flow of the procedure	Most time (more than half the time) demonstrates forward planning allowing for proper flow of the procedure	Almost always or always demonstrates forward planning allowing for proper flow of the procedure	
13. Knowledge of specific procedure (<i>check one</i>)	0	1	2	3	4	Not observed
	Almost never or never demonstrates familiarity with all aspects of the operation	A few times (less than half the time) demonstrated familiarity with all aspects of the operation	Sometimes (about half the time) demonstrates familiarity with all aspects of the operation	Most time (more than half the time) demonstrates familiarity with all aspects of the operation	Almost always or always demonstrates familiarity with all aspects of the operation	
Comments:						

Simulation of surgical skills seems to offer an opportunity for a structured assessment of technical proficiency. Simulation exercises could potentially complement knowledge assessments, such as professional board examinations. However, the value of simulation-based assessment has not yet gained wide acceptance. An exception is in the board certification process for general surgeons. Since 2008, candidates for the American Board of Surgeons certification process have been required to complete the Fundamentals of Laparoscopic Surgery course, including a simulation exercise. Surgeons are not eligible for board certification until they have successfully completed this curriculum. This provides a potential model for the incorporation of surgical simulation exercises into the credentialing process.

In the future, credentialing bodies may require surgeons to demonstrate technical proficiency in a simulation environment. However, for such an assessment to be used in the assessment of surgeon quality, it would be necessary to demonstrate its construct validity, as well as the ability of raters to provide reproducible and consistent assessments of performance. In addition, members of the profession would have to agree that the tasks included in such an assessment are critical to surgical performance and representative of critical tasks in clinical practice. Nevertheless, this type of assessment seems desirable and potentially could play a role in a more comprehensive evaluation of surgeon proficiency.

At the present time, there is not a standard evaluation process for assessing surgeons as they progress through training, and the number of evaluations needed to determine competency in surgery has yet to be determined. Training programs are given guidance from the Accreditation Council for Graduate Medical Education (ACGME) with regard to the type of surgical cases residents should perform, and recently, the Residency Review Committee for Obstetrics and Gynecology has established minimal thresholds for surgical procedures at the residency level. However, ACGME notes that the achievement of the minimum numbers of listed procedures does not signify achievement of an individual resident's competence in a particular listed procedure. Therefore, each program is charged with the task of determining how, what, when, and how often residents need to have their surgical skills evaluated. The ACGME provides Reznick's GRS as an assessment instrument for evaluating surgical skills. Some surgical training programs have chosen to use a combination of structured simulation assessments, as well as global and procedure-specific evaluation tools. When and how often a learner is assessed is also variable; while some institutions require formal evaluation after every procedure, other programs only evaluate when a resident or fellow believes that he/she has achieved "competency" for a certain procedure and requests an assessment or at the end of a rotation. Also, it is not known how many surgeries are required before a surgeon becomes "competent" and can perform that particular surgery independently. Thus, residency requirements for surgical volume are not evidence based; there is limited evidence in the literature about the optimal number of cases needed to achieve or maintain competence. A study performed to establish minimum cutoff scores for intraoperative assessments using both the GRS and VSSI determined on average, trainees met cutoffs for competency after performing 21 and 27 vaginal hysterectomies, respectively. Obviously, more studies are needed to determine if an "ideal number" exists, given the variation of learning styles and that some surgical trainees acquire technical skills faster than others.

CHALLENGES IN SURGICAL EDUCATION

The challenges in resident surgical education include shrinking resources for the training of residents as well as an expanding variety of surgeries in the gynecologic armamentarium. Residents must master an increasing number of surgeries within a 4-year curriculum. For example, as the number of hysterectomies performed in the United States continues to decrease, the variety of approaches to hysterectomy has increased. Traditionally, gynecologists performed abdominal and vaginal hysterectomies. However, current practice also includes laparoscopic-assisted vaginal hysterectomy, total (and subtotal) laparoscopic hysterectomy, and robotic hysterectomy. The skills required for one of these approaches may not translate into proficiency with the alternative approaches. Thus, it is a challenge for a gynecologic resident to acquire adequate experience in all of these techniques during a 4-year residency.

Our profession also faces a challenge in the development of training options for practicing gynecologists who wish to expand their areas of expertise or to master a new surgical technique. Currently, there are limited opportunities for the acquisition of new surgical skills after residency. New techniques may be discussed at a postgraduate course, sometimes with an opportunity to practice on an inanimate model or in a cadaver laboratory. However, it is not obvious that this type of training translates into the effective mastery of a new skill or the successful incorporation of new skills into technical practice. Hospitals face the challenge of determining when an established surgeon should be considered sufficiently proficient as to allow surgical privileges. In addition, there are limited avenues for retraining surgeons who have been out of the profession for a period of time and for those who require remediation. Outside of a traditional residency training environment, such surgical "retraining" and proctoring raise a number of very complicated ethical, legal, and economic issues. Nevertheless, to insure that all women have access to expert surgical care, our profession must develop strategies for evaluating and monitoring surgical proficiency after the completion of residency training.

FUTURE DIRECTIONS

Apprenticeship Model to Structured Curriculum

Due in part to the increasing evidence that the traditional model of surgical education is not sufficient and due also to increasing concerns about the impact of work hour restrictions on surgical experience, more teaching institutions are augmenting operating room experience with a formal surgical curriculum. More than a decade ago, only 29% of US obstetrics and gynecology residency programs provided a formal surgical curriculum. In contrast, a more recent survey of obstetriciangynecologist residencies indicated that more than two thirds had created some type of formal surgical curriculum. Of those, 62% had developed a curriculum

specifically for laparoscopic skills. In addition, an increasing number of residency programs were using validated assessment tools for evaluating surgical skills.

Developing a formal surgical curriculum across residency programs would require a consensus about several key issues, including how and when skills are taught, which tasks are the most critical, and how to accurately assess competency. To avoid the inconsistencies inherently associated with training surgeons using the traditional apprenticeship model, a surgical curriculum cannot rely solely on “in operating room” surgical

P.91

experiences. The ideal curriculum would augment operating room learning opportunities with a combination of lectures and simulation activities (possibly including bench models, animal laboratory, and/or computer simulation). Surgical simulation should have a strong focus on the acquisition, refinement, and formal assessment of fundamental surgical skills. Incorporating simulation models into residency and fellowship training will provide a safe, low-stress environment in which students can gain surgical skills and receive constructive feedback.

CONCLUSION

Surgical education continues to evolve through the standardization of surgical training, competency-based assessments, and evidence-based educational research. The historical teaching adage of “see one, do one, teach one” will soon be replaced with the new surgical teaching adage of “read about and see several,” “do many first in a simulated environment with assessment” before operating room experience, and “teach using effective and constructive feedback.” However, it is important to note that the mastery of surgical technical skills, which has been the focus of this chapter, is just one component of surgical competence. Training the gynecologic surgeon requires that we not only focus on the acquisition of clinical and technical skills but the development of surgeons with sound decision-making abilities, communication, leadership, and surgical skills capable of educating the next generation of surgeons.

BEST SURGICAL PRACTICES

- Although the regulatory agencies have created some guidelines for education in the surgical specialties, there is considerable latitude for optimization of the educational experience.
- Training the gynecologic surgeon should be based on evidence-based educational research and a structured curriculum to assure acquisition, refinement, and formal assessment of fundamental surgical skills.

Chapter 7

Surgical Anatomy of the Female Pelvis

John O.L. DeLancey

DEFINITIONS

Endopelvic fascia—The endopelvic fascias are those tissues outside of the muscularis of the pelvic organs that attach these organs to the pelvic sidewall. There is also some extension of loose areolar tissue over the surfaces of the organ. The surgical fascia used by gynecologists during pelvic reconstructive surgery, however, is primarily composed of the muscularis of the vaginal wall.

Pelvic diaphragm—The term *pelvic diaphragm* refers to the levator ani muscle and its covering fasciae, both the superior fascia and the inferior fascia. The term *pelvic floor* refers to all of the supportive structures that are involved with pelvic organ support. Sometimes the term *pelvic floor* and *pelvic diaphragm* can be used interchangeably, especially in the British literature.

Pelvic spaces—The space between the bladder and the anterior portion of the pelvic walls is the perivesical space or space of Retzius. The space between the lower urinary tract and the genital tract is the vesicovaginal or vesicocervical space. This is bounded laterally by the “bladder pillars,” which is the region in which the tissues that go to the vagina separate from those that go to the bladder base. The rectovaginal space lies between the posterior vaginal wall and the anterior surface of the rectum, and lies primarily above the top of the perineal body.

Urethra and vesicle neck—The urethra is that portion of the lower urinary tract outside of the bladder that the urethral lumen traverses. That portion of the urethra lumen that is surrounded by the bladder vasculature is referred to as the vesicle neck.

Urinary trigone—The urinary trigone is a triangular visible area in the bladder, the apices of which are the ureteral orifices and the internal urinary meatus. This is a layer of smooth muscle connecting the ureters and the urethra, the edges of which are visible cystoscopically and when the bladder is open.

VULVA AND ERECTILE STRUCTURES

The bony pelvic outlet is bordered by the ischiopubic rami anteriorly and the coccyx and sacrotuberous ligaments posteriorly. It can be divided into anterior and posterior triangles, which share a common base along a line between the ischial tuberosities. The tissues filling the anterior triangle have a layered structure similar to that of the abdominal wall ([Table 7.1](#)). There is a skin and adipose layer (vulva) overlying a fascial layer (perineal membrane) that lies superficial to a muscular layer (levator ani muscles).

Subcutaneous Tissues of the Vulva

The structures of the vulva lie on the pubic bones and extend caudally under the pubic arch ([Fig. 7.1](#)). They consist of the mons, labia, clitoris, vestibule, and associated erectile structures and their muscles. The mons consists of hair-bearing skin over a cushion of adipose tissue that lies on the pubic bones. Extending posteriorly from the mons, the labia majora are composed of similar hair-bearing skin and adipose tissue, which contain the termination of the round ligaments of the uterus and the obliterated processus vaginalis (canal of Nuck). The round ligament can give rise to leiomyomas in this region, and the obliterated processus vaginalis can be a dilated embryonic remnant in the adult.

The labia minora, vestibule, and glans clitoris can be seen between the two labia majora. The labia minora are hairless skin folds, each of which splits anteriorly to run over, and under, the glans of the clitoris. The more anterior folds unite to form the hood-shaped prepuce of the clitoris, whereas the posterior folds insert into the underside of the glans as the frenulum.

Unlike the skin of the labia majora, the cutaneous structures of the labia minora and vestibule do not lie on an adipose layer but on a connective tissue stratum that is loosely organized and permits mobility of the skin during intercourse. This loose attachment of the skin to underlying tissues allows the skin to be easily dissected off the underlying fascia during skinning vulvectomy in the area of the labia minora and vestibule.

In the posterior lateral aspect of the vestibule, the duct of the major vestibular gland can be seen 3 to 4 mm outside

P.94

the hymenal ring. The minor vestibular gland openings are found along a line extending anteriorly from this point, parallel to the hymenal ring and extending toward the urethral orifice. The urethra bulges slightly around the surrounding vestibular skin anterior to the vagina and posterior to the clitoris. Its orifice is flanked on either side by two small labia. Skene ducts open into the inner aspect of these labia and can be seen as small, punctate openings when the urethral labia are separated.

Within the skin of the vulva are specialized glands that can become enlarged and thereby require surgical removal. The holocrine sebaceous glands in the labia majora are associated with hair shafts, and in the labia minora, they are freestanding. They lie close to the surface, which explains their easy recognition with minimal enlargement. In addition, lateral to the introitus and anus, there are numerous apocrine sweat glands, along with the normal eccrine sweat glands. The former structures undergo change with the menstrual cycle, having increased secretory activity in the premenstrual period. They can become chronically infected, as in hidradenitis suppurativa, or neoplastically enlarged, as in hidradenomas, both of which may require surgical therapy. The eccrine sweat glands in the vulvar skin rarely present abnormalities, but on occasion form palpable masses as syringomas.

The subcutaneous tissue of the labia majora is similar in composition to that of the abdominal wall. It consists of lobules of fat interlaced with connective tissue septa. Although there are no well-defined layers in the subcutaneous tissue, regional variations in the relative quantity of fat and fibrous tissue exist. The superficial region of this tissue, where fat predominates, has been called Camper fascia, as it is on the abdomen. In this region, there is a continuation of fat from the anterior abdominal wall, called the digital process of fat.

In the deeper layers of the vulva, there is less fat, and the interlacing fibrous connective tissue septa are much more evident than those in Camper fascia. This more fibrous layer is called Colles fascia and is similar to Scarpa fascia on the abdomen. Its interlacing fibrous septa of the subcutaneous tissue attach laterally to the ischiopubic rami and fuse posteriorly with the posterior edge of the perineal membrane (i.e., urogenital diaphragm).

Anteriorly, however, there is no connection to the pubic rami, and this permits communication between the area deep to this layer and the abdominal wall. These fibrous attachments to the ischiopubic rami and the posterior aspect of the perineal membrane limit the spread of hematomas or infection in this compartment posterolaterally but allow spread into the abdomen. This clinical observation has led to the consideration of Colles fascia as a separate entity from the superficial Camper fascia, which lacks these connections.

Superficial Compartment

The space between the subcutaneous tissues and perineal membrane, which contains the clitoris, crura, vestibular bulbs, and ischiocavernosus and bulbocavernosus muscles, is called the superficial compartment of the perineum (**Fig. 7.2**). The deep compartment is the region just above the perineal membrane; it is discussed later.

The erectile bodies and their associated muscles within the superficial compartment lie on the caudal surface of the perineal membrane. The clitoris is composed of a midline shaft (body) capped with the glans. This shaft lies on, and is suspended from, the pubic bones by a subcutaneous suspensory ligament. The paired crura of the clitoris bend downward from the shaft and are firmly attached to the pubic bones, continuing dorsally to lie on the inferior aspects of the pubic rami. The ischiocavernosus muscles originate at the ischial tuberosities and the free surfaces of the crura to insert on the upper crura and body of the clitoris. A few muscle fibers, called the superficial transverse perineal muscles, originate in common with the ischiocavernosus muscle from the ischial tuberosity and lie medial to the perineal body.

The paired vestibular bulbs lie immediately under the vestibular skin and are composed of erectile tissue. They are covered by the bulbocavernosus muscles, which originate in the perineal body and lie over their lateral surfaces. These muscles, along with the ischiocavernosus muscles, insert into the body of the clitoris and act to pull it downward.

The Bartholin greater vestibular gland is found at the tail end of the bulb of the vestibule and is connected to the vestibular mucosa by a duct lined with squamous epithelium. The gland lies on the perineal membrane and beneath the bulbocavernosus muscle. The intimate relation between the enormously vascular erectile tissue of the vestibular bulb and the Bartholin gland is responsible for the hemorrhage associated with removal of this latter structure.

The perineal membrane and perineal body are important to the support of the pelvic organs. They are discussed in the section on the pelvic floor.

Pudendal Nerve and Vessels

The pudendal nerve is the sensory and motor nerve of the perineum. Its course and distribution in the perineum parallel the pudendal artery and veins that connect with the internal iliac vessels (**Fig. 7.3**). The course and division of the nerve are described with the understanding that the vascular channels parallel them.

The pudendal nerve arises from the sacral plexus (S2-S4), and the vessels originate from the anterior division of the internal iliac artery. They leave the pelvis through the greater sciatic foramen by hooking around the ischial spine and sacrospinous ligament to enter the pudendal (Alcock) canal through the lesser sciatic foramen.

FIGURE 7.2 Superficial compartment and perineal membrane.

FIGURE 7.3 Pudendal nerve and vessels, with the position of the ischioanal fossa (*asterisk*) and the perineal body (*x*) indicated. (From Anson BJ. *An atlas of human anatomy*. Philadelphia, PA: WB Saunders, 1950, with permission.)

P.96

The nerve and vessels have three branches: the clitoral, perineal, and inferior hemorrhoidal. The clitoral branch lies on the perineal membrane along its path to supply the clitoris. The perineal branch (the largest of the three branches) enters the subcutaneous tissues of the vulva behind the perineal membrane. Here, it supplies the bulbocavernosus, ischiocavernosus, and transverse perineal muscles. It also supplies the skin of the inner portions of the labia majora, labia minora, and vestibule. The inferior hemorrhoidal branch goes to the external anal sphincter and perianal skin.

Lymphatic Drainage

The pattern of the vulvar lymphatic vessels and drainage into the superficial inguinal group of lymph nodes has been established by both injection studies and clinical observation. It is important to the treatment of vulvar malignancies; an overview of this system is provided here. This area is described and illustrated in more detail in [Chapter 33](#).

Tissues external to the hymenal ring are supplied by an anastomotic series of vessels in the superficial tissues that coalesce to a few trunks lateral to the clitoris and proceed laterally to the superficial inguinal nodes ([Fig. 7.4](#)). The vessels draining the labia majora also run in an anterior direction, lateral to those of the labia minora and vestibule. These lymphatic channels lie medial to the labiocrural fold, establishing it as the lateral border of

surgical resection.

Injection studies of the urethral lymphatics have shown that lymphatic drainage of this region terminates in either the right or left inguinal nodes. The clitoris has been said to have some direct drainage to deep pelvic lymph nodes, bypassing the usual superficial nodes, but the clinical significance of this appears to be minimal.

The inguinal lymph nodes are divided into two groups—the superficial and the deep nodes. There are 12 to 20 superficial nodes, and they lie in a T-shaped distribution parallel to and 1 cm below the inguinal ligament, with the stem extending down along the saphenous vein. The nodes are often divided into four quadrants, with the center of the division at the saphenous opening. The vulvar drainage goes primarily to the medial nodes of the upper quadrant. These nodes lie deep in the adipose layer of the subcutaneous tissues, in the membranous layer, just superficial to the fascia lata.

FIGURE 7.4 Lymphatic drainage of the vulva and femoral triangle. Superficial inguinal nodes are shown in the right thigh, and deep inguinal nodes are shown in the left thigh. Fascia lata has been removed on the left.

The large saphenous vein joins the femoral vein through the saphenous opening. Within 2 cm of the inguinal ligament, several superficial blood vessels branch from the saphenous vein and femoral artery. They include the superficial epigastric vessels that supply the subcutaneous tissues of the lower abdomen; the superficial circumflex iliac vessels that course laterally to the region of the iliac crest; and the superficial external pudendal vessels that supply the mons, labia majora, and clitoral hood.

Lymphatics from the superficial nodes enter the fossa ovalis and drain into one to three deep inguinal nodes, which lie in the femoral canal of the femoral triangle. They pass through the fossa ovalis (saphenous opening) in the fascia lata, which lies approximately 3 cm below the inguinal ligament, lateral to the pubic tubercle, along with the saphenous vein on its way to the femoral vein. The membranous layer of the subcutaneous tissues spans this opening as a trabeculate layer called a fascia cribrosa, pierced by lymphatics. The deep nodes are found under this fascia in the femoral triangle.

The femoral triangle is the subfascial space of the upper one third of the thigh. It is bounded by the inguinal ligament, sartorius muscle, and adductor longus muscle. Its floor is formed by the pectineal, adductor longus, and iliopsoas muscles. The femoral artery bisects it vertically between the anterosuperior iliac spine and pubic tubercle. The femoral vein lies medial to the artery; the femoral nerve is lateral to it.

As these vessels pass under the inguinal ligament, they carry with them an extension of the transversalis fascia, which is the extraperitoneal connective tissue deep to the rectus abdominis muscle called the femoral sheath. These sheaths extend about 2 to 3 cm below the inguinal ligament before fusing with the vascular adventitia. Besides the two parts of the femoral sheath that accompany these vessels, a third portion—the femoral canal—can be found in the space medial to the vein. The abdominal opening of this is the femoral ring. The femoral canal contains the deep inguinal lymph nodes. Lymph channels from these nodes pierce the membrane, filling the femoral ring to communicate with the external iliac nodes. Also within this region, the femoral vessels give rise to the deep external pudendal vessels. The external pudendal vessels run deep to the femoral vein over the pectineal muscle to pierce the fascia lata. Here, they become subcutaneous and form anastomoses

P.97

with branches of the internal pudendal vessels as well as the deep femoral and lateral circumflex femoral arteries.

THE PELVIC FLOOR

When humans assumed the upright posture, the opening in the bony pelvis came to lie at the bottom of the abdominopelvic cavity. This required the evolution of a supportive system to prevent the pelvic organs from being pushed downward through this opening. In the woman, this system must withstand these downward forces but allow for the passage of the large and cranially dominant human fetus. The supportive system that has evolved to meet these needs consists of a fibromuscular floor that forms a shelf spanning the pelvic outlet and that contains a cleft for the birth canal and excretory drainage. A series of visceral ligaments and fasciae tethers the organs and maintains their position over the closed portions of the floor. The floor consists of the levator ani muscles and perineal membrane. The openings in these structures for parturition and elimination have required the development of ancillary fibrous elements that are concentrated over open areas in the muscular floor to support the viscera in these weak areas. This section discusses the structures of the pelvic floor; the fibrous supportive system is described in the section on the pelvic viscera and cleavage planes and fascia.

Perineal Membrane (Urogenital Diaphragm)

The perineal membrane forms the inferior portion of the anterior pelvic floor. It is a triangular sheet of dense, fibromuscular tissue that spans the anterior half of the pelvic outlet (**Fig. 7.2**). It was previously called the urogenital diaphragm, and this change in name reflects the appreciation that it is not a two-layered structure with muscle in between, as was previously thought. It lies just caudal to the skeletal muscle of the striated urogenital sphincter (formerly the deep transverse perineal muscle). Because of the presence of the vagina, the perineal membrane cannot form a continuous sheet to close off the anterior pelvis in the woman, as it does in the man. It does provide support for the posterior vaginal wall by attaching the perineal body and vagina and perineal body to the ischiopubic rami, thereby limiting their downward descent. This layer of the floor arises from the inner aspect of the inferior ischiopubic rami above the ischiocavernosus muscles and the crura of the clitoris. The medial attachments of the perineal membrane are to the urethra, walls of the vagina, and perineal body.

FIGURE 7.5 Structures visible after removal of the perineal membrane and superficial perineal muscles. (Copyright 1995 John O. L. DeLancey, with permission.)

Just cephalad to the perineal membrane lie two archshaped muscles that begin posteriorly to arch over the urethra (**Fig. 7.5**). These are the compressor urethral and the urethrovaginal sphincters. They are a part of the striated urogenital sphincter muscle in the woman and are continuous with the sphincter urethrae muscle. They act to compress the distal urethra. Posteriorly, intermingled within the membrane are skeletal muscle fibers of the transverse vaginal muscle and some smooth muscle fibers. The dorsal and deep nerve and vessels of the clitoris are also found within this membrane and are described later.

The primary function of the perineal membrane is related to its attachment to the vagina and perineal body. By attaching these structures to the bony pelvic outlet, the perineal membrane supports the pelvic floor against the effects of increases in intra-abdominal pressure and against the effects of gravity. The pubococcygeal and puborectal portions of the levator ani muscles lie just at the upper margin of the perineal membrane contacting its cranial surface. Contraction of these muscles elevates the medial margin of the perineal membrane along with the vagina and relaxation allows for its caudal movement. The amount of downward descent that is permitted by the connections of the perineal membrane to the midline structures can be assessed during an examination under anesthesia by placing a finger in the rectum, hooking it forward, and gently pulling the perineal body downward. If the perineal membrane has been torn during parturition, then an abnormal amount of descent is detectable, and the pelvic floor sags and the introitus gapes.

Perineal Body

Within the area bounded by the lower vagina, perineal skin, and anus is a mass of connective tissue called the perineal body (**Fig. 7.3**). The term *central tendon of the perineum* has also been applied to this structure and is descriptive, suggesting its role as a central point into which many muscles insert.

The perineal body is attached to the inferior pubic rami and ischial tuberosities through the perineal membrane and

superficial transverse perineal muscles. Anterolaterally, it receives the insertion of the bulbocavernosus muscles.

On its lateral margins, the upper portions of the perineal body are connected with some fibers of the pelvic diaphragm. Posteriorly, the perineal body is indirectly attached to the coccyx by the external anal sphincter that is embedded in the perineal body, and it is attached at its other end to the coccyx. These connections anchor the perineal body and its surrounding structures to the bony pelvis and help to keep it in place.

Posterior Triangle: Ischiorectal Fossa

In the posterior triangle of the pelvis, the ischiorectal fossa lies between the pelvic walls and the levator ani muscles (**Fig. 7.3**). It has an anterior recess that lies above the perineal membrane. It is bounded medially by the levator ani muscles and anterolaterally by the obturator internus muscle. The main portion of the fossa is lateral to the levator ani and external anal sphincter, and it has a posterior portion that extends above the gluteus maximus. Traversing this region is the pudendal neurovascular trunk.

Anal Sphincters

The external sphincter lies in the posterior triangle of the perineum (**Fig. 7.6**). It is a single mass of muscle that has traditionally been divided into superficial and deep portions. The subcutaneous portion lies attached to the perianal skin and forms an encircling ring around the anal canal. It is responsible for the characteristic radially oriented folds in the perianal skin. The superficial part attaches to the coccyx posteriorly and sends a few fibers into the perineal body anteriorly and forms the bulk of the anal sphincter seen separated in third-degree midline obstetric tears. The fibers of the deep part generally encircle the rectum and blend indistinguishably with the puborectalis, which forms a loop under the dorsal surface of the anorectum and which is attached anteriorly to the pubic bone (**Fig. 7.6**).

The internal anal sphincter is a thickening in the circular smooth muscle of the anal wall. It lies just inside the external anal sphincter and is separated from it by a visible intersphincteric groove. It extends downward inside the external anal sphincter to within a few millimeters of the external sphincter's caudal extent. The internal sphincter can be identified just beneath the anal submucosa in repair of a chronic fourth-degree laceration of the perineum as a rubbery white layer that is often erroneously been referred to as fascia during obstetrical repair of fourth-degree laceration. The longitudinal smooth muscle layer of the bowel, along with some fibers of the levator ani, separates the external and internal sphincters as they descend in the intersphincteric groove.

FIGURE 7.6 Semidiagrammatic dissection of the anorectal region in the woman with the external sphincter cut in the anterior midsagittal plane and reflected posteriorly (mucosa removed). The origin of the anterior muscle bundle is clarified, and the remaining anterolateral portions of the external sphincters are interdigitated into the transverse perinei. (From Oh C, Kark AE. Anatomy of the external anal sphincter. *Br J Surg* 1972;59:717, with permission.)

Levator Ani and Pelvic Wall

The typical depiction of the levator ani muscles in anatomy textbooks is unfortunately distorted by the extreme abdominal pressures generated during embalming that forces them downward. Many of these illustrations therefore fail to give a true picture of the horizontal nature of this strong supportive shelf of muscle. Examination of the normal standing patient is the best way to appreciate the nature of this closure mechanism, because the lithotomy position causes some relaxation of the musculature. During routine pelvic examination of the nullipara, the effectiveness of this closure can be appreciated, because it is often difficult to insert a speculum if the muscles are contracted and not relaxed.

The pelvic canal is spanned by the muscles of the pelvic diaphragm. This diaphragm consists of two components: (a) a thin horizontal shelf-like layer formed by the iliococcygeal muscle and (b) a thicker “U”-shaped sling of muscles that surround the levator hiatus that include the medial pubococcygeal and lateral puborectal muscles (**Fig. 7.7**). The open area within the U through which the urethra, vagina, and rectum pass is called the levator hiatus, and the portion of the hiatus anterior to the perineal body is called the urogenital hiatus.

The pubococcygeal muscle arises from a thin aponeurotic attachment to the inner surface of the pubic bone and inserts to the distal lateral vagina, perineal body, and anus. Some fibers also attach to the superior surface of the coccyx; hence the name pubococcygeus. Because the majority of the attachments, however, are to the vagina and anus, the term pubovisceral muscle is replacing this older term. The puborectal muscle is distinct from the pubococcygeal muscle and lies lateral to it. Its fibers originate from the lower pubis and some from the top of the perineal membrane. The muscle fibers pass beside the rectum forming a sling behind the anorectal junction.

FIGURE 7.7 Anatomy of the pelvic floor. The *asterisk* indicates the puborectalis portion of the levator ani muscle. (From Anson BJ. *An atlas of human anatomy*. Philadelphia, PA: WB Saunders, 1950, with permission.)

The iliococcygeal muscle arises from a fibrous band overlying the obturator internus called the arcus tendineus levatoris ani. From these broad origins, the fibers of the iliococcygeal muscle pass behind the rectum and insert into the midline anococcygeal raphe and the coccyx. The coccygeal muscle arises from the ischial spine and sacrospinous ligament to insert into the borders of the coccyx and the lowest segment of the sacrum.

These muscles are covered on their superior and inferior surfaces by superior and inferior fasciae. When the levator ani muscles and their fasciae are considered together, they are called the pelvic diaphragm, not to be confused with the urogenital diaphragm (perineal membrane).

The normal tone of the muscles of the pelvic diaphragm keep the base of the U pressed against the backs of the pubic bones, keeping the vagina and rectum closed. The region of the levator ani between the anus and coccyx formed by the anococcygeal raphe (see previous discussion) is clinically called the levator plate. It forms a supportive shelf on which the rectum, upper vagina, and uterus can rest. The relatively horizontal position of this shelf is determined by the anterior traction on the fibrous levator plane by the pubococcygeal and puborectal muscles and is important to vaginal and uterine support.

The levator ani muscles receive their innervation from an anterior branch of the ventral ramus of the third and fourth sacral nerves called, appropriately, the nerve to the levator ani. Some aspects of the puborectal muscle may also receive a small contribution to the inferior hemorrhoidal branch of the pudendal nerve.

This section on the pelvic viscera discusses the structure of the individual pelvic organs and considers specific aspects of their interrelations (**Fig. 7.8**). Those aspects of blood supply, innervation, and lymphatic drainage that are idiosyncratic to the specific pelvic viscera are covered here. However, the section on the retroperitoneum, where the overall description of these systems is given, provides the general consideration of these latter three topics.

Genital Structures

Vagina

The vagina is a pliable hollow viscus with a shape that is determined by the structures surrounding it and by its attachments to the pelvic wall. These attachments are to the lateral margins of the vagina, so that its lumen is a transverse slit, with the anterior and posterior walls in contact with one another. The lower portion of the vagina is constricted as it passes through the urogenital hiatus in the levator ani. The upper part is much more capacious. The vagina is bent at an angle of 120 degrees by the anterior traction of the levator ani muscles at the junction of the lower one third and upper two thirds of the vagina (**Fig. 7.9**). The cervix typically lies within the anterior vaginal wall, making it shorter than the posterior wall by about 3 cm. The former is about 7 to 9 cm in length, although there is great variability in this dimension.

When the lumen of the vagina is inspected through the introitus, many landmarks can be seen. The anterior and posterior walls have a midline ridge, called the anterior and posterior columns, respectively. These are caused by the impression of the urethra and bladder and the rectum on the vaginal lumen. The caudal portion of the anterior column is distinct and is called the urethral carina. The recesses in front of and behind the cervix are commonly called the anterior and posterior fornices of the vagina, and the creases along the side of the vagina, where the anterior and posterior walls meet, are called the lateral vaginal sulci.

The vagina's relations to other parts of the body can be understood by dividing it into thirds. In the lower third, the

P.100

vagina is fused anteriorly with the urethra, posteriorly with the perineal body, and laterally to each levator ani by the “fibers of Luschka.” In the middle third are the vesical neck and trigone anteriorly, the rectum posteriorly, and the levators laterally. In the upper third, the anterior vagina is adjacent to the bladder and ureters (which allow these latter structures to be palpated on pelvic examination), posterior to the cul-de-sac, and lateral to the cardinal ligaments of the vagina.

FIGURE 7.8 The pelvic viscera.

The vaginal wall contains the same layers as all hollow viscera (i.e., mucosa, submucosa, muscularis, and adventitia). Except for the area covered by the cul-de-sac, it has no serosal covering. The mucosa is of the nonkeratinized stratified squamous type and lies on a dense, dermislike submucosa. The similarity of these layers to dermis and epidermis has resulted in their being called the “vaginal skin.”

The vaginal muscularis is fused with the submucosa, and the pattern of the muscularis is a bihelical arrangement. Outside the muscularis, there is an adventitia that has varying degrees of development in different areas of the vagina. This layer is a portion of the connective tissue in the pelvis called the endopelvic fascia and has been given a separate name because of its unusual development. When it is dissected in the operating room, the muscularis is usually adherent to it, and this combination of specialized adventitia and muscularis is the surgeon's “fascia,” which might better be called the fibromuscular layer of the vagina, as Nichols and Randall suggested in *Vaginal Surgery*.

Uterus

The uterus is a fibromuscular organ with shape, weight, and dimensions that vary considerably, depending on both estrogenic stimulation and previous parturition. It has two portions: an upper muscular corpus and a lower fibrous cervix. In a woman of reproductive age, the corpus is considerably larger than the cervix, but before menarche, and after the menopause, their sizes are similar. Within the corpus, there is a triangularly shaped endometrial cavity surrounded by a thick muscular wall. That portion of the corpus that extends above the top of the endometrial cavity (i.e., above the insertions of the fallopian tubes) is called the fundus.

The muscle fibers that make up most of the uterine corpus are not arranged in a simple layered manner, as is true

P.101

in the gastrointestinal tract, but are arranged in a more complex pattern. This pattern reflects the origin of the uterus from paired paramesonephric primordia, with the fibers from each half crisscrossing diagonally with those of the opposite side.

FIGURE 7.9 Bead chain cystourethrogram with barium in the vagina showing normal vaginal axis in a patient in the standing position.

The uterus is lined by a unique mucosa, the endometrium. It has both a columnar epithelium that forms glands and a specialized stroma. The superficial portion of this layer undergoes cyclic change with the menstrual cycle. Spasm of hormonally sensitive spiral arterioles that lie within the endometrium causes shedding of this layer after each cycle, but a deeper basal layer of the endometrium remains to regenerate a new lining. Separate arteries supply the basal endometrium, explaining its preservation at the time of menses.

FIGURE 7.10 Uterine adnexa and collateral circulation of uterine and ovarian arteries. The uterine artery crosses over the ureter in the cardinal ligament and gives off cervical and vaginal branches before ascending adjacent to the wall of the uterus and anastomosing with the medial end of the ovarian artery. Note the small branch of the uterine or ovarian artery that nourishes the round ligament (Sampson's artery).

The cervix is divided into two portions: the portio vaginalis, which is that part protruding into the vagina; and the portio supravaginalis, which lies above the vagina and below the corpus.

The substance of the cervical wall is made up of dense fibrous connective tissue with only a small (about 10%) amount of smooth muscle. What smooth muscle is there lies on the periphery of the cervix, connecting the myometrium with the muscle of the vaginal wall. This smooth muscle and accompanying fibrous tissue are easily dissected off the fibrous cervix and form the layer reflected during intrafascial hysterectomy. It is circularly arranged around the fibrous cervix and is the tissue into which the cardinal and uterosacral ligaments and pubocervical fascia insert.

The portio vaginalis is covered by nonkeratinizing squamous epithelium. Its canal is lined by a columnar mucus-secreting epithelium that is thrown into a series of V-shaped folds that appear like the leaves of a palm and are therefore called plicae palmatae. These form compound clefts in the endocervical canal, not tubular racemose glands, as formerly thought.

The upper border of the cervical canal is marked by the internal os, where the narrow cervical canal widens out into the endometrial cavity. The lower border of the canal, the external os, contains the transition from squamous epithelium of the portio vaginalis to the columnar epithelium of the endocervical canal. This occurs at a variable level relative to the os and changes with hormonal variations that occur during a woman's life. It is in this active area of cellular transition that the cervix is most susceptible to malignant transformation.

There is little adventitia in the uterus, with the peritoneal serosa being directly attached to most of the corpus. The anterior portion of the uterine cervix is covered by the bladder; therefore, it has no serosa. Similarly, as discussed in the following, the broad ligament envelops the lateral aspects of the cervix and corpus; therefore, it

has no serosal covering there. The posterior cervix does have a serosal covering.

Adnexal Structures and Broad Ligament

The fallopian tubes are paired tubular structures 7 to 12 cm in length (**Fig. 7.10**). Each has four recognizable portions. At the uterus, the tube passes through the cornu as an interstitial

P.102

portion. On emerging from the corpus, a narrow isthmic portion begins with a narrow lumen and thick muscular wall. Proceeding toward the abdominal end, next is the ampulla, which has an expanding lumen and more convoluted mucosa. The fimbriated end of the tube has many frondlike projections to provide a wide surface for ovum pickup. The distal end of the fallopian tube is attached to the ovary by the fimbria ovarica, which is a smooth muscle band responsible for bringing the fimbria and ovary close to one another at the time of ovulation. The outer layer of the tube's muscularis is composed of longitudinal fibers; the inner layer has a circular orientation.

The lateral pole of the ovary is attached to the pelvic wall by the infundibulopelvic ligament and the ovarian artery and vein contained therein. Medially, it is connected to the uterus through the utero-ovarian ligament. During reproductive life, it measures about 2.5 to 5 cm long, 1.5 to 3 cm thick, and 0.7 to 1.5 cm wide, varying with its state of activity or suppression, as with oral contraceptive medications. Its surface is mostly free but has an attachment to the broad ligament through the mesovarium, as discussed in the following.

The ovary has a cuboidal to columnar covering and consists of a cortex and medulla. The medullary portion is primarily fibromuscular, with many blood vessels and much connective tissue. The cortex is composed of a more specialized stroma, punctuated with follicles, corpora lutea, and corpora albicantia.

FIGURE 7.11 Composition of the broad ligament.

The round ligaments are extensions of the uterine musculature and represent the homolog of the gubernaculum testis. They begin as broad bands that arise on each lateral aspect of the anterior corpus. They assume a more rounded shape before they enter the retroperitoneal tissue, where they pass lateral to the deep inferior epigastric vessels and enter each internal inguinal ring. After traversing the inguinal canal, they exit the external ring and enter the subcutaneous tissue of the labia majora. They have little to do with uterine support.

The ovaries and tubes constitute the uterine adnexa. They are covered by a specialized series of peritoneal folds called the broad ligament. During embryonic development, the paired müllerian ducts and ovaries arise from the lateral abdominopelvic walls. As they migrate toward the midline, a mesentery of peritoneum is pulled out from the pelvic wall from the cervix on up. This leaves the midline uterus connected on either side to the pelvic wall by a double layer of peritoneum.

Within the upper layers of these two folds, called the broad ligament, lie the fallopian tubes, round ligaments, and ovaries (**Fig. 7.11**). The cardinal and uterosacral ligaments are at the lower margin of the broad ligament. These structures are visceral ligaments; therefore, they are composed of varying amounts of smooth muscle, vessels, connective tissue, and other structures. They are not the pure ligaments associated with joints in the skeleton.

The ovary, tube, and round ligament each have their own separate mesentery, called the mesovarium, mesosalpinx,

P.103

and mesoteres, respectively. These are arranged in a constant pattern, with the round ligament placed ventrally, where it exits the pelvis through the inguinal ligament, and the ovary placed dorsally. The tube is in the middle and is the most cephalic of the three structures. At the lateral end of the fallopian tube and ovary, the broad ligament ends where the infundibulopelvic ligament blends with the pelvic wall. The cardinal ligaments lie at the base of the broad ligament and are described under the section on supportive tissues and cleavage planes.

Blood Supply and Lymphatics of the Genital Tract

The blood supply to the genital organs comes from the ovarian arteries and uterine and vaginal branches of the internal iliac arteries. A continuous arterial arcade connects these vessels on the lateral border of the adnexa, uterus, and vagina (**Fig. 7.10**).

The blood supply of the upper adnexal structures comes from the ovarian arteries that arise from the anterior surface of the aorta just below the level of the renal arteries. The accompanying plexus of veins drains into the vena cava on the right and the renal vein on the left. The arteries and veins follow a long, retroperitoneal course before reaching the cephalic end of the ovary. They pass along the mesenteric surface of the ovary to connect with the upper end of the marginal artery of the uterus. Because the ovarian artery runs along the hilum of the ovary, it not only supplies the gonad but also sends many small vessels through the mesosalpinx to supply the fallopian tube, including a prominent fimbrial branch at the lateral end of the tube.

The uterine artery originates from the internal iliac artery. It usually arises independently from this source but can have a common origin with either the internal pudendal or vaginal artery. It joins the uterus near the junction of the corpus and cervix, but this position varies considerably, both with the individual and the amount of upward or downward traction placed on the uterus. Accompanying each uterine artery are several large uterine veins that drain the corpus and cervix.

On arriving at the lateral border of the uterus (after passing over the ureter and giving off a small branch to this structure), the uterine artery flows into the side of the marginal artery that runs along the side of the uterus. Through this connection, it sends blood both upward toward the corpus and downward to the cervix. Because the marginal artery continues along the lateral aspect of the cervix, it eventually crosses over the cervicovaginal

junction and lies on the side of the vagina.

The vagina receives its blood supply from a downward extension of the uterine artery along the lateral sulci of the vagina and from a vaginal branch of the internal iliac artery. These form an anastomotic arcade along the lateral aspect of the vagina at the 3- and 9-o'clock positions. Branches from these vessels also merge along the anterior and posterior vaginal walls. The distal vagina also receives a supply from the pudendal vessels, and the posterior wall has a contribution from the middle and inferior hemorrhoidal vessels.

Lymphatic drainage of the upper two thirds of the vagina and uterus is primarily to the obturator and internal and external iliac nodes, and the distal-most vagina drains with the vulvar lymphatics to the inguinal nodes. In addition, some lymphatic channels from the uterine corpus extend along the round ligament to the superficial inguinal nodes, and some nodes extend posteriorly along the uterosacral ligaments to the lateral sacral nodes. These routes of drainage are discussed more fully in the discussion of the retroperitoneal space.

The lymphatic drainage of the ovary follows the ovarian vessels to the region of the lower abdominal aorta, where they drain into the lumbar chain of nodes (paraaortic nodes).

The uterus receives its nerve supply from the uterovaginal plexus (Frankenhäuser ganglion) that lies in the connective tissue of the cardinal ligament. Details of the organization of the pelvic innervation are contained in the section on retroperitoneal structures.

Lower Urinary Tract

Ureter

The ureter is a tubular viscus about 25 cm long, divided into abdominal and pelvic portions of equal length. Its small lumen is surrounded by an inner longitudinal and outer circular muscle layer. In the abdomen, it lies in the extraperitoneal connective tissue on the posterior abdominal wall, crossed anteriorly by the left and right colic vessels. Its course and blood supply are described in the section on the retroperitoneum.

Bladder

The bladder can be divided into two portions: the dome and base ([Fig. 7.12](#)). The musculature of the spherical bladder does not lie in simple layers, as do the muscular walls of tubular viscera, such as the gut and ureter. It is best described as a meshwork of intertwining muscle bundles. The musculature of the dome is relatively thin when the bladder is distended. The base of the bladder, which is thicker and varies less with distention of the dome, consists of the urinary trigone and a thickening of the detrusor, called the detrusor loop. This is a U-shaped band of musculature, open posteriorly, that forms the bladder base anterior to the intramural portion of the ureter. The trigone is made of smooth muscle that arises from the ureters that occupy two of its three corners. It continues as the muscle of the vesical neck and urethra. There it rests on the upper vagina. The shape of the bladder depends on its state of filling. When empty, it is a somewhat flattened disk, slightly concave upward. As it fills, the dome rises off the base, eventually assuming a more spherical shape.

The distinction between the base and dome has functional importance, because they have differing innervations. The bladder base has α -adrenergic receptors that contract when stimulated and thereby favor continence. The dome is responsive to β or cholinergic stimulation, with contraction that causes bladder emptying.

Anteriorly, the bladder lies against the lower abdominal wall. It lies against the pubic bones laterally and inferiorly and abuts the obturator internus and levator ani. Posteriorly, it rests against the vagina and cervix. These relations are discussed further in consideration of the pelvic planes and spaces.

The blood supply of the bladder comes from the superior vesical artery, which comes off the obliterated umbilical artery and inferior vesical artery, which is either an independent branch of the internal pudendal artery or arises

P.104

two prominent openings on the inner aspects of the external urethral orifice can be seen when the orifice is opened. Chronic infection of these glands can lead to urethral diverticula, and obstruction of their terminal duct can result in cyst formation. Their location on the dorsal surface of the urethra reflects the distribution of the structures from which they arise.

At the level of the perineal membrane, the distal portion of the urogenital sphincter begins. Here the skeletal muscle of the urethra leaves the urethral wall to form the urethrovaginal sphincter ([Fig. 7.5](#)) and compressor urethrae (formerly called the deep transverse perineal muscle). Distal to this portion, the urethral wall is fibrous and forms a nozzle for aiming the urinary stream. The mechanical support of the vesical neck and urethra, which are so important to urinary continence, is discussed in the section of this chapter devoted to the supportive tissues of the urogenital system.

The urethra receives its blood supply both from an inferior extension of the vesical vessels and from the pudendal vessels.

Sigmoid Colon and Rectum

The sigmoid colon begins its S-shaped curve at the pelvic brim. It has the characteristic structure of the colon, with three tenia coli lying over a circular smooth muscle layer. Unlike much of the colon, which is retroperitoneal, the sigmoid has a definite mesentery in its midportion. The length of the mesentery and the pattern of the sigmoid's curvature vary considerably. It receives its blood supply from the lowermost portion of the inferior mesenteric artery: the branches called the sigmoid arteries.

As it enters the pelvis, the colon straightens its course and becomes the rectum. This portion extends from the pelvic brim

P.105

until it loses its final anterior peritoneal investment below the cul-de-sac. It has two bands of smooth muscle (anterior and posterior). Its lumen has three transverse rectal folds that contain the mucosa, submucosa, and circular layers of the bowel wall. The most prominent fold, the middle one, lies anteriorly on the right about 8 cm above the anus, and it must be negotiated during high rectal examination or sigmoidoscopy.

FIGURE 7.13 Rectosigmoid colon and anal canal showing collateral arterial circulation from superior hemorrhoidal (inferior mesenteric), middle hemorrhoidal (hypogastric or internal iliac), and inferior hemorrhoidal (internal pudendal) arteries.

As the rectum passes posterior to the vagina, it expands into the rectal ampulla. This portion of the bowel begins under the cul-de-sac peritoneum and fills the posterior pelvis from the side. At the distal end of the rectum, the anorectal junction is bent at an angle of 90 degrees where it is pulled ventrally by the puborectalis fibers' attachment to the pubes and posteriorly by the external anal sphincter's dorsal attachment to the coccyx.

Below this level, the gut is called the anus. It has many distinguishing features. There is a thickening of the circular involuntary muscle called the internal sphincter. The canal has a series of anal valves to assist in closure, and at their lower border, the mucosa of the colon gives way to a transitional layer of non-hair-bearing squamous epithelium before becoming the hair-bearing perineal skin.

The relations of the rectum and anus can be inferred from their course. They lie against the sacrum and levator plate posteriorly and against the vagina anteriorly. Inferiorly, each half of the levator ani abuts its lateral wall and sends fibers to mingle with the longitudinal involuntary fibers between the internal and external sphincters. Its distal terminus is surrounded by the external anal sphincter.

The anorectum receives its blood supply from a number of sources ([Fig. 7.13](#)). From above, the superior rectal (hemorrhoidal) branch of the inferior mesenteric artery lies within the layers of the sigmoid mesocolon. As it reaches the beginning of the rectum, it divides into two branches and ends in the wall of the gut. A direct branch

from the internal iliac artery arises from the pelvic wall on either side and supplies the rectum and ampulla above the pelvic floor. The anus and external sphincter receive their blood supply from the inferior rectal (hemorrhoidal) branch of the internal pudendal artery, which reaches the terminus of the gastrointestinal tract through the ischiorectal fossa.

PELVIC CONNECTIVE TISSUE AND CLEAVAGE PLANES

The pelvic viscera are connected to the lateral pelvic wall by their adventitial layers and thickenings of the connective tissue that lie over the pelvic wall muscles (**Fig. 7.14**). These attachments, as well as the attachments of one organ to another, separate the different surgical cleavage planes from one another. These condensations of the adventitial layers of the pelvic organs have assumed supportive roles, connecting the viscera to the pelvic walls, in addition to their role in transmitting

P.106

the organs' neurovascular supply from the pelvic wall. They are somewhat like a mesentery that connects the bowel, for example, to the body wall. They have a supportive function as well as a role in carrying vessels and nerves to the organ. An understanding of their disposition is important to both vaginal and abdominal surgery.

FIGURE 7.14 Cross section of the pelvis showing cleavage planes.

The tissue that connects the organs to the pelvic wall has been given the special designation of *endopelvic fascia*. It is not a layer similar to the layer encountered during abdominal incisions (rectus abdominis “fascia”). It is composed of blood vessels and nerves, interspersed with a supportive meshwork of irregular connective tissue containing collagen and elastin. These structures connect the muscularis of the visceral organs to pelvic wall muscles. In some areas, there is considerable smooth muscle within this tissue, as is true in the area of the uterosacral ligaments. Although surgical texts often speak of this fascia as a specific structure separate from the viscera, this is not strictly true. These layers can be separated from the viscera, just as the superficial layers of the bowel wall can be artificially separated from the deeper layers, but they are not themselves separate structures.

Pelvic Connective Tissue

The term *ligament* is most familiar when it describes a dense connective tissue band that links two bones, but it

also describes ridges in the peritoneum or thickenings of the endopelvic fascia. The ligaments of the genital tract are diverse. Although they share a common designation (i.e., ligament), they are composed of many types of tissue and have many different functions.

Uterine Ligaments

The broad ligament comprises peritoneal folds that extend laterally from the uterus and cover the adnexal structures. They have no supportive function and were discussed in the section on the pelvic viscera.

At the base of the broad ligament, beginning just caudal to the uterine arteries, there is a thickening in the endopelvic fascia that attaches the cervix and upper vagina to the pelvic side walls (**Fig. 7.15**), consisting of the cardinal and uterosacral ligaments (parametrium). Use of the term *ligament* has caused confusion over the years because it implies a separate structure that connects two structures. In fact, they are mesenteries that transmit vessels and nerves to the genital tract.

The term *uterosacral ligament* refers to that portion of this tissue that forms the medial margin of the parametrium and that borders the cul-de-sac of Douglas. The term *cardinal ligament* is used to refer to that portion that attaches the lateral margins of the cervix and vagina to the pelvic walls. The course of the ureter as it forms a tunnel between the cardinal and uterosacral ligament forms a point of division between these two structures. The term *parametrium* refers to all of the tissue that attaches to the uterus (both cardinal and uterosacral ligaments), and the term *paracolpium* refers to the portion that attaches to the vagina (cardinal ligament of the vagina).

The uterosacral ligament portion of the parametrium is composed predominantly of smooth muscle, the autonomic nerves of the pelvic organs, and some intermixed connective tissue and blood vessels, whereas the cardinal ligament portion consists primarily of perivascular connective tissue and the pelvic vessels. Although they are often described as extending laterally from the cervix to the pelvic wall, in the standing position, they are almost vertical as one would expect for a suspensory tissue. Near the cervix, they are discrete, but they fan out in the retroperitoneal layer to have a broad, if somewhat ill-defined, area of attachment over the second, third, and fourth segments of the sacrum. These ligaments hold the cervix posteriorly in the pelvis over the levator plate of the pelvic diaphragm.

The cardinal ligaments lie at the lower edge of the broad ligament, between their peritoneal leaves, beginning just caudal to the uterine arteries. They attach to the cervix below the isthmus and fan out to attach to the pelvic walls over the piriformis muscle in the area of the greater sciatic foramen. Although when placed under tension they feel like ligamentous bands, they are composed simply of perivascular connective tissue and nerves that surround the uterine artery and veins. Nevertheless, these structures have considerable strength, and the lack of a separate “ligamentous band” in this area does not detract from their supportive role. They provide support not only to the cervix and uterus but also to the upper portion of the vagina (paracolpium) to keep these structures positioned posteriorly over the levator plate of the pelvic diaphragm and away from the urogenital hiatus.

Vaginal Fasciae and Attachments

The attachments of the vagina to the pelvic walls are important in maintaining the pelvic organs in their normal positions. Failure of these attachments, along with damage to the levator ani muscles, result in the clinical conditions of uterine prolapse, cystocele, rectocele, and enterocele.

The term fascia has many meanings. The layer that is dissected during anterior or posterior colporrhaphy and referred to as the vaginal fascia is the muscularis of the vagina. Histologically, it has an abundance of connective tissue interspersed between the smooth muscle. It is not a layer that is separate from the vagina. Laterally, the mesenteric structures of the cardinal and uterosacral ligaments connect the vagina and uterus to the muscles and connective tissues that cover the lateral walls of the pelvis. They suspended these structures within the

pelvis by the downward extension on the lateral margins of the genital track (**Fig. 7.15**). Between the vagina and bladder is the vesicovaginal space; posterior to it is the cul-de-sac and rectovaginal space. In the midvagina, the vagina is attached laterally to the arcus tendineus fasciae pelvis. The arcus tendineus fasciae pelvis is a fibrous band that extends from its ventral attachment at the pubic bone to its dorsal attachment to the ischial spine. These

P.107

lateral attachments suspend the anterior vaginal wall across the pelvis and prevent its downward descent with increases in abdominal pressure. The structural layer formed by the vaginal wall and its lateral attachments to the arcus tendineus is clinically referred to as the pubocervical fascia.

FIGURE 7.15 A: Suspensory ligaments of the female genital tract seen with the bladder removed. **B:** Close-up of the lower portion of the middle vagina (level II) shows how the lateral attachments of the vagina result in an anterior layer under the bladder (pubocervical fascia) and a posterior layer in front of the rectum (rectovaginal fascia). The cephalic surfaces of the transected distal urethra and vagina (level III) are shown. (From DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717, with permission. Copyright © 1992, Elsevier.)

Support of the posterior vaginal wall prevents the rectum from bulging forward in the clinical condition known as rectocele. This support varies in different levels of the vagina. In the distal 2 or 3 cm of the posterior vaginal wall, attachments of the perineal body to the ischiopubic rami hold the perineal body in place and prevent protrusion of the distal rectum (**Fig. 7.16**). In the midvagina above this, the vagina is attached laterally to the fascia covering the inside of the levator ani muscles (**Fig. 7.17**). This connection prevents the middle of the posterior vaginal wall from moving forward and downward during increases in abdominal pressure. The adventitial tissues between the vaginal wall and rectum contain a thickened layer called the *fascia of Denonvilliers* that extends from the bottom of the cul-de-sac of Douglas to the top of the perineal body. It is relatively thin and whether or not it provides significant support is a matter of controversy.

Urethral Supports

The support of the proximal urethra plays a role in the maintenance of urinary continence during times of increased abdominal pressure. Although it is now known that stress incontinence is primarily caused by a weak urethral sphincter mechanism (low urethral closure pressure), urethral support does play an important, if secondary, role. Therefore, considering the normal mechanisms of urethral support is appropriate.

The distal portion of the urethra is inseparable from the vagina because of their common embryologic derivation from the urogenital sinus. These tissues are fixed firmly in position by connections of the periurethral tissues and vagina to the pubic bones through the perineal membrane (**Fig. 7.18**). Cranial to this, beginning in the mid-urethra, a hammocklike layer composed of the endopelvic fascia, and anterior vaginal wall provides the support of the proximal urethra. This layer is stabilized by its lateral attachments both to the arcus tendineus fasciae pelvis and the medial margin of the levator ani muscles. The arcus tendineus fasciae pelvis is a fibrous band stretched from a ventral attachment at the lower portion of the pubic bones about 1 cm above the lower margin of the pubic bones and 1 cm from the midline to the ischial spine. The muscular attachment of the endopelvic fascia allows contraction and relaxation of the levator ani muscles to elevate the urethra and to let it descend.

It had previously been thought that the status of the urethral support system was the primary factor determining whether a woman had stress incontinence of urine. Recent studies have, however, shown that the strength of the urethral sphincter is the primary determining factor with urethral support playing a secondary role. The way in which urethral support plays a role in continence can be understood as follows. During increases in abdominal pressure, the downward force caused by increased abdominal pressure on the ventral surface of the urethra compresses the urethra closed against the hammocklike supportive layer, thereby closing the urethral lumen against the increases in intravesical pressure. The stability of the fascial layer determines the effectiveness of this closure mechanism. If the layer is unyielding, it forms a firm backstop against which the urethra can be compressed closed; however, if it is unstable, the effectiveness of this closure is compromised. Therefore, the integrity of the attachment to the arcus tendineus and the levator ani is critical to the stress continence mechanism.

FIGURE 7.16 The peripheral attachments of the perineal membrane to the ischiopubic rami and direction of tension on fibers uniting through the perineal body. (From DeLancey JOL. Structural anatomy of the posterior compartment as it relates to rectocele. *Am J Obstet Gynecol* 1999;180:815, with permission. Copyright © 1999, Elsevier.)

FIGURE 7.17 Lateral view of the pelvic organs after removal of the left ischial bone and ischial tuberosity. The bladder, vagina, and cervix have been cut in the sagittal plane to reveal their lumens. The rectum has been left intact. A strip of the posterior/lateral vaginal wall with its attached endopelvic fascia are shown, indicating their position relative to the levator ani muscle and this fascia's course and attachment. The two portions of the levator ani muscle (puborectalis and iliococcygeus) are visible. The ischial spine and the intact sacrospinous ligament are above the level of the removed ischial tuberosity. The left half of the perineal membrane (urogenital diaphragm) is shown just caudal to the puborectalis portion of the levator ani muscle after its detachment from the inferior pubic ramus that has been removed. (From DeLancey JOL. Structural anatomy of the posterior

compartment as it relates to rectocele. *Am J Obstet Gynecol* 1999;180:815, with permission. Copyright © 1999, Elsevier.)

FIGURE 7.18 Lateral view of the urethral supportive mechanism transected just lateral to the midline. The lateral wall of the vagina and a portion of the endopelvic fascia have been removed so that one can see the deeper structures. (Redrawn from DeLancey JOL. Structural support of the urethra as it relates to stress urinary incontinence: the hammock hypothesis. *Am J Obstet Gynecol* 1994;170:1713, with permission. Copyright © 1994, Elsevier.)

P.109

The muscular attachment is responsible for the voluntary control of vesical neck position visible during vaginal examination or fluoroscopy when the pelvic muscles are contracted and relaxed. Relaxation of these muscles with descent of the vesical neck is associated with the initiation of urination and contraction with arrest of the urinary stream. The limit of downward vesical neck motion is determined by the connective tissue elasticity in the attachments to the arcus tendineus fasciae pelvis.

Cul-de-sacs, Cleavage Planes, and Spaces

Each of the pelvic viscera can expand somewhat independently of its neighboring organs. The ability to do this comes from their relatively loose attachment to one another, which permits the bladder, for example, to expand without equally elongating the adjacent cervix. This allows the viscera to be easily separated from one another along these lines of cleavage. These surgical cleavage planes are called spaces, although they are not empty but rather are filled with fatty or areolar connective tissue. The pelvic spaces are separated from one another by the connections of the viscera to one another and to the pelvic walls.

Anterior and Posterior Cul-de-sacs

Properly termed the *vesicouterine and rectouterine pouches*, the anterior and posterior cul-de-sac separate the

uterus from the bladder and rectum.

The anterior cul-de-sac is a recess between the dome of the bladder and the anterior surface of the uterus (**Fig. 7.19**). The peritoneum is loosely applied in the region of the anterior culde-sac, unlike its dense attachment to the upper portions of the uterine corpus. This allows the bladder to expand without stretching its overlying peritoneum. This loose peritoneum forms the vesicouterine fold, which can easily be lifted and incised to create a bladder flap during abdominal hysterectomy or cesarean section. It is the point at which the vesicocervical space is normally accessed during abdominal surgery.

The posterior cul-de-sac is bordered ventrally by the vagina anteriorly, the rectosigmoid posteriorly, and the uterosacral ligaments laterally. Its peritoneum extends for approximately 4 cm along the posterior vaginal wall below the posterior vaginal fornix where the vaginal wall attaches to the cervix. This allows direct entry into the peritoneum from the vagina when performing a vaginal hysterectomy, culdocentesis, or colpotomy. The anatomy here contrasts with the anterior cul-de-sac. Anteriorly, the peritoneum lies several centimeters above the vagina whereas posteriorly, the peritoneum covers the vagina. Keeping this anatomic difference in mind facilitates entering both the anterior and the posterior cul-de-sacs during vaginal hysterectomy.

FIGURE 7.19 Sagittal section from the cadaver of a 28-year-old woman showing the anterior cul-de-sac (aCDS) and the posterior culde-sac (pCDS). Note how the posterior cul-de-sac peritoneum lies on the vaginal wall, whereas the anterior cul-de-sac lies several centimeters from the depth of the peritoneum in this area. (Peritoneum digitally enhanced in photograph to aid visibility.) (Copyright 2001 John O. L. DeLancey, with permission.)

Prevesical Space

The prevesical space of Retzius (**Fig. 7.14**) is separated from the undersurface of the rectus abdominis muscles by the transversalis fascia and can be entered by perforating this layer. Ventrolaterally, it is bounded by the bony pelvis and the muscles of the pelvic wall; cranially, it is bounded by the abdominal wall. The proximal urethra and bladder lie in a dorsal position. The dorsolateral limit to this space is the attachment of the bladder to the cardinal ligament and the attachment of the pubocervical fascia to the arcus tendineus fasciae pelvis. These separate

this space from the vesicovaginocervical space. This lateral attachment is to the arcus tendineus fasciae pelvis, which lies on the inner surface of the obturator internus and pubococcygeal and puborectal muscles.

Important structures lying within this space include the dorsal clitoral vessels under the symphysis at its lower border and the obturator nerve and vessels as they enter the obturator canal. A branch to the obturator canal often comes off the external iliac artery and lies on the pubic bone; therefore, dissection in this area should be performed with care (Fig. 7.20). Lateral to the bladder and vesical neck is a dense plexus of vessels that lie at the border of the lower urinary tract. They are deep to the pubovesical muscle, and although they bleed when sutures are placed here, this venous ooze usually stops when the sutures are tied. Also within this tissue, lateral to the bladder and urethra, lie the nerves of the lower urinary tract. The upper border of the pubic bones that form the anterior surface of this region has a ridgelike fold of periosteum called the iliopectineal line. This is sometimes used to anchor sutures during urethral suspension operations.

Vesicovaginal and Vesicocervical Space

The space between the lower urinary tract and the genital tract is separated into the vesicovaginal and vesicocervical spaces

P.110

(Fig. 7.14). The lower extent of the space is the junction of the proximal one third and distal two thirds of the urethra, where it fuses with the vagina, and it extends to lie under the peritoneum at the vesicocervical peritoneal reflection. It extends laterally to the pelvic side walls, separating the vesical and genital aspects of the cardinal ligaments.

FIGURE 7.20 Structures of the pelvic wall. (From Anson BJ. *An atlas of human anatomy*. Philadelphia, PA: WB

Rectovaginal Space

On the dorsal surface of the vagina lies the rectovaginal space ([Fig. 7.14](#)). It begins at the apex of the perineal body, about 2 to 3 cm above the hymenal ring. It extends upward to the cul-de-sac and laterally around the sides of the rectum to the attachment of the rectovaginal septum to the parietal endopelvic fascia. It contains loose areolar tissue and is easily opened with finger dissection.

At the level of the cervix, some fibers of the cardinal-uterosacral ligament complex extend downward behind the vagina, connecting it to the lateral walls of the rectum and then to the sacrum. These are called the rectal pillars. They separate the midline rectovaginal space in this region from the lateral pararectal spaces. These pararectal spaces allow access to the sacrospinous ligament (mentioned later). They also form the lateral boundaries of the retrorectal space between the rectum and sacrum.

Region of the Sacrospinous Ligament

The area around the sacrospinous ligament is another region that has become more important to the gynecologist operating for problems of vaginal support. The sacrospinous ligament lies on the dorsal aspect of the coccygeal muscle ([Fig. 7.20](#)). The rectal pillar separates it from the rectovaginal space.

As its name implies, the sacrospinous ligament courses from the lateral aspect of the sacrum to the ischial spine. In its medial portion, it fuses with the sacrotuberous ligament and is a distinct structure only laterally. It can be reached from the rectovaginal space by perforation of the rectal pillar to enter the pararectal space or by dissection directly under the enterocele peritoneum. This area is covered in more detail in [Chapter 35](#).

Many structures are near the sacrospinous ligament, and their location must be remembered during surgery in this region. The sacral plexus lies immediately to the ligament on the inner surface of the piriformis muscle. Just before its exit through the greater sciatic foramen, the plexus gives off the pudendal nerve, which, with its accompanying vessels, passes lateral to the sacrospinous ligament at its attachment to the ischial spine. The nerve to the levator ani muscles lies on the inner surface of the coccygeal muscle in its midportion. In developing this space, the tissues that are reflected medially and cranially to gain access contain the pelvic venous plexus of the internal iliac vein, as well as the middle rectal vessels. If they are mobilized too vigorously, they can cause considerable hemorrhage.

RETROPERITONEAL SPACES AND LATERAL PELVIC WALL

The retroperitoneal space of the posterior abdomen, presacral space, and pelvic retroperitoneum contain the major neural, vascular, and lymphatic supply to the pelvic viscera. These areas are explored during operations to identify the ureter, interrupt the pelvic nerve supply, arrest serious pelvic hemorrhage, and remove potentially malignant lymph nodes. Because this area is free of the adhesions from serious pelvic infection or endometriosis, it can be used as a plane of dissection when the peritoneal cavity has become obliterated.

P.111

The structures found in these spaces are discussed in a regional context, because that is the way they are usually approached in the operating room.

Retroperitoneal Structures of the Lower Abdomen

The aorta lies on the lumbar spine slightly to the left of the vena cava, which it overlies. The portion of this vessel below the renal vessels is encountered during retroperitoneal dissection to identify the paraaortic lymph nodes ([Fig. 7.21](#)). The renal blood vessels arise at the second lumbar vertebra. The ovarian vessels also arise from the anterior surface of the aorta in this region. In general, the branches of the vena cava follow those of the aorta,

except for the vessels of the intestine, which flow into the portal vein, and the left ovarian vein, which empties into the renal vein on that side.

Below the level of the renal vessels and just below the third portion of the duodenum, the inferior mesenteric artery arises from the anterior aorta. It gives off ascending branches of the left colic artery and continues caudally to supply the sigmoid through the three or four sigmoid arteries that lie in the sigmoid mesentery. These vessels follow the bowel as it is pulled from side to side, so that their position can vary, depending on retraction.

FIGURE 7.21 Structures of the retroperitoneum. Note the anomalous origin of the left ovarian artery from the left renal artery rather than from the aorta. (The original illustration is in the Max Brödel Archives in the Department of Art as Applied to Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD, USA, with permission.)

Inferiorly, a continuation of the inferior mesenteric artery forms the superior rectal artery. This vessel crosses over the external iliac vessels to lie on the dorsum of the lower sigmoid. It supplies the rectum, as described in the section concerning that viscus.

The aorta and vena cava have segmental branches that arise at each lumbar level and are called the lumbar arteries and veins. They are situated somewhat posteriorly to the aorta and vena cava and are not visible from the front. When the vessels are mobilized, as is done in excising the lymphatic tissue in this area, they come into view.

At the level of the fourth lumbar vertebra (just below the umbilicus), the aorta bifurcates into the left and right common iliac arteries. After about 5 cm, the common iliac arteries (and the medially placed veins) give off the internal iliac vessels from their medial side and continue toward the inguinal ligament as the external iliac arteries. These internal iliac vessels lie within the pelvic retroperitoneal region and are discussed later.

P.112

The aorta and vena cava in this region are surrounded by lymph nodes on all sides. Surgeons usually refer to this lumbar chain of nodes as the paraaortic nodes, reflecting their position. They receive the drainage from the common iliac nodes and are the final drainage of the pelvic viscera. In addition, they collect the lymphatic drainage from the ovaries that follows the ovarian vessels and does not pass through the iliac nodes. The nodes of the lumbar chain extend from the right side of the vena cava to the left of the aorta and can be found both anterior and posterior to the vessels.

The ureters are attached loosely to the posterior abdominal wall in this region, and when the overlying colon is mobilized, they remain on the body wall. They are crossed anteriorly by the ovarian vessels, which contribute a branch to supply the ureter. Additional blood supply to the abdominal portion comes from the renal vessels at the kidney and the common iliac artery.

This region can be exposed either by a midline peritoneal incision to the left of the small bowel mesentery or, retroperitoneally, by reflection of the colon. During embryonic development, the colon and its mesentery fuse with the abdominal wall. A cleavage plane exists here that allows the colon and its vessels to be elevated to expose the structures of the posterior abdominal wall. Because the ureter and ovarian vessels originally arise in this area, they are not elevated with the colon.

FIGURE 7.22 Presacral nerve plexus, showing passage of sympathetic trunk over bifurcation of aorta. Observe the division of the trunk into left and right presacral nerves. (Redrawn from Curtis AH, Anson BJ, Ashley FL, et al. The anatomy of the pelvic autonomic nerves in relation to gynecology. *Surg Gynecol Obstet* 1942;75:743, with permission.)

Presacral Space

The presacral space begins below the bifurcation of the aorta and is bounded laterally by the internal iliac arteries (**Figs. 7.22** and **7.23**). Lying directly on the sacrum are the middle sacral artery and vein, which originate from the dorsal aspect of the aorta and vena cava (and not from the point of bifurcation, as sometimes shown). Caudal and lateral to this are the lateral sacral vessels. The venous plexus of these vessels can be extensive, and bleeding from it can be considerable.

Within this area lies the most familiar part of the pelvic autonomic nervous system, the presacral nerve (superior hypogastric plexus). The autonomic nerves of the pelvic viscera can be divided into a sympathetic (thoracolumbar) and parasympathetic (craniosacral) system. The former is also called the adrenergic system, and the latter is called the cholinergic system, according to their neurotransmitters. α -Adrenergic stimulation

causes increased urethral and vesical neck tone, and cholinergic stimulation increases contractility of the detrusor muscle. Similarly, adrenergic stimulation in the colon and rectum favors storage, and cholinergic stimulation favors evacuation. β -Adrenergic agonists, which are used for tocolysis, suggest that these influence contractility of the uterus. As is true in the man, damage to the autonomic nerves during

P.113

pelvic lymphadenectomy can have a significant influence on orgasmic function in the woman.

FIGURE 7.23 Nerves of the female pelvis. (From Anson BJ. *An atlas of human anatomy*. Philadelphia, PA: WB Saunders, 1950, with permission.)

How these autonomic nerves reach the organs that they innervate has surgical importance. The terminology of this area is somewhat confusing, because many authors use idiosyncratic terms. However, the structure is simple: It consists of a single ganglionic midline plexus overlying the lower aorta (superior hypogastric plexus) that splits into two trunks without ganglia (hypogastric nerves), each of which connects with a plexus of nerves and ganglia lateral to the pelvic viscera (inferior hypogastric plexus).

The superior hypogastric plexus lies in the retroperitoneal connective tissue on the ventral surface of the lower aorta and receives input from the sympathetic chain ganglia through the thoracic and lumbar splanchnic nerves. It also contains important afferent pain fibers from the pelvic viscera, which makes its transection effective in

primary dysmenorrhea. It passes over the bifurcation of the aorta and extends over the proximal sacrum before splitting into two hypogastric nerves that descend into the pelvis in the region of the internal iliac vessels. The hypogastric nerves end in the inferior hypogastric plexus. The hypogastric plexuses are broad expansions of the hypogastric nerves. Their sympathetic fibers come from the downward extensions of the superior hypogastric plexus and pelvic splanchnic nerves from the continuation of the sympathetic chain into the pelvis. Parasympathetic fibers come from sacral segments two through four by way of the pelvic splanchnic nerves (nervi erigentes) to join these ganglia. They lie in the pelvic connective tissue of the lateral pelvic wall, lateral to the uterus and vagina.

The inferior hypogastric plexus (sometimes called the pelvic plexus) is divided into three portions: the vesical plexus anteriorly, uterovaginal plexus (Frankenhäuser ganglion), and the middle rectal plexus. The uterovaginal plexus contains fibers that derive from two sources. It receives sympathetic and sensory fibers from the tenth thoracic through the first lumbar spinal cord segments. The second input comes from the second, third, and fourth sacral segments and consists primarily of parasympathetic nerves that reach the inferior hypogastric plexus through the pelvic splanchnic nerves. The uterovaginal plexus lies on the dorsal (medial) surface of the uterine vessels, lateral to the sacrouterine ligaments' insertion into the uterus. It has continuations cranially along the uterus and caudally along the vagina. This latter extension contains the fibers that innervate the vestibular bulbs and clitoris. These nerves lie in the tissue just lateral to the area where the uterine artery, cardinal ligament, and uterosacral ligament pedicles are made during a hysterectomy for benign disease, and within the tissue removed during a radical hysterectomy.

The location of the sensory fibers from the uterine corpus in the superior hypogastric nerve (the presacral nerve) allows the surgeon to alleviate visceral pain from the corpus by transecting this structure. It does not provide sensory innervation to the adnexal structures or to the peritoneum and is therefore

P.114

not useful for alleviating pain in those sites. Another important way in which the autonomic nervous system is involved is through damage to the inferior hypogastric plexus during radical hysterectomy. The extension of the surgical field lateral to the viscera interrupts the connection of the bladder and sometimes the rectum to their central attachments.

The ovary and uterine tube receive their neural supply from the plexus of nerves that accompany the ovarian vessels and that originate in the renal plexus. These fibers originate from the tenth thoracic segment, and the parasympathetic fibers come from extensions of the vagus.

As the lumbar and sacral nerves exit from the intervertebral and sacral foramina, they form the lumbar and sacral plexuses. The lumbar nerves and plexus lie deep within the psoas muscle on either side of the spine. The sacral plexus lies on the piriformis muscle, and its major branch, the sciatic nerve, leaves the pelvis through the lower part of the greater sciatic foramen. The sacral plexus supplies nerves to the muscles of the hip, pelvic diaphragm, and perineum, as well as to the lower leg (through the sciatic nerve). The femoral nerve from the lumbar plexus is primarily involved in supplying the muscles of the thigh.

Pelvic Retroperitoneal Space

Division of the internal and external iliac vessels occurs in the area of the sacroiliac joint. Just before passing under the inguinal ligament to become the femoral vessels, the external iliac vessels contribute the deep inferior epigastric and deep circumflex iliac arteries. There are no other major branches of the external iliac artery in this region.

Internal Iliac Vessels

Unlike the external iliac artery, which is constant and relatively simple in its morphology, the branching pattern of

the internal iliac arteries and veins is extremely variable (**Figs. 7.24** and **7.25**). A description of a common variant is included here. The internal iliac artery supplies the viscera of the pelvis and many muscles of the pelvic wall and gluteal region. It usually divides into an anterior and posterior division about 3 to 4 cm after leaving the common iliac artery (**Table 7.2**). The vessels of the posterior division (the iliolumbar, lateral sacral, and superior gluteal) leave the internal iliac artery from its lateral surface to provide some of the blood supply to the pelvic wall and gluteal muscles. Trauma to these hidden vessels should be avoided during internal iliac artery ligation as the suture is passed around behind vessels.

FIGURE 7.24 Arteries and veins of the pelvis. (From Anson BJ. *An atlas of human anatomy*. Philadelphia, PA: WB Saunders, 1950, with permission.)

The anterior division has both parietal and visceral branches. The obturator, internal pudendal, and inferior gluteal vessels primarily supply muscles, whereas the uterine, superior vesical, vaginal (inferior vesical), and middle rectal vessels supply the pelvic organs. The internal iliac veins begin lateral and posterior to the arteries. These veins form a large and complex plexus within the pelvis, rather than having single branches, as do the arteries. They tend to be deeper in this area than the arteries, and their pattern is highly variable.

Ligation of the internal iliac artery has proved helpful in the management of postpartum hemorrhage. Burchell's arteriographic studies showed that physiologically active anastomoses between the systemic and pelvic arterial supplies were immediately patent after ligation of the internal iliac artery (**Fig. 7.25**). These anastomoses, shown in **Table 7.2**, connected the arteries of the internal iliac system with systemic blood vessels either directly from the aorta, as is true for the lumbar and middle sacral artery, or indirectly through the inferior mesenteric artery, as with the superior hemorrhoidal vessels. These *in vivo* pathways were quite different from the anastomoses that had previously been hypothesized on purely anatomic grounds.

Pelvic Ureter

The course of the ureter within the pelvis is important to gynecologic surgeons and is fully considered in [Chapter 37](#). A few of the important anatomic landmarks are considered here ([Fig. 7.24](#)). After passing over the bifurcation of the

P.115

internal and external iliac arteries, just medial to the ovarian vessels, the ureter descends within the pelvis. Here, it lies in a special connective tissue sheath that is attached to the peritoneum of the lateral pelvic wall and medial leaf of the broad ligament. This explains why the ureter still adheres to the peritoneum and does not remain laterally with the vessels when the peritoneal space is entered.

FIGURE 7.25 Collateral circulation of the pelvis.

The ureter crosses under the uterine artery (“water flows under the bridge”) in its course through the cardinal ligament. There is a loose areolar plane around it to allow for its peristalsis here. At this point, it lies along the anterolateral surface of the cervix, usually about 1 cm from it. From there, it comes to lie on the anterior vaginal wall and then proceeds for a distance of about 1.5 cm through the wall of the bladder.

TABLE 7.2 Collateral Circulation after Internal Iliac Artery Ligation

INTERNAL ILIAC SYSTEMIC

Iliolumbar

Lateral sacral

Middle hemorrhoidal

Lumbar

Middle sacral

Superior hemorrhoidal

During its pelvic course, the ureter receives blood from the vessels that it passes, specifically the common iliac, internal iliac, uterine, and vesical arteries. Within the wall of the ureter, these vessels are connected to one another by a convoluted vessel that can be seen running longitudinally along its outer surface.

Lymphatics

The lymph nodes and lymphatic vessels that drain the pelvic viscera vary in their number and distribution, but they can be organized into coherent groups. Because of the extensive interconnection of the lymph nodes, spread of lymph flow, and thus malignancy, is somewhat unpredictable. Therefore, some important generalizations about the distribution and drainage of these tissues are still helpful. Distribution of the pelvic lymph nodes is discussed further in [Chapter 46](#) on invasive carcinoma of the cervix. Figures 46.22 through 46.25 show this anatomy.

The nodes of the pelvis can be divided into the external iliac, internal iliac, common iliac, medial sacral, and pararectal nodes. The medial sacral nodes are few and follow the middle sacral artery. The pararectal nodes drain the part of the rectosigmoid above the peritoneal reflection that is supplied by

P.116

the superior hemorrhoidal artery. The medial and pararectal nodes are seldom involved in gynecologic disease.

The internal and external iliac nodes lie next to their respective blood vessels, and both end in the common iliac chain of nodes, which then drain into the nodes along the aorta. The external iliac nodes receive the drainage from the leg through the inguinal nodes. Nodes in the external iliac group can be found lateral to the artery, between the artery and vein, and on the medial aspect of the vein. These groups are called the anterosuperior, intermediate, and posteromedial groups, respectively. They can be separated from the underlying muscular fascia and periosteum of the pelvic wall along with the vessels, thereby defining their lateral extent. Some nodes at the distal end of this chain lie in direct relation to the deep inferior epigastric vessels and are named according to these adjacent vessels. Similarly, nodes that lie at the point where the obturator nerve and vessels enter the obturator canal are called obturator nodes.

The internal iliac nodes drain the pelvic viscera and receive some drainage from the gluteal region along the posterior division of the internal iliac vessels as well. These nodes lie within the adipose tissue that is

interspersed among the many branches of the vessels. The largest and most numerous nodes lie on the lateral pelvic wall, but many smaller nodes lie next to the viscera themselves. These nodes are named for the organ by which they are found (e.g., parauterine).

Not only is it difficult in the operating room to make some of the fine distinctions mentioned in this anatomic discussion, but also there is little clinical importance in doing so. Surgeons generally refer to those nodes that are adjacent to the external iliac artery as the external iliac group of nodes and to those next to the internal iliac artery as the internal iliac nodes. This leaves those nodes that lie between the external iliac vein and internal artery, which are called interiliac nodes.

The direction of lymph flow from the uterus tends to follow its attachments, draining along the cardinal, uterosacral, and even round ligaments. This latter connection can lead to metastasis from the uterus to the superficial inguinal nodes, whereas the former connections are to the internal iliac nodes, with free communication to the external iliac nodes and sometimes to the lateral sacral nodes. The anastomotic connection of the uterine and ovarian vessels makes lymphatic connections between these two drainage systems likely and metastasis in this direction possible.

The vagina and lower urinary tract have a divided drainage. Superiorly (upper two thirds of the vagina and the bladder), drainage occurs along with the uterine lymphatics to the internal iliac nodes, whereas the lower one third of the vagina and distal urethra drain to the inguinal nodes. However, this demarcation is far from precise.

The common iliac nodes can be found from the medial to the lateral border of the vessels of the same name. They continue above the pelvic vessels and occur around the aorta and the vena cava. These nodes can lie anterior, lateral, or posterior to the vessels.

THE ABDOMINAL WALL

Knowledge of the layered structure of the abdominal wall allows the surgeon to enter the abdominal cavity with maximum efficiency and safety. A general summary of these layers is provided in [Table 7.3](#). The abdomen's superior border is the lower edge of the rib cage (ribs 7 through 12). Inferiorly, it ends at the iliac crests, inguinal ligaments, and pubic bones. It ends posterolaterally at the lumbar spine and its adjacent muscles.

TABLE 7.3 Table of Abdominal Wall Layers

Skin
Subcutaneous layer
Camper fascia
Scarpa fascia
Musculoaponeurotic layer
Rectus sheath—formed by conjoined aponeuroses of the external oblique muscle
Internal oblique muscle: fused in lower abdomen
Transverse abdominal muscle

Transversalis fascia

Peritoneum

Skin and Subcutaneous Tissue

The fibers in the dermal layer of the abdominal skin are oriented in a predominantly transverse direction following a gently curving concave upward line. This predominance of transversely oriented fibers results in more tension on the skin of a vertical incision and in a wider scar.

Between the skin and musculoaponeurotic layer of the abdominal wall lie the subcutaneous tissues. It is made of globules of fat held in place and supported by a series of branching fibrous septa. In the more superficial portion of the subcutaneous layer, called Camper fascia, the fat predominates, and the fibrous tissue is less apparent. Closer to the rectus sheath, the fibrous tissue predominates relative to the fat in the region known as Scarpa fascia. Camper and Scarpa fasciae are not discrete or well-defined layers but represent regions of the subcutaneum. Scarpa fascia is best developed laterally and is not seen as a well-defined layer during vertical incisions.

Musculoaponeurotic Layer

Deep to the subcutaneous tissue is a layer of muscle and fibrous tissue that holds the abdominal viscera in place and controls movement of the lower torso (**Figs. 7.26** and **7.27**). Within this area are two groups of muscles: vertical muscles in the anterior abdominal wall and oblique flank muscles. The rectus abdominis muscle is found on either side of the midline, and the pyramidalis muscle is located just above the pubes. Lateral to these are the flank muscles: the external oblique, internal oblique, and transverse abdominal. The broad, sheetlike tendons of these muscles form aponeuroses that unite with their corresponding member of the other side, forming a dense white covering of the rectus abdominis muscle properly called the rectus sheath (rectus “fascia”).

Rectus Abdominis and Pyramidal Muscles

Each paired rectus abdominis muscle originates from the sternum and cartilages of ribs 5 through 7 and inserts into the anterior surface of the pubic bone. Each muscle has three tendinous inscriptions. These are fibrous interruptions within the muscle that firmly attach it to the rectus abdominis sheath. In general, they are confined to the region above the umbilicus, but they can be found below it. When this happens, the rectus sheath is attached to the rectus muscle there, and these two structures become difficult to separate during a Pfannenstiel incision.

The pyramidal muscles arise from the pubic bones and insert into the linea alba in an area several centimeters above the symphysis. Their development varies considerably among individuals. Their strong attachment to the midline makes separation of their attachment here difficult by blunt dissection.

FIGURE 7.26 External oblique, internal oblique, and pyramidal muscles. (The original illustration is in the Max Brödel Archives in the Department of Art as Applied to Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD, USA, with permission.)

FIGURE 7.27 Transverse abdominal and rectoabdominal muscles. (The original illustration is in the Max Brödel Archives in the Department of Art as Applied to Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD, USA, with permission.)

P.118

Flank Muscles

Lateral to the rectus abdominis muscles lie the broad, flat muscles of the flank. The aponeurotic insertions of these muscles join to form the conjoint tendon, or rectus sheath, which covers the rectus abdominis. Because of its importance, the rectus sheath is further discussed below.

The most superficial of these muscles is the external oblique. Its fibers run obliquely anteriorly and inferiorly from their origin on the lower eight ribs and iliac crest. Unlike the external oblique muscle's fibers, which run obliquely downward, the fibers of the internal oblique muscle fan out from their origin in the anterior two thirds of the iliac crest, the lateral part of the inguinal ligament, and the thoracolumbar fascia in the lower posterior flank. In most areas, they are perpendicular to the fibers of the external oblique muscle, but in the lower abdomen, their fibers arch somewhat more caudally and run in a direction similar to those of the external oblique muscle.

As the name *transversus abdominis* implies, the fibers of the deepest of the three layers have a primarily transverse orientation. They arise from the lower six costal cartilages, the thoracolumbar fascia, the anterior three fourths of the iliac crest, and the lateral inguinal ligament. The caudal portion of the transverse abdominal

muscle is fused with the internal oblique muscle. This explains why, during transverse incisions of the lower abdomen, only two layers are discernible at the lateral portion of the incision.

Although the fibers of the flank muscles are not strictly parallel to one another, their primarily transverse orientation and the transverse pull of their attached muscular fibers place vertical suture lines in the rectus sheath under more tension than transverse ones. For this reason, vertical incisions are more prone to dehiscence.

Rectus Sheath (Conjoined Tendon)

The line of demarcation between the muscular and aponeurotic portions of the external oblique muscle in the lower abdomen occurs along a vertical line through the anterosuperior iliac spine (**Fig. 7.28**). The internal oblique and transverse abdominal muscles extend farther toward the midline, coming closest at their inferior margin, at the pubic tubercle. Because of this, fibers of the internal oblique muscle are found underneath the aponeurotic portion of the external oblique muscle during a transverse incision. In addition, it is between the internal oblique and transverse abdominal muscles that the nerves and blood vessels of the flank are found and their injury avoided.

FIGURE 7.28 Cross section of lower abdominal wall. **A:** The anterior fascial sheath of the rectus muscle from external oblique (1) and split aponeurosis of internal oblique (2) muscles. The posterior sheath is formed by aponeurosis of the transverse abdominal muscle (3) and split aponeurosis of the internal oblique muscle. **B:** Lower portion of the abdominal wall below arcuate line (linea semicircularis) with absence of a posterior fascial sheath of the rectus muscle and all of the fascial aponeuroses (1,2,3) forming the anterior rectus muscle sheath.

In forming the rectus sheath, the conjoined aponeuroses of the flank are separable lateral to the rectus muscles but fuse near the midline. As they reach the midline, these layers lose their separate directions and fuse. Many specialized aspects of the rectus sheath are important to the surgeon. In its lower one fourth, the sheath lies entirely anterior to the rectus muscle. Above that point, it splits to lie both ventral and dorsal to it. The transition between these two arrangements occurs midway between the umbilicus and the pubes and is called the arcuate line. Cranial to this line, the midline ridge of the rectus sheath, the linea alba, unites these two layers. Sharp dissection is usually required to separate these layers during a Pfannenstiel incision. A vertical peritoneal incision cuts the posterior sheath.

The lateral border of the rectus muscle is marked by the semilunar line of the rectus sheath. Above the arcuate line, this is the level at which the anterior and posterior layers of the sheath split. Below it the transversalis fascia fuses with the sheath. The semilunar line is not always where the three layers of flank muscles join. During a

transverse lower abdominal incision, the external and internal oblique aponeuroses are often separable near the midline.

The inguinal canal lies at the lower edge of the musculofascial layer of the abdominal wall. Through the inguinal canal, in the woman, the round ligament extends to its termination in the labium majus. In addition, the ilioinguinal nerve and the genital branch of the genitofemoral nerve pass through the canal.

Transversalis Fascia, Peritoneum, and Bladder Reflection

Inside the muscular layers, and outside the peritoneum, lies the transversalis fascia, a layer of fibrous tissue that lines the abdominopelvic cavity. It is visible during abdominal incisions as the layer just underneath the rectus abdominis muscles suprapubically. It is separated from the peritoneum by a variable layer of adipose tissue. It is frequently incised or bluntly dissected off the bladder to take the tissues in this region “down by layers.”

The peritoneum is a single layer of serosa. It is thrown into five vertical folds by underlying ligaments or vessels that converge toward the umbilicus. The single median umbilical fold is caused by the presence of the urachus (median umbilical ligament). Lateral to this are paired medial umbilical folds that are raised by the obliterated umbilical arteries that connected the internal iliac vessels to the umbilical cord in fetal life, and the corresponding lateral umbilical folds caused by the inferior epigastric arteries and veins.

The reflection of the bladder onto the abdominal wall is triangular in shape, with its apex blending into the medial umbilical ligament. Because the apex is highest in the midline, incision in the peritoneum lateral to the midline is less likely to result in bladder injury.

Neurovascular Supply of the Abdominal Wall

Vessels of the Abdominal Wall

Knowing the location and course of the abdominal wall blood vessels helps the surgeon anticipate their location during abdominal incisions and during the insertion of laparoscopic

P.119

trocars (**Fig. 7.29**). The blood vessels that supply the abdominal wall can be separated into those that supply the skin and subcutaneous tissues and those that supply the musculofascial layer. Although there is only one set of epigastric vessels in the subcutaneous tissues (superficial epigastric), there are both superior and inferior epigastric vessels in the musculofascial layer, so care must be taken in using these terms to avoid confusion.

FIGURE 7.29 Normal variation in epigastric vessels. *A*, *B*, and *C* designate safe spots for laparoscopic trocar insertion. *Dotted lines* indicate lateral border of rectus muscle. (From Hurd WW, Bude RO, DeLancey JOL, et al. The location of abdominal wall blood vessels in relationship to abdominal landmarks apparent at laparoscopy. *Am J Obstet Gynecol* 1994;171:642, with permission. Copyright © 1994, Elsevier.)

The superficial epigastric vessels run a diagonal course in the subcutaneum from the femoral vessels toward the umbilicus, beginning as a single artery that branches extensively as it nears the umbilicus. Its position can be anticipated midway between the skin and musculofascial layer, in a line between the palpable femoral pulse and the umbilicus. The external pudendal artery runs a diagonal course from the femoral artery medially to supply the region of the mons pubis. It has many midline branches, and bleeding in its territory of distribution is heavier than that from the abdominal subcutaneous tissues. The superficial circumflex iliac vessels proceed laterally from the femoral vessels toward the flank.

The blood supply to the lower abdominal wall's musculofascial layer parallels the subcutaneous vessels. The branches of the external iliac, the inferior epigastric, and the deep circumflex iliac arteries parallel their superficial counterparts (**Fig. 7.29**). The circumflex iliac artery lies between the internal oblique and transverse abdominal muscle. The inferior epigastric artery and its two veins originate lateral to the rectus muscle. They run diagonally toward the umbilicus and intersect the muscle's lateral border midway between the pubis and umbilicus. Below the point at which the vessels pass under the rectus, they are found lateral to the muscle deep to the transversalis fascia. After crossing the lateral border of the muscle, they lie on the muscle's dorsal surface, between it and the posterior rectus sheath. As the vessels enter the rectus sheath, they branch extensively, so that they no longer represent a single trunk. The angle between the vessel and the border of the rectus muscle forms the apex of the Hesselbach triangle (inguinal triangle), the base of which is the inguinal ligament.

Lateral laparoscopic trocars are placed in a region of the lower abdomen where injury to the inferior epigastric and superficial epigastric vessels can occur easily. The inferior epigastric arteries and the superficial epigastric arteries run similar courses toward the umbilicus. Knowing the average location of these blood vessels helps in choosing insertion sites that will minimize their injury and the potential hemorrhage and hematomas that this injury can cause. Just above the pubic symphysis, the vessels lie approximately 5.5 cm from the midline, whereas at the level of the umbilicus, they are 4.5 cm from the midline (**Fig. 7.30**). Therefore, placement either lateral or medial to the line connecting these points minimizes potential vascular injury. In addition, the location of the inferior epigastric vessel can often be seen (**Fig. 7.31**) by following the round ligament to its point of entry into the inguinal ring, recognizing that the vessel lies just lateral to this point.

Nerves of the Abdominal Wall

The innervation of the abdominal wall (**Fig. 7.30**) comes from the abdominal extension of intercostal nerves 7 through 11, subcostal nerve (T12), and iliohypogastric and ilioinguinal nerves (both L1). Dermatome T10 lies at the umbilicus.

After giving off a lateral cutaneous branch, each intercostal nerve pierces the lateral border of the rectus sheath. There it provides a lateral branch that ends in the rectus muscle. The anterior branch then passes through the muscle and perforates the rectus sheath to supply the subcutaneous tissues and skin as the anterior cutaneous branches. Incisions along the lateral border of the rectus lead to denervation of the muscle, which can render it atrophic and weaken the abdominal wall. Elevation of the rectus sheath off the muscle during the Pfannenstiel incision stretches the perforating nerve, which is sometimes ligated to provide hemostasis from the accompanying artery. This may leave an area of cutaneous anesthesia.

The iliohypogastric and ilioinguinal nerves pass medial to the anterosuperior iliac spine in the abdominal wall. The former supplies the skin of the suprapubic area. The latter supplies the lower abdominal wall, and by

sending a branch through the inguinal canal, it supplies the upper portions of the labia majora and medial portions of the thigh. These nerves can be entrapped in the lateral closure of a transverse incision and may lead to chronic pain syndromes.

The genitofemoral (L1 and L2) and femorocutaneous (L2 and L3) nerves can be injured during gynecologic surgery. The genitofemoral nerve lies on the psoas muscle (**Fig. 7.31**), where pressure from a retractor can damage it and lead to anesthesia in the medial thigh and lateral labia. The femoral cutaneous nerve can be compressed either by a retractor blade lateral to the psoas or by too much flexion of the hip in the lithotomy position, causing anesthesia over the anterior thigh.

BEST SURGICAL PRACTICES

- Important anatomic relationships of the ureter include the following:
 - The ureter lies medial to the ovarian vessels at the bifurcation of the internal and external iliac arteries entering the pelvic brim.
 - The ureter courses under the uterine artery approximately at 1.5 cm lateral to the cervix.
 - The ureter lies directly on the anterior vaginal wall very near the place where the vagina is detached from the cervix during the hysterectomy.
- Branches of the ilioinguinal and iliohypogastric nerves run in the region of the abdominal wall involved in lower abdominal transverse incision and can be involved with nerve entrapment syndromes after these incisions.

FIGURE 7.30 Nerve supply to the abdomen. **Right:** Deep innervation of T6BT12 to the transverse abdominal, internal oblique, and rectal muscles. **Left:** Superficial distribution, including cutaneous nerves, after penetration and innervation of the external oblique muscle and fascia. Innervation of the groin and thigh also is shown.

FIGURE 7.31 Sagittal view of female pelvis, showing inguinal and femoral anatomy. (The original illustration is in the Max Brödel Archives in the Department of Art as Applied to Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD, USA, with permission.)

P.121

- Support of the pelvic organs comes from the combined action of the levator ani muscles that close the genital hiatus and provide a supportive layer on which the organs can rest and by the attachment of the vagina and uterus to the pelvic sidewalls.
- The internal iliac vessels supply the pelvic organs and pelvic wall and gluteal regions. The complexity of these multiple branches varies from individual to individual, but the key feature is the multiple areas of collateral circulation that come into play immediately after internal iliac artery ligation so that blood supply to the pelvic organs has diminished pulse pressure but continues to have flow even after the ligation.
- The blood supply to the female genital tract is an arcade that begins at the top with input from the ovarian vessels, lateral supply by the uterine vessels, and distal supply by the vaginal artery. There is an anastigmatic artery that runs along the entire length of the genital tract. For this reason, ligation of any single one of these arteries does not diminish flow to the uterus itself.

Chapter 8

Preoperative Care of the Gynecologic Patient

Victoria L. Handa

Preoperative care is a critical factor in achieving successful outcomes of both emergent and scheduled gynecologic surgical procedures. This chapter is designed to address the essential features of preoperative care from the preoperative examination in the office, or emergency room, to the time of surgery. Included are suggestions relating to appropriate preoperative testing and evaluation. Foremost, it is essential to keep in mind that each woman must be considered individually, based on her medical findings and needs, and that no suggestions can be completely adapted to all women preparing for gynecologic surgery.

The goals of the preoperative evaluation are to answer the following three questions, as outlined by Roizen:

1. Is the patient in optimal health?
2. Can, or should, the patient's physical or mental condition be improved before surgery?
3. Does the patient have health problems or use any medications that could unexpectedly influence perioperative events?

PREOPERATIVE COUNSELING

It is most important to dedicate a portion of the preoperative care time to a discussion with the patient of options for management of her gynecologic problem, including both short and long-term potential complications. All patients must be given sufficient medical information to allow them to make an educated decision about whether to proceed with the planned surgery. Not only is the discussion time useful in fostering a good physician-patient relationship, but it becomes extremely important if outcomes of surgery are less than expected, particularly if the discussion was documented in the patient's record. The informed consent process should include patient education regarding the goals of the planned surgery, the alternatives, and the possible hazards. The preoperative discussion is also an opportunity to discuss expectations for the recovery period, including the expected duration of hospitalization and recommended activity restrictions for the postoperative period. This is also an opportunity to review the patient's wishes regarding advanced directives.

SCREENING FOR PERIOPERATIVE RISK

Once a decision has been made to proceed with surgery, it is the responsibility of the surgeon to assess the patient for medical and surgical conditions that could increase her risk of complications. The most important part of the evaluation is the history. A screening questionnaire may also be of value ([Table 8.1](#)). The goal is to detect preexisting conditions shown to be associated with perioperative adverse events. Women with these risk factors should be further evaluated. Depending on the complexity of the situation, the surgeon may partner with the patient's primary physician or with consultants to provide additional evaluation and management.

The risks of perioperative morbidity and mortality are strongly associated with the type of surgery planned. For example, the risk of cardiac death or myocardial infarction is 1% to 5% after major intraperitoneal surgery but less than 1% for ambulatory surgeries. Thus, the extent of the planned surgery, the nature of the pathologic condition indicating surgery, and the impact of any planned adjuvant treatments should be considered.

Risk factors for major cardiac complications (including myocardial infarction, pulmonary edema, ventricular fibrillation, cardiac arrest, and complete heart block) are well established. These risk factors include history of prior myocardial infarction, heart failure, cerebrovascular disease, insulin-dependent

diabetes, and serum creatinine >2.0 mg/dL. Among gynecologic surgery patients with none of these risk factors, the risk of a major cardiac complication is less than 1%. Other important factors include the age of the patient, dependent functional status (defined as unable to perform activities of daily living without assistance), and American Society of Anesthesiologists' class ([Table 8.2](#)). The patient's exercise tolerance can be used as a guide: Poor exercise tolerance is defined as inability to walk four blocks or to climb two flights of stairs as a part of normal daily activities. A more diligent preoperative evaluation is appropriate for women at high risk, possibly including exercise stress test and referral for cardiology evaluation.

TABLE 8.1 Preanesthetic Screening Questionnaire

1.	Do you usually get chest pain or breathlessness when you climb up two flights of stairs at normal speed?
2.	Do you have kidney disease?
3.	Has anyone in your family (blood relatives) had a problem following an anesthetic?
4.	Have you ever had a heart attack?
5.	Have you ever been diagnosed with an irregular heartbeat?
6.	Have you ever had a stroke?
7.	If you have been put to sleep for an operation, were there any anesthetic problems?
8.	Do you suffer from epilepsy or seizures?
9.	Do you have any problems with pain, stiffness, or arthritis in your neck or jaw?
10.	Do you have thyroid disease?
11.	Do you suffer from angina?
12.	Do you have liver disease?
13.	Have you ever been diagnosed with heart failure?
14.	Do you suffer from asthma?
15.	Do you have diabetes that requires insulin?
16.	Do you have diabetes that requires tablets only?

17. Do you suffer from bronchitis?

TABLE 8.2 Classification of Physical Status, Established by the American Society of Anesthesiologists

CLASS	DESCRIPTION
P1	A normal healthy patient
P2	A patient with mild systemic disease
P3	A patient with severe systemic disease
P4	A patient with severe systemic disease that is a constant threat to life
P5	A moribund patient who is not expected to survive without the operation
P6	A declared brain-dead patient whose organs are being removed for donor purposes

Excerpted from ASA Manual for Anesthesia Department Organization and Management, American Society of Anesthesiologists, Park Ridge, IL, 2003-2004. A copy of the full text can be obtained from ASA, 520 N. Northwest Highway, Park Ridge, IL 60068-2573.

Diabetes mellitus is a potential risk factor for cardiovascular morbidity and perioperative infections. The risk of surgical site infection is higher among women with preoperative serum glucose >200 mg/dL. The risk of infection is also significantly increased by postoperative hyperglycemia. In addition, an assessment for end-organ failure (such as renal or cardiac disease) is appropriate for women with long-standing diabetes, and especially those with a history of poor control and those with other sequelae from their diabetes.

Clinically significant pulmonary complications occur in 5% to 10% of surgeries. In a systematic review, Smetana and colleagues found that risk factors for pulmonary complications include age over 50 years, functional dependence (requiring assistance to perform activities of daily living), obstructive sleep apnea, surgery lasting greater than 3 hours, and cigarette smoking. Smoking duration is also a risk factor for perioperative complications. Well-controlled asthma is not a risk factor for perioperative pulmonary complications.

VALUE OF SCREENING LABORATORY STUDIES AND OTHER TESTING

The practice of a routine battery of preoperative laboratory tests is no longer recommended. Using data from National Surgical Quality Improvement Program, Benarroch-Gampel and colleagues demonstrated that the patient's medical history, age, and the type of surgery planned are better predictors of surgical complications than are the results of laboratory tests. Similar findings were obtained by Fritsch and colleagues. The indiscriminate use of "routine" preoperative tests not only fails to identify high-risk patients but also leads to

unnecessary costs. Also, false-positive results can lead to unnecessary surgical delays and interventions. Thus, preoperative tests should not be ordered routinely but should be based on the characteristics of the patient and the planned surgery.

Preoperative testing recommendations at Johns Hopkins Bayview Medical Center are summarized in [Table 8.3](#). Testing recommendations for gynecologic surgery are based on the patient's risk factors, which are derived from the history and physical examination. Coagulation studies are rarely recommended prior to gynecologic surgery but may be considered for those with menorrhagia, if clinically indicated. Chest x-ray is indicated only if the patient has experienced a recent acute episode of respiratory distress or flare of chronic pulmonary disease. A urine pregnancy test is obtained on the day of surgery for women who, by history, may be pregnant. Tests that have been performed recently (within 6 months) should not be repeated if the patient's condition has not changed. This is because the result is unlikely to be different; Macpherson and colleagues found a less than 1% probability of an abnormal laboratory test result in an adult with a normal value within the past year.

Preoperative hematocrit (or complete blood count) is probably the most commonly used preoperative laboratory study. Baseline hemoglobin can be useful in the interpretation of postoperative anemia and the management of patients with acute surgical blood loss. Therefore, a preoperative hematocrit should be ordered if the planned surgery is likely to result in substantial blood loss or if the patient's history suggests a high risk for preoperative anemia.

Serum electrolytes should not be ordered routinely but may be useful in women on diuretics or with a history that suggests an electrolyte imbalance is likely. A routine BUN and creatinine are appropriate for women with diabetes or hypertension. Routine BUN and creatinine may also be useful in older patients. Serum glucose is recommended for women on chronic corticosteroids.

A preoperative electrocardiogram should be considered in women with known cardiovascular disease, peripheral artery disease, or cerebrovascular disease. This is because a baseline electrocardiogram can be useful in the management of acute perioperative cardiovascular events. However, an electrocardiogram is a poor screening test and is unlikely to alter management in the asymptomatic patient. Routine preoperative electrocardiogram should be considered in women over age 50.

A cardiac stress test should be considered if the patient reports poor exercise tolerance or if cardiac symptoms are present. Other indications for a preoperative cardiac evaluation include a history of prior myocardial infarction, known or suspected heart failure, cerebrovascular disease, insulindependent diabetes, and serum creatinine >2.0 mg/dL.

Preoperative chest x-ray and pulmonary function tests do not predict postoperative pulmonary complications and therefore should not be routinely ordered before surgery. A thorough clinical assessment will detect most high-risk conditions. Women with dyspnea, poor exercise tolerance, or unexplained cough should be considered for further evaluation.

Cervical cytology should be obtained before hysterectomy for benign disease. The goal is to identify women with cervical cancer, for whom a simple hysterectomy is not appropriate. If the patient is up to date on screening cytology and the last study was normal, cytology should not be repeated.

**TABLE 8.3 Johns Hopkins Bayview Medical Center Preoperative Evaluation Center
Preadmission Screening Guidelines**

LIVER

MEDICAL CONDITION	CBC	SERUM ELECTROLYTES	PT/PTT	FUNCTION TESTS	EKG
Age >50					X
Hypertension		X			X
Cardiac disease or arrhythmia	X	X			X
Diabetes		X			X
Renal disease		X			X
Diuretic/ACE inhibitor/chemotherapy		X			X
Hematologic or liver disease	X		X	X	
Hysterectomy	X				
Hysteroscopy		X			
Highly invasive procedures:	X	X	X		X
Radical surgery					
Preoperative bowel prep					
Anticipate >500 mL blood loss					
These are screening guidelines only; further testing based on the patient's medical history, surgeon's evaluation, or primary care physician's discretion. Data from Johns Hopkins Bayview Medical Center Preoperative Evaluation Center pre-admission guidelines.					

To minimize infectious complications of surgery, active infections (such as urinary tract infection) should be identified and treated completely before surgery unless surgery is urgent. In addition, American College of Obstetricians and Gynecologists recommends screening for and treating bacterial vaginosis before hysterectomy to minimize the risk of cuff infection. However, an alternative is the routine use of preoperative metronidazole. This option may be cost-effective at the time of hysterectomy if the prevalence of bacterial vaginosis is at least 1%.

PERIOPERATIVE MANAGEMENT OF MEDICATIONS TAKEN CHRONICALLY

The management of chronic medications varies by institution, and there is little evidence to guide best practices. However, most medications taken chronically are safely continued in the perioperative period. Cessation should not be recommended for beta-blockers (especially if used to control arrhythmia or angina), statins, alpha 2 agonists, H2 blockers, proton pump inhibitors, and inhaled asthma medications (including steroids, beta-agonists, and anticholinergics).

There is considerable controversy about whether to stop oral contraceptives in the perioperative period. The rationale for stopping hormonal contraception is to minimize phlebitis risk. However, concerns regarding unwanted pregnancy are also valid. Therefore, the most practical option is probably to continue oral contraception.

Medications that should be stopped before surgery include herbal preparations, including Ephedra, Garlic, Ginkgo, Ginseng, Kava, and St. John's Wort.

Typically, warfarin is stopped before elective surgery to minimize the risks of significant bleeding or hematoma formation. However, the risk of thrombosis is increased by cessation of warfarin before surgery. Thus, patients at high risk of thrombosis should be managed by transitioning from warfarin to enoxaparin (Lovenox) 1 mg/kg subcutaneously twice a day in the preoperative period, usually beginning 5 days before elective surgery. Once the international normalized ratio is less than 1.5, the risk of bleeding is further minimized if enoxaparin can be held for 24 hours before surgery. An inferior vena cava filter is an alternative to perioperative enoxaparin. Warfarin can be continued if the planned procedure is such that the risk of surgical bleeding is minimal.

Traditionally, patients have been asked to refrain from using aspirin before elective surgery. The rationale to stop aspirin is the increased risk of hematoma and bleeding complications. However, among women who are on maintenance therapy with aspirin for cardiovascular prevention, aspirin cessation may lead to an increase in thrombosis. Aspirin withdrawal leads to an increase in perioperative risk of cardiac and thromboembolic complications among women who use aspirin for cardiovascular prevention. Therefore, current recommendations are to continue maintenance aspirin therapy for women who use this for cardiovascular prevention. However, casual use of aspirin in the perioperative period should be avoided.

PREOPERATIVE MANAGEMENT OF RISK FACTORS

Women at highest risk for perioperative cardiac events should be considered for treatment with a beta-blocker. A number of large clinical trials have investigated the benefit of perioperative beta-blockers to reduce cardiac events. Based on evidence of benefit, especially for women undergoing cardiac surgery, the American Heart Association has recommended that high-risk patients receive perioperative beta-blockers, beginning at

P.125

least 1 week before surgery (preferably 30 days). Those felt to benefit from this intervention included women with ischemic heart disease, those with heart failure, women with a history of cerebrovascular disease, women with diabetes mellitus, and those with renal insufficiency (serum creatinine >2 mg/dL).

However, the 2008 PeriOperative ISchemic Evaluation (POISE) trial suggested that perioperative beta-blockade was associated with an increased risk of stroke. As a result, enthusiasm for prophylaxis has waned. The current recommendations for perioperative beta-blockade are focus on high-risk groups, with initiation of therapy well before the planned surgery in order to titrate dosage to control heart rate while avoiding bradycardia and hypotension. Beta-blockers should not be initiated on the day of surgery. As previously noted, withdrawal of beta-blockers should be avoided in patients receiving this therapy chronically.

Revascularization, including angioplasty and coronary stents, may be employed as a strategy to reduce risk in women with ischemic heart disease. However, the risk of myocardial infarctions or death is increased in the first few weeks after angioplasty or stenting. Therefore, if possible, elective gynecologic surgery should not be

performed in the first 6 weeks after angioplasty or stenting. For women who have received a drug-eluting stent, elective surgery should be avoided for 1 year.

Optimal control of diabetes should be obtained before elective surgery to reduce surgical complications, especially surgical site infections. The risk of surgical infection is higher in diabetics with poor glucose control before surgery and in the immediate postoperative period. More specifically, among 55,000 diabetics undergoing surgery, King and colleagues found that infection risk was marginally increased for postoperative serum glucose 150 to 250 mg/dL but increased 50% for women with serum glucose greater than 250 mg/dL. Thus, the goal of perioperative management of diabetes is to maintain a serum glucose <200 mg/dL in the perioperative period. Women with diabetes should be assessed preoperatively for renal impairment.

Perioperative adrenal insufficiency can occur among women receiving glucocorticoids. Women who have received more than 20 mg/day of prednisone (or equivalent) for at least 3 weeks over the 6 months preceding surgery should be treated with “stress steroids.” A typical regimen for “stress steroids” would include preoperative administration of 50 mg IV hydrocortisone and postoperative administration of 25 mg IV hydrocortisone every 8 hours for 24 hours.

Women who smoke cigarettes should be encouraged to quit prior to elective surgery. Smoking cessation should be attempted as far in advance of surgery as possible. Risks related to smoking are dramatically reduced by at least 2 months of smoking cessation prior to surgery.

Controversy surrounds the practice of perioperative mechanical bowel preparation. A 2005 meta-analysis demonstrated no benefit to preoperative mechanical bowel preparation. Some surgeons continue the practice for vaginal or laparoscopic surgery with the goal of decompressing the bowel.

RISK REDUCTION ON THE DAY OF SURGERY

Most gynecologic surgeons are familiar with strategies for prevention of deep venous phlebitis. The risk of perioperative phlebitis is influenced by both patient and surgical characteristics. Most women undergoing gynecologic surgery will be classified as moderate or high risk, depending on the duration of the procedure (<30 or >30 minutes) and the age of the patient (<60 or >60 years). For both groups, recommended prophylactic options include heparin (5,000 u SQ q12h), enoxaparin (Lovenox) 40 mg daily, or intermittent pneumatic compression stockings. Prophylaxis should be initiated before surgery and continued at least through hospital discharge. It is not clear whether these measures are beneficial if they are initiated after surgery.

Surgical site infection is defined by the Centers for Disease Control and Prevention (CDC) as infections at or near the surgical incision occurring within 30 days of an operative procedure or within 1 year if an implant is left in place. Surgical site infections can be minimized by preoperative preparation, such as optimal glucose control among diabetics and identification and preoperative treatment of infection. Prevention of surgical site infection includes skin preparation. Hair removal does not reduce surgical site infections. If hair removal at the surgical site is necessary or preferred by the surgeon, the hair should be clipped rather than shaved. Specifically, the risk for surgical site infection is more than doubled by shaving versus clipping.

Traditionally, skin preparation with povidone-iodine has been used to minimize surgical site infection. However, a randomized study by Darouiche and colleagues suggested that chlorhexidine-alcohol is superior to povidone-iodine preparation. Thus, chlorhexidine-alcohol should be preferred for preparation of abdominal skin.

Povidone-iodine remains the standard for vaginal skin preparation. The optimal vaginal preparation for women with iodine allergy is not established. Chlorhexidine has been suggested as an alternative, but the current labeling of chlorhexidine warns of use in genital area, and therefore many surgeons are hesitant to consider the use of this agent in the vagina. Moreover, the value of chlorhexidine preparation was questioned by a recent retrospective cohort study of greater than 7,000 abdominal hysterectomies in Sweden. Kjølhede and colleagues

found no difference between vaginal cleansing with chlorhexidine solution versus no vaginal preparation. In contrast, other studies have suggested a benefit from chlorhexidine vaginal preparation. In summary, povidone-iodine remains the preferred preparation, with some surgeons opting to use chlorhexidine in women who report allergy to iodine.

Preoperative intravenous antibiotics can further reduce surgical site infections in clean-contaminated surgeries, such as hysterectomy. The American College of Obstetricians and Gynecologists recommends antibiotic prophylaxis prior to hysterectomy and urogynecology procedures (including those involving mesh). Cephazolin is recommended, although alternatives include cefotetan, cefoxitin, cefuroxime, or ampicillin-sulbactam. In case of penicillin allergy, clindamycin plus gentamicin is the recommended alternative. Prophylactic antibiotics should be administered within 60 minutes prior to the start of surgery. The goals are to insure serum levels of the drug at the time of incision and to minimize the risk of a severe allergic reaction at the time of induction of anesthesia.

Recommendations have changed for perioperative antibiotics for prevention of endocarditis. The American Heart Association and other international organizations no longer recommend endocarditis prophylaxis for any gynecologic procedures, including hysterectomy.

In contrast, the use of prophylactic antibiotics for women with prosthetic joints undergoing invasive procedures remains controversial. In the past, intravenous antibiotics were recommended to reduce bacteremia at the time of genital tract surgery, in an effort to reduce hematogenous infection of prosthesis. However, in December 2012, The American Academy of Orthopedic Surgeons and the American Dental Association issued a statement recommending against the practice of routinely prescribing prophylactic antibiotics for patients with hip and knee prosthetic joint implants undergoing dental

P.126

procedures. This was after an evidence-based review failed to demonstrate any benefit from antibiotics in this setting. However, it is not clear whether those recommendations represent the best practices for women undergoing gynecologic surgery. For women at highest risk, the gynecologic surgeon might consider administering a single dose of cefazolin, cefoxitin, or ampicillin-sulbactam. Risk factors have been defined as immunosuppression, history of inflammatory arthropathies (e.g., rheumatoid arthritis, systemic lupus erythematosus), history of joint infection, and insulin-dependent (Type 1) diabetes. The value of antibiotic prophylaxis in these groups is unclear.

Chapter 9

Postanesthesia and Postoperative Care

Alexander Duncan
Jonathan E. Sevransky
Ira R. Horowitz

DEFINITIONS

Hospital-acquired pneumonia (HAP)—Pneumonia that develops 48 hours or more after hospital admission because of organisms that were not incubating at the time of admission.

Hypoxic pulmonary vasoconstriction—Local reflex in the lung that diverts blood away from poorly oxygenated regions.

Low molecular weight heparin (LMWH)—Product that acts by inhibiting factor Xa.

Tissue plasminogen activator (t-PA)—Compound used for nonsurgical thrombolysis.

Venous thrombotic event—A venous thromboembolism that includes vascular clotting, such as deep vein thrombosis, and pulmonary embolism.

Virchow triad—Factors that increase the risk of vascular thromboembolism, for example, hypercoagulability, stasis, trauma to vessels.

V/Q abnormalities—Ventilation/perfusion abnormalities, which can lead to mismatching of pulmonary blood flow and ventilation.

Postoperative complications are the most important factors in defining the outcome of the first 72 hours following a patient's surgical procedure. It is critical to monitor basic physiologic parameters—such as renal, cardiovascular, and respiratory functions—and laboratory tests to optimize and sustain recovery from surgery and anesthesia.

Postoperative morbidity can be minimized by an appropriate preoperative assessment of the surgical patient. This should include emphasis on identifying the patient at risk for venous thromboembolic complications and administering prophylactic anticoagulation. Optimized nutritional status and support has also been shown to improve wound healing and decrease the postoperative recovery time and length of hospital stay.

POSTOPERATIVE VASCULAR COMPLICATIONS

About 3 million venous thrombotic events, or venous thromboembolisms (VTEs), occur in the United States each year. About 2,000,000 plus of these events are deep vein thrombosis (DVT) in the hospital, and as many as 600,000 are pulmonary embolisms (PEs). Twenty-five percent of PEs are fatal, and VTE has been recognized as the biggest preventable cause of morbidity and mortality in United States hospitals. Ten percent of hospital deaths in the US are due to PE, and some patient groups, especially gynecologic malignancy patients, have a higher-than-usual risk for VTE, with a general incidence of about 15% to 20%. The risk of fatal postoperative PE among these patients is closer to 40% with no prophylaxis. More than 90% of PE patients have a lower or upper extremity DVT concomitantly.

PE has few defining characteristics, but the onset of respiratory distress compounded by hypotension, chest pain, and cardiac arrhythmias can be harbingers of impending death and are complications that convert an otherwise successful surgery into a postoperative fatality. Only 70% of patients who die of a PE have it considered in their differential diagnosis.

Modern diagnostic studies have provided more accurate information about the frequency of vascular complications and can identify those patients at risk of an embolic event. Pre- and postoperative prophylaxis with heparin or low molecular weight heparins (LMWHs) and concomitant use of embolic stockings and intermittent pneumatic compression (IPC) devices have significantly reduced the risk of VTE in the moderate- and high-risk patients. Clarke-Pearson and colleagues, using univariate and regression analysis, designed a prognostic model to evaluate the risk of postoperative VTE for an individual patient. In a group of 411 gynecology patients, the prognostic factors they identified included type of surgery, age, leg edema, non-Caucasian ethnicity, severity of varicose veins, previous radiotherapy, and a prior history of DVT.

More than 130 years ago, Rudolph Virchow conceptualized the factors leading to postoperative thrombosis. These included venous stasis, changes in the blood constituents, and impaired function of the vessel wall. The blood clotting process is complicated ([Fig. 9.1](#)), but it is initiated by the actions of tissue factor (TF) on factor VIIa after injury to vessels exposes the subendothelium and promotes platelet adhesion and aggregation to form a primary platelet plug. The process is completed by the actions of multiple components and factors in the blood that generate thrombin, the potent rate-regulating enzyme, which then interacts with fibrinogen and factor XIII to form an insoluble clot ([Fig. 9.2](#)). Much recent evidence has focused on the role of cell-derived circulating microparticles (MPs) as potent etiologic agents for enhanced risk of VTE. This is because these MPs carry TF and other procoagulant phospholipids on their surfaces that potentiate activation of the coagulation pathways and may promote angiogenesis.

When patients have cancer or sustain venous damage from the surgical procedure, such as occurs with skeletonization of the pelvic vasculature, the up-regulation of thrombin generation has more profound effects. TF, fibrin, and thrombin

P.128

all have angiogenic properties that can interfere with tissue structural properties by degrading matrix metalloproteinases, promoting cell migration, and enhancing metastasis. Tumors also up-regulate the production of TF and its inclusion into MPs as well as plasminogen activator inhibitor-1 (PAI-1), thus promoting the generation of procoagulant activity. This multifactorial derived activity helps to explain the high incidence of VTE in the gynecologic cancer patient.

FIGURE 9.1 Formation of venous thrombus following various surgical procedures with the activation of clotting factors and aggregation of platelets. AP, activated protein, PC,

protein C, TFP, tissue factor peptide.

FIGURE 9.2 Schematic representation of the cascade clotting mechanism, illustrating the role of extrinsic and intrinsic factors. Increases in tissue thromboplastin-like substance and collagen-activated factor XII initiate the formation of fibrin through the extrinsic and intrinsic pathways, principally by the activation of factor X. ADP, adenosine diphosphate.

These tumorigenic effects on coagulation occur in addition to the typical acute postsurgical reactions seen in many hemostasis proteins. These include increases in fibrinogen, factor V, factor VIII, and von Willebrand factor, which promotes platelet adhesion and function. There is usually an increase in platelet number in the postoperative period, and the normal fibrinolytic response is blunted by the increase in PAI-1 and thrombin-activatable fibrinolysis inhibitor. Essentially, the fibrinolytic system is nonfunctional for several days following surgery, which down-regulates the ability of plasmin to impede wound healing by preventing degradation of fibrin and other matrix proteins.

Venous stasis is thought to be the cornerstone of postoperative thrombosis. Venous stasis in the pelvis and lower extremities results in platelet activation, promoting the adhesion of platelets to the endothelial cells lining the vessel, which are already stressed in a procoagulant mode. This results in conditions that encourage the development of a thrombus. These physiologic changes in venous hemodynamics occur in the pre-, peri-, and postoperative periods. Doran has shown that venous return from the lower extremities is decreased by half during surgical procedures because of the impact of muscle relaxation from anesthetic agents. Scanning using I¹²⁵ fibrinogen has demonstrated that venous thrombosis is initiated during the surgery in 50% of patients who subsequently manifest a DVT. Lower extremity blood flow has been shown to decrease to about 75% of the normal drainage flow in the immediate postoperative period. This is an important reflection of Virchow triad on the role of adequate vessel flow. This reduction in flow persists for about 14 days after surgery because of the loss of muscle-pumping function in the legs. The major site of thrombus formation is the soleal venous sinuses of the calf, a portion of the venous arcade that joins the posterior tibial and peroneal veins draining the soleal muscle. Thrombi from these sinuses often occur posterior to valves located at the junction where these sinuses drain into the collecting veins. Thrombi often occur in these sinuses and in valve cusps in bedridden patients.

Another contributing factor to venous stasis during prolonged surgery is the use of tight packing of the intestines in the upper abdomen with obstruction of the underlying vena cava. The type and length of operation are directly related to the incidence of postoperative VTE, as outlined in [Table 9.1](#).

Diagnosis of Venous Thromboembolism

The traditional clinical methods used to diagnose venous thrombosis of the lower extremities are of limited value, with error rates approaching 50% for both false-negative and falsepositive rates. Most of the diagnostics problems occur because of the insidious nature of venous thrombosis in the lower extremity, which takes place in the soleal veins. Modern imaging methods have evolved considerably in recent years, ranging from I¹²⁵ fibrinogen scanning to venography to Doppler duplex ultrasound, impedance plethysmography (IPG), and magnetic resonance imaging (MRI) technique studies. Although for DVT venography remains the gold standard, modern compression ultrasonography is now the dominant technique, having a good negative predictive value (98%) for proximal DVT and slightly lower (96%) for calf DVT. However, it is still inferior to venography, which remains the reference source ([Table 9.2](#)).

Venography

The venogram has had the most extensive and rigorous use in clinical practice of all imaging techniques. However, it is no longer routinely used because it is invasive, uses contrast dye, has limitations, and provides an increased risk in many

P.129

patients who have renal compromise. However, the use of computed tomography (CT) venography in conjunction with CT angiography had proven to increase the sensitivity of DVT diagnosis from 83% to 90% in the PIOPEd-II study.’

TABLE 9.1 Levels of Thromboembolism Risk in Surgical Patients without Prophylaxis

LEVEL OF RISK EXAMPLES	CALF DVT, %	PROXIMAL DVT, %	CLINICAL PE, %	FATAL PE, %	SUCCESSFUL PREVENTION STRATEGIES
Low risk	2	0.4	0.2	0.002	No specific measures
Minor surgery in patients <40 y with no additional risk factors					Aggressive mobilization
Moderate risk	10-20	2-4	1-2	0.1-0.4	LDUH q12h, LMWH, ES, or IPC
Minor surgery in patients with additional risk factors; nonmajor surgery in patients aged 40-60 y with no additional risk factors; major surgery in patients <40 y with no additional risk factors					
High risk	20-40	4-8	2-4	0.4-1.0	LDUH q8h,

Nonmajor surgery in patients >60 y or with additional risk factors; major surgery in patients >40 y or with additional risk factors

Highest risk	40-80	10-20	4-10	0.2-5	LMWH, oral anticoagulants, IPC/ES + LDUH/LMWH, or ADH
Major surgery in patients >40 y plus prior VTE, cancer, or molecular hypercoagulable state; hip or knee arthroplasty, hip fracture surgery; major trauma; spinal cord injury

¹²⁵I-Labeled Fibrinogen Scanning

This technique first developed in the 1960s was used widely for many years. It involves the intravenous injection of isotopelabeled fibrinogen, which is expected to be incorporated into the evolving thrombus and can be imaged by a scintillation scanner. Because of the use of isotopes, it is technically cumbersome and rarely used, despite many large studies validating its use in the 1970s and 1980s and its high correlation with venography.

Impedance Plethysmography

Impedance plethysmography is based on the principal of electrical resistance in specific areas of the body. When there is resistance to blood flow that is due to a thrombus, there is marked reduction in the electrical resistance over that vessel. IPG is most useful in proximal venous thrombosis but is relatively poor in visualizing thrombi below the knee because of the small caliber and slow flow rates through the soleal sinuses. The technique is only about 50% accurate compared with venography in detecting DVT below the popliteal vessels.

Huisman and colleagues evaluated 471 outpatients clinically suspected of acute-onset DVT. Four sequential IPGs were obtained on days 1, 2, 5, and 10 of the study. Of the 137 patients with abnormal results, 117 (85%) had abnormal results on day 1, with the other 20 patients becoming positive by day 10. When compared with venography, serial IPG had a specificity of 92% and a sensitivity of 100%. The use of serial testing clearly improved the ability to diagnose DVT. Another similar study by Vaccaro and associates involving 252 patients using single-test IPG gave a sensitivity of 84% and a specificity of 78%, confirming the superiority of the serial testing protocol. Given the short length of hospital stays now, it is unlikely that serial IPG would be possible despite its proven high correlation with venography.

Doppler Ultrasound

The use of Doppler ultrasound, often with computer color enhancement, has become the most widely used imaging technique for diagnosis of DVT. Its major physiologic use is in the measurement of flow velocity in larger blood vessels. In this technique, a reflected sound signal is converted to both an audible form and visual image on a computer screen. In the presence of a thrombosis, there is a decrease in the reflected signal that can be heard or, more likely, can be visualized. Most modern ultrasound machines use color enhancement to identify arteries (red) and veins (blue). This technique is again very useful to identify DVTs in the iliac, femoral, or popliteal veins, but its sensitivity falls off markedly when applied to the small vessels in the calf, usually to less than 60%.

Real-Time Ultrasound

Real-time ultrasound has been compared with venography, and in a study by Aitken and Godden, it demonstrated a sensitivity of 94% and a specificity of 100% in a small study of

P.130

46 patients. In a slightly larger study of 121 patients by Appelman and colleagues, the sensitivity was found to be 96%, and specificity was 97%.

TABLE 9.2 Diagnosis of Deep Venous Thrombosis

METHOD	SENSITIVITY AND SPECIFICITY	INDICATION AND COMMENTS
Clinical history and physical examination		Classic symptoms often absent in proven DVT <60% with suggestive symptoms proven to have DVT Absence of symptoms does not exclude PE
D-dimer ELISA (plasma)	Sensitivity 97% Specificity: poor	Useful to exclude the diagnosis if D-dimer ELISA is <500 µg/mL Many conditions increase D-dimer levels (false-positive results)
B-mode compression ultrasonography ± Doppler	Symptomatic proximal DVT: Sensitivity 93%-97% Specificity 98% Asymptomatic DVT: Sensitivity 38%-59% Specificity: high	Noninvasive test First-line modality for confirming diagnosis in symptomatic patients Not useful for screening of asymptomatic patients Compression component best for thigh DVT
IPG	Symptomatic DVT: Sensitivity 90% Specificity 95% Asymptomatic DVT: Sensitivity 22% Specificity 98%	Noninvasive test Limited to <i>serial</i> examination in symptomatic patients with proximal DVT Insensitive to calf-vein thrombi and nonocclusive thrombi
MR venography	Proximal DVT: Sensitivity 100% Specificity 96% Calf-vein DVT: Sensitivity 87%	Noninvasive but expensive Ability to screen for DVT in asymptomatic patients Can also image lungs for PE in same setting

Specificity 97%		
Contrast-enhanced CT venography	Distal and proximal DVT: Sensitivity 100% Specificity 96%	Noninvasive test Superior to venography in evaluating the great vessels Expensive Less contrast than conventional venography Can image lungs for PE in same setting
Ascending contrast venography phlebography	Reference standard	Invasive test Reference standard but expensive Risk for contrast nephropathy and allergic reactions Risk for thrombogenicity (usually superficial veins) Negative test does not exclude PE Equivocal results in recurrent DVT

Compression Ultrasound

This technique has been used in some large DVT trials, such as the PREVENT trial, but there have been few studies directly comparing it with venography. In a recent small study by Tomkowski and colleagues involving 160 medically ill patients, 12 patients had venographically proven DVT. Compression ultrasound technique had a sensitivity of 28% and a specificity of 98%, but despite the small numbers of venographically confirmed patients, the method performed poorly, having both false-positive and false-negative findings.

Duplex Doppler Ultrasound

This is a combination technique using real-time and Doppler methods in a procedure known as B mode or duplex Doppler imaging. It allows a radiologist to visualize the vessel and identify any thrombus in it. In a study by Langsfeld and colleagues, 431 patients were examined; 86 patients had a DVT. This gave a sensitivity of 100%, but two false positives dropped the specificity to 78%. Technical issues may have given one incorrect result, the second patient was pregnant, and the study was considered falsely positive because of aortocaval compression from the pregnant uterus.

In a study by Kristo and associates comparing duplex Doppler, venography, and single bilateral IPG, the respective sensitivities and specificities were as follows: ultrasound, 92% and 100%; venography, 100% and 75%; and IPG, 50% and 83%.

P.131

For many reasons, duplex B mode imaging has become the noninvasive imaging method of choice, essentially replacing venography as the "practical" gold standard.

Light Reflection Rheography

Light reflection rheography (LRR) uses infrared light directed at the skin. The backscattered rays are quantitated, which allow an estimation of blood volume. A decreased venous emptying rate of 0.35 is considered positive for DVT. In a study in patients with gastrointestinal problems in which 69 limbs were tested by venography and LRR, the sensitivity for LRR was 96%, the specificity was 83%, the positive predictive value was 79%, and the negative predictive value was 97%.

Light reflection rheography could prove to be a low-cost, sensitive tool for DVT detection. Further studies are needed to determine if the technique fulfills its early promise. However, in one study of 411 asymptomatic pregnant women in the second and third trimesters who did not have DVT, the use of LRR denoted a significant false-positive rate of 25% and an inadequate study rate of 19%. This gave an overall specificity of only 45%, indicating that LRR is not for use in DVT diagnosis in pregnant women.

Radioisotope Imaging

Various imaging methods have been tried using radioisotopes to try to detect thrombi in both arteries and veins by labeling components of the clotting system, such as platelets or fibrinogen. These labeled components became incorporated into the developing thrombus, and the focused radioactivity would then allow "visualization" by a detector. Radioactive-tagged antibodies to both platelets and factors have also been used for DVT diagnosis.

Indium¹¹¹-labeled platelets have demonstrated good success with high sensitivity and specificity. The same is true for fibrinogen¹²⁵- and technetium^{99m}-labeled platelets.

Although all of these radioisotope-labeled methods have some proponents, the advances in computer software technology and imaging methods will probably outweigh significant development of radioisotopic methods for routine clinical VTE diagnosis.

Indirect Computed Tomography Venography

The new and evolving technique of indirect CT venography, using intravenous contrast medium injection followed by CT scanning of the limbs or chest, has a high potential for detecting DVT or PE. Some early studies have indicated detection of thrombi at least to calf level and perhaps lower. There are few studies comparing CT venography and CT pulmonary angiography. A recent study by Nchimi evaluated 1,408 patients with both techniques for PE detection and included lower-extremity DVT as a secondary finding. They found that in 48% of patients with DVT, the upper end of the thrombus was between the ankle and the knee. Comparing the two techniques, CT venography detected 17% more VTE than did CT pulmonary angiography.

Magnetic Resonance Imaging/Magnetic Resonance Imaging Venography

The use of MRI techniques with or without contrast media is another new approach to VTE detection. There are several different technologies using MRI, but all basically use the differences in signal intensities to distinguish flowing blood from stagnant blood (i.e., clot). Although there have been few largescale studies published, the major advantage of MRI is that no contrast medium is required, allowing the technique to be used in pregnant women. One study by Carpenter and colleagues indicated no statistical differences between contrast venography and MRI in DVT diagnosis. Magnetic resonance imaging techniques for routine VTE and arterial thromboses diagnosis will likely continue, as improvements in computer software will provide for the advancement of MRI-based method as tools for vascular diagnostics.

Evolving Imaging Techniques

Because of progress in instruments and computer software in conjunction with ongoing concerns about radiation exposure to patients, several new technical modifications are being evaluated, especially for PE diagnosis. These include multidetector computed tomography angiography (MDCTA), electrocardiogram (ECG)-gated CT angiography, and dual-energy/dual-source CT angiography. Early studies suggest that these methods, especially the dual-source CT angiography, may have significantly enhanced accuracy using the very latest detection technology to minimize the radiation required to provide good diagnostic images.

Nonimaging Methods

The use of laboratory tests as a means of exclusion of VTE has gained momentum in the last decade. The use of the *automated quantitative D-dimer assays* has gained widespread acceptance, especially in emergency rooms, to exclude VTE. In a study by Wells and associates comparing IPG and D-dimer with contrast venography, the combination of IPG and a negative (normal) D-dimer test gave a negative predictive value of 97%. In this same study, the combination of positive IPG and positive D-dimer had a positive

predictive value of 93% for any DVT and 90% for proximal DVT.

The use of an appropriate D-dimer assay in isolation has been shown to have about 98% negative predictive value for exclusion of DVT. Despite numerous studies, there is still no proven consistent correlation between a positive D-dimer assay and the presence of venous thrombosis.

The utility and power of D-dimer assays for exclusion of PE and DVT have been enhanced by the use of pretest probability scores. Several of these exist, namely, the Wells model criteria for DVT and PE diagnosis as well as the Geneva score or other modifications such as the Pisa score. All of these scoring systems are simple and applicable to most emergent VTE diagnostic situations. In conjunction with D-dimer assays, they all enhance the negative predictive value for VTE exclusion and hence the need for unnecessary imaging studies.

Because the diagnosis of PE can be difficult in many older patients, especially those with heart failure or other cardiovascular complications, some preliminary studies have been done using combinations of D-dimer, B-type natriuretic peptide, and cardiac troponins to determine if a better distinction can be made between a PE and an underlying cardiac complication. These studies are likely to be the forerunners for other combinations of biomarker lab tests to identify more specific negative or even positive predictive markers for VTE. This is especially important since many older patients with VTEs have some degree of renal impairment, and the use of contrast dyes in imaging can be problematic.

Risk Factors for Vascular Complications

Several clinical factors are known to identify the patient with an increased risk for VTE (Table 9.3). The most prevalent and important include age >40 years, obesity >20% above ideal weight, prolonged surgery, and immobility in the pre-, peri-, and postoperative periods. Pelvic malignancy, prior VTE, known thrombophilia risk, severe diabetes, heart failure, prior radiation therapy, and chronic obstructive pulmonary disease all increase the VTE risk.

TABLE 9.3 Profile of Patient at High Risk for Venous Thrombosis	
FACTOR	CONDITION
Age	<40 Major surgery
Age	>60 Nonmajor surgery
Obesity	
Moderate	75-90 kg or >20% above ideal weight
Morbid	115 kg or >30% above ideal weight with reduced fibrinolysin and immobility
Immobility	
Preoperative	Prolonged hospitalization; venous stasis
Intraoperative	Prolonged operative time; loss of pump action of calf muscles; compression of vena cava
Postoperative	Prolonged bed confinement; venous stasis
Trauma	Damage of wall of pelvic veins
Radical pelvic surgery	
Malignancy	Release of tissue thromboplastin ^a
Activation of factor X; reduced fibrinolysin	
Radiation	Prior radiation therapy
Medical diseases	Diabetes mellitus
Cardiac disease; heart failure	
Severe varicose veins	
Previous venous thrombosis with or without embolization ^a	
Chronic pulmonary disease	
Molecular hypercoagulable state	
^a Highest risk.	

Age

An autopsy study by Sevitt and Gallagher demonstrated that DVT was most prevalent in patients older than 60 years. Several studies have shown a linear risk of fatal PE with increasing age. Approximately 10% of hospitalized patients' deaths are due to PE, and only about 35% of these are diagnosed ante mortem. Contributing factors include degenerative changes in the vascular tree, increases that occur in the concentration of many coagulation factors, and, possibly, increased platelet adhesiveness.

Immobility

Prolonged inactivity in the preoperative patient promotes an impairment of venous flow in the lower extremities. Many diagnostic techniques also produce a decrease in muscle tone with a secondary decrease in venous flow. These hemodynamic changes promote sludging of red cells and activation of platelets, setting the stage for VTE during the operative period. This is one of the main risk factors described by Virchow for the etiology of thrombosis.

Studies done using I¹²⁵ fibrinogen scanning presurgery and immediately postsurgery have indicated that in 50% of patients who subsequently developed VTE, the initiation of clot formation occurred during the surgical procedure. This is amplified during prolonged anesthesia, with generalized muscle relaxation further promoting venous stasis in the lower extremities, which compounds the thromboembolic risk. For this risk, the judicious use of prophylactic anticoagulation in the high-risk patient should include the operative phase and continue at a minimum until the patient is fully ambulatory.

Postoperative immobility also promotes VTE risk by continuing venous stasis, and studies have shown that 66% of patients who develop a DVT do so in the first 48 hours after surgery. Other compounding issues include sitting with legs crossed or dangling over the bed or the exaggerated Fowler position. These positions all produce impairment of lower extremity venous return. Postoperative patients should be ambulated early and aggressively; if ambulation is not possible, they should have their legs elevated to 15 degrees above the horizontal.

Other Factors

Other factors include previous VTE, varicose veins, severe diabetes, cardiac failure, chronic obstructive pulmonary disease, and underlying thrombophilia. Given the high incidence of factor V Leiden (5%) and the G20210A prothrombin gene mutations (3%) in the Caucasian populations, which are wellrecognized risk factors for venous thrombosis (Table 9.4), these genetic risk factors are common enough to make a major contribution to preoperative thrombosis, even in the patient with no prior VTE history.

Underlying malignancy is a huge contributor to risk, most likely because of the significant up-regulation of TF that is known to occur with many malignancies. Up-regulation of TF increases thrombin generation by several mechanisms, promotes platelet activation, and enhances the generation of MPs and angiogenesis, as discussed earlier.

A review of these risk factors clearly identifies the high-risk VTE patient, and it is essential that these surgical risk variables are identified and understood in designing appropriate thromboprophylaxis and monitoring parameters to prevent venous thrombosis. Many countries including the United States have produced national consensus documents from their clinical

oncology societies for both treatment and prophylaxis for VTE in cancer patients.

TABLE 9.4 Risk of Thromboembolism

Deficiency/dysfunction

Anticardiolipin
Hyperhomocystinuria
Dysfibrinogenemia
Decreased levels of plasminogen
Decreased levels of plasminogen activators
Heparin-induced thrombocytopenia

Prophylaxis

Prevention remains the most effective tool in the treatment of VTE. Between 5% and 45% of gynecologic surgery patients develop DVT in their legs; of these, 20% have popliteal or femoral involvement; and of these, 40% will progress to PE with its high mortality. It is imperative that methods for prophylaxis are planned and implemented before surgery (Table 9.5).

TABLE 9.5 Agents Used in Venous Thromboembolism

AGENT	MECHANISM OF ACTION	COMMENTS
Heparin	Combines with AT-III and neutralizes activated factors: IIa (thrombin activity) Xa (responsible for thrombin generation) XIIa, XIa, IXa	Prevention and treatment of VTE Risk of heparin-induced thrombocytopenia Requires monitoring (APTT) when used for treatment

LMWH Ardeparin Dalteparin Enoxaparin	Combines with AT-III and prevents thrombin generation through its anti-factor Xa effect	Prevention and treatment of VTE Risk of heparin-induced thrombocytopenia No anti-IIa activity (if molecular weight <5.6 kDa) APTT does not reflect anticoagulation state More predictable pharmacokinetic profile Renal failure and dehydration increase effective plasma concentration
Heparinoid Danaparoid	Same as LMWH High anti-Xa/IIa ratio	Prevention and treatment of VTE Similar to LMWH but may be used for anticoagulation when heparin-induced thrombocytopenia is present
Direct thrombin inhibitors and hirudin	Directly inhibits thrombin activity	Prevention and treatment of VTE May be used for heparin-induced thrombocytopenia
Plasminogen activators: Nonselective Streptokinase Urokinase	Activates plasminogen, which leads to the formation of plasmin, which dissolves fibrin clot (no effect on polymerized fibrin clot) Also degrades fibrinogen, which leads to fibrinogen degradation products and decreases in plasma fibrinogen	Treatment of life-threatening DVT or PE High risk of bleeding Many contraindications such as recent surgery or trauma
Thrombus-selective tissue plasminogen activator	Activates fibrin-bound plasminogen Degrades fibrinogen (to a lesser extent)	
Warfarin	Inhibits correct synthesis of vitamin K-dependent coagulation factors (II, VII, IX, X) These factors cannot bind calcium and therefore remain inactive Inhibits protein C (vitamin K dependent)	Long-term treatment and prevention of VTE Contraindicated in pregnancy (teratogenic) High risk of bleeding Requires anticoagulation monitoring Numerous drug interactions
Inferior vena caval filters	Trap larger emboli	Used as prevention of PE when anticoagulation fails or is contraindicated Used prior to pulmonary embolectomy or pulmonary endarterectomy
External pneumatic leg compression	Prevents venous stasis Stimulates fibrinolytic system	Used as prophylaxis for DVT Possibly contraindicated in peripheral arterial disease

In the Sixth American College of Chest Physicians (ACCP) Consensus Conference, Geerts and colleagues—in a review of PE in 7,000 gynecologic surgery patients in prospective clinical trials—reported a reduction in the rate of fatal PE of 75% using thromboprophylaxis ([Table 9.6](#)). The current 2012 Chest (ACCP) guidelines recommend the routine use of LMWH or unfractionated heparin (UFH) and mechanical compression stockings given the high risk in this population. They do not recommend the use of inferior vena cava (IVC) filters.

Low-Dose Unfractionated Heparin

Low-dose UFH has been the mainstay of prophylactic treatment for many years, with numerous prospective randomized clinical trials validating a risk reduction in DVT incidence from 35% to 45% to about 7% in the high-risk patient. In one large study by Kakkar and colleagues ([Table 9.7](#)) incorporating 4,000 patients at multiple centers, patients were randomized to 5,000 U USP calcium heparin subcutaneously starting 2 hours before surgery and subsequently every 8 hours thereafter for the next 7 days. The reduction in VTE between the control group (25%) and the treatment group (8%) was highly significant. The most important finding was the decrease in fatal PE from 16 patients in the control group to 2 in the treatment group confirmed by autopsy.

Because there is no change in the activated partial thromboplastin time (APTT) because of the low level of subcutaneous heparin, there was no increase in postoperative bleeding.

This is because the main impact of the low-dose heparin is exerted via antithrombin through factor Xa, as well as directly on thrombin. There is also a secondary effect in which heparin releases tissue factor pathway inhibitor (TFPI), which also helps to down-regulate factor Xa by forming a complex involving TF:F Xa:F VIIa:TFPI.

TABLE 9.7 Pulmonary Embolism and Deep Venous Thrombosis in Patients on Low-Dose Heparin and in Controls		
	LOW-DOSE HEPARIN	CONTROL
Number of patients	2045	2076
Number of deaths from all causes	80	100
Deaths caused by PE (verified at autopsy)	2	16
Deep venous thrombosis	8%	25%
Reprinted with permission from Kakkar W, Corrigan TP, Fossard DP. Prevention of postoperative pulmonary embolism by low dose heparin. <i>Lancet</i> 1975;2:45. Copyright © 1975, Elsevier.		

These studies, as well as those shown in [Table 9.8](#), clearly validate the efficacy of low-dose UFH in reducing VTE in surgical patients using an initial dose of 5,000 U 2 hours before surgery and then 5,000 U every 12 hours for the next 5 days. For the truly high-risk patient, such as those with a prior VTE or multiple risk factors, 5,000 U every 8 hours should be used. In current clinical practice, the use of UFH has been superseded by the use of LMWHs.

Low-Dose Unfractionated Heparin/Dihydroergotamine

The combination of low-dose UFH and dihydroergotamine (DHE) treatment was shown to work well by adding the known effect of DHE as a selective venous vasoconstricting agent to the anticoagulant properties of UFH.

Dextran 70/Dextran 40

In 1972, Bonnar and Walsh described the use of dextran 70 to prevent thrombosis after pelvic surgery. A subsequent study by Bernstein and colleagues involving radical hysterectomy patients using dextran 70 as prophylaxis showed a decrease in DVT incidence from 33% to 5%. Dextran works by interfering with platelet function, interacts with factor V and VIII, and inhibits fibrinolysis. Despite some comparable studies between dextran and low-dose UFH, the Sixth ACCP Consensus Conference in 2001 recommended against using dextran products in VTE prophylaxis.

Low Molecular Weight Heparins

Low molecular weight heparins (LMWHs) act by primarily inhibiting factor Xa with a small component of activity against thrombin. They have become mainstay of anticoagulant prophylaxis and treatment and continue to replace all other forms of drug therapy. The drugs have a longer half-life than does UFH and are much more biopredictable. If LMWH levels are measured in patients using an anti-Xa assay, there is a remarkable homogeneity of response. This has led the U.S. Food and Drug Administration to recommend against the need to monitor when LMWHs are used for VTE prophylaxis. There are currently four LMWH drugs available in the United States (Fragmin, Lovenox, Innohep, and Arixtra). They are subtly different in molecular weights and in manufacturing processes but in essence are almost identical in clinical efficacy. They are not, however, dosed in the same way, some using milligrams and other units, or even units per kilogram. Pharmacists can provide accurate dosage information about any of the products available.

^bOne patient had PE 3 days after discontinuation of LMWH.
AC, anticoagulants; LMWH, low-molecular-weight heparin.

Multiple studies reported in the literature essentially show equivalence or better for the LMWHs compared with UFH and/or Coumadin in the prevention of VTE, but almost all of these show a much lower bleeding risk for the LMWH treatment groups, even with hard data for bleeding risk being quantitated by transfusion requirements. LMWHs have also been compared with dextran and used in combination with DHE with good outcomes, but the reality is that *in normal clinical practice, LMWHs by themselves provide adequate protections with minimal complications*. One other advantage of the LMWH preparations is their much lower incidence of heparin-induced thrombocytopenia (HIT) when used as de novo therapy. However, if a patient has had HIT in the past, these preparations should not be used because there is a 90% cross-reactivity between UFH and LMWH for the antibody causing HIT. The one exception to this is Arixtra, the synthetic factor Xa inhibitor, which has been shown to cause clinical HIT in two to three cases to date.

It is highly likely, given the once-per-day dosage requirement and the lack of HIT risk, that LMWHs will continue to dominate for thromboprophylaxis therapy in VTE.

Newer Oral Anticoagulants

In the past 18 months, three new oral anticoagulants have been approved for use in various medical conditions. One of these drugs, dabigatran (Pradaxa), is an anti-IIa (thrombin) inhibitor approved for atrial fibrillation similar to a new oral anti-Xa inhibitor apixaban (Eliquis). However, the third new drug, an oral anti-Xa inhibitor, rivaroxaban (Xarelto), has been approved for treatment and prophylaxis of VTE although not specifically tried in cancer-related VTE.

The fact that Xarelto is oral, does not require any monitoring, and has few side effects is likely to promote increased use especially from the patient compliance perspective where the need for subcutaneous injections remains a problem.

Compression Modalities

As long ago as 1944, Stanton et al. used static compression to decrease venous stasis by decreasing the luminal diameter of the veins, thereby increasing blood flow velocity. In the mid-1970s, Sigel and colleagues showed an increase in blood velocity of 20% using graduated compression stockings but a 200% increase in velocity using intermittent sequential compression.

Mittelman and colleagues showed that uniform intermittent calf compression was not as effective as intermittent sequential compression at increasing thigh blood flow. This is another example of a component of Virchow triangle, namely, stasis being involved in the VTE protection mechanism.

It is possible that another component of the triad—the coagulation system—is also influenced by IPC because several groups have shown that it stimulates fibrinolysis, perhaps by increasing prostacyclin production. Prostacyclin is a potent natural vasodilator and antiplatelet agent released from endothelial cells. Guyton and colleagues found increased quantities of 6-keto prostaglandin F_{1α} in patients undergoing IPC compared with controls. The 6-keto prostaglandin F_{1α} is a

P.136

specific breakdown product of prostacyclin. Frango and associates have shown a 16-fold increase in prostacyclin production in cultured endothelial cells submitted to pulsatile shear stress compared with a twofold increase with contact shear stress.

Graduated Compression Stockings

Initial studies evaluating antiembolic stockings proved inconclusive and relied on several different methods to diagnose VTE, which compounded the uncertainty. Sigel and colleagues designed a compression thromboembolism deterrent (TED) hose with graduated pressures of 18, 14, 12, 10, and 8 mm Hg from the ankle to the upper thigh. Scurr and associates evaluated TED hose in a study of 70 patients older than 40 years undergoing major abdominal surgery in which only one leg had TED hose applied. Using I¹²⁵ fibrinogen scanning as the diagnostic tool, 19 patients had DVTs in the control leg, and only 1 had a DVT in the TED hose leg. A subsequent similar study by Inada and colleagues found a DVT frequency of 14.5% in the control leg and only 3.6% in the TED leg. Malignancy is a powerful predisposition to VTE secondary to stasis and tissue factor production by the tumor. In a study by Allan and associates assessing the efficacy of TED stocking in patients undergoing abdominal surgery for malignant and benign diseases, the incidence of DVT in the benign disease group was 24.5% in the control limb and 6.1% in the TED limb. However, in the malignant disease group, the incidence of DVT was only slightly increased in the control limb at 27.9%, but the incidence of DVT in the TED limb was significantly higher at 11.5%, clearly amplifying the impact of the tumor on the DVT risk. The Sixth ACCP Consensus Conference suggested that TED hose with early ambulation was an acceptable and effective means of VTE prophylaxis in the low-risk gynecology surgery patient.

External Intermittent Pneumatic Compression

These techniques also promote increased blood flow in the lower extremities that is due to decreased stasis and improved fibrinolysis. Nicolaides and colleagues compared intermittent sequential pneumatic compression, nonsequential (one chamber) pneumatic compression, and UFH in the prevention of DVT. Using pressures of 35, 30, and 20 mm Hg sequentially for 12 seconds at the ankle, calf, and thigh, respectively, they observed a 240% increase in peak blood velocity. In contrast, using the single-chamber device at 35 mm Hg, the increase was only 180%. The intermittent sequential device was more effective than was the single-chamber device and was as effective as 5,000 U of UFH every 12 hours in preventing DVT. In addition, the intermittent sequential device increased the time interval for clot formation proximal to the calf compared with UFH. In another study, the same authors compared electrical calf stimulus, low-dose UFH, intermittent sequential compression, and TED hose in 150 patients older than 30 years undergoing major abdominal surgery. The incidence of proven DVT was 18%, 9%, and 4%, respectively.

In a similar study in patients undergoing surgery for gynecologic malignancy comparing no thromboprophylaxis to nonsequential external compression, the control group had a VTE frequency of 34.6%. In the compression treatment group, the VTE incidence was reduced to 12.7%. Diagnostic tools for VTE were IPG and I¹³¹.

Treatment of Venous Thrombosis

The initial treatment of VTE in most hospitals still involves the use of intravenous UFH, although LMWHs are approved for treatment of VTE. Given the potential variability of the hypercoagulable state in these patients, constant intravenous infusion UFH still remains the easiest drug to use. Most patients are now treated using a weight-based heparin nomogram and are given a loading dose of 80 U/kg to a maximum of 10,000 U. They are maintained on a constant infusion of 18 U/kg, and the first APTT or factor Xa assay should be done at 4 to 6 hours after the initiation of therapy. Because of the large thrombus burden these patients may have, they can clear or use UFH at an accelerated rate; thus, they are often undertreated. Patients with gynecologic malignancies will typically require higher-than-average doses until the cancer has been surgically removed or treated. Care must be taken to reduce the infusion, or these patients are susceptible to bleeding that is due to heparin overdose. There is little place for intermittent bolus treatment with UFH in modern anticoagulation practice.

If the APTT is used to monitor efficacy of UFH therapy, it should be used in conjunction with the laboratory heparin monitoring nomogram. Because APTT reagents can vary widely between institutions, the old concept of using a ratio of 1.5 to 2 times some poorly defined control APTT value is completely outmoded and can lead to erroneous and inadequate anticoagulation therapy. Any modern coagulation lab should have a heparin treatment weight-based nomogram specific for their reagent and APTT instrument combination.

Standard clinical practices—such as leg elevation to minimize or treat leg edema after a DVT—are still appropriate. Patients should probably not be aggressively mobilized as long as they have significant leg edema. Most patients will require 5 to 7 days of UFH or LMWH treatment, and the modern trend is to rapidly introduce oral anticoagulation, usually within 24 to 48 hours after initiation of heparin therapy. This will not always be possible in this population, but any UFH or LMWH treatment should be continued until the international normalized ratio is in the therapeutic range of 2 to 3 for several days. The new oral anticoagulants (Xarelto) can be initiated in place of Coumadin anticoagulation immediately after

surgery and do not require any time to become therapeutic. Similar to Coumadin, they need to be continued for 3 to 6 months or longer, depending on the circumstances and any other complicating factors (i.e., prior VTE or congenital thrombophilia).

The patient who is found to have an asymptomatic DVT of the lower extremity poses a dilemma for some physicians. Some feel that this is not a significant risk and should not be treated, but the risk of thrombus extension into the proximal and popliteal veins remains high and is a possibility. Although this is still a small risk for most patients, the longer-term complications of postphlebitic syndrome from the damaged valves in those veins can produce significant morbidity for such patients, leading to chronic leg edema and venous stasis ulceration. For that reason, most practitioners would elect to anticoagulate women with asymptomatic DVT. With the onset of widespread DVT prophylaxis in many hospitals, the problem of whether to treat asymptomatic DVT is becoming moot.

POSTOPERATIVE PULMONARY COMPLICATIONS

Postoperative pulmonary complications (PPCs) after abdominal surgery remain an important cause of increased morbidity, mortality, and resource use. Atelectasis, pneumonia, and pulmonary thromboembolic disease following abdominal surgery continue to occur frequently despite continuing advances in anesthetic, surgical, and postoperative treatment. The incidence of PPCs has surpassed that of postoperative cardiac complications, and PPCs have a greater impact on postoperative outcomes. Gynecologic surgery is increasingly performed in patients with advanced age, multiple comorbid conditions, and increased risk for the development of PPCs. Risk factors

P.137

for PPCs in patients undergoing a gynecologic surgery procedure vary among studies but are consistent with other patient groups undergoing abdominal surgical procedures (Table 9.9). The most important PPCs in terms of incidence, morbidity, mortality, and resource use are atelectasis, pneumonia, respiratory failure, and pulmonary thromboembolic disease.

TABLE 9.9 Risk Factors for Postoperative Pulmonary Complications in Gynecologic Surgery Patients

Age >60 y
Cancer
Congestive heart failure
Smoking within 8 wk of surgery
Upper abdominal incision
Vertical incision
Incision length >20 cm

An understanding of the physiology that predisposes to PPCs, the risk factors for their development, and the preventive and therapeutic measures to minimize and treat them are of critical importance to gynecologic surgeons.

Perioperative Respiratory Physiology

Effects of Anesthesia

General anesthesia results in important alterations in respiratory physiology (Table 9.10). Anesthetic agents influence not only the ventilatory response to oxygen and carbon dioxide but also the pattern of respiration. Inhalational agents and intravenous agents both result in a reduction of the ventilatory response but differ in their effects on respiratory pattern. The classic breathing pattern produced by inhalational anesthetics is a rhythmic, rapid, and shallow pattern of respiration with no intermittent sighs (large breaths), whereas intravenous anesthesia is associated with slow, deep respirations. Little metabolism of inhalational anesthetics occurs during surgery, with most of the anesthetic agents stored in the tissues, such as muscle and fat.

At the conclusion of anesthesia, most of the stored anesthetic agent is eliminated via the lungs. As a result of tissue stores, significant concentrations of the anesthetic agent may be present well into the recovery phase, particularly after high anesthetic doses, long anesthetic times, or the presence of cardiopulmonary disease. This prolonged anesthetic effect can lead to clinically significant respiratory depression in the postoperative period.

The number of functional alveolar units participating actively in gas exchange is directly related to the functional residual capacity (FRC). General anesthesia is associated with a reduction in FRC by approximately 16%, irrespective of the anesthetic techniques used. The cause of the reduction in FRC is multifactorial and includes cranial movement of the diaphragm, chest wall relaxation with reduction in thoracic volume, reduction in respiratory compliance, and shift of central blood volume from the thorax into the abdomen. Reduction in FRC can have marked adverse effects on perioperative gas exchange, especially the development of hypoxemia.

TABLE 9.10 Effects of Anesthesia on Respiratory Physiology

Reduced ventilatory response to oxygen and carbon dioxide
Rhythmic rapid shallow breathing pattern
Reduced functional residual capacity
Diaphragmatic dysfunction
Atelectasis
Ventilation-perfusion mismatching
Blunting of hypoxic pulmonary vasoconstriction
Impairment in mucociliary clearance

Atelectasis is defined as the absence of gas from a part or the whole of the lungs that is due to the failure of expansion or resorption of gas from the alveoli. It occurs in the dependent areas of the lungs within 5 minutes of anesthetic induction in a patient with healthy lungs and leads to shunt physiology. Atelectasis may be caused by compression, gas resorption, or surfactant impairment. Compression occurs when the distending pressure in the alveolus is reduced to a level that causes the alveolus to collapse. In the setting of general anesthesia, compression occurs mainly as result of impairments in diaphragmatic position and function. In addition to the cephalad movement of the diaphragm that is due to relaxation from anesthesia as described above, increased intra-abdominal pressure from bowel edema, peritoneal fluid, and hematoma forces the diaphragm cephalad and contributes substantially to compressive atelectasis. The contractile function of the diaphragm is not altered as a result of an effect of anesthesia itself because diaphragmatic dysfunction, which almost always presents after upper abdominal surgery, does not arise after lower abdominal surgery.

Other factors contributing to postanesthesia pulmonary complications include reabsorption hypoxic pulmonary vasoconstriction and ventilation/perfusion abnormalities.

Although most gynecologic surgery is done in the pelvis, upper abdominal operations are sometimes done by gynecologic oncologists, and extension of the surgical incision and operative procedure into the upper abdomen produce increased respiratory effects. Respiratory muscle dysfunction is the major effect of upper abdominal surgery on respiratory physiology (Table 9.11). Tidal breathing depends on inspiratory muscle function, especially the function of the diaphragm. Other accessory muscles of respiration are recruited when work of breathing increases, such as when diaphragmatic dysfunction is present, during states of increased oxygen consumption, and in the presence of cardiopulmonary disease. In addition to breathing, respiratory muscles play an integral role in the generation of cough and act as stabilizers of the thorax and abdomen. Upper abdominal surgery may affect each of these respiratory muscle functions by several different mechanisms.

An important change following upper abdominal surgery is a shift in respiratory pump function from the diaphragm to accessory inspiratory and expiratory muscles of respiration. This results in a rapid shallow breathing pattern of respiration. The contractile function of the diaphragm is impaired by inhibition of phrenic nerve output by stimulation of visceral and somatic nerve pathways during manipulation of the abdominal

viscera and the peritoneum. The less efficient accessory muscles of inspiration, such as the intercostals and neck muscles, assume an increased share of the respiratory effort. Tonic and phasic contraction of the expiratory abdominal muscles also occurs. The net effect on respiratory mechanics is a reduction in lung volumes, including the FRC (which leads to atelectasis), V/Q abnormalities, and hypoxemia. These changes may be aggravated by hypoventilation that is due to the residua of general anesthesia, postoperative sedative-hypnotic therapy, and pain. In addition to a submaximal voluntary activation of inspiratory muscles, pain may also have a direct effect, through unknown mechanisms, on inspiratory muscle function.

TABLE 9.11 Effects of Upper Abdominal Surgery on Respiratory Physiology

Reduction in lung volumes: residual volume, total lung capacity, functional residual capacity and vital capacity
Reflex inhibition of phrenic nerve activity resulting in decreased diaphragmatic function
Increased neck and intercostal inspiratory accessory muscle use
Tonic and phasic contraction of abdominal expiratory muscles

Atelectasis

Clinically significant atelectasis occurs in 15% to 20% of patients undergoing abdominal surgery. The pathophysiologic effects of atelectasis include decreased respiratory compliance, increased pulmonary vascular resistance, predisposition to acute lung injury, and hypoxemia. Atelectasis may also be a precursor to more serious PPCs, such as postoperative pneumonia. The definition of atelectasis is not uniform across clinical studies, with most investigations incorporating a global definition of a PPC that includes atelectasis. However, generally accepted criteria for the diagnosis of atelectasis include impaired oxygenation in a clinical setting where atelectasis is likely, unexplained temperature of greater than 38°C, and chest radiographic evidence of volume loss or new airspace opacity. Risk factors implicated in the development of atelectasis after abdominal surgery include advanced age, obesity, intraperitoneal sepsis, prolonged anesthesia time, nasogastric tube placement, and smoking.

The risk of atelectasis may be reduced by a number of interventions (Table 9.12). Preoperative smoking cessation is effective if it is started well in advance of surgery (6 to 8 weeks before operation). If smoking cessation is attempted in close proximity to a planned surgical procedure, the improvement in mucociliary clearance in combination with reduced cough may lead to a secretion burden that paradoxically increases the risk of PPCs. Atelectasis is effectively prevented and treated by deep breathing exercises and mobilization. Voluntary lung inflation exercises enable redistribution of gas into areas of low compliance. Mechanical aids, such as incentive spirometry, have not been shown to be superior to properly performed deep breathing maneuvers. Effective deep breathing exercises require the patient to be conscious and cooperative. Chest physiotherapy is extremely labor intensive and has potential disadvantages in that it may exhaust the patient, cause pain, induce bronchospasm, and cause transient hypoxemia. Because chest physiotherapy has never been shown to be superior to deep breathing exercises in preventing or treating atelectasis, it is not recommended after abdominal surgery. Continuous positive airway pressure reduces the incidence of significant postoperative hypoxemia and may reduce rates of pneumonia and intubation. However, the cost, complexity, and potential complications of continuous positive airway pressure limit the practicality of routine application of this technique to patients undergoing abdominal surgery.

TABLE 9.12 Prevention and Treatment of Atelectasis

Smoking cessation 8 wk before elective surgery
Laparoscopic procedure
Deep breathing exercises
Mobilization
Adequate analgesia (epidural or patient-controlled analgesia preferred)
Selective gastric decompression

Although evidence suggests that effective postoperative pain control reduces PPC, there is inconclusive evidence as to whether postoperative epidural analgesia is superior to patient-controlled analgesia. Both modalities, however, appear to be superior to on-demand narcotic analgesia in reducing PPCs. Laparoscopic procedures reduce postoperative pain scores, as well as have less adverse effect on postoperative respiratory muscle function. Through these mechanisms, atelectasis is reduced with a laparoscopic as opposed to

open abdominal surgical procedure. Irrespective of the procedure used, postoperative gastric decompression should be used selectively rather than routinely for postoperative nausea, symptomatic abdominal distention, or inability to tolerate oral intake. Routine nasogastric tube use significantly increases rates of atelectasis without reducing risk of aspiration in comparison with selective decompression.

Postoperative Pneumonia

Hospital-acquired pneumonia (HAP) is defined as pneumonia that develops 48 hours or more after hospital admission because of an organism that was not incubating at the time of hospitalization. Hospital-acquired pneumonia after abdominal surgery has a high attributable mortality, increases hospital length of stay and cost, and has lasting effects on patient-centered outcomes, including increased hospital length of stay of approximately 11 days and increased hospital charges by 75%. Hospital-acquired pneumonia is also associated with a fourfold increase in risk of discharge to a skilled nursing facility. Women have a risk of developing HAP after abdominal surgery that is twice that of men.

Hospital-acquired pneumonia is caused by a wide spectrum of bacterial pathogens and is occasionally due to viral or fungal pathogens in immunocompetent patients (Table 9.13). Common pathogens include the aerobic gram-negative bacilli and *Staphylococcus aureus* species. Early-onset HAP, defined as occurring within the first 4 days of hospitalization, is usually associated with a better prognosis and is more likely to be caused by antibiotic-susceptible pathogens. Late-onset HAP (occurring on or after 5 days of hospitalization) is more likely to be caused by multidrug-resistant (MDR) pathogens, which are associated with increased morbidity and mortality. The risk of HAP from MDR pathogens is related to characteristics of the patient, the health care environment, and the prescribed medical treatment (Table 9.14).

TABLE 9.13 Common Pathogens Causing Hospital-Acquired Pneumonia

Early onset (≤4 d)
<i>Streptococcus pneumoniae</i>
Methicillin-sensitive <i>Staphylococcus aureus</i>
Methicillin-resistant <i>S. aureus</i>
<i>Haemophilus influenzae</i>
<i>Escherichia coli</i>
<i>Klebsiella pneumoniae</i>
<i>Enterobacter</i> species
<i>Proteus</i> species
<i>Serratia marcescens</i>
Late onset (≥5 d)
All of the above plus:
<i>Pseudomonas aeruginosa</i>
Multidrug-resistant <i>Klebsiella pneumoniae</i>
<i>Acinetobacter</i> species

TABLE 9.14 Risk Factors for Multidrug-Resistant Pathogens Causing Hospital-Acquired Pneumonia

Immunosuppressive disease or therapy
Home infusion therapy
Chronic dialysis
Home wound care
Residence in a nursing home or extended care facility Antimicrobial therapy in the preceding 90 d
Current hospitalization of 5 d or more
Hospitalization for 2 d or more in the preceding 90 d
High frequency of antibiotic resistance in the community, hospital, or patient care unit

Bacterial colonization of the lower respiratory tract under conditions that promote bacterial invasion is necessary for HAP to develop. Sources of colonization include air, water, equipment, fomites, and direct transfer from health care providers. Among conditions that promote invasion are severity of underlying illness, comorbid conditions, prior exposure to antimicrobials, and exposure to invasive devices, such as nasogastric and endotracheal tubes. Risk of colonization may be modified by several means (Table 9.15). Infection control

procedures, including guidelines for alcohol-based hand disinfection and appropriate barrier precautions, should strictly be observed. Early removal of invasive devices, in particular nasogastric tubes, and avoidance of endotracheal intubation when noninvasive ventilation is feasible, will reduce the risk of HAP. As one of the mechanisms for initial colonization of the lower respiratory tract includes microaspiration of gastrically residing bacteria, measures to minimize aspiration and to reduce gastric bacterial overgrowth are important preventive measures. All patients should be maintained in at least a semirecumbent position with the head elevated to 30 to 45 degrees. Restriction of the use of stress ulcer prophylaxis to patients who meet criteria (i.e., receiving mechanical ventilation or coagulopathy/therapeutic anticoagulation) is critical in controlling a possible risk factor for HAP. Implementation of a restrictive red blood cell transfusion strategy in patients without evidence of active bleeding is proven to reduce infectious complications of all kinds, including HAP. Adherence to such a strategy not only reduces infectious complications but reduces overall in-hospital mortality and may reduce recurrence of malignancy. In most patients, a hemoglobin target of 7.0 should be adopted, with a hemoglobin target of 9.0 reserved for patients with active cardiac ischemia or hemodynamic instability. Strict control of hyperglycemia has been widely adopted as a means of reducing morbidity and mortality, including the risk of infection. Although the optimal glucose target and the means of achieving that target remain controversial, an attempt to limit capillary blood glucose to less than 150 mg/dL in both diabetic and nondiabetic patients appears warranted.

TABLE 9.15 Interventions to Decrease Risk for Hospital-Acquired Pneumonia

Strict adherence to infection control procedures
Early removal of invasive devices
Semirecumbent positioning of the patient
Early mobilization of the patient
Restriction of acid suppression therapy
Restrictive red blood cell transfusion strategy
Strict control of hyperglycemia

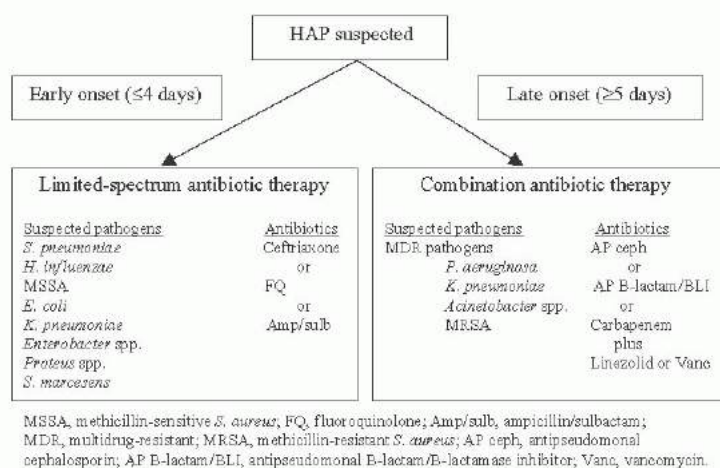

FIGURE 9.3 Algorithm for initiating empiric antibiotic therapy for hospital-acquired pneumonia (HAP).

The clinical definition of HAP includes a new opacity on chest radiograph (posterior-anterior and lateral views preferred) plus two of the following: fever greater than 38°C, leukocytosis or leukopenia, and purulent respiratory secretions. The diagnosis of HAP should be supported by sampling of lower respiratory tract secretions, with either an endotracheal aspirate or a bronchoscopic specimen, before the initiation of empiric antibiotic therapy. Importantly, antibiotics should not be excessively delayed while awaiting obtaining these samples in patients who are critically ill. The initial step in choosing antibiotic therapy for suspected HAP is determination of the patient's risk of infection with an MDR pathogen (Fig. 9.3). Knowledge of local microbiologic data including pathogens and sensitivity will assist with proper selection of antimicrobials. One of the consequences of increasing antimicrobial resistance is an increased probability of inappropriate initial empiric treatment. Inappropriate or delayed empiric treatment results in a substantial excessive attributable mortality

P.140

and hospital length of stay. Prompt institution of appropriate empiric therapy based on risk stratification for the presence of a possible MDR pathogen is crucial to improving patient outcome in HAP.

Initial therapy should be administered intravenously, with a switch to the enteral route of administration in selected patients with a good clinical response and a functional gastrointestinal tract. Combination therapy should be used initially if patients are at high risk of being infected with an MDR pathogen. Monotherapy is appropriate for those patients deemed to be low risk. Duration of therapy should be based on clinical response and may often be safely terminated after 8 days, provided the etiologic pathogen is not *Pseudomonas aeruginosa*, which requires a longer course of 15 days. Clinical improvement usually takes 48 to 72 hours, and therapy should not be changed during this time unless there is a rapid clinical decline. The responding patient should have therapy tailored to the most focused regimen possible on the basis of microbiologic studies. The nonresponding patient should be evaluated for drug-resistant organisms, complications of pneumonia (e.g., parapneumonic effusion or empyema), extrapulmonary sites of infection, or noninfectious causes of symptoms and signs of pneumonia (e.g., drug fever with drug-induced lung injury).

Respiratory Failure

Respiratory failure denotes either the inability to maintain normal tissue oxygen transport or the normal excretion of carbon dioxide. Clinically, respiratory failure is usually diagnosed by levels of arterial PO₂ and PCO₂, although the levels that constitute the threshold for respiratory failure are arbitrary. An arterial PO₂ of less than 60 mm Hg or an arterial PCO₂ of greater than 45 mm Hg generally indicates significant respiratory compromise in patients without preexisting lung disease. The diagnostic and therapeutic approach to the patient with respiratory failure is dictated by the underlying mechanism of abnormal gas exchange (Table 9.16).

Five basic pathophysiologic mechanisms cause acute hypoxemic respiratory failure. These include hypoventilation, V/Q abnormalities, shunt, diffusion limitation, and low inspired fraction of oxygen. All of these causes of hypoxemia are responsive to supplemental oxygen except shunt. Hypoventilation is usually due to depression of respiratory drive at the

level of the central nervous system as a result of drug therapy or the residua of anesthesia as described above. V/Q abnormalities are common causes of hypoxemic respiratory failure and result from such conditions as airflow obstruction from asthma and chronic obstructive pulmonary disease and pulmonary thromboembolic disease. Shunt is frequently caused by pneumonia and atelectasis. Diffusion limitation and low inspired fraction of oxygen are uncommon causes of hypoxemia in the absence of chronic lung disease and high altitude, respectively.

TABLE 9.16 Pathophysiologic Mechanisms of Hypoxemic Respiratory Failure and Ventilatory Failure

HYPOXEMIC RESPIRATORY FAILURE	VENTILATORY FAILURE
Hypoventilation	Insufficient respiratory drive
V/Q abnormalities (shunt, dead space)	Excessive respiratory workload
Venous admixture	Respiratory pump dysfunction
Diffusion limitation	
Low inspired fraction of oxygen	

The spectrum of causes of hypoxemia often can be narrowed according to the appearance of the chest radiograph. A simplified approach to chest radiographic interpretation for other than the pulmonary or critical care medicine specialist involves classifying the pulmonary parenchyma as generally white or black (normal). The causes of a white chest radiograph include atelectasis, pneumonia, pulmonary edema, and acute lung injury. Further characterization of a white chest radiograph includes the description of the radiographic opacities as diffuse or localized. Diffuse infiltrates are commonly associated with hydrostatic pulmonary edema that is due to cardiac pump failure, nonhydrostatic pulmonary edema that is due to lung injury from a variety of causes (e.g., aspiration or pancreatitis), or atypical pneumonias that are rarely hospital acquired (e.g., influenza, *Mycoplasma*, or *Chlamydia pneumoniae*). Focal infiltrates are suggestive of atelectasis or pneumonia. The causes of a black or a normal chest radiograph include pulmonary thromboembolic disease, microatelectasis, exacerbation of underlying obstructive lung disease, intracardiac or pulmonary arteriovenous right-to-left shunt, and a low cardiac output state. In the case of a black or white chest radiograph, information obtained from the history and physical examination may be crucial for determining the nature of further diagnostic testing to pinpoint the etiology of respiratory failure.

Ventilatory failure, the inability to maintain an appropriate arterial PCO₂, is caused by three major mechanisms: insufficient respiratory drive, excessive respiratory workload including increased dead space, or respiratory pump dysfunction. Insufficient ventilatory drive is usually due to drug therapy or the residua of anesthesia as stated above but may also be due to a primary central nervous system disorder (such as stroke, intracranial hemorrhage, and obesity-hypoventilation syndrome) or due to toxic-metabolic encephalopathy as a result of a wide variety of underlying conditions. Increased ventilatory workload may result from increased CO₂ production, increased dead space, altered respiratory mechanics (increased airway resistance or decreased pulmonary compliance), or compensation for metabolic acidosis.

Increased CO₂ production is a by-product of overall increases in metabolism. Fever, delirium with marked agitation, severe sepsis, overfeeding, and hyperthyroidism are examples of clinical states associated with increased CO₂ production. Increased dead space is a hallmark of severe chronic obstructive pulmonary disease; in patients with normal lung function, increased dead space is usually due to either pulmonary thromboembolic disease or a change in respiratory pattern. Rapid shallow breathing as a result of the physiologic changes is induced by anesthesia, and upper abdominal surgery produces an increase in the proportion of ventilation to the anatomic dead space and a decrease in effective alveolar ventilation. In addition to anesthesia and upper abdominal surgery as causes of respiratory pump dysfunction in the postoperative patient, any other cause of respiratory muscle weakness may result in ventilatory failure. Endocrine disorders, such as myasthenia gravis or hypothyroidism, as well as electrolyte abnormalities, such as hypophosphatemia, are examples of conditions that could significantly contribute to respiratory muscle weakness and pump dysfunction.

Treatment of acute respiratory failure depends on the underlying cause and is best accomplished in an appropriately

monitored environment, such as the intensive care unit with the aid of a specialist in critical care medicine, as mechanical support of ventilation—via either conventional invasive mechanical ventilation through an endotracheal tube or noninvasively through a tight fitting nasal or facial mask—may be necessary (Fig. 9.4). Management of mechanical ventilation and its consequences has acquired a level of complexity that mandates subspecialist care and is beyond the scope of this chapter.

FIGURE 9.5 Method of inserting a suprapubic tube into the bladder through a needle, with resultant drainage into a bottle. Suprapubic catheterization avoids the trauma to the urethra caused by repeated catheterization of an indwelling catheter.

Alternatively, at the Emory University Hospital, a Foley catheter is placed through the abdominal wall. After placing a Kelly clamp through the urethra and elevating the dome of the bladder, an incision is made in the abdominal wall superior to the Kelly clamp. A 14F Foley catheter is then pulled into the bladder and connected to gravity drainage. If a suprapubic urethropexy is performed, a 2- to 3-cm opening is made in the dome of the bladder, and the bladder is inspected to ensure that no sutures penetrated the mucosa. The Foley catheter is placed in the bladder and sutured in place with a no. 2.0 absorbable purse-string suture. Using the preceding techniques for insertion of a suprapubic Foley catheter, we have decreased the frequency of catheter obstruction. Seven to ten days postoperatively, the suprapubic catheters are clamped and postvoid residuals are evaluated. Patients with more than 100 mL of residual urine after spontaneous voiding require an extended period of catheterization. If the urinary residual is less than

P.143

100 mL on two successive voidings of more than 200 mL each, the suprapubic catheter can be removed. In many patients who require prolonged catheterization following radical hysterectomy or pelvic support surgery, intermittent self-catheterization using a clean but not sterile technique has become favored by many gynecologists. We believe, as do other authors, that prophylactic antibiotics given during the use of an indwelling bladder catheter are ineffective in preventing urinary tract infection. Although urinary tract symptoms may be delayed with the use of prophylactic antibiotics, it is our experience that the incidence of infection is unchanged and that a subsequent urinary tract infection may result from resistant organisms that are more difficult to treat later. Therefore, we prefer to treat only patients who have significant bacteriuria and pyuria, which includes about 10% to 15% of the patients with suprapubic drainage.

POSTOPERATIVE GASTROINTESTINAL TRACT MANAGEMENT

Dysfunction of the gastrointestinal tract remains a challenge in postoperative management. Each patient should be treated as an individual and not placed on a standard protocol for advancing diets. Patients who have had uncomplicated surgery may be given a regular diet on the first postoperative day if bowel sounds are present, if abdominal examination reveals no distention, and if the patient is no longer nauseated from her anesthesia. Seriously ill or malnourished patients or patients requiring extensive bowel surgery may benefit from preoperative and postoperative parenteral nutrition.

It is important to differentiate between postoperative ileus and postoperative obstruction (Table 9.17) if proper therapy is to be initiated promptly with beneficial results. The distinction may be difficult. This is because partial bowel obstruction is often accompanied by a secondary ileus as part of the clinical picture. Only by close clinical monitoring of the bowel sounds, serial abdominal radiographic studies, and frequent white blood cell counts can one clearly separate these two postoperative complications. Adynamic ileus is the more common clinical entity, a fact that may mislead the surgeon into a false sense of security unless he or she remains acutely aware of the distinguishing features of intestinal obstruction. Serial monitoring of the white blood cell count and differential count is an important method for differentiating between bowel obstruction and paralytic ileus. A key feature of advancing bowel obstruction is necrosis of the bowel wall, which causes progressive leukocytosis, along with distention and peritonitis. The most common gynecologic disease process associated with both ileus and intestinal obstruction is severe pelvic inflammatory disease (PID). Notoriously acute exacerbation of PID or rupture of a pelvic abscess is associated with prolonged ileus. Occasionally, fibrous adhesions form, and secondary bowel obstruction occurs. Postoperative pelvic peritonitis from any cause, including cellulitis resulting from hematoma formation and secondary infection of the vaginal cuff, is often associated with ileus, whereas intestinal obstruction only rarely results from such a complication.

TABLE 9.17 Differential Diagnosis Between Postoperative Ileus and Postoperative Obstruction

CLINICAL FEATURE	POSTOPERATIVE ILEUS	POSTOPERATIVE OBSTRUCTION
Abdominal pain	Discomfort from distention but not cramping pains	Cramping progressively severe
Relation to previous surgery	Usually within 48-72 h of surgery	Usually delayed, may be 5-7 d for remote onset
Nausea and vomiting	Present	Present
Distention	Present	Present
Bowel sounds	Absent or hypoactive	Borborygmi with peristaltic rushes and highpitched tinkles
Fever	Only if related to associated peritonitis	Rarely present unless bowel becomes gangrenous
Abdominal radiographs	Distended loops of small and large bowels; gas usually present in the colon	Single or multiple loops of distended bowel (usually small bowel) with air-fluid levels
Treatment	Conservative with nasogastric suction, enemas, cholinergic stimulation	Conservative management with nasogastric decompression Surgical exploration

Total Parenteral Nutrition

Nutritional support has proved efficacious in patients undergoing major surgery and in patients with impaired bowel function, inadequate oral intake, or cancer. A few patients require total parenteral nutrition (TPN) for prolonged periods secondary to their inability to obtain adequate calories orally. Parenteral nutrition may be administered through a peripheral or central access, depending on the patient's initial nutritional status and the time required on TPN.

Hospitalized patients may require TPN for disease processes such as gastrointestinal tract obstruction, prolonged ileus, short-bowel syndrome, radiation enteritis, intra-abdominal abscess, pancreatitis, regional enteritis, and enterocutaneous fistula. A patient with any condition that prevents oral intake of adequate amounts of food for more than 7 to 10 days probably requires central parenteral nutrition. Because it is much easier to maintain an adequate nutritional state than to improve a poor one, the decision to use TPN should not be delayed.

TPN is not without complications. Many of these pertain to the need for central venous access. Catheter tip infection is one of the more frequently encountered problems. Meticulous aseptic technique when placing the central venous catheter and adherence

P.144

to aseptic technique when using the catheter minimizes the risk of infection. Antibiotic-coated central venous catheters have been around for more than a decade and are coming more into favor as compelling data surface suggesting decreased infection rates with their use. At the Emory University Hospital, central venous catheters coated with chlorhexidine and silver sulfasalazine are being used. Other potential problems with central venous catheters include catheter or air embolism and pneumothorax or hemothorax. Total parenteral nutrition itself can cause fluid overload, electrolyte abnormalities, or metabolic disturbances.

Patient Evaluation

A complete medical history and physical examination must be obtained before parenteral nutrition is initiated. Particular attention should be paid to identifying patients with cardiovascular or renal disease, hyperlipidemia, diabetes, and thyroid disease. Total parenteral nutrition modification can include decreasing or eliminating fat emulsion in patients with severe cardiovascular disease or hyperlipidemia, administering low-nitrogen TPN to patients with renal failure, and increasing the insulin dosage in patients with diabetes mellitus.

The patient's degree of malnutrition should be assessed by taking measurements of several physical indicators, such as actual body weight (ABW) and ideal body weight (IBW), usual body weight (UBW; preillness), creatinine-to-height index, triceps skin fold thickness (TSFT), and arm circumference (AC). The arm muscle circumference (AMC) is calculated and used as an index of nutritional status.

AMC = AC-(TSFT × 3.14)

Fat stores are reflected in the triceps skin fold measurement, whereas somatic proteins are evaluated by measuring muscle mass, such as the AMC. The Frisancho standards (1984) are used to interpret body weight (kilograms), triceps (millimeters), and bone-free arm muscle area (square centimeters). Patients found to be in the 5th to 10th percentiles are severely malnourished and require an anabolic environment. Weight loss is considered significant when the (UBW – ABW)/UBW × 100 is >10%. Weight loss during starvation occurs at a rate of 0.4 kg/d. Survival also is compromised when the ABW falls below the 70th percentile of the IBW. In addition to the preceding physical measurements, a thorough evaluation of chemical indicators is required (Table 9.18) before initiating TPN. Extensive monitoring is required while the patient is receiving TPN (Table 9.19).

Copper	Monthly, or as needed
Selenium	Monthly, or as needed

The physical and chemical measurements of malnutrition are subject to many influences during illness and should be treated as confounding variables. For example, albumin values less than 3.2 g/dL are frequently used to indicate malnutrition. Starker and colleagues observed that in hospitalized patients, albumin and body weight measurements in conjunction provided better indications of sodium balance and extracellular fluid volume. In addition, albumin serum levels are required for maintenance of the intravascular colloid oncotic

pressure and as a carrier protein.

The half-life of albumin is 20 days and thus reflects a depletion of visceral proteins of at least 3 weeks' duration. Transferrin, with a half-life of 8 to 9 days, provides the clinician with a measurement of recent protein status changes. Because transferrin is required to bind Fe^{2++} , its level is affected by intravascular iron status and can increase during pregnancy, in patients with hepatitis, and in patients receiving estrogen supplementation. Serum protein content can be reduced in protein-losing enteropathy, nephropathy, chronic infections, uremia, and during catabolism. Transferrin reflects recent losses and remains a better indicator of protein status and change than is albumin. Total lymphocyte counts of less than 1,500/mL are indicative of an immunocompromised patient. Immunologic skin testing for recall antigens and total lymphocyte counts has been correlated with both nutritional status and morbidity and mortality. Its usefulness in the assessment of nutritional status is limited to confounding variables such as cancer, side effects of cancer treatment protocols, stress of trauma or surgery, and infection. Phosphorus and the trace elements are thoroughly evaluated before initiating TPN and during TPN because they are often depleted with many disease states and are required when alimenting ([Tables 9.7, 9.8, and 9.18, 9.19, 9.20 and 9.21](#)).

Nutritional Requirements

Total parenteral nutrition consists of six components: carbohydrates, fat, protein, electrolytes, vitamins, and trace elements. The Harris-Benedict basal energy expenditure (BEE) accounts for two thirds of the total daily energy requirements, with the remaining one third obtained from protein. Daily requirements for protein are between 1.5 and 2.5 g/kg/d. Patients receiving TPN who are severely malnourished and stressed require larger amounts of protein daily.

The BEE is calculated as follows:

$$\text{BEE(kcal/d)} = 655 + 9.56(\text{wt}) + 1.85(\text{ht}) - 4.68(\text{age})$$

P.145

TABLE 9.20 Design of Parenteral Nutrition Programs: Examples

Nonobese patient weighing 60 kg; assume basal Harris-Benedict equation estimate of daily caloric requirements of 1,250 kcal/d

Patient characteristics

1. Euvolemic, normal urine output, and no unusual gastrointestinal losses; therefore, appropriate initial estimate of daily fluid requirement is 30 mL/kg body weight
2. Moderately stressed with normal renal and hepatic function; therefore, appropriate to provide 1.2 g protein per kg body weight
3. Nonobese; therefore, appropriate to provide Harris-Benedict estimate plus 20% for calories, i.e., 1,250 kcal plus 20% = 1,500 kcal

Program design

1. Fluid requirement: 30 mL \times body weight; 30 \times 60 = 1,800 mL
2. Caloric requirement: Harris-Benedict estimate plus 20%; 1250 kcal + 250 kcal = 1,500 kcal
3. Protein requirement for moderately stressed patient: 1.2 g/kg body weight; 60 \times 1.2 = 70 g protein. 70 g protein \times 4 kcal/g protein = 280 kcal
4. Fat requirement: 30% of total calories; 30% \times 1,500 kcal = 450 kcal
5. Carbohydrate requirement: caloric requirement minus the sum of protein and fat calories; 1,500 – (280 + 450 kcal) = 770 kcal. 770 kcal carbohydrate – kcal/g carbohydrate (3.4) = 225 g carbohydrate
6. Therefore, consider the following parenteral nutrition formula: 1.5 L amino acids, 5% dextrose, 15%; plus 250 mL of 20% fat emulsion, which provides 1,750 mL, 1565 kcal, 75 g protein, 225 g carbohydrate, and 500 fat calories. Note that 5% amino acids equals 50 g protein per liter
7. If institution uses three-in-one admixture (amino acids plus dextrose plus fat in one container) and stock solutions of 10% amino acids, 70% dextrose, and 20% lipid, a comparable parenteral nutrition program would be 1.5 L amino acids, 5%; dextrose, 15%; fat, 3.5%

Similar patient characteristics except patients volume-expanded

1. Consider the following fluid-restricted parenteral nutrition formula: 1 L of amino acids, 7%; dextrose, 20%; plus 250 mL 20% fat emulsion, which provides 1,250 mL, 1,460 calories, 70 g protein, 200 g carbohydrate, and 500 fat calories

Height is in centimeters; weight is in kilograms.

Once the patient has reached the estimated daily calorie goal, a 24-hour nitrogen balance study is performed by obtaining a 24-hour urine collection and an am electrolyte panel. If a large quantity of fluid from the nasogastric tube, ileostomy, fistula, or wound is present, this also should be collected and sent for nitrogen measurements.

$$\text{N}_2 \text{ (g) balance} = \text{N}_2 \text{ (g) in} - \text{N}_2 \text{ (g) out}$$

Adding 4 to the N_2 out value accounts for nitrogenous losses in the stool and skin. This does not include an estimate of the losses from the gastrointestinal tract and wound, as previously described.

$$\text{N}_2 \text{ (g) balance} = \text{N}_2 \text{ (g) in} \times [\text{N}_2 \text{ (g) out} + 4]$$

$$\text{N}_2 \text{ (g) out} = \text{urine volume (mL)} \times \text{urine urea N}_2 \text{ (mg / dL)}$$

$$\text{N}_2 \text{ (g) in} = \text{amino acids per day} / 6.24$$

$$6.24 = \text{g protein} / \text{g nitrogen}$$

Patients with normal renal and liver function are started on standard total hyperalimentation solution (THAS) ([Table 9.18](#)). Each liter provides a total of 1,020 kcal, including 41 g of amino acids and 250 g of dextrose. The osmolality of this solution is 1,850 mOsm, which therefore necessitates a central venous access. The calories-to-nitrogen ratio of this solution is 157:1 and is optimal in nonstressed patients. The addition of lipids also is effective in promoting a positive nitrogen balance. The total daily sodium concentration should be equivalent to that of normal saline (150 mEq/L). This can be altered to accommodate patients who require sodium restriction or loading. [Table 9.22](#) outlines the recommendation for daily electrolyte requirements. It should be noted that acetate serves as a precursor to bicarbonate, because the latter is not compatible in the THAS solution. Multivitamins are added daily to 1 L of THAS, whereas trace elements are divided equally in the volume to be infused during a 24-hour period. The recommended daily allowances for both fat- and water-soluble vitamins are outlined in [Table 9.23](#).

Blood glucose levels in patients receiving TPN should be between 100 and 200 mg/dL. A minimum of 10 IU should be added to each liter when required. This permits about 50% to

adhere to the plastic tubing. This can be supplemented with subcutaneous doses of regular insulin to obtain the desired blood glucose level. About one half to two thirds of the previous day's requirements are added in divided doses to the THAS solutions.

Intravenous lipids provide a nonprotein source of energy and serve as a source of essential fatty acids. Ten percent fat emulsions (550 kcal/500 mL) and 20% fat emulsions (1,000 kcal/500 mL) are commercially available. In patients receiving standard TPN, 500 mL of 10% fat emulsion are infused twice weekly at a rate of 42 mL/h. However, when fat emulsion is used with peripheral THAS, the patient requires 2 L of peripheral THAS and 1 L of 10% fat emulsion daily. Twenty percent fat emulsions also can be used for calories in patients with glucose intolerance or patients who require a decreased protein-calorie percentage.

P.146

TABLE 9.21 Trace Minerals

MINERALS AND LEVELS	DEFICIENCY		TOXICITY	
	SYMPTOMS	ETIOLOGY	SYMPTOMS	ETIOLOGY
Zinc, 55-150 mg/dL	Diarrhea, mental depression, alopecia, night blindness, dermatosis, impaired taste, hypogonadism, impaired wound healing	Gastrointestinal (failure of ingestion, absorption, retention) Large wounds Protein-energy malnutrition Cancer	Vomiting Diarrhea Neurologic damage ("zinc shakes")	Increased ingestion from galvanized containers Metal fume fever
Selenium, 90-150 µg/dL (synergism with vitamin E)	Myositis with muscle weakness Cardiomyopathy with arrhythmias and congestive heart failure	Unsupplemented TPN	Liver cirrhosis Alopecia Pathologic loss of nails Dermatitis	Increased ingestion (rare)
Chromium, 50-200 µg/d	Neuropathy Encephalopathy New insulin-dependent diabetes mellitus	Unsupplemented TPN Increased renal loss secondary to injury Gastrointestinal losses	Respiratory Lung cancer	Workers manufacturing products containing hexavalent chromium
Phosphorus, 3.0-4.5 mg/dL	Nausea, vomiting, anorexia, dysarthria, paresthesia, hemolytic anemia, peripheral neuropathy, respiratory depression, congestive heart failure, renal glycosuria	Gastrointestinal (failure of ingestion, absorption, retention) Cellular anabolism Respiratory or metabolic alkalosis Al(OH) ₃ antacids Alcoholism	Neurotoxicity secondary to compensatory hypocalcemia	Renal failure Hypoparathyroidism
Magnesium, 136-145 mEq/L	Nausea, vomiting, muscle weakness, lethargy, tetany, muscle tremor, personality changes	Gastrointestinal (failure of ingestion, absorption, retention) Cellular catabolism, acidosis, K ⁺ depletion Glomerular dysfunction	Hyporeflexia, lethargy, respiratory depression, cardiac arrest	Magnesium supplementation in patients with renal compromise
Copper, 70-155 µg/dL	Hypochromic anemia not responsive to iron, neutropenia	THAS without copper or high amino acids Gastrointestinal (failure of ingestion, absorption, retention) Pregnancy, lactation (increased requirements) Renal losses	Jaundice-hepatic necrosis Intravascular hemolysis Gastric hemorrhage Tremors, choreoathetoid movements, dementia, rigidity, dysarthria	Iatrogenic Wilson disease Absorption of copper nitrate salves in burn patients

THAS, total hyperalimentation solution; TPN, total parenteral nutrition.

Patients deficient in fatty acids present with dermatitis, hemolytic anemia, thrombocytopenia, elevated liver enzymes, and poor wound healing.

To improve glucose tolerance, the first liter should be started at a rate of 42 mL/h. On the second day, the solution can be increased to 84 mL/h; on day three, it can be increased to 124 mL/h. If the patient is unable to tolerate this schedule, increments can be decreased to 21 mL/h each day. Treatment monitoring is outlined in [Table 9.19](#). Total nitrogen balance should be recalculated if there is a marked change in the patient's condition or in the parenteral nutrition administered.

Recent data in the surgical literature suggest that supplementing TPN with glutamine dipeptides improves nitrogen balance, preserves intestinal permeability and absorption, and improves recovery of lymphocytes. These authors also demonstrated a shorter hospital stay in postoperative patients receiving glutamine dipeptide-enriched TPN compared with controls receiving TPN alone.

Initiating Total Parenteral Nutrition

Safe venous access is required for initiating TPN. A reliable intravenous catheter should be placed into a large central vein with the catheter tip located so that blood flow dilutes the highly concentrated nutritional fluids. The insertion site also should allow easy fixation of the catheter at the entrance site, minimum catheter movement during body

P.147

movements, and easy dressing changes. A subclavian vein approach satisfies the requirements for safe catheter placement, but neither internal jugular vein nor antecubital fossa placement is optimal. The internal jugular vein should be used only if the subclavian approach has failed. Movement of the head and neck results in an increased incidence of occluding venous access when the internal jugular vein has been cannulated.

TABLE 9.22 Daily Electrolyte Requirements for Parenteral Nutrition

ELECTROLYTE	DOSAGE (mEq/d)
Sodium	60-150
Potassium	60-240
Phosphate	30-45
Calcium	10-15
Magnesium	8-26
Acetate	80-120
Chloride	60-150

Anatomy of Infraclavicular Subclavian Vein

In 1952, Aubaniac, a French physician, was among the first to advocate use of the subclavian vein for intravenous infusions. Wilson and colleagues cannulated the superior vena cava through a percutaneous puncture of the subclavian vein. They reported a high percentage of successful cannulations and a low incidence of complications.

As **Figure 9.6** shows, the subclavian vein is located within the costoclavicular-scalene triangle, which is bounded anteriorly by the medial end of the clavicle, posteriorly by the upper surface of the first rib, and laterally by the anterior scalene muscle. The anterior scalene muscle separates the subclavian vein from the subclavian artery, which lies beneath and along the lateral aspect of the muscle. The subclavian vein is covered by 5 cm of the clavicle medially and joins the internal jugular vein near the medial border of the anterior scalene muscle to form the innominate vein. The innominate vein descends behind the sternum and joins with the opposite innominate vein to form the superior vena cava. The subclavian vein, which is about 3 or 4 cm long, continues as the axillary vein below the clavicle en route to the axilla. Several other significant structures occupy this region. The phrenic nerve courses across the anterior surface of the anterior scalene muscle near its attachment to the first rib and courses medially to lie posterior to the subclavian vein. It can be injured if the posterior wall of the vessel is penetrated. The internal thoracic nerve and apical pleura are in contact with the posterior surface of the subclavian vein at its junction with the internal jugular vein. The roots of the brachial plexus formed by the fifth, sixth, seventh, and eighth cervical and first thoracic nerves lie lateral to the anterior scalene muscle on the lateral side of the subclavian artery. If a cannulating needle is directed too far laterally, the brachial nerve plexus could be injured or the subclavian artery could be punctured. The thoracic duct on the left side and the lymphatic duct on the right cross the anterior scalene muscle on either side of the thorax to enter the superior aspect of each subclavian vein near its junction with the internal jugular vein. These lymphatic vessels are rarely encroached on during subclavian catheterization.

FIGURE 9.6 Anatomic relations of the subclavian vein. The broken line represents the location of the transverse section for lateral view.

Subclavian Catheter Placement

As illustrated in **Figure 9.7A**, the subclavian catheter is inserted with the patient in the supine position, with the foot of the bed elevated 6 to 12 inches to increase the pressure in the subclavian vein and produce venous distention. After meticulous

P.148

aseptic preparation of the skin with povidone-iodine (Betadine), the skin and subcutaneous tissues are infiltrated with a 1% solution of lidocaine (Xylocaine) if the patient is awake. The point of needle insertion is about 1 cm below the junction of the inner and middle third of the clavicle. Most central venous catheter units include an external introducer catheter (Teflon) and an internal (silicone) infusion catheter. The outer Teflon sheath accommodates a no. 12 needle, which fits snugly into and protrudes beyond the end of the Teflon catheter. The needle and sheath are introduced into the skin with the shaft of the needle held almost parallel with the anterior chest wall (**Fig. 9.7A**). The needle is directed medially and advanced along the undersurface of the clavicle. It is not necessary to scrape the posterior surface of the clavicle to ensure that the pleura is protected from puncture. By applying suction constantly, the needle passes beneath the skin and immediately aspirates dark red blood, which confirms entry into the vein. If the vein is not entered, the needle is withdrawn

P.149

and readvanced in a similar manner but in a slightly more cranial or caudal direction. Use of real-time sonography has been shown to increase the likelihood of successful subclavian catheter placement. As soon as a free flow of blood is obtained, the introduced Teflon sheath is advanced far enough to be certain that it is securely placed within the vein. The sheath is held in place by the connector, the finger is placed over the end of the needle to prevent air embolism, and the internal needle is replaced (**Fig. 9.7B**) by the silicone infusion catheter that accompanies the central venous pressure kit (**Fig. 9.7C**). A thin wire stylet inside the infusion catheter allows the catheter to be advanced easily; occasionally, the stylet must be withdrawn slightly to advance the catheter as far as possible into the innominate vein and superior vena cava. The silicone infusion catheter is advanced until the attached connector can be securely wedged into the connector of the Teflon sheath (**Fig. 9.7C**). After the infusion catheter is connected to an intravenous fluid line, the Teflon sheath is carefully withdrawn from the vein, remaining partially in the subcutaneous tissue while leaving an ample length of the infusion catheter in the vena cava (**Fig. 9.7D**). A suture sleeve on the introducer sheath is slid down to the puncture site and sutured to the skin (**Fig. 9.7E**). The tip of the catheter is preferably positioned in the superior vena cava and should not be advanced into the right atrium or ventricle, where it could cause accidental trauma to the heart wall or cardiac arrhythmias. To ensure its

continued sterility and proper function, the subclavian vein catheter should not be used to replace fluids or withdraw blood for laboratory studies, if it is at all possible to avoid these uses. A central venous line for hyperalimentation is an exception to this rule. The dressing should be changed daily and the catheterization site cleaned with povidone-iodine or a similar antimicrobial solution.

TABLE 9.23 Recommended Dietary Allowances

FIGURE 9.7 Insertion of subclavian catheter for monitoring central venous pressure. A: After locally anesthetizing the puncture site, the needle with overlying introducer catheter is directed medially between the first rib and the clavicle at the junction of the middle and inner third of the clavicle. The needle is held parallel to the anterior chest wall and advanced along the undersurface of the clavicle. Entry into the vein is evident with aspiration of blood in the attached syringe. B: The needle and syringe are removed from the Teflon sheath, and a finger is held over the end of the open catheter to prevent entry of air. C: The silicone infusion catheter is inserted through the introducer catheter until the two connectors meet and lock firmly. D: The intravenous fluid line is connected to the silicone infusion catheter. E: The suture sleeve is advanced to the skin surface, where the catheter is sutured firmly to the skin.

Cardiac and Respiratory Insufficiency

Patients with congestive heart failure require decreased sodium and decreased total fluid volume. The best solution can be prepared from the most concentrated solutions of glucose, amino acid, and fat available. Fluid-restricted solutions also may be beneficial for patients with respiratory failure, who should receive less total glucose in favor of more fat because the respiratory quotient (CO₂/O₂) of glucose (1.00) is greater than that of fat (0.70) and because excess glucose will increase the load of CO₂ the lungs must excrete. Excessive total caloric intake resulting in fat synthesis from glucose substrate may severely compromise respiratory function because large amounts of CO₂ are released (respiratory quotient 8.0).

Discontinuing Total Parenteral Nutrition

Before discontinuing TPN, the patient should tolerate an enteral diet that provides adequate calories. It is permissible to aliment patients with an enteral diet before decreasing the THAS solution. An abrupt discontinuation of central parenteral nutrition results in rebound hypoglycemia. Our recommendation is to decrease the THAS stepwise to 42 mL/h before discontinuation. Some institutions recommend that the patient receive 10% dextrose for an additional 12 hours once central parenteral nutrition has been discontinued.

Team Approach to Total Parenteral Nutrition

Total parenteral nutrition can now be safely administered to patients in many hospitals because of the existence of a team of physicians, nurses, and health care professionals. Although the composition and exact function of the team members vary between hospitals, most teams consist of a physician, nurse, pharmacist, and nutritionist. The role of the team varies in each institution from consultation to complete management of the patient's nutritional needs. The team approach by either method is highly beneficial because it provides a high concentration of personnel with knowledge, expertise, and interdisciplinary communication at the patient's bedside. Team members can provide continuing education on nutrition therapy, continuously audit and collect quality control data, and investigate ways to improve the safety and efficacy of TPN as a treatment modality. Most teams operate with a standardized protocol that covers patient assessment, catheter insertion techniques, solutions used, and monitoring functions performed.

Enteral Nutrition

Enteral nutrition is preferable to TPN. The old adage “if the gut works, use it,” applies for several reasons. Ease of administration, economic considerations, and decreased number of complications are all advantages of enteral feeding over parenteral nutrition. Several studies have shown TPN and

P.150

enteral nutrition equally efficacious in achieving nitrogen balance. Patients with good bowel function should receive enteral feedings. Relative contraindications to enteral feeding include gastrointestinal bleeding, diarrhea, and intestinal obstruction. Small-bore nasal feeding tubes are placed in the stomach, duodenum, or jejunum. An abdominal radiograph should be obtained to confirm placement. Failure to obtain appropriate studies may result in tube placement in the trachea. Alternatively, a gastrostomy or jejunostomy tube could be placed for long-term enteral nutrition (Table 9.24). Several products are commercially available (Table 9.25). Enteral tube feedings are routinely administered by pump, with either bolus feeds to the stomach or continuous feeds to the small bowel, and should be administered by pump at 25 to 30 mL/h with gastric residuals evaluated every 4 hours. Table 9.26 shows the essential and nonessential amino acids.

TABLE 9.24 Protocol for Enteral Tube Feeding

Nasogastric route: Use small-bore, flexible tube (8F preferred); obtain radiograph after placement to confirm position.
Elevate the head of the bed at least 30 degrees.
Use feeding pump for continuous feeding.
Begin with full-strength formula at 25-30 mL/h and, if tolerated, increase by 25-30 mL/h at 12-h intervals until desired total volume is reached. ^a
Check gastric residuals every 4 h; if > 100 mL, hold feeding, and repeat at hourly intervals until residuals are <100 mL before resuming feeding.
Irrigate with 30-50 mL of water after each residual check or after any medications are given. (If the patient requires additional free water, use greater volumes of water for irrigation.)
If the patient experiences diarrhea or intestinal cramping, slow rate of feeding or decrease concentration of formula.

^aWhen using hypertonic formulas or feeding into the jejunum with a nasojejunal or jejunostomy tube, diluting the formula to one-half or three-quarter strength may improve tolerance initially. The concentration then can be increased after the desired volume is reached.

ROUTINE ORDERS

When the patient has fully recovered from the anesthetic and is ready for return to the nursing floor and routine postoperative care, we have found the basic postoperative orders shown in [Figure 9.8](#) to be useful. They are only a general outline. This list should be expanded to include the special needs of each postoperative patient.

It is imperative that each patient be evaluated before being transferred from the recovery room. If the patient is not ready for transfer, additional efforts are made to stabilize the patient or transfer her to an intensive care bed. On transferring, the frequency of physicians' rounds should be based on the severity of the patient's condition. All patients should be evaluated on the evening of surgery and appropriate documentation made in the chart. A thorough evaluation of the vital signs, catheter drainage (nasogastric, peritoneal, and Foley), and pulmonary status is required, and abdominal examination is performed. Each physician has a desired protocol for postoperative management. The routine orders outlined in this chapter provide

P.151

the clinician with a framework to design patient care plans that address the individual patient's requirements. Laboratory and radiographic evaluation of the postoperative patient also is tailored to the individual patient. Unfortunately, many physicians are predominantly concerned with quantitative test values. However, it is just as important to develop a close rapport with the patient, the patient's family, and the nursing staff. Only through good communication can the gynecologic surgeon deliver optimum medical care.

TABLE 9.26 Amino Acids	
ESSENTIAL	NONESSENTIAL
Arginine	Alanine
Histidine	Asparagine
Isoleucine	Aspartic acid
Leucine	Cysteine
Lysine	Glutamic acid
Methionine	Glutamine
Phenylalanine	Glycine
Threonine	Proline
Tryptophan	Serine
Valine	Tyrosine

BEST SURGICAL PRACTICES

- Approximately 500,000 hospitalized patients develop DVT and approximately 200,000 PE.
- Ten percent of hospital deaths in the United States are secondary to a PE.
- Tumors up-regulate the production of TF and PAI-1, which promotes coagulation and VTE.
- Anti-factor Xa assay can be used to monitor patients who are anticoagulated with LMWHs.
- General anesthesia is associated with a reduction of FRC by approximately 16%.
- Atelectasis occurs in 15% to 20% of patients undergoing abdominal surgery.
- An arterial PO₂ of less than 60 mm Hg or an arterial PCO₂ of greater than 45 mm Hg indicates significant respiratory compromise in patients without preexisting lung disease.
- Increased CO₂ production is a by-product of increased metabolism (i.e., fever, marked agitation, severe sepsis, overfeeding, and hypothyroidism).
- During stress, urinary nitrogen levels may increase greater than or equal to 20 g in 24 hours, corresponding to a loss of 600 g of hydrated body protein.

P.152

BASIC POSTOPERATIVE ORDERS		
Patient's Name: _____		
1. Admit to Unit # _____		
2. Diagnosis: _____		
3. Allergies: _____		
4. Condition: _____		
5a. Vital signs: _____		
_____ q 15 minutes until stable		
_____ q 2 hours for 24 hours		
_____ q 8 hours, if stable		
5b. Notify House Officer (H.O.) if _____		
BP < 90/60, > 160/100		
Pulse < 60, > 120		
Temp > 38.0°C		
6. Activity: _____		
_____ Bed rest		
_____ Ambulate		
_____ Other (specify) _____		
7. Diet: _____		
_____ NPO		
_____ Other (specify) _____		
8. Intravenous fluids: _____		
9. Incentive spirometer q 2 hours while awake		
10. Encourage deep breathing		
11. Drains: _____		
Type	Location	Drainage
_____ Nasogastric	_____ Stomach	_____ Low/intermittent suction
_____ Peritoneal	_____ Pelvis	_____ Bulb suction
_____ Foley catheter	_____ Bladder	_____ Gravity
12a. Fluid intake and output chart		
12b. Notify H.O. if urine output < 30 cc/h		
13. Pain medication: Specify _____		
(a) route of administration _____		
(b) dosage _____		
14. Antiemetic medication: Specify _____		
(a) route of administration _____		
(b) dosage _____		
15. Antibiotics _____		
16. Venous thrombosis prophylaxis _____		
17. Other medications _____		
18. Catheterize q 6 hours, or sooner, if bladder is full and patient unable to void.

Chapter 10

Water, Electrolyte, and Acid-Base Metabolism

Jack B. Basil

Devin D. Namaky

DEFINITIONS

Anion gap—The anion gap is the difference between the measured cations and anions in serum, plasma, or urine. For serum, it is estimated by subtracting the sum of the chloride and bicarbonate anions from the sodium cations and is usually expressed in mmol/L or mEq/L:

$$[\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$$

Bowman space—This is the capsular-shaped space that surrounds the glomerulus at the beginning of the tubular nephron in the kidney. It receives the initial glomerular filtrate.

Effective intravascular volume—This is the proportion of the intravascular volume that is effective in determining the filling pressure of the ventricles and is usually directly related to the central venous pressure. This may not always correlate with the *actual* intravascular volume.

Extracellular fluid—The body fluid that exists outside of cells. It contains approximately one third of the volume of total body water.

Fractional excretion of sodium—This is the amount of sodium excreted in the urine, expressed as a percentage of the sodium that is filtered by the kidney:

$$\%E / F_{\text{Na}} = 100 \left\{ ([\text{Na}^+]_{\text{Urine}} [\text{Cr}]_{\text{Serum}}) / ([\text{Na}^+]_{\text{Serum}} [\text{Cr}]_{\text{Urine}}) \right\}$$

where $[\text{Na}^+]_{\text{Urine}}$ is the concentration of sodium in the urine. $[\text{Na}^+]_{\text{Serum}}$ is the concentration of sodium in the serum, $[\text{Cr}]_{\text{Serum}}$ is the concentration of creatinine in the serum, and $[\text{Cr}]_{\text{Urine}}$ is the concentration of creatinine in the urine.

Henderson-Hasselbalch—An equation for calculating the pH of an acid or buffered solution. A modification of this

P.156

equation may be used to calculate the pH of blood as follows:

$$\text{pH} = \text{pK}_{\text{aH}_2\text{CO}_3} + \log \left\{ [\text{HCO}_3^-] / [k_{\text{HCO}_2} (\text{PCO}_2)] \right\}$$

where $\text{pK}_{\text{aH}_2\text{CO}_3} = 6.1$, HCO_3^- = concentration of bicarbonate in the blood, $k_{\text{HCO}_2} = 0.03$ mmol/mm Hg.

Intracellular fluid—The body fluid that exists inside of cells. It contains approximately two thirds of the volume of total body water.

Intravascular volume—This is the same as blood volume and includes intravascular water, as well as plasma, plasma proteins, and other blood products such as red cells.

Metabolic acidosis—Acidosis resulting from increase in acids other than carbonic acid or resulting from

the inability of the body to form bicarbonate in the kidney.

Metabolic alkalosis—Alkalosis in which plasma bicarbonate is increased directly, or indirectly as a result of decreased hydrogen ion concentration.

Oncotic pressure—The osmotic pressure exerted by proteins in solution, usually pulling water into the intravascular space. This is also commonly called the *colloid osmotic pressure*.

Orthostatic hypotension—A decrease in perfusion that is caused by a change from a supine to a standing position. This is generally diagnosed by a decrease in systolic blood pressure of more than 20 mm Hg, or a decrease in diastolic blood pressure of more than 10 mm Hg, and is further suggested by a pulse increase of more than 30 bpm.

Osmotic pressure—The pressure that is needed to prevent water flow between two solutions of different concentrations that are separated by a semipermeable membrane.

Plasma osmolality—The measure of solute per kilogram of plasma. For the purposes of this chapter, this is used interchangeably with plasma *osmolarity*, which is the measure of solute per *liter* of plasma. This can be estimated for normal plasma:

$$P_{\text{OSM}} = 2 \left[\text{Na}^+ \right] + \left[\text{glucose} \right] + \left[\text{urea} \right]$$

Respiratory acidosis—Acidosis secondary to decreased ventilation, usually with a proportionate increase in plasma carbon dioxide.

Respiratory alkalosis—Alkalosis secondary to increased ventilation, usually with a proportionate decrease in plasma carbon dioxide.

Specific gravity—This is the ratio of the density of a substance to the density of water. Under most conditions encountered, this is equal to the *apparent* specific gravity, which is the ratio of the weight of a substance to the weight of an equal volume of water.

Proper management of fluids and electrolytes in the gynecologic surgical patient is of extreme importance. Gynecologic surgical patients can differ in age, baseline nutritional status, and in the complexity of medical problems that they possess. The stresses of surgery and the bodies' complex responses to that stress need to be understood to best care for these patients. The tendency to standardize postoperative care for all patients should be avoided.

This chapter focuses on the clinical aspects of water and electrolyte balance, and an understanding of basic renal physiology is a prerequisite.

CLINICAL ASSESSMENT OF DISORDERS OF WATER AND ELECTROLYTE METABOLISM

Disorders of extracellular fluid (ECF) electrolyte composition may be detected by measurement of the serum electrolyte concentrations. Identification of the process (or processes) behind the disturbance of electrolyte composition and the planning of subsequent therapy are critically dependent on the clinician's ability to accurately assess whether the disturbance in ECF electrolyte composition is associated with volume expansion, volume contraction, or a normal volume.

In the evaluation of a patient's ECF volume status, it must be kept clearly in mind that the critical volume that is effective in determining cardiac output is the effective intravascular volume (IVV). The most effective IVV is that which maintains an optimal cardiac output and thus maximizes tissue perfusion. Although the actual IVV and the effective IVV are the same in many clinical situations and can be expected to change in direct proportion, in a

number of important clinical states, the actual IVV is different from the effective IVV. For example, in acute metabolic acidosis, increased venoconstriction can develop, resulting in an abnormal increase in central venous pressure (CVP) and cardiac output. Under this circumstance, the actual IVV could be less than normal, whereas the effective IVV is greater than normal. Because of the increase in venous tone, an IVV that is lower than normal can maintain a normal effective IVV.

Acute changes in venous tone induced by drugs (e.g., morphine, furosemide, norepinephrine), changes in acid-base status, and the presence of bacterial endotoxin also can disrupt the normal relation between the actual IVV and the effective IVV.

The most reliable clinical means for assessing the status of the effective IVV is the pulmonary capillary wedge pressure. This measurement is an estimate of the pulmonary capillary pressure, which is a measure of the filling pressure of the left ventricle. Factors that increase pulmonary capillary wedge pressure tend to increase cardiac output by increasing capillary outflux. When effective IVV is considered within these constraints, it becomes clear that under virtually any physiologic or pathophysiologic circumstance, an optimal effective IVV is one that results in a pulmonary capillary wedge pressure that is high enough to promote optimal cardiac output but low enough to prevent pulmonary edema.

Fortunately, in most clinical situations, it is not necessary to resort to measuring pulmonary wedge pressure to assess whether a disturbance of ECF composition is associated with an effective IVV that is abnormally high, abnormally low, or normal. Instead, an accurate assessment of the effective IVV usually can be made by a careful clinical assessment using the criteria listed in [Table 10.1](#). This table lists the bedside and laboratory means to assess volume status according to whether the findings are consistent with an effective IVV that is less than normal or an effective IVV that is nearly normal or expanded.

Also shown in [Table 10.1](#) are the conditions under which the given means for evaluating the IVV must be qualified (i.e., the conditions that may render the meaning of the finding indeterminate with respect to the evaluation of IVV). For example, the relation between an increase in weight and a change in IVV is rendered indeterminate if, at the same time, the patient has developed a third space, as in bowel obstruction. In this instance, the entire weight gain could be caused by the accumulation of fluid outside the IVV. Thus, the finding of weight gain in this setting cannot be used as evidence of an increase in effective IVV. Whenever a finding can be significantly qualified,

P.157

it should not be used in the assessment of the effective IVV. As many independent means as practical should be used to assess the effective IVV to minimize the effect of possible error on the final decision. The greater the number of independent, unqualified findings that agree in favor of a given clinical decision, the more likely it is that the decision is correct. If such a systematic approach to clinical decision making is used, it should be possible to arrive at an accurate evaluation of volume status in most circumstances.

TABLE 10.1 Assessment of Effective Intravascular Volume

SUGGESTIVE EVIDENCE	QUALIFYING CONDITIONS ^a
Significantly decreased effective IVV	
History of fluid and electrolyte deprivation or loss (e.g., vomiting, diarrhea)	Difficulty in establishing by history whether the magnitude of loss or deprivation is sufficient to result in negative balance of water and electrolytes

Decrease in body weight below normal not explained by inadequate caloric intake

None

Blood pressure less than usual for the patient with orthostatic hypotension

1. The patient receiving methyldopa (Aldomet), prazosin (Minipress), minoxidil (Loniten), or other drugs that interfere with vascular α -receptors
2. Autonomic insufficiency as in diabetics, quadriplegics, and after prolonged bed rest

Elevated serum creatinine associated with concentrated urine ($U_{\text{osm}}/P_{\text{osm}} > 1.5$) and Na^+ conservation: ($U_{\text{Na}} < 20 \text{ mEq/L}$) or $\%E/F_{\text{Na}} < 1\%$

Decreased renal perfusion owing to (a) severe hepatic failure (hepatorenal syndrome) and (b) severe cardiac failure. Acute, high-grade urinary tract obstruction (see text)

Low CVP or pulmonary capillary wedge pressure

See text

Decreased tissue turgor

See text

Hematocrit above normal

Presence of conditions that may cause erythrocytosis

Nearly normal or expanded effective IVV (i.e., absence of significant intravascular volume depletion)

Hypertension with the patient in sitting or standing position and no orthostatic fall in blood pressure

None

Presence of cardiac failure: left ventricular failure: audible third heart sound or pulmonary edema

Patients with markedly reduced cardiac output and very large left ventricles may have decreased effective IVV despite an audible third heart sound

Right ventricular failure: peripheral edema with increased venous pressure (neck vein distention, increased intravenous pressure)

Right ventricular failure but normal left ventricular function (see text)

Increase in weight above normal not explained by increased caloric intake

1. Significant hypoalbuminemia
2. Development of third spaces (e.g., ascites, bowel obstruction)

Increased CVP

See text

Increased pulmonary capillary wedge

See text

pressure

Edema, ascites, or pleural effusion

See text

Hematocrit less than normal

Presence of conditions that can cause loss, destruction, or decreased production of red blood cells

^aQualifying conditions are circumstances that can render the meaning of the finding indeterminate with respect to the evaluation of the effective IVV.

%E/F_{Na}, percentage of excretion of filtered sodium (see text).

DATABASE FOR ASSESSMENT OF EFFECTIVE INTRAVASCULAR VOLUME

Body Weight

All patients should be weighed on admission to the hospital and then periodically during their hospital stay. In patients undergoing surgery, or in whom problems in fluid and electrolyte balance are anticipated, weight must be measured daily.

Alterations in body weight are the result of changes in body water content plus solid tissue content (fat, protein, bone). Gains or losses of solid tissue are almost always related to changes in caloric intake and seldom exceed 0.25 kg/24 hours. For example, a patient who takes no calories for 24 hours is forced to consume her endogenous stores of fat and protein to meet the energy requirements for continued life. The complete oxidation of fat yields 9 cal/g, and protein yields 4 cal/g. It can be readily calculated that the complete oxidation of 0.25 kg of solid tissue (in starvation, a mixture of about 87% fat, 13% protein) yields enough calories to meet basal daily energy needs. Thus, changes in weight exceeding 0.25 kg/24 hours are almost always attributable to changes in water balance. Although the relation between body weight and effective IVV can be variable, usually the relation between changes in body weight and IVV can be correctly assessed by the application of the guidelines. The first is that a decrease in body weight below normal (for the patient), and not explained on the basis of inadequate caloric intake, can be assumed

P.158

to be accompanied by a decrease in IVV. The second is that an increase in body weight above normal not explained by increased nutrition can be assumed to be accompanied by an increase in IVV except when the weight gain develops in association with the following conditions:

- Significant hypoalbuminemia: serum albumin less than 2.5 g/dL
- Venous obstruction or congestion
- Development of third spaces (e.g., obstructed or ischemic bowel)

Under these three general conditions, an increase in body weight may not reflect an increase in the effective IVV.

Renal Function

Creatinine, a by-product of muscle energy metabolism, is produced at a constant rate that is related to muscle mass. Nearly all of the creatinine produced is excreted by glomerular filtration. Therefore, changes in the concentration of serum creatinine reflect changes in the glomerular filtration rate (GFR), and the clearance of creatinine is an index of the GFR.

Normally, as muscle mass increases, the GFR increases proportionately less. Therefore, on the average, children have lower serum creatinine values than do adults, and large adults have higher serum creatinine levels than do small adults. Because of these considerations, a single range of serum creatinine values cannot be applied to everyone.

The following guidelines are suggested for the evaluation of the IVV in light of the state of renal function. Azotemia can be assumed to result from decreased renal perfusion if the serum creatinine level is elevated, the urine is concentrated (specific gravity higher than 1.015), and renal sodium conservation is present (urine sodium level <20 mEq/L) on a random and untimed urine sample. If the fractional excretion of sodium is below 1%, azotemia can be attributed to decreased IVV, unless the patient has severe liver or cardiac disease causing end-organ hypoperfusion. If severe cardiac failure and severe liver failure (hepatorenal syndrome) can be excluded, the decreased renal perfusion can be assumed to be caused by a decreased effective IVV.

Edema, Ascites, and Pleural Effusion

Effective IVV is increased when edema, pleural effusion, or ascites occurs in the setting of congestive heart failure (CHF). Increased effective IVV cannot be assumed in the presence of edema, ascites, or pleural effusion if there is significant hypoalbuminemia or venous obstruction or if the accumulation of fluid is in a relatively small area of capillary injury (e.g., pleural effusion caused by pulmonary infarction).

Tissue Turgor

Tissue turgor is a function of the elasticity of the solid components of tissue and the degree of distention of the tissues by interstitial fluid. If tissue is depleted of interstitial fluid, it becomes less elastic (i.e., it less readily returns to its original shape after being deformed). Skin turgor is best assessed on the forehead and anterior chest. In patients less than 50 years of age, the turgor of the dorsum of the hand also can be used. In older patients, the elasticity of the solid components of tissue is decreased, and the turgor of the skin becomes unreliable in interpreting changes in interstitial volume.

Central Venous Pressure

The measurement of CVP is a relatively simple but useful means for monitoring cardiac function and cardiovascular status. For the valid measurement of CVP, the catheter must be placed in the large intrathoracic veins near the right atrium (as assessed by chest radiograph), and the catheter must be patent (as assessed by the cyclic variation of CVP with ventilatory movements: decreased CVP during inspiration, increased CVP during expiration).

In normal adults, CVP is about 5 to 12 cm H₂O. CVPs below 3 cm H₂O are commonly seen in children and young adults who have no evidence of a decreased effective IVV. In older adults and elderly persons, CVP of less than 3 cm H₂O can be assumed to reflect a significant decrease in effective IVV.

Central venous pressure is an index of the filling pressure of the right atrium, which, in turn, is an index of the filling pressure of the right ventricle. In uncomplicated circumstances, expansion of the IVV results in increased CVP, whereas contraction of the IVV results in decreased CVP. Central venous pressure cannot be used to assess the adequacy of left ventricular function in patients in whom left ventricular function may be impaired relative to right ventricular function. Central venous pressure also is unreliable when lung disease is present, because it is commonly falsely elevated. In such patients, left ventricular function can be monitored by observing for signs and symptoms of left ventricular failure (dyspnea, development of an audible third heart sound, or pulmonary edema), or by direct measurement of pulmonary capillary wedge pressure. Under normal circumstances, the pulmonary capillary wedge pressure is about equal to the CVP plus 6 mm Hg.

Pulmonary Capillary Wedge Pressure

Technical refinements of the Swan-Ganz catheter make it possible to measure pulmonary artery systolic and diastolic pressure, CVP, pulmonary wedge pressure, and cardiac output using the thermodilution technique with the same catheter. This permits a definitive assessment of the volume status of the patient, because it can be determined whether the cardiac output is appropriate for a given pulmonary wedge pressure. Specific guidelines for the interpretation of the relation between pulmonary wedge pressure and cardiac output are discussed in the following sections.

Patients with Normal Volume Status

Pulmonary wedge pressure can be expected to be between 8 and 12 mm Hg in a patient with a normal cardiopulmonary system and a normal effective IVV. Cardiac output is normal. Pulmonary wedge pressure can be less than 8 mm Hg without indicating volume contraction; in this circumstance, the cardiac output is normal despite the unusually low pulmonary wedge pressure.

Patients Who Are Volume Contracted

Patients who have a normal cardiopulmonary system but who are significantly volume depleted usually have a pulmonary wedge pressure below 8 mm Hg and their cardiac output is less than normal. In patients with chronic pulmonary hypertension (e.g., those with chronic left ventricular failure), a higher than normal pulmonary wedge pressure is needed to drive a satisfactory cardiac output. Thus, in such patients, pulmonary wedge pressure can be above the normal range but be inappropriately low for the patient. This situation can be identified by showing that: (a) cardiac output is less than normal, despite the elevated pulmonary wedge pressure; (b) volume infusion causes an increase in cardiac output toward a more favorable range; and (c) despite further increase in pulmonary wedge pressure with volume expansion, pulmonary function does not deteriorate. (P_{aO_2} does not decrease, P_{aCO_2} does not increase, and pulmonary compliance does not worsen.)

P.159

Patients Who Are Volume Expanded

In patients with a normal cardiopulmonary system, pulmonary wedge pressure usually is above 18 mm Hg when volume expansion is substantial. Cardiac output is above normal. If cardiac function is impaired, cardiac output will be inappropriately low for the level of pulmonary wedge pressure.

When a given pulmonary wedge pressure is being interpreted, the serum albumin level also should be taken into consideration, because this opposes the effect of capillary hydrostatic pressure to cause migration of fluid from the capillary lumen to the interstitial space. Thus, at any given elevated pulmonary wedge pressure, pulmonary edema develops more rapidly in a patient who is hypoalbuminemic than in one who has a normal serum albumin concentration. In some patients, it is not possible to obtain a reliable pulmonary wedge pressure. In most of these patients, the pulmonary artery diastolic pressure is a good estimate of the pulmonary wedge pressure. If pulmonary hypertension is present, then pulmonary vascular resistance is increased; thus, pulmonary artery diastolic pressure may not be a good index of the pulmonary wedge pressure. In such patients, it is important to be able to obtain a wedge pressure. Finally, in patients who are being ventilated with high levels of positive end-expiratory pressure, pulmonary wedge pressure may become an unreliable index of left atrial filling pressure because the high intrapulmonary pressures may cause obstruction of the catheter orifice. Patients must be briefly taken off the ventilator for accurate measurements. Other circumstances in which pulmonary artery wedge pressure measurements may be inaccurate include the presence of mitral stenosis or pulmonary venous obstruction.

Blood Pressure

The following guidelines are suggested for the evaluation of the effective IVV from measurement of blood pressure.

1. A nearly normal or expanded effective IVV can be assumed in patients with hypertension that is demonstrated in the sitting or standing position.
2. Effective IVV may be decreased in patients who previously were hypertensive but who have become normotensive.
3. Effective IVV may be decreased in patients who develop orthostatic hypotension (a drop in systolic pressure greater than 10 mm Hg in changing from the supine to the sitting or standing position).

Orthostatic hypotension also can be present, in the absence of volume contraction, as a result of prolonged bed rest, during the use of such antihypertensive agents as methyldopa (Aldomet) or of vasodilators (prazosin, minoxidil). If the pulse rate does not rise as blood pressure falls when a patient stands, autonomic neuropathy should be considered as a cause of postural hypotension.

Systemic Vascular Resistance

Normal values are 50 to 150 dyne-s/cm for pulmonary vascular resistance and 800 to 1,200 dyne-s/cm for systemic vascular resistance. Pulmonary vascular resistance is elevated in hypovolemic shock, cardiogenic shock, pulmonary embolism, or airway obstruction; it is diminished in septic shock. Systemic vascular resistance is elevated in hypovolemic shock, cardiogenic shock, pulmonary embolism, and sometimes in right ventricular infarct and cardiac tamponade; it is decreased in end-stage liver disease and septic shock.

CLINICAL ASSESSMENT OF DISORDERS OF EXTRACELLULAR FLUID COMPOSITION

Hyponatremia

The schema for the evaluation of a hyponatremic patient depends on the assessment of volume status. That is, it must first be determined whether the patient's hyponatremia is associated with an effective IVV that is decreased, normal, or increased. Once this is decided on the basis of the assessment of IVV, a further separation, based only on the state of renal sodium and water excretion, is made. Each of the final categories contains relatively few diagnostic possibilities, and the presence or absence of each of these conditions in a given patient usually can be readily determined. The scheme for the evaluation of a hypernatremic patient is analogous, except that it depends on the assessment of the state of renal water excretion.

Clinical Assessment

In the discussion that follows, only patients with true hyponatremia are considered (i.e., hyponatremia in which serum osmolality is decreased in proportion to the reduction in serum sodium concentration, after appropriate correction for any elevation in the plasma urea nitrogen). By making this distinction, hyponatremia caused by accumulation of ECF solutes such as glucose or mannitol can be excluded. In this type of hyponatremia, the decreased concentration of ECF sodium is the result of the shift of water from cells to the ECF in response to the osmotic gradient caused by the accumulation of the solute. As a consequence, the hyponatremia is associated with an increased plasma osmolality. These patients also can be readily identified either by the presence of hyperglycemia sufficient to explain the decrease in serum sodium concentration or by a history of administration of large amounts of mannitol (0.100 g in adults), usually in the presence of a decreased capacity to excrete mannitol (decreased GFR).

Also to be excluded are patients with spurious hyponatremia that results from the abnormal accumulation of plasma lipids or proteins. In such circumstances, the concentration of sodium in plasma water is normal;

however, the concentration of sodium expressed per liter of whole plasma is reduced because an abnormally large volume of whole plasma is occupied by the lipids or proteins, which do not contain plasma water and electrolytes. Thus, when aliquots of hyperlipemic or hyperproteinemic plasma are analyzed, a lower amount of sodium is determined to be present in a given volume of whole plasma. Plasma osmolality, however, is normal because lipids and proteins do not contribute importantly to plasma osmolality (see section on osmotic forces). Patients with spurious hyponatremia can be readily identified by the presence of markedly elevated total serum protein levels (e.g., multiple myeloma) or grossly lipemic serum. The distinction can be readily made if lipemic serum is subjected to centrifugation and the lipoprotein layer is removed before evaluation, if flame photometry is being used for measurement of serum Na^+ . Spurious hyponatremia is no longer a consideration in most laboratories, because serum Na^+ concentration is determined by ion-specific electrodes, and increased levels are not affected by lipemic serum. Symptoms of hyponatremia include increased tendon reflexes, lethargy, mental confusion, and muscle twitching, which are followed by convulsions, coma, and possibly death if levels fall below 115 mEq/L.

Hyponatremia and Volume Depletion Associated with Renal Sodium Wasting

The normal renal response to volume depletion and hyponatremia is the virtual elimination of sodium from the urine

P.160

(**Fig. 10.1**; see section on sodium balance). Thus, the presence of an excessive amount of urinary sodium under these conditions indicates that renal sodium loss is the cause or a major contributing factor to the state of sodium depletion. A spot urine sodium concentration greater than 40 mEq/L, a $\%E/F^{\text{Na}}$ above 1%, or a urinary sodium excretion rate greater than intake indicates such renal sodium wasting. The conditions discussed in the following sections are associated with hyponatremia, IVV depletion, and renal sodium wasting.

Chronic Renal Disease

All types of renal disease can be associated with renal salt wasting. In adults with such a disorder, the serum creatinine level is virtually always above 2 mg and usually much higher before a significant salt leak develops. These azotemic patients usually require 85 to 170 mEq of sodium daily (5 to 10 g of sodium chloride) to maintain salt balance at a normal effective IVV. Thus, if sodium intake is decreased in azotemic patients by anorexia or vomiting, or if additional sodium losses occur (e.g., diarrhea or diuretic therapy), the inability of the diseased kidneys to conserve sodium and water normally may rapidly lead to the development of significant sodium and water deficits. Water intake usually continues; therefore, sodium balance is more adversely affected than is water balance. As a consequence, the patient becomes volume contracted with hyponatremia. With the onset of CHF or the nephrotic syndrome, the salt leak of chronic renal failure usually disappears, and salt intake must be restricted.

Diuretic Therapy

The diuretics include thiazide agents or loop diuretics, such as furosemide, bumetanide, and ethacrynic acid. Diuretics induce a renal salt-wasting state, and if the urinary output of sodium exceeds intake, sodium depletion ensues. Rarely, diuretics cause hyponatremia without evidence of volume depletion if severe potassium depletion has resulted from their use (**Fig. 10.1**).

Adrenal Insufficiency (Addison Disease)

Destruction of the adrenal gland or sudden withdrawal of chronic, daily glucocorticoid therapy results in inadequate adrenal function. The lack of mineralocorticoid causes wasting of renal salt but retention of renal potassium and leads to sodium depletion. The lack of glucocorticoid results in a decreased capacity to excrete a

water load and leads to hyponatremia but not to volume depletion or hyperkalemia.

Hyponatremia and Volume Depletion Associated with Renal Sodium Conservation

A spot urine sodium concentration of less than 20 mEq/L or a %E/F_{Na} below 1% in a hyponatremic, volume-contracted patient is evidence of normal renal sodium conservation and indicates that the cause of the sodium depletion is nonrenal in origin or that it occurred during previous diuretic therapy. The fact that the serum sodium concentration is lower than normal indicates that water balance is less negative than is sodium

P.161

balance. The conditions discussed in the following sections can result in volume depletion and hyponatremia as a result of extrarenal losses of sodium.

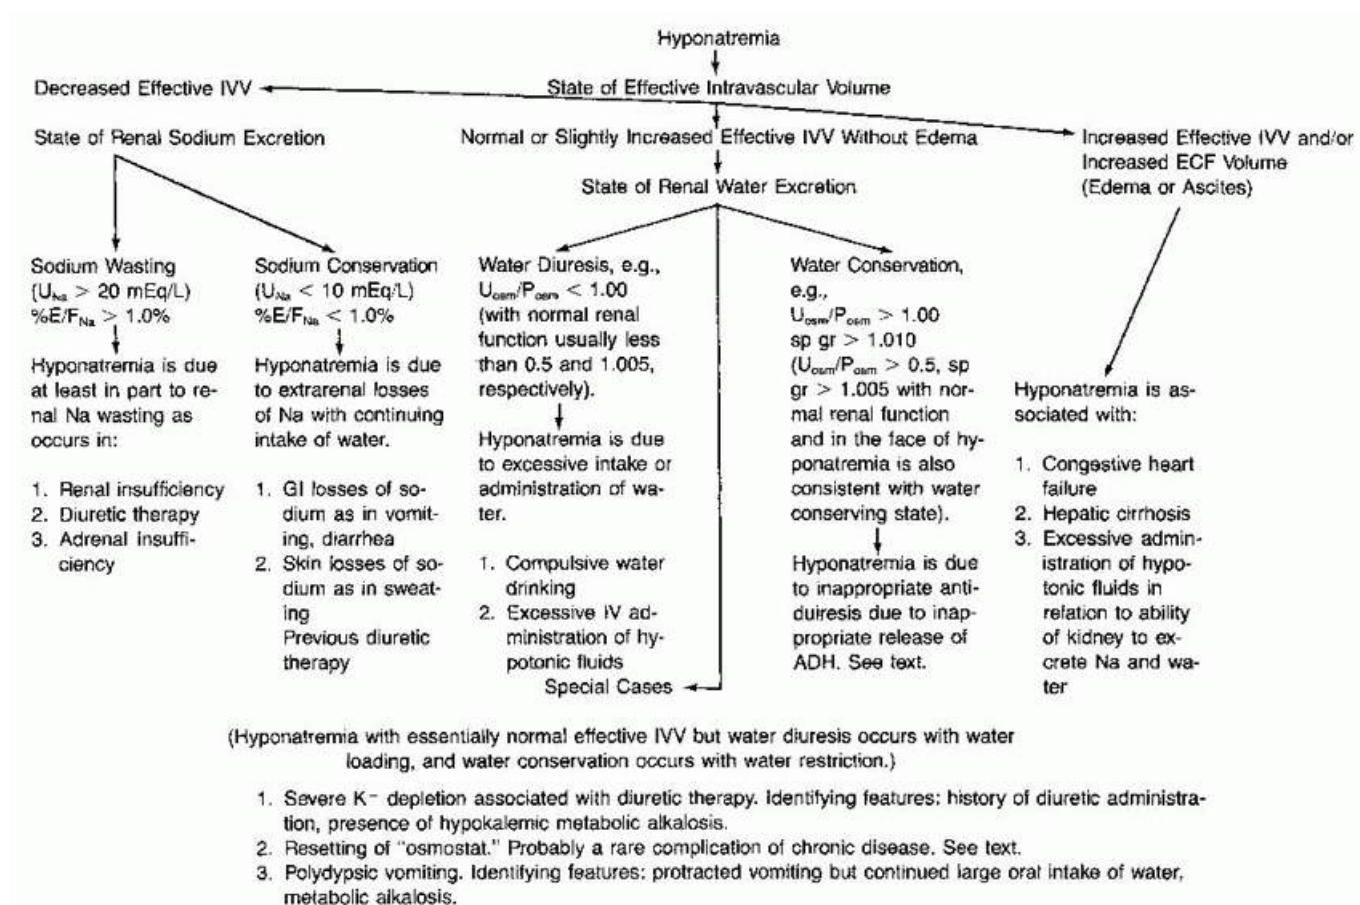

FIGURE 10.1 Approach to the assessment of a hyponatremic patient. This approach considers only patients with true hyponatremia (i.e., in nonazotemic patients, serum osmolality is reduced in proportion to the decrease in serum sodium). Thus, patients are excluded who have lowered concentrations of serum sodium because of hyperlipidemia, hyperproteinemia, or the abnormal accumulations of solutes in the extracellular fluid (ECF), such as glucose or mannitol. ADH, antidiuretic hormone; ECF, extracellular fluid; %E/F_{Na}, fractional excretion of sodium; GI, gastrointestinal; IVV, intravascular volume.

Gastrointestinal Losses

If losses of fluid from the upper gastrointestinal tract (e.g., vomiting, gastric aspiration) cause the hyponatremia, and if the gastric juice is normally acid, metabolic alkalosis is present. If diarrheal losses cause the hyponatremia, metabolic acidosis may be present. In patients with gastric achlorhydria, upper gastrointestinal losses also can lead to metabolic acidosis.

Losses of Sodium from the Skin

Sweat contains about 50 mEq/L of sodium and is a hypotonic fluid. If sweat losses are not replaced, then

hypernatremia can develop. In most situations, the water losses from the skin are replaced more adequately than are the sodium losses. Thus, most patients with significant sodium losses that are due to sweating become hyponatremic. Skin losses of fluid and electrolytes also can occur after burns or other skin injuries. These are isotonic losses of sodium and lead to hyponatremia if the water losses are more adequately replaced than are the sodium losses.

Losses of Sodium from Prior Diuretic Therapy

The natriuretic action of most diuretics lasts less than 24 hours. Hyponatremia is made worse if water intake is excessive.

Hyponatremia and Normal Volume Status Associated with Water Diuresis

In a patient with normal renal function who has become hyponatremic as a result of the administration or ingestion of excessive amounts of water, intravascular and ECF volume are normal to slightly expanded, and high rates of urine flow in association with maximally, or nearly maximally, dilute urine can be expected. In a patient with preexisting renal functional impairment, water loading also increases urine flow rate and dilution of the urine; however, maximally dilute urine cannot be formed. Hyponatremia secondary to water loading may occur in compulsive water drinkers, who usually are severely neurotic or psychotic, or after excessive IV administration of hypotonic fluids. Many of these patients also have high levels of antidiuretic hormone (ADH) for various reasons (e.g., drugs, psychosis). Without this elevation of ADH, presuming normal renal function, consumption of 20 L of water a day would be necessary for development of frank hyponatremia.

Hyponatremia and Normal to Slightly Elevated Volume Status Associated with Water Conservation

As discussed, it is appropriate to observe a brisk water diuresis in a patient with normal renal function who is hyponatremic and has evidence of normal or slightly elevated IVV without edema. When high flow rates of hypotonic urine are not observed, the patient is exhibiting an inappropriate antidiuresis. This may result from the inappropriate release of ADH, although other mechanisms also can be involved (e.g., decreased renal blood flow, certain drugs). Another characteristic of such patients is that administered sodium is promptly excreted in the urine, perhaps because of the effect of atrial natriuretic factors. On the other hand, when sodium intake is curtailed, renal sodium conservation is observed. These patients also exhibit normal adrenal and renal function and are not edematous. The syndrome of inappropriate antidiuresis has been associated with various clinical states, including malignant tumors (e.g., in the lung or pancreas), central nervous system (CNS) disorders (e.g., head trauma, meningitis), infections (e.g., tuberculosis, bacterial pneumonias), the postoperative state, hypopituitarism, and myxedema, as well as with many drugs ([Table 10.2](#)). Infusion of oxytocin to induce uterine contraction also can cause hyponatremia because of the antidiuretic effects of oxytocin.

Within the category of hyponatremia associated with normal IVV are three special categories. The feature that sets these apart is that patients may exhibit evidence of water conservation when water is withdrawn or an appropriate or nearly appropriate water diuresis when water is administered. That is, it appears that osmoregulation has been reset to “defend” a lowered plasma osmolality. The first special category includes patients who have an unusual response to diuretic therapy, characterized by hyponatremia, severe potassium depletion, and metabolic alkalosis. Despite the hyponatremia and normal IVV, exchangeable sodium is nearly normal, suggesting intracellular movement of sodium. Magnesium levels should be assessed, and potassium replacement must be accomplished before specific treatment of hyponatremia. The second category involves patients with an unusual manifestation of a chronic illness, such as pulmonary tuberculosis, that resets the osmostat. The third category includes patients with sodium depletion resulting from any cause in whom the decrease in effective IVV is minimized by excessive water intake and retention. This effect of excessive water intake can occur in any of the causes of sodium depletion.

Hyponatremia Associated with Increased Effective Intravascular Volume or Increased Extracellular Fluid Volume (Edema or Ascites)

Congestive Heart Failure

When hyponatremia develops spontaneously in the course of chronic CHF (i.e., is not the result of excessive water administration or diuretic therapy), it usually is indicative of severe cardiac insufficiency and has a poor prognosis. The cause of the hyponatremia in such patients has been ascribed to a decreased capacity to increase renal free water clearance perhaps because of (a) increased fractional reabsorption of glomerular filtrate proximal to the renal diluting sites of the distal nephron and (b) an elevated ADH level.

Cirrhosis of the Liver

Patients with cirrhosis and ascites have a decreased capacity to excrete a water load, possibly because of the same mechanisms at work in patients with CHF.

Excessive Administration of Hypotonic Fluids

This usually is an iatrogenic situation and must be especially guarded against

P.162

in postoperative patients whose ADH levels are elevated because of stress, pain, hypovolemia, or drugs, as well as in elderly patients who are unable to maximally dilute their urine.

Hypernatremia

All patients with hypernatremia are volume contracted, except those in whom the disorder develops as a result of excessive administration of hypertonic saline or sodium bicarbonate and the rare patients with essential hypernatremia (**Fig. 10.2**). The following discussion considers only the first group of patients; the latter section on treatment discusses all forms of hypernatremia. Patients with hypernatremia usually have CNS deficits, and they may also have confusion and neuroseizures. Autopsy findings often reveal hemorrhages or thromboses of brain tissue.

Hypernatremia Associated with Formation of Concentrated Urine

The normal renal response to decreased intake of water or increased extrarenal losses of water is the formation of maximally concentrated urine. In most clinical situations in which hypernatremia is the result of water depletion, the expected renal response is a $U_{\text{osm}}:P_{\text{osm}}$ ratio greater than 1.5 and a specific gravity above 1.015. Thus, the finding of hypernatremia with evidence of renal conservation of water indicates that the hypernatremia is caused by excessive nonrenal losses of water or solute diuresis.

Excessive Nonrenal Water Loss

Hypernatremia typically develops in patients with accelerated rates of nonrenal water loss owing to a hot environment, fever, or hyperventilation, and in whom water losses are not replaced because the patient cannot perceive or communicate thirst. Despite the hypernatremia, sodium deficits usually are present because initially, as water deficits develop, renal sodium excretion increases to maintain normal plasma osmolality and serum sodium concentration.

When more than about 15% of ECF volume is lost, renal conservation of sodium occurs; if the water losses continue, hypernatremia develops. The presence of volume deficits is indicated by the signs of IVV depletion, as previously described. Urine flow rate usually is less than 35 mL/h.

Solute Diuresis

The amount of water that must accompany the excretion of a given amount of solute in the urine is determined by the osmolality of the renal medullary interstitial fluid (with which the collecting duct fluid must equilibrate) and the plasma level of ADH activity (which determines the permeability of the collecting duct to water and, therefore, the rate at which water moves from the collecting duct to medullary interstitial fluid to achieve osmotic equilibrium). Hypernatremia results if water intake does not keep pace with renal water losses, because although renal sodium excretion also is increased in solute diuresis, renal sodium reabsorption is affected proportionately less than is water reabsorption. Large amounts of mannitol infused intravenously or high-protein mixtures fed by nasogastric tube (each gram of protein yields 8 mOsm as urea, phosphate, and potassium) can cause a solute diuresis sufficient to cause hypernatremia if water intake is inadequate. In solute diuresis, urine volume usually is greater than 35 mL/h.

Hypernatremia Associated with Formation of Dilute Urine

The finding of hypernatremia in combination with isotonic or hypotonic urine indicates that, at least in part, the hypernatremia results from failure of normal renal conservation of water. Failure to concentrate the urine under

these conditions may result from the lack of ADH (hypothalamic-pituitary diabetes insipidus) or impaired renal tubular function that interferes with the development of a hypertonic medullary interstitium (renal tubular damage).

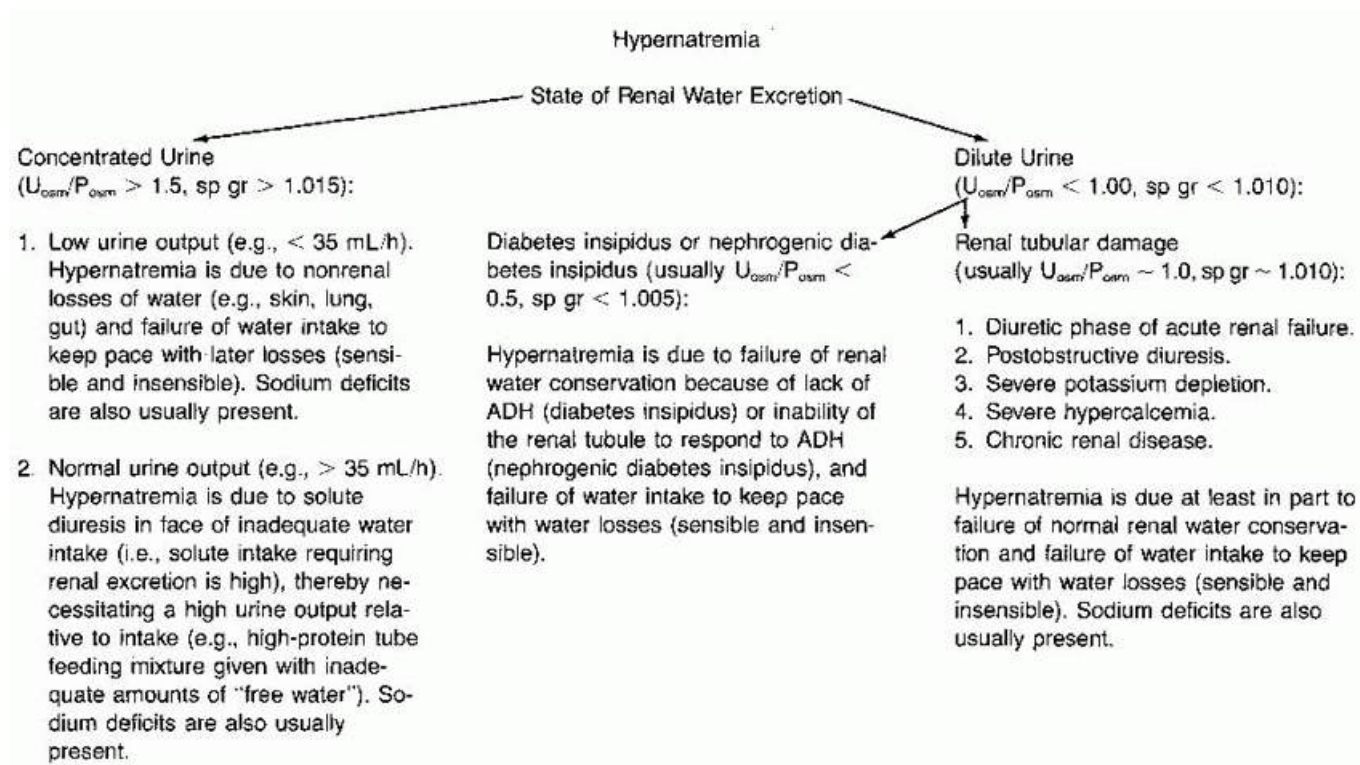

FIGURE 10.2 Approach to the assessment of a hypernatremic patient. This approach does not consider patients with hypernatremia secondary to excessive administration of hypertonic saline. ADH, antidiuretic hormone.

P.163

Central diabetes insipidus or nephrogenic diabetes insipidus should be suspected immediately in a patient with hypernatremia when the urine is very dilute (a $U_{osm}:P_{osm}$ ratio <0.5 , or specific gravity <1.005).

In patients with renal tubular damage, the ability to concentrate and dilute the urine is decreased. As a result, under all conditions, the urine is isotonic or nearly isotonic with plasma. Hypernatremia can supervene when water losses exceed sodium losses and water intake does not keep pace with water losses. Despite the hypernatremia, significant sodium deficits usually are present because renal sodium wasting also usually is a feature of these disorders. The following sections are examples of clinical situations in which renal tubular damage can be associated with hypernatremia.

Diuretic Phase of Acute Renal Failure

Occasionally, in a patient recovering from acute renal injury, tubular function is more severely affected than is glomerular function. Thus, an inordinately large fraction of the glomerular filtrate escapes reabsorption, resulting in high urine flow rates. The period of inappropriate diuresis can persist for a few days to several weeks.

Postobstructive Diuresis

The sudden release of chronic urinary tract obstruction often is followed by several days or weeks in which urine flow rates are abnormally high. Shortlived nephrogenic diabetes insipidus develops in some patients.

MANAGEMENT OF WATER AND ELECTROLYTE BALANCE

Water requirements should be carefully monitored, especially in hospitalized patients. Patients with known fluid deficits or excesses should be approached as demonstrated in [Tables 10.3](#)

and 10.4. *Minimum* maintenance requirements can be calculated from two simple formulas.

TABLE 10.3 General Guidelines for Planning Fluid and Electrolyte Therapy in Complicated Cases

Volume-contracted patients (from water and electrolyte loss)

Deficit Replacement

Moderate volume contraction (e.g., decreased effective IVV causing azotemia but not hypotension). Plan to replace deficits in about 24 h (e.g., 0.9% saline at 200-250 mL/h). If the patient is hypernatremic, 0.9% and 0.45% saline can be alternated.

Severe volume contraction (e.g., decreased effective IVV causing hypotension). Give 0.9% saline as rapidly as practicable until the hypotension is corrected.

Estimate maintenance needs, and add this amount to the fluids used to correct the preexisting water and electrolyte deficits.

For patients with normal renal function and no abnormal losses:

Maintenance

Equivalent Intravenous Fluid Orders

Water: 2,500-3,000 mL/24 h

Alternate:

Sodium: 150 mEq/24 h

5% dextrose in 0.45% saline with

Potassium: 40 mEq/24 h

5% dextrose in 0.25% saline

Each day add:

Multivitamins to first liter

Potassium chloride 20 mEq to first and second liters

Infuse at 100-125 mL/h

Nutrition (Short Term)

At least 400 carbohydrate calories/24 h

For patients with acute renal failure with no urine output and no abnormal losses:

Maintenance

Equivalent Intravenous Fluid Orders

Water: 600 mL/24 h

600 mL 20% glucose in water and multivitamins per 24 h

Sodium: 0

Potassium: 0

Nutrition (Long Term)

At least 400 carbohydrate calories/24 h

Monitor the patient frequently:

Weigh daily.

Measure serum creatinine and electrolyte levels daily or more frequently if necessary.

Measure CVP or pulmonary wedge pressure in complicated cases. If the patient has normal cardiopulmonary function, CVP is sufficient. If cardiac disease or pulmonary hypertension is suspected, pulmonary wedge pressure measurement is preferred.

Evaluate water and electrolyte needs daily or more frequently in patients with high rates of abnormal losses.

Volume-expanded patients (increased effective IVV)

Correct volume excess:

Mild (e.g., simple edema): Decrease NaCl intake.

Moderate (e.g., mild pulmonary vascular congestion): Induce diuresis with diuretic and allow the sodium and water losses to go unreplaced.

Severe volume excess (e.g., severe pulmonary edema): Steps 1 and 2 and phlebotomy or ultrafiltration (if the patient is anemic) and/or digitalis, vasodilators, if heart disease is present.

Estimate ongoing losses (as above) and begin replacing when volume excesses have been corrected.

Monitor the patient frequently.

CVP, central venous pressure; IVV, intravascular volume.

TABLE 10.4 Major Sources, Loss Rates, and Replacement Fluids in Abnormal Water and Electrolyte Loss

SOURCES	RATE OF LOSS	REPLACEMENT FLUID
Fever	Insensible water losses (normally 450 mL/24 h from the skin and 450 mL/24 h from the lung) increase by about 10% per degree Fahrenheit or 20% per degree Celsius for each degree of temperature above normal.	Replace with 5% dextrose in water
Hyperventilation	Doubling alveolar ventilation (i.e., 50% reduction in PaCO ₂) increases insensible water losses from the lung by 50%. Thus, the increase in alveolar ventilation required to reduce PaCO ₂ from 40 to 20 mm Hg increases insensible loss from the lung from 450 to 675 mL/24 h.	Replace with 5% dextrose in water
Gastric fluid	Rates of loss from nasogastric suction usually are 1-2 L/24 h but can be much greater. Normal composition of gastric juice is about H ⁺ , 100 mEq/L; sodium, 40 mEq/L; potassium, 10 mEq/L; and chloride, 150 mEq/L.	Replace with 0.45 normal saline and potassium chloride (usually 20-40 mEq/L) as needed ^a
Diarrheal fluid	Losses can vary from trivial to several liters daily. In	Replace with 0.45

adults, diarrheal fluid usually resembles ECF except that the bicarbonate concentration is higher (about 30-50 mEq/L) and chloride concentration is lower (about 80 mEq/L). Potassium concentration is variable (10-40 mEq/L)

normal saline and 50 mEq of sodium bicarbonate/liter and potassium chloride (usually 20 mEq/L), as needed^a

Urine in acute renal failure

Because of tubular injury, urine sodium concentration usually is between 40 and 80 mEq/L and is largely independent of urine flow rate.

Replace with 0.45 normal saline and potassium chloride, as needed^a

^aThe rate of potassium replacement usually is determined by the serum potassium concentration rather than the rates of potassium loss. For example, even though a patient in acute renal failure may be losing 30 mEq/24 h potassium in the urine, it may not be necessary to replace this amount, since potassium may be entering the extracellular fluid (ECF) at an even faster rate because of catabolism of cellular proteins. On the other hand, the potassium losses in gastric fluid may amount to only 10-20 mEq/24 h, yet far greater amounts of potassium may have to be administered to maintain a normal serum potassium level, since gastric aspiration may lead to metabolic alkalosis, causing renal potassium wasting and extensive diffusion of potassium into intracellular fluid.

The first is the 4-2-1 rule ([Table 10.5](#)). A more simplified method of calculation using this formula in adults would be to administer 60 mL/h of fluid for the first 20 kg of body weight. Subtract 20 from the patient's weight (in kilograms) and add this difference to calculate the hourly rate. For example, a patient who weighs 65 kg has a maintenance requirement of 105 mL/h. The 4-2-1 method was originally established in children, and characteristically overestimates fluid needs for adults since adults have lower body surface area per unit of weight and, as a result, less insensible losses.

The second method is to calculate the body surface area and multiply by 1,000. A patient with a body surface area of 1.5 m² would require 1,500 mL of fluid daily.

Intraoperative Fluid Administration

The guidelines for fluid replacement during the perioperative period are dictated by (maintenance) basal requirements, deficits, intraoperative losses, and third space losses. The basal requirement has been discussed. Deficits include actions of general or spinal anesthesia on effective blood volume, intestinal losses (bowel obstruction or diarrhea), perspiration, and blood loss. In some cases, a CVP or Swan-Ganz catheter may be needed to assess IVV.

Intraoperative losses of fluid occur through several routes. Evaporation from peritoneal surfaces occurs, but quantifying it is difficult. The most obvious source of fluid loss, blood loss, is first assessed by looking into the suction canister. Fluid from irrigation should be subtracted. A soaked lap pad contains about 50 mL of blood, and a 4 × 4 pad contains about 5 mL. These are crude approximations. For instance, a moistened lap pad absorbs less than a dry one. Most researchers recommend a replacement rate of 3 to 1 for blood loss using crystalloid suspension and 1 to 1 using colloid suspension. While anesthetized, patients experience third space loss. This phenomenon is the movement of isotonic fluid from the intravascular space to the interstitial space. A replacement of 2 to

4 mL/kg/h is usually adequate to accommodate third space losses. Actual total intraoperative losses may be difficult or impossible to monitor during long and difficult surgical procedures. Monitoring of vital signs and urine output (optimal, 0.5 mL/kg/h) is extremely important. Sometimes invasive monitoring can be used to guide the clinician.

TABLE 10.5 Maintenance Requirements by 4-2-1 Rule^a

BODY WEIGHT CATEGORY	FLUID RATE (ML/KG)	WEIGHT CATEGORY (KG)	FLUID (ML/H)
0-10	4	10	40
11-20	2	10	20
21+	1	40	40

^aPatient weighs 60 kg. Fluid requirement would be 100 mL/h.

TABLE 10.6 Composition of Parenteral Fluids^a

SOLUTIONS	CATIONS				ANIONS		
	Na	K	Ca	Mg	Cl	HCO ₃	OSMOLALITY (mOsm)
Extracellular fluid	142	4	5	3	103	27	280-310
Lactated Ringer solution	130	4	3	—	109	28 ^b	273
0.9% sodium chloride	154	—	—	—	154	—	308

D ₅ W	—	—	—	—	—	—	253
3% sodium chloride	513	—	—	—	513	—	1,026

^aElectrolyte count in mEq/L.
^bPresent in solution as lactate that is converted to bicarbonate.

Crystalloid solutions contain only sugars and electrolytes (Table 10.6). Lactated Ringer solution is usually used

because its composition more closely resembles the extracellular component than does normal saline. Generally, solutions that contain less sodium than lactated Ringer solution does should not be used in the perioperative setting. Although D₅W solutions have an osmolality greater than 250, they are unsuitable as routine perioperative replacement because the sugar is metabolized. Normal saline is another popular crystalloid solution. It is preferred over lactated Ringer solutions in the perioperative period when the patient is hyponatremic or if brain injury is present. Hypertonic saline is rarely used in the perioperative setting. Because water tends to follow sodium, its theoretic advantage is that water is drawn into the intravascular space from the interstitial space; hence, smaller volumes of hypertonic solution than isotonic solution are needed to provide the same intravascular expansion. Crystalloid solutions are preferentially used over colloid solutions for perioperative fluid replacement.

Colloid solutions include albumin, hetastarch, and dextran. Blood is also a colloid but is discussed in another chapter. Colloids are used primarily when patients have a low colloid oncotic pressure or when large amounts of crystalloids have been infused. For example, if a patient has suffered a significant protein loss from ascites secondary to pelvic malignancy, colloids should be used early in the fluid replacement process. If a patient's blood pressure becomes difficult to maintain after infusion of sufficient crystalloid, colloids should be used.

Albumin, hetastarch, and dextran are three commonly used colloid solutions. Albumin is the most popular of the colloid solutions. It is a blood product but has the advantage of complete absence of infectious agents. In addition, it is treated with heat, eliminating the possibility of transmission of hepatitis or human immunodeficiency virus (HIV). It comes in 5% and 25% concentrations. In a prior Cochrane review, perioperative use of albumin in critically ill patients was shown to be associated with an increased risk of death. However, several subsequent studies in various populations, including septic and critically ill patients, have shown that albumin is safe and may reduce morbidity and mortality. Albumin may be especially useful when large volumes of fluid may be needed or if other blood products are limited or not available. Hetastarch consists of large polymer molecules and comes in a solution of saline. It is synthetic; therefore, its use does not affect the blood supply. There is no risk for viral transmission. Hetastarch is metabolized by the kidney and so must be used judiciously in those who have renal disease. Other disadvantages include potential volume overload, dilution hypoproteinemia, and decreased coagulation. The half-life of hetastarch can be as long as 13 days. More recently, serious safety concerns have arisen regarding the use of hetastarch. Hetastarch has been associated with an increased risk of mortality and kidney injury in critically ill and septic patients. In addition, several trials utilizing hetastarch have been retracted because of scientific misconduct. Given the associated risks, with questionable benefit, further use of hetastarch compounds should be limited to clinical trials. Dextran is similar to hetastarch in mode of action. Additional problems with this substance are interference with cross matching and histamine release.

In summary, crystalloids should be used primarily for perioperative volume replacement. Colloid solutions may be considered under the following conditions:

1. Large amounts of crystalloid are needed to maintain normal hemodynamics.
2. Assessment of circulatory status is difficult.
3. The patient has an elevated pulmonary capillary wedge pressure.
4. The colloid pressure is below 12 mm Hg.

Colloid oncotic pressure may be difficult to ascertain in a routine clinical setting; therefore, total protein or albumin levels can be used to give a rough approximation of colloid pressure. If blood loss is more than 25% of total blood volume, transfusion of red cells may be considered. Hemoglobin concentrations can be useful. Experience has shown that hemoglobin levels between 7 and 8 g/dL are generally well tolerated in healthy adults. If the patient has significant comorbidities, then transfusion may be considered to achieve a higher

hemoglobin level, especially prior to surgery.

Correction of Volume Deficits

Estimating the Magnitude of Sodium or Water Deficits

If the patient has been weighed daily, the magnitude of the water deficit owing to external losses of water can be estimated from the decrease in body weight. The coexisting

P.166

sodium deficits can be estimated by examining the weight deficits in light of the serum sodium concentration. For example, if the patient has acutely lost 3 kg and the serum sodium concentration is within 10% either way of normal serum sodium concentration (i.e., 126 to 154 mEq/L), little error is incurred by assuming that the patient has lost 3 L of ECF (i.e., isotonic saline); therefore, replacement therapy should be about 3 L of 0.9% saline (155 mEq/L). Using an equivalent amount of lactated Ringer solution offers no advantage, because the kidneys adjust electrolyte excretion to make up for small differences between the composition of the ECF and the isotonic saline.

In patients in whom sodium and water deficits cannot be documented by changes in body weight, or in whom the losses are from the IVV into internal third spaces, approximate but useful guidelines are available to estimate the magnitude of the IVV deficit. These guidelines are as follows:

1. A loss equivalent to 15% of ECF volume (about 2 to 3 L in the average adult) results in a decrease in tissue turgor, but blood pressure and renal function, as judged by serum creatinine level, usually are normal.
2. Losses of sodium and water in excess of 15% of ECF volume usually are accompanied by decreased tissue turgor, orthostatic or frank hypotension, and significant elevation of serum creatinine level.

Correction Rates and Criteria for Assessment

Sodium and water losses great enough to result in hypotension represent a medical emergency, and rapid IV administration of isotonic saline is indicated until the hypotension is reversed. Thereafter, the rate of IV therapy is guided by the adequacy of the IVV as assessed by other criteria, particularly the measurement of blood pressure and pulse in the supine and sitting positions, urine flow rate, and CVP. In patients with less severe degrees of volume depletion, salt and water deficits often can be corrected by increasing oral intake. Salt can be added to food (the salt packets commonly present on hospital trays provide slightly more than 1 g of sodium chloride), or plain sodium chloride tablets can be given, with unrestricted water allowance, letting the patient's thirst mechanism dictate water intake. As a guide to the amount of sodium chloride that should be added to the diet to restore the deficits, 1 L of ECF contains 140 mEq of sodium, or about 9 g of sodium chloride. The adequacy of replacement therapy can be assessed over the ensuing days by measurement of change in body weight and blood pressure and by the decrease in serum creatinine level.

Correction of Volume Excess

Expansion of effective IVV sufficient to precipitate pulmonary edema is a medical emergency and requires the usual treatment of pulmonary edema, including placement of the patient in the sitting position or elevation of the head of the bed and administration of oxygen, vasodilators—such as nitrates, hydralazine, or angiotensin-converting enzyme inhibitors (e.g., captopril, enalapril, lisinopril)—digitalis, and loop diuretics, as needed. If the pulmonary edema does not improve, then phlebotomy may be required to relieve the vascular congestion. If the volume excess is less severe (e.g., simple edema), the problem usually can be controlled by decreasing salt intake, adding a diuretic drug, or both. The effectiveness of treatment can be guided by the decrease in body weight and periodic measurement of serum electrolyte and creatinine levels.

Correction of Hyponatremia

The approach to the correction of hyponatremia depends on (a) whether the patient has significant CNS symptoms as a result of the hyponatremia (coma or seizures) and (b) the cause of the hyponatremia. If the patient has coma or seizures as a result of hyponatremia, the serum sodium level is commonly below 125 mEq/L and the reduction usually has occurred rapidly, over a few hours to days. In these situations, regardless of the cause of the hyponatremia, the serum sodium level should be rapidly raised toward normal by the IV administration of 3% saline. The serum sodium level should be raised to 125 mEq/L at a rate of 1 to 2 mEq/h. The rate of replacement can be slowed once the serum sodium level reaches 125 mEq/L, because neurologic symptoms are rare above this concentration. Rapid elevation of the serum sodium concentration to normal or hypernatremic levels must be avoided, because it may cause central pontine myelinolysis. The correction using 3% saline (513 mEq/L) can be calculated as follows:

volume TBW = 0.6 H total body weight in kg

$$\text{volume TBW} \times (\text{desired } [\text{Na}^+] - \text{actual } [\text{Na}^+]) \\ = \text{total Na}^+ (\text{mEq})$$

where:

$[\text{Na}^+]$ is expressed in mEq/L; and TBW = total body water.

The total amount of sodium required can then be replaced at a rate of 2 mEq/h using hypertonic saline. For example, if a 71-kg woman with neurologic symptoms has a serum sodium level of 113 mEq/L, correction to a serum sodium level of 125 mEq/L can be achieved as follows:

$$\begin{aligned} \text{volume TBW} &= 0.6 \times 71 = 42.6 \\ 42.6 \times (125 - 113) &= 511 \text{ mEq Na}^+ \end{aligned}$$

Therefore, since 1 L of 3% saline contains 513 mEq of sodium, this patient requires 1 L of 3% saline to raise her serum sodium level by 12 mEq. The liter of hypertonic saline is administered over 6 to 12 hours. Serum electrolyte levels should be checked every few hours and rates of replacement readjusted as necessary. The infusion of hypertonic saline results in diffusion of water from ICF to ECF until isosmotic conditions are restored. This results in reduction of cell volume and an increase of ICF osmolality toward normal as well as in an expansion of ECF volume. The expansion of the ECF by the hypertonic saline may precipitate or worsen CHF. Therefore, patients who receive hypertonic saline should be carefully observed for signs of pulmonary edema and, if such signs are present, vigorously treated with a loop diuretic.

Hyponatremia Associated with Volume Depletion

The administration of isotonic saline in amounts sufficient to replace existing sodium deficits usually results in complete correction of the hyponatremia, as discussed, in connection with the treatment of volume depletion, because restoration of effective IVV toward normal allows a water diuresis. If specific disease states, such as adrenal insufficiency or diarrhea, are associated with the development of the hyponatremia and volume depletion, these also require treatment.

Hyponatremia Associated with Normal Intravascular Volume

If the hyponatremia is associated with excessive intake of water, restricting water intake to normal corrects the problem.

If the hyponatremia is owing to an inappropriate antidiuresis, water intake must be restricted below normal—for example, to about 800 mL of measured liquid intake daily in an average-sized adult. This usually results in negative water balance, a decrease in body weight, and an increase in serum sodium concentration toward normal. If a specific cause for the inappropriate antidiuresis can be identified, it should be eliminated.

Hyponatremia Associated with Expanded Intravascular Volume and Extracellular Fluid

The spontaneous development of hyponatremia in the course of severe CHF or liver failure is an ominous sign. The hyponatremia usually does not cause any clinical symptoms, and although it can be successfully treated by water restriction, clinical improvement usually does not follow. Furthermore, during such treatment, patients complain bitterly of thirst. Thus, water restriction sufficient to raise the serum sodium concentration to normal is not indicated. Water intake should be restricted, however, to prevent the serum sodium concentration from decreasing to less than 120 mEq/L in an effort to prevent possible CNS symptoms of hyponatremia.

Correction of Hypernatremia

Hypernatremia Secondary to Water Depletion

The amount of water needed to correct the serum sodium concentration toward normal should be determined based on the clinical volume status of the patient. Hypotonic solutions can be used to correct hypernatremia over a period of 24 to 48 hours. Serial sodium levels should be used to avoid overcorrection and hyponatremia. Furosemide should not be used to correct hypernatremia or decreased urine output in a patient with decreased IVV.

Hypernatremia Secondary to Excessive Administration of Hypertonic Saline

In the rare instance of hypernatremia secondary to excessive administration of hypertonic saline, which occurs when intraamniotic infusion of hypertonic saline is used to induce abortion, hypernatremia is owing solely to positive sodium chloride balance. Therefore, treatment involves simply inducing a state of negative sodium chloride balance while maintaining a slightly positive water balance. If the hypernatremia is associated with impairment of CNS function (Na^+ usually exceeds 160 mEq/L), 2 to 3 L of 5% solution of glucose in water should rapidly be given IV, along with sufficient furosemide to induce a urine flow rate of about 10 to 20 mL/min. About 100 mg of IV furosemide is an appropriate initial dose. This results in the excretion of urine containing about 140 mEq/L of sodium and chloride and 10 mEq/L of potassium. If, at the same time, only the water and potassium are replaced (e.g., replacement of each 1,000 mL of urine with 1,000 mL of 5% solution of glucose in water plus 10 to 20 mEq of potassium chloride, given IV), the patient is selectively depleted of sodium chloride, and plasma electrolytes can be restored to normal within several hours. During this period of correction, serum and urine electrolyte levels must be monitored frequently to assess the adequacy of IV replacement therapy, particularly the rate of potassium administration.

POTASSIUM METABOLISM

Disorders of potassium metabolism frequently coexist with disorders of sodium and water balance. For example, sodium and potassium losses often accompany gastrointestinal losses of water and electrolytes. The recognition and management of potassium depletion under these circumstances were discussed earlier in connection with the management of disorders of sodium and water balance. Even small movements of potassium into and out of cells can cause significant changes in the serum potassium since more than 90% of potassium resides intracellularly. It also is important to recognize disorders in which disturbances of potassium balance are the primary abnormality or the major feature of the electrolyte disturbances.

Hyperkalemia

Hyperkalemia is defined as a serum potassium level greater than 5 mEq/L. Serum potassium levels between 5 and 6 mEq/L usually cause little or no functional abnormality, but such levels indicate that an abnormality of potassium regulation is present. This sign should be heeded and its cause investigated, because further small elevations in serum potassium concentration can seriously impair cardiac and skeletal muscle function. At a serum potassium level of 6 or 7 mEq/L, the electrocardiogram (ECG) begins to show tall, peaked T waves, and skeletal muscle weakness may be present. At a serum potassium level greater than 7 mEq/L, severe ECG abnormalities may be present, including complete suppression of atrial activity and an idioventricular rhythm that can then lead to ventricular tachycardia and fibrillation. Profound skeletal muscle weakness leading to respiratory arrest also may develop. If serious hyperkalemia is suspected, an ECG should be obtained immediately along with a blood specimen for potassium measurement. The ECG findings establish whether life-threatening hyperkalemia is present. **Table 10.7** lists the principal clinical conditions associated with hyperkalemia.

Pseudohyperkalemia can result from hemolysis of red blood cells as a result of the mechanical trauma of venipuncture. Such pseudohyperkalemia should be readily recognized, because both potassium and hemoglobin are released by the damaged cells. If the serum potassium level has been significantly raised by in vitro hemolysis, the serum is visibly pink because of the presence of free hemoglobin. Patients with extraordinarily high white blood cell counts or platelet counts also can exhibit pseudohyperkalemia as the result of excessive traumatic in vitro lysis of these cells. Pseudohyperkalemia can be avoided by drawing venous blood samples under low pressure into a heparinized syringe.

Management

Life-Threatening Hyperkalemia

Electrocardiogram shows sine waves or loss of atrial activity and a broad QRS complex. Serum potassium level usually is higher than 7 mEq/L.

1. Infuse 10 mL of 10% calcium gluconate intravenously over a few minutes with ECG monitoring to observe for reversal of ECG changes toward normal. The same infusion of 10 mL of 10% calcium gluconate can be repeated once. Calcium ion directly antagonizes the effects of potassium on myocardial metabolism. The onset of action is a few minutes. If the patient is taking digitalis, consider not giving the calcium and proceed on to the next step.
2. Infuse 50 g of glucose, 10 U of regular insulin, and 50 mEq of sodium bicarbonate. The onset of action is about 15 minutes. Additionally, an IV infusion of glucose, insulin, and sodium bicarbonate (e.g., 500 mL of 10% dextrose in water plus 15 units of regular insulin plus 50 mEq of sodium bicarbonate) may be started. Infuse over several hours. This maneuver causes potassium to

P.168

move intracellularly. The amount of glucose infused must be altered or omitted in hyperglycemic diabetic patients.

TABLE 10.7 Causes of Hyperkalemia	
CAUSE	EFFECT
Excessive intake of potassium	Shortened life span of stored RBCs after transfusion leads to excessive release of RBC potassium to ECF. Plasma potassium of stored blood also is increased (30 mEq/L) after 14 days of storage.
Transfusion of	

blood stored for
prolonged periods

Excessive oral or
intravenous intake of
potassium

Acute ingestion of 500 mEq potassium chloride can cause fatal hyperkalemia with normal renal function. If renal function is impaired, even normal potassium intake can cause severe hyperkalemia.

Excessive release of
intracellular stores of
potassium

Chemotherapy of
malignancies
Catabolism of
hematomas
Rhabdomyolysis

The potential for any of these conditions to cause serious hyperkalemia is greatly increased when they coexist with impaired renal function.

Succinylcholine
action on muscle
Sepsis with
excessive
catabolism of
muscle protein
Acute digitalis
poisoning
Familial
hyperkalemic
periodic paralysis
Intravenous
hypertonic glucose
or mannitol

Intravenous
arginine
Metabolic acidosis

H⁺ displaces K⁺ from intracellular sites, causing increased diffusion of K⁺ into ECF.

Impaired renal capacity
to excrete potassium

Grossly reduced
GFR

Almost all of filtered potassium is reabsorbed. Excreted potassium represents almost exclusively potassium secreted by the tubules. Nevertheless, grossly reduced GFR is associated with grossly reduced tubular function and hence the tendency to hyperkalemia.

Impaired tubular
function

Hyperkalemic renal

Some patients with normal or mildly reduced GFR can have substantial

tubular acidosis	impairment of potassium secretion (e.g., lupus patients with interstitial nephritis, mild obstructive uropathy).
Decreased aldosterone secretion	Aldosterone is necessary for normal potassium and H ⁺ secretion and normal Na ⁺ absorption in the distal renal tubule.
Addison disease Primary hypoaldosteronism	
Hyporeninemic hypoaldosteronism	Common in patients with diabetes mellitus or obstructive uropathy.
Drugs that suppress angiotensin formation	
β-Blocking agents (e.g., propranolol) Prostaglandin synthetase inhibitors (e.g., indomethacin, ibuprofen) Angiotensin- converting enzyme inhibitors (e.g., captopril, enalapril, lisinopril)	Angiotensin II causes aldosterone secretion; β-blockers and nonsteroidal anti-inflammatory drugs directly suppress angiotensin formation by suppressing renin production. Captopril prevents angiotensin II formation by blocking conversion of angiotensin I.
Drugs that interfere with renal potassium secretion	Spirolactone competitively inhibits the action of aldosterone. Triamterene and amiloride block potassium secretion even in the absence of aldosterone.
Ureteral implantation into jejunal loop	Increased reabsorption of potassium from jejunum causes predisposition to hyperkalemia.
ECF, extracellular fluid; GFR, glomerular filtration rate; RBCs, red blood cells.	

3. Nebulized albuterol at a dose of 10 to 20 mg is recommended. The peak action is approximately 90 minutes.
4. As soon as practical, give sodium polystyrene sulfonate (Kayexalate) by mouth, nasogastric tube, or retention enema (e.g., 20 to 50 g of Kayexalate every 2 to 4 hours). An equal number of grams of sorbitol should be given if the Kayexalate is administered into the upper gastrointestinal tract. Sorbitol, a sugar that is poorly absorbed from the intestine, causes an osmotic diarrhea and prevents concretions of Kayexalate from forming within the gut. Kayexalate is an ion-exchange resin that removes potassium by binding potassium and releasing sodium into body fluids.
5. Hemodialysis may be required in patients in whom these measures fail.

TABLE 10.8 Causes of Hypokalemia

CAUSE	COMMENTS ON PATHOGENESIS
Decreased potassium intake	With 0 mEq potassium intake, stool potassium is about 10 mEq/2 h, urinary potassium is <30 mEq/24 h or is <20 mEq/L.
Excessive renal losses of potassium	Urinary potassium usually >30 mEq/24 h or 20 mEq/L.
Diuretic therapy	All diuretics except for spironolactone, triamterene, and amiloride cause renal potassium wasting. <i>Mechanism:</i> Diuretics cause increased sodium delivery to distal tubular sites where sodium is reabsorbed in exchange for potassium or hydrogen ion.
Diuretic phase of acute tubular necrosis and other causes of osmotic diuresis	<i>Mechanism:</i> Same as above.
Metabolic alkalosis	<i>Mechanism:</i> renal tubular cell potassium concentration increased resulting in enhanced potassium secretion.
Gentamicin or amphotericin B nephrotoxicity	Renal tubular damage presumably causes increased back flux of potassium into renal tubules in the case of amphotericin.
Increased renal mineralocorticoid effects	Increased activity of distal tubular site, which reabsorbs sodium in exchange for potassium or H ⁺ .
Mineralocorticoid therapy (deoxycorticosterone acetate, 9 α -fludrocortisone) Primary aldosteronism Secondary aldosteronism (e.g., cirrhosis of the liver, renal artery stenosis, malignant hypertension) Cushing syndrome Excessive licorice or chewing tobacco (glycyrrhizic acid) Bartter syndrome	

Renal tubular acidosis	<p><i>Mechanism:</i></p> <p>Distal: Possibly increased renal potassium secretion in exchange for sodium at the distal tubular site because of decreased availability of H^+ for secretion</p> <p>Proximal: Increased bicarbonate excretion leads to increased renal potassium excretion.</p>
Excessive gastrointestinal losses of potassium	
Vomiting, gastric drainage, diarrhea, laxative abuse	Renal potassium excretion also increased in the case of vomiting or gastric drainage.
Villous adenoma of the rectum	Loss of potassium-rich mucus per rectum
Shift of potassium from the extracellular to the intracellular fluid	
Correction of metabolic acidosis	H^+ leaves cells, K^+ enters cells during correction of metabolic acidosis.
Correction of hyperglycemia	K^+ enters cells with glucose to provide cation to balance anion that forms during metabolism of glucose
Hypokalemic periodic paralysis	Unexplained familial disorder
Miscellaneous	
Ureterosigmoidostomy	Colonic secretion of HCO_3^- and K^+ with absorption of Na^+ and Cl^- results in hypokalemic metabolic acidosis.

Moderate Hyperkalemia

Electrocardiogram shows only peaked T waves; serum potassium level usually is below 7 mEq/L.

1. Reduce potassium intake (normal potassium intake is 60 to 100 mEq/24 h). Reducing dietary potassium to 50 to 60 mEq/24 h usually is sufficient to correct mild hyperkalemia.
2. Kayexalate may be needed periodically to control the serum potassium level.
3. Correct metabolic acidosis if present.
4. Stop administration of medications that can contribute to hyperkalemia, such as angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, and potassium-sparing diuretics.

Hypokalemia

Hypokalemia is defined as a serum potassium level below 3.5 mEq/L ([Table 10.8](#)). Significant symptoms usually do not result from hypokalemia unless the serum potassium level is less than 3 mEq/L. An important exception is in patients who are receiving digitalis preparations. In such patients, hypokalemia, or even low-normal serum potassium levels, can increase myocardial irritability and lead to serious arrhythmias. In addition to increasing myocardial irritability, hypokalemia can cause

P.170

profound muscle weakness and ileus. Chronic severe hypokalemia also can cause metabolic alkalosis and decreased capacity to concentrate the urine. The ECG in hypokalemia often shows U waves, although this finding is not diagnostic of hypokalemia.

Management

Mild Asymptomatic Hypokalemia

This usually can be corrected simply by eliminating the cause of the potassium wasting or by increasing potassium intake. If the hypokalemia is caused by diuretic therapy, potassium depletion usually can be avoided by administering spironolactone or triamterene. Potassium supplementation also can be used, but if the patient is on a low sodium chloride intake, the potassium supplement must be given as potassium chloride. The use of other, more palatable potassium salts (e.g., gluconate, citrate, acetate) and all forms of potassium in food is much less effective in correcting hypokalemia, and this treatment is used primarily in patients on a normal sodium chloride intake.

Severe or Symptomatic Hypokalemia

This usually requires IV administration of potassium chloride. In general, the use of IV solutions that contain more than 40 mEq/L of potassium should be avoided, because infusing high concentrations of potassium can cause hyperkalemia or cardiac disturbance. In correcting even severe potassium deficits, it is seldom necessary to infuse more than 120 to 160 mEq/24 hours of potassium chloride. When higher rates are used, frequent monitoring of the patient's ECG and serum potassium level is essential. Intravenous replacement of potassium should never run at a rate of greater than 10 mEq/h. The oral route of potassium replacement should be used whenever possible.

Calcium

Approximately 99% of body calcium is contained in bone. Up to 40% of the extracellular calcium that circulates in the bloodstream is bound to plasma proteins. However, the unbound or ionized form of calcium is the form that exerts physiologic activity. Total calcium is a measure of both the bound and unbound or ionized form. Serum albumin levels affect the total serum calcium, as albumin is the plasma protein to which the majority of calcium is bound.

$$\begin{aligned} \text{corrected calcium in mg / dL} \\ = \text{measured calcium} + [(4 - \text{albumin in g / dL}) \times 0.8] \end{aligned}$$

Ionized or unbound calcium can be measured if specifically requested. Its concentration is affected by the serum pH. With alkalosis when the pH is increased, a decrease in ionized calcium results from the increased protein binding of calcium. Conversely, with acidosis, a decrease in protein binding causes an increase in ionized calcium.

The homeostasis of calcium is quite complex, and calcium serves many important functions. Calcium plays a role in regulation of muscle contraction and nerve conduction. Additionally, it functions in the coagulation cascade.

The majority of calcium is stored in bone; however, calcium is under the control of several other organ systems, including the integument, endocrine, and renal. Parathyroid hormone (PTH) appears to be the major hormone effecting calcium homeostasis. Vitamin D must be present, however, for it to exert its maximal effect. PTH causes the following.

- Mobilization of calcium and phosphorus from bone
- Increased renal tubular reabsorption of calcium
- Increased intestinal absorption of calcium
- Decreased renal tubular reabsorption of phosphorus

Hypocalcemia

Clinical manifestations of hypocalcemia (defined as a calcium level below 8 to 8.5 mg/dL) are characterized by neuromuscular irritability. Symptoms can include numbness, muscle cramping, paresthesias, Chvostek (twitching of facial muscles) and Trousseau (carpal spasm) signs, tetany, and seizures. Patients can also experience psychosis and memory loss. On physical examination, patients may have hyperactive deep tendon reflexes. ECG findings of hypocalcemia include a prolonged QT interval, which can lead to heart block or ventricular fibrillation. Causes of hypocalcemia are shown in [Table 10.9](#).

Treatment of hypocalcemia should be directed at its underlying cause. A low total calcium level with a normal ionized calcium level signifies a low level of plasma proteins. These patients usually are asymptomatic, and calcium replacement in this setting usually is not necessary.

For patients with acute symptomatic hypocalcemia, calcium gluconate or chloride should be given intravenously. These may cause a local cellulitis or tissue necrosis if infiltration occurs. If infiltration occurs, especially with the chloride solution in emergent situations, 10 mL of 10% calcium gluconate can be administered intravenously over 15 minutes. In addition, 10 to 20 mL of calcium gluconate can be placed in 1 L of D₅W and administered over 24 hours. If the serum albumin level is below 2 mg/dL, then it may be prudent to replace albumin, especially if the urine output is low. Because albumin is heat treated, there is no risk of hepatitis or HIV exposure. In cases of symptomatic hypocalcemia, magnesium levels must be checked and corrected if necessary. In those patients with metabolic acidosis and hypocalcemia, the hypocalcemia should be treated initially followed by the correction of the acidosis.

Long-term treatment of hypocalcemia involves adequate nutritional supplementation of calcium, vitamin D, or both. If the serum phosphorus level is high, hypoparathyroid disease must be suspected and the patient treated accordingly. If the serum phosphorus is normal or low, then primary bone disease (hungry bone) must be considered. It is imperative that magnesium levels be checked because replenishment of calcium cannot be accomplished in a patient who is hypomagnesemic.

Hypercalcemia

The clinical manifestations of hypercalcemia usually are seen when the total serum calcium is greater than 12 mg/dL. Common presenting symptoms include weakness, fatigue, nausea, vomiting, constipation, polyuria, polydipsia, lethargy, and confusion. Psychiatric disturbances and coma can be seen in severe cases of hypercalcemia. Electrocardiogram changes include prolongation of PR and QRS intervals with a shortening of the QT interval. Complete heart block and cardiac arrest can occur in profound hypercalcemia. Additional laboratory

abnormalities can include elevations in serum amylase and creatinine levels. The phosphorus level is critical in establishing the cause of hypercalcemia. A phosphorus level below 3.5 mg/dL suggests hyperparathyroidism,

whereas an elevated phosphorus level suggests an underlying malignancy.

TABLE 10.9 Causes of Hypocalcemia

Deficiency or absence of PTH
Vitamin D deficiency—decreased intestinal absorption
Septic shock—suppression of PTH products
Renal failure—decreased 1:25 dihydroxycholecalciferol
Hypomagnesemia—decreased PTH release and decreased organ response to calcium
Hyperphosphatemia

Hypercalcemia, unlike many other electrolyte disturbances, is rarely iatrogenically induced. There are several causes of hypercalcemia. The majority of hospitalized patients with hypercalcemia have an underlying malignancy, whereas the most common etiology of hypercalcemia in the ambulatory setting is hyperparathyroidism. Additional causes of hypercalcemia include thiazide diuretics, lithium, vitamin D intoxication, hyperthyroidism, and sarcoidosis. In the setting of gynecology, hypercalcemia is most often seen with malignancy. In patients with cancer, hypercalcemia results from increased bone resorption and decreased renal excretion. Metastasis to the bony skeleton causes an increase in osteoclastic activity that increases bone resorption. Some gynecologic tumors, however, may cause hypercalcemia by production of a substance similar to PTH, causing bone resorption without evidence of bony metastasis.

Volume expansion is crucial in the treatment of acute hypercalcemia. Replacement with normal saline solution decreases calcium reabsorption in the proximal renal tubule, thus improving renal function. Initial IV fluid therapy should be aggressive, with rates of 250 to 500 mL/h, as most patients are volume contracted. Addition of loop diuretics such as furosemide may aid in increasing urinary calcium excretion, but caution must be used because these drugs may result in volume contraction and hypokalemia. After initial volume is restored, 3 to 6 L/d of normal saline solution should be given. Close monitoring of daily patient weights, intake and output, and frequent monitoring of serum electrolytes is necessary in patients with hypercalcemia.

Bisphosphonates are commonly used for the treatment of hypercalcemia. This class of drugs inhibits osteoclast precursors and induces osteoclast cytotoxicity, thereby decreasing serum calcium levels. Etidronate disodium (Didronel) is given at a dose of 7.5 mg/kg IV over 2 hours daily for 3 to 7 days. Alternatively, pamidronate (Aredia) is given as a single dose of 60 to 90 mg IV over 4 to 24 hours. Peak onset of action with these medications is usually seen in 48 to 96 hours and may last 2 to 3 weeks. The single dose of 90 mg IV of pamidronate is recommended for severe cases of hypercalcemia because of its effectiveness.

Zoledronic acid (Zometa) is a new-generation, nitrogencontaining bisphosphonate that has been shown to be superior to pamidronate at inhibiting the induction of hypercalcemia of malignancy. Zometa can be given over 5 minutes in a 4-mg dose for the initial treatment of hypercalcemia and an 8-mg dose for relapsed or refractory hypercalcemia. The duration of response with zoledronic acid is approximately 32 days with a 4-mg dose and 43 days with an 8-mg dose compared with 18 days with a 90-mg dose of pamidronate.

Calcitonin increases renal excretion of calcium and inhibits osteoclastic activity. In patients with hypercalcemia, calcitonin can be given at a dose of 4 to 8 IU/kg intramuscularly or subcutaneously every 6 to 12 hours. Commercial calcitonin preparations are generally from salmon. It has a rapid onset of action, and serum calcium levels may decrease within several hours. Its effect usually subsides after several days but may be potentiated by concomitant glucocorticoid administration. Calcitonin has minimal side effects. Tachyphylaxis is seen with calcitonin, limiting its repeated usage and causing it to be less consistently effective compared with other available hypercalcemic treatments.

Glucocorticoids decrease the intestinal absorption of calcium, promote urinary excretion of calcium, and may lower calcium levels by a direct cytolytic effect on some tumor cells. Lowering of serum calcium levels with glucocorticoids may take 5 to 10 days. Dosages may vary from 20 to 100 mg of oral prednisone or its IV equivalent per day. Side effects limit the long-term use of glucocorticoids for hypercalcemia.

Another potent inhibitor of bone resorption is gallium nitrate. Its onset of action is usually seen in 1 to 2 days, with a peak at 5 to 10 days after administration. Gallium nitrate is administered in a dose of 100 to 200 mg/kg/d for 5 days in a continuous drip. It is important to maintain a saline diuresis of at least 2 L/d during this therapy. Side effects are relatively uncommon, but renal toxicity may be seen. Gallium nitrate in early studies was significantly more effective than was calcitonin with or without the addition of corticosteroids. Its obvious disadvantage over the biphosphonates is that it requires continuous IV infusion over 4 or 5 days.

Oral and IV phosphorus has been used successfully to treat hypercalcemia. It has fallen out of favor, however, because it causes decreased excretion of calcium from the kidneys. Intravenous phosphorus can also lead to soft tissue deposition of calcium compounds and renal failure. It was used in patients with serum phosphorus levels less than 3 mg/dL and normal renal function. For patients with extremely high calcium levels and severe symptoms (e.g., coma, arrhythmia), renal dialysis may be necessary for rapid correction of hypercalcemia.

Plicamycin (mithramycin) is an antibiotic that blocks bone resorption, thus lowering serum calcium. The recommended dose of plicamycin in the treatment of hypercalcemia is 25 mg/kg IV over 4 to 6 hours and may be repeated every 24 to 48 hours. Its onset of action is relatively quick, and peak action is usually noted in 2 to 3 days. Side effects can be severe and include nausea, vomiting, bleeding, thrombocytopenia, renal failure, and hepatotoxicity. These side effects are more common with repeated doses of plicamycin. Because of these side effects, plicamycin usually is reserved for hypercalcemia of malignancy or hypercalcemia refractory to other therapies.

Magnesium

Magnesium has several functions in the human body. Its primary role is in neuromuscular function, but it also serves as an enzyme cofactor in protein and carbohydrate metabolism. The majority (60%) of magnesium in the body is contained within the bone. Most of the remainder is found intracellularly, with only about 1% found in the ECF. Normal serum magnesium levels are between 1.2 and 2.2 mEq/L. Magnesium metabolism depends on potassium and calcium levels. The kidney serves as the organ primarily responsible for magnesium homeostasis. Magnesium is filtered at the glomerulus and reabsorbed in the ascending loop of Henle and to a lesser degree in the proximal and distal tubules.

Hypomagnesemia

Hypomagnesemia is more common than hypermagnesemia. Hypomagnesemia results from decreased gastrointestinal absorption with conditions such as chronic diarrhea, malabsorption syndromes, and nasogastric suction. Increased renal and gastrointestinal losses from osmotic diuresis, hypercalcemia, and medications such as cisplatin, diuretics, and aminoglycosides also can cause hypomagnesemia. Hypomagnesemia can result from decreased intake in malnutrition. For example, 10% to 15% of hospitalized patients and more than half of

patients in intensive care units exhibit low magnesium levels. Patients with heavy alcohol use may have hypomagnesemia.

Symptoms and signs of hypomagnesemia are usually nonspecific but may manifest by neuromuscular excitability. Hypomagnesemia is often seen in combination with hypokalemia, hypocalcemia, and metabolic alkalosis.

Neurologic

P.172

abnormalities include weakness, dizziness, lethargy, confusion, tremors, fasciculations, and seizures. Typical ECG findings are prolonged PR and QT intervals; however, atrial and ventricular arrhythmias can result.

The treatment of hypomagnesemia involves the replacement of magnesium. Mild or chronic cases may be treated with oral magnesium supplements. Oral repletion is also preferred in asymptomatic patients. This is accomplished by giving 240 mg of elemental magnesium one to four times a day. Diarrhea is the most common side effect. For severe or acute cases, IV magnesium is indicated. Obstetricians and gynecologists are familiar with the 4-g magnesium load mixed with 50 mL of D₅W infused over 30 minutes. Deep tendon reflexes should be evaluated frequently because hyperreflexia suggests hypermagnesemia. Long-term oral therapy can be provided with magnesium oxide 300 mg/d. Patients should receive proper nutritional counseling and be warned to avoid alcohol. Any underlying medical disorder that may contribute to magnesium losses should be treated. Hydration status should be evaluated because overhydration can lead to mild forms of hypomagnesemia. Gastrointestinal tract losses and alcohol consumption also should be addressed in the evaluation of this disease process.

Hypermagnesemia

Hypermagnesemia is rare and usually iatrogenic. Causes of hypermagnesemia include therapy with magnesium-containing antacids or laxatives or secondary to administration of parenteral hyperalimentation. Often hypermagnesemia is seen in patients with some degree of renal insufficiency and in preeclamptic or preterm labor patients treated with IV magnesium.

Mild to moderate hypermagnesemia usually is asymptomatic, but patients with severe cases may present with several symptoms. Clinical manifestations are normally seen if magnesium levels are greater than 4 mEq/L. Signs and symptoms include nausea, vomiting, weakness, lethargy, and somnolence. A prolonged PR interval, widening of the QRS complex, and increased T-wave amplitude can be seen with levels greater than 5 mEq/L. Areflexia occurs at levels above 6 to 7 mEq/L. Respiratory arrest, bradycardia, and hypotension can be seen when levels are higher than 10 to 11 mEq/L. Finally, cardiac arrest can occur when serum magnesium is above 14 mEq/L.

Discontinuation of magnesium intake is the primary therapy for symptomatic hypermagnesemia. Patients with severe cases should be given 10% calcium gluconate, 10 to 20 mL IV over 10 minutes. The calcium therapy antagonizes the effects of magnesium and is cardioprotective. Supportive therapy and mechanical ventilation may be necessary in those with respiratory failure. Hemodialysis may be required in patients with hypermagnesemia and renal insufficiency.

Phosphorus

As with magnesium, the majority of phosphorus is contained in the bony skeleton and the intracellular space, and only 1% is found in the ECF. As a result, serum phosphate levels may not accurately reflect total body phosphate stores. A normal range for serum phosphorus is 3 to 4.5 mg/dL. Phosphorus serves as an important energy source by means of high-energy phosphates. It is a key component to protein and lipid structure and is a vital component for carbohydrate metabolism.

Hypophosphatemia

Causes of hypophosphatemia defined as a serum phosphate below 2.5 mg/dL include a redistribution of phosphate into the cells, a decrease in intestinal absorption, or an increase in renal excretion. Several causes of hypophosphatemia are listed in **Table 10.10**. Most patients with mild hypophosphatemia are asymptomatic. Moderate to severe hypophosphatemia causes neuromuscular abnormalities, including weakness, rhabdomyolysis, paresthesias, confusion, seizures, and coma. Erythrocyte, leukocyte, and platelet dysfunction also can be seen because of a depletion of cellular adenosine triphosphate and 2,3-diphosphoglycerate.

TABLE 10.10 Causes of Moderate to Severe Hypophosphatemia (<1.5 mg/dL)

Respiratory alkalosis
Malabsorption
Vitamin D deficiency
Hyperalimentation
Treatment of diabetic ketoacidosis
Hyperparathyroidism
Excessive alcohol use

Most patients with serum phosphate levels between 1 and 2.5 mg/dL usually are asymptomatic. Treatment is aimed at correcting the underlying cause. In cases of chronic hypophosphatemia, oral repletion can be instituted at a dose of 500 to 1,000 mg of elemental phosphorus two to three times per day, and the most common side effect is diarrhea. This can be given in the form of sodium/potassium phosphate tablets called Neutra-Phos or Neutra-Phos K (each contains 250 mg of elemental phosphorus). Parenteral administration of phosphorus is indicated when serum phosphorus levels are below 1 mg/dL. Infusion at a dose of 2.5 to 5 mg elemental phosphorus/kg given every 6 hours is recommended. When the serum levels are greater than 1.5 to 2 mg/dL, patients may be switched to oral supplements. Care must be taken to avoid hyperphosphatemia. Also, concomitant calcium supplementation often is needed to prevent hypocalcemia. Serum magnesium, calcium, and potassium levels should be monitored closely.

Hyperphosphatemia

Hyperphosphatemia is relatively rare and is seen either with an increased endogenous or exogenous phosphorus load or with a decrease in renal clearance of phosphorus. Renal failure is the most common cause of hyperphosphatemia. Elevated phosphorus levels also may be seen secondary to rhabdomyolysis, tumor lysis syndrome, hypoparathyroidism, and respiratory or metabolic acidosis. Clinical manifestations include numbness, tingling, muscle cramps, paresthesias, and tetany and are caused by hypocalcemia. Hyperphosphatemia causes hypocalcemia by decreasing calcium absorption from the gastrointestinal tract.

Addressing the underlying cause is the cornerstone of management for hyperphosphatemia. In acute cases, saline diuresis can be used in patients with normal renal function. Additionally, administration of glucose and insulin causes a shift in phosphorus from ECF to the intracellular space. Dialysis may be required if renal failure

is present. Oral phosphate binders such as calcium carbonate can be used in patients with chronic hyperphosphatemia.

ACID-BASE METABOLISM

Chemicals that are able to provide a hydrogen ion (H^+), such as HCl and H_2CO_2 , are defined as acids. Bases are defined as chemicals with the ability to accept a H^+ and include OH^- and HCO_3^- . The acidity of a solution is governed by the concentration of hydrogen ions it contains. The pH of a system is defined as the negative logarithm of hydrogen ions within that system expressed in moles per liter. The normal pH of human ECF ranges from 7.35 to 7.45.

Buffer Systems

In order for optimal cellular function to occur within the body, the pH must remain in this range. Humans have the ability to absorb excess acids or alkali in circumstances of abnormal pH. The lungs correct for acid-base disorders in an acute setting until the kidneys can compensate. In acidotic states, patients will hyperventilate to decrease CO_2 levels in the blood. Conversely, in alkalotic states, patients will hypoventilate, driving up the level of CO_2 in the blood. Renal function will gradually compensate by retaining or releasing bicarbonate and hydrogen ions. The most important human buffer system is the bicarbonate system. It is the principal extracellular buffer. Organic phosphates and peptides are the other major intracellular buffers.

Table 10.11 shows the directional changes in acid-base parameters for the primary acid-base disorders. If the kidney detects a respiratory acidotic state, CO_2 and H_2O in renal tubule cells are converted by carbonic anhydrase to carbonic acid (H_2CO_3). This dissociates into H_2CO_3 , which is secreted back into ECF, and H^+ , which is exchanged for sodium from the renal tubule. This in effect causes excretion of the hydrogen ion into the urine, where it is buffered with ammonium and phosphate ions or acted on by carbonic anhydrase (in the tubule) to ultimately form CO_2 and H_2O . The CO_2 is absorbed back into the cell, where more bicarbonate can be generated to buffer ECF acidosis. If a patient has a respiratory alkalosis, available levels of CO_2 are low, causing a decrease in hydrogen excretion.

Primary Acid-Base Disorders

Metabolic Acidosis

Metabolic acidosis begins as a reduction in plasma HCO_3 and a rise in H^+ . In response to these changes, alveolar ventilation is increased, resulting in a decrease in $PaCO_2$ and restoration of H^+ toward normal. Metabolic acidosis can be divided into normal anion gap and increased anion gap acidosis. **Table 10.12** shows the major causes of metabolic acidosis.

Increased Anion Gap

Renal failure, either acute or chronic, can result in an increased anion gap metabolic acidosis resulting from the kidneys' inability to excrete inorganic acids, such as phosphate and sulfate. Organic acid accumulation also results in an increased anion gap metabolic acidosis. In the case of lactic acidosis, cellular respiration is disturbed. This occurs as a result of anaerobic glycolysis in muscle, red blood cells, and other tissues. Conditions such as shock, hypoxemia, and septicemia can produce lactic acidosis by causing inadequate oxygen delivery to tissues. Conditions such as diabetic ketoacidosis, alcoholic ketoacidosis, and starvation cause an accelerated rate of organic acid production by lipolysis and ketogenesis. Ingestion of substances such as

salicylates, methanol, ethylene glycol, and paraldehyde can result in an increased anion gap metabolic acidosis.

Normal Anion Gap

Normal anion gap metabolic acidosis occurs with abnormal increases in net bicarbonate losses. This can occur when the kidney fails to reabsorb bicarbonate in proximal renal tubular acidosis. The administration of carbonic anhydrase inhibitors can also cause normal anion gap metabolic acidosis. Excessive diarrhea or small bowel/pancreatic drainage can cause bicarbonate losses from the gastrointestinal tract. Hyperchloremic acidosis occurs when the kidney fails to regenerate bicarbonate in conditions such as distal renal tubular acidosis and hyporeninemic hypoaldosteronism. Administration of acid salts can result in chloremic acidosis.

MANAGEMENT

The treatment for metabolic acidosis depends on the severity of acidosis and the underlying cause. A clinical manifestation of metabolic acidosis is hyperventilation. In the surgical patient, metabolic acidosis is commonly due to hypoxia secondary to inadequate tissue perfusion and subsequent accumulation of lactic acid. Volume resuscitation, including blood transfusion, will correct many of these cases of metabolic acidosis. Volume resuscitation and insulin are recommended to correct diabetic ketoacidosis. Patients with this form of metabolic acidosis will often require 4 to 5 L of intravenous fluid on diagnosis. Regular insulin can be given with a loading dose of 15 to 20 IU, followed by a continuous insulin infusion at 5 to 10 IU/h. In cases of renal tubular acidosis, bicarbonate therapy, thiazide diuretics, and a low-salt diet are used for correction.

In cases of acute, severe acidosis (pH <7.1, bicarbonate <10), patients will become dyspneic with depressed cardiac function and mental status changes. It may be necessary to administer intravenous bicarbonate to these patients. In general, the serum bicarbonate concentration should not be acutely raised to levels greater than 15 to 18 mEq/L. Too-rapid correction requires infusion of large amounts of sodium bicarbonate, which can cause overexpansion of the ECF and CHF. Finally,

P.174

rapidly restoring the plasma bicarbonate level to normal may produce alkalosis because of persistence of a low PaCO₂. That is, if plasma bicarbonate is rapidly restored to normal or above in the treatment of metabolic acidosis, alveolar ventilation frequently persists at elevated levels for an additional 24 to 48 hours. Thus, the low PCO₂ with normal plasma bicarbonate level can result in severe alkalosis, which, in turn, can cause cardiac arrhythmias, tetany, and seizures.

TABLE 10.11 Primary Disorders of Acid-Base Regulation

ACID-BASE DISTURBANCE	PRIMARY (INITIATING) EVENT	SECONDARY (COMPENSATORY) EVENT	RESULTANT CHANGE IN BLOOD H ⁺ AND PH
Metabolic acidosis	↓ HCO ₃ ⁻	↓ PCO ₂ ⁻	H ⁺ ↑, pH ↓
Metabolic alkalosis	↑ HCO ₃ ⁻	↑ PCO ₂ (minimal and only with severe increase in HCO ₃ ⁻)	H ⁺ ↓, pH ↑

Respiratory acidosis

Acute (24 h)	$\uparrow \text{PaCO}_2$	Negligible $\uparrow \text{HCO}_3^-$	$\text{H}^+ \uparrow$, $\text{pH} \downarrow$
Chronic (3-7 days or longer)	$\uparrow \text{PaCO}_2$	Important $\uparrow \text{HCO}_3^-$	
Respiratory alkalosis	$\downarrow \text{PaCO}_2$	$\downarrow \text{HCO}_3^-$	$\text{H}^+ \downarrow$, $\text{pH} \uparrow$

TABLE 10.12 Major Causes of Metabolic Acidosis

Increased anion gap

Accumulation of acids

Alcoholic ketoacidosis
 Diabetic ketoacidosis
 Lactic acidosis
 Starvation
 Salicylate ingestion
 Methanol ingestion
 Ethylene glycol ingestion
 Paraldehyde ingestion

Reduced excretion of acids

Renal failure

Normal anion gap

Excessive bicarbonate loss

Diarrhea
 Ureterosigmoidostomy
 Proximal renal tubular acidosis
 Small bowel or pancreatic drainage
 Carbonic anhydrase inhibitors

Excessive acid production

Ammonium chloride
 Arginine HCl
 Lysine HCl
 Hyperalimentation-containing acids

Decreased renal bicarbonate production

Distal renal tubular acidosis

Hyporeninemic hypoaldosteronism

METABOLIC ALKALOSIS

Metabolic alkalosis occurs when extracellular bicarbonate concentration is increased and renal excretion of this excess bicarbonate is decreased. This cascade may begin with the loss of a hydrogen ion. The major causes of metabolic alkalosis are listed in [Table 10.13](#).

One of the most common causes of metabolic alkalosis is vomiting or gastric suction. Volume contraction ensues, and bicarbonate is saved in the kidney. Profound potassium depletion can also increase renal reabsorption of bicarbonate and cause a metabolic alkalosis. Diuretics cause a metabolic alkalosis by inducing a sodium chloride excretion without bicarbonate, excretion of potassium, and secondary aldosteronism.

Gastric acid secretion normally has no net effect on acidbase regulation. If the gastric HCl is lost from the body and is not replaced, metabolic alkalosis will ensue ([Fig. 10.3](#)).

Mineralocorticoid excess in conditions such as hyperaldosteronism, Bartter syndrome, Liddle syndrome, and Cushing syndrome can cause metabolic alkalosis. The mechanism for alkalosis in these conditions is an increase in bicarbonate via the kidneys. Hypercalcemia can result in an increase in proximal tubular reabsorption of bicarbonate leading to metabolic alkalosis. Massive alkali administration in the form of massive blood and/or platelet transfusion or NaHCO_3 ingestion can lead to metabolic alkalosis.

TABLE 10.13 Major Causes of Metabolic Alkalosis

Extracellular volume depletion

Mineralocorticoid excess

Increased renal acid excretion

Massive alkali administration

Management

Metabolic alkalosis can have serious consequences, such as tetany, major motor seizures, production of hypokalemia and cardiac arrhythmias (particularly in patients receiving digitalis), suppression of alveolar ventilation, and decrease in cerebral blood flow. Furthermore, the presence of metabolic alkalosis often is a sign that the patient is significantly volume contracted. For these reasons, it is important to treat metabolic alkalosis and its underlying causes. Effective treatment consists of replacing sodium, potassium, and chloride deficits as they occur, as discussed. Rarely, it is necessary to treat metabolic alkalosis with IV infusion of hydrochloric acid, ammonium chloride, arginine hydrochloride, or a carbonic anhydrase inhibitor (acetazolamide). This form of treatment is necessary in patients who cannot undergo the sodium bicarbonate diuresis necessary to correct the

metabolic alkalosis. This inability usually is the result of severely impaired renal or cardiac function.

Respiratory Acidosis

Inadequate alveolar ventilation leads to respiratory acidosis. Acutely, this can occur with depression of the medullary respiratory center by sedating drugs or narcotics, by impaired respiratory excursion of the thorax by paralysis or trauma, and by airway obstruction. Chronic respiratory acidosis can be seen in conditions such as emphysema, severe kyphoscoliosis, and extreme obesity with Pickwickian syndrome.

Management

The treatment for respiratory acidosis is to increase alveolar ventilation (by endotracheal intubation, mechanical ventilation, or bronchodilation). Within minutes, severe respiratory acidosis can be reversed with adequate ventilation. In patients with chronic respiratory acidosis, severe posthypercapnic alkalosis develops if the PaCO_2 is rapidly restored to normal and the patient is unable to initiate and sustain a bicarbonate diuresis. This inability usually results from sodium chloride or potassium chloride deficits. If sodium chloride or potassium chloride is provided to correct volume contraction and intracellular potassium deficits, a bicarbonate diuresis ensues, and correction of metabolic alkalosis is achieved.

Respiratory Alkalosis

Respiratory alkalosis occurs when hyperventilation decreases PCO_2 , resulting in an increase in pH.

Hyperventilation may be secondary to conditions such as pulmonary embolism and CHF, which can cause hypoxia. Fever, sepsis, salicylate toxicity, and hepatic failure all can increase alveolar ventilation and cause respiratory alkalosis. This condition can also be iatrogenically induced by mechanical ventilation. Chronic hyperventilation can be seen in pregnancy, exposure to high altitudes, and underlying pulmonary disease.

Management

The symptoms of acute respiratory alkalosis (e.g., paresthesia, lightheadedness, tetany) can be rapidly controlled by raising PaCO_2 to normal (e.g., by rebreathing into a paper bag). If the patient is being supported on a ventilator, the dead space can be increased, or tidal volume and respiratory rate can be decreased

P.175

while oxygenation is maintained. Definite treatment consists of removing the cause of hyperventilation.

Respiratory alkalosis also can cause tetany and seizures and predispose to cardiac arrhythmias (by causing an intracellular shift of potassium), particularly in patients receiving digitalis. If the patient is septic, aggressive measures should be taken to alleviate this. She should be treated with appropriate antibiotics and adequate volume replacement. Surgery may be necessary if the patient has an abscess.

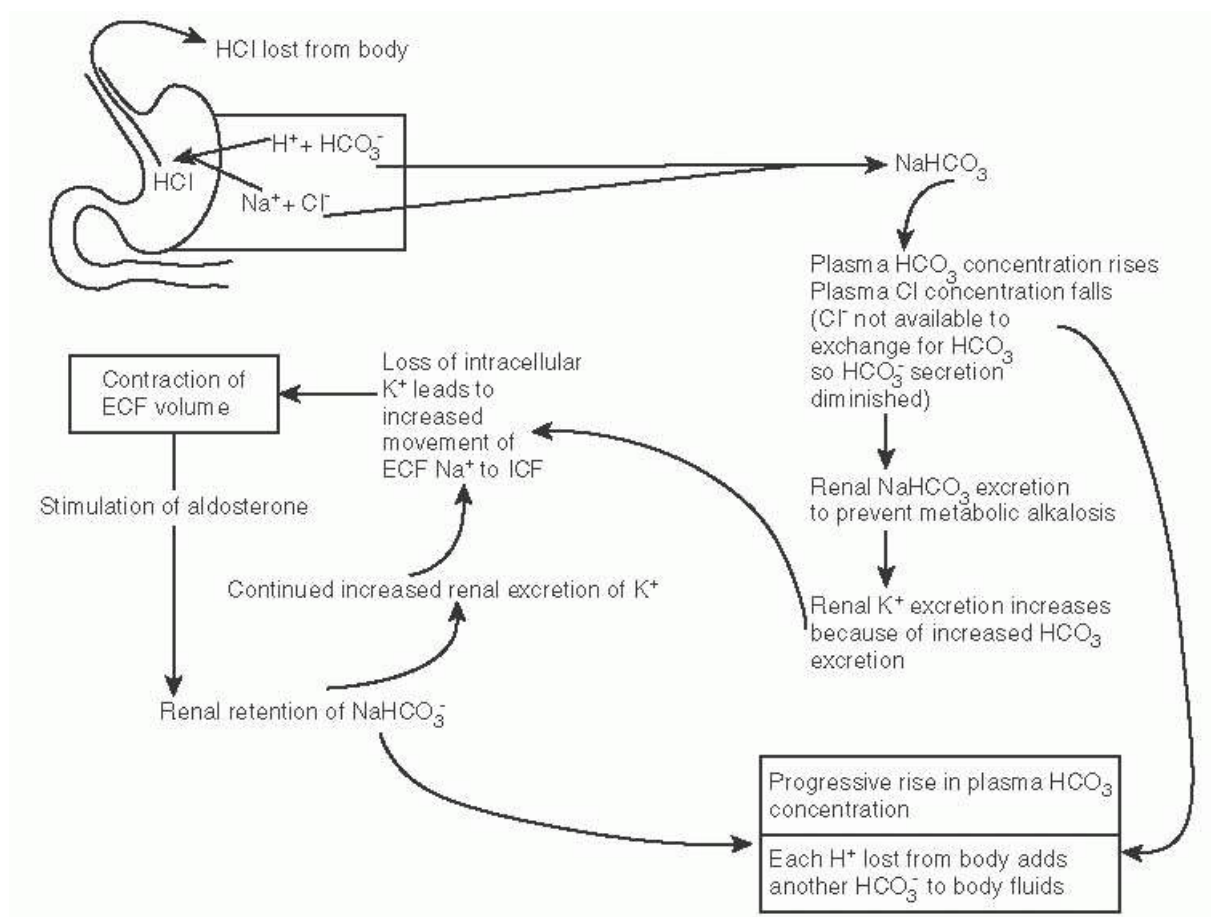

FIGURE 10.3 Pathogenesis of metabolic alkalosis from loss of gastric hydrochloric acid.

Mixed acid-base disturbances can commonly be seen in severely ill patients. Anion gap measurements and careful evaluation of compensatory changes in the pH, HCO_3^- , and PCO_2 are necessary in the workup and management of these patients. The treatment of mixed acid-base disturbances is aimed at the underlying disease process.

BEST SURGICAL PRACTICES

- An accurate assessment of the effective IVV usually can be made based on a careful clinical assessment of the patient.
- Maintenance fluids in a hospitalized patient should be calculated by taking the body surface area and multiplying by 1,000 to come up with the daily fluid requirement in mL.
- The syndrome of inappropriate antidiuresis has been associated with malignant tumors, CNS disorders, infections, the postoperative state, hypopituitarism, and myxedema, as well as with many drugs. Infusion of oxytocin to induce uterine contraction also can cause hyponatremia because of the antidiuretic effects of oxytocin.
- Symptoms of hyponatremia include increased tendon reflexes, lethargy, mental confusion, and muscle twitching, which are followed by convulsions, coma, and possibly death if levels fall below 115 mEq/L.
- The initial step in correcting either hyponatremia or hypernatremia is an accurate assessment of the patient's volume status.
- Furosemide should not be used to correct hypernatremia or decreased urine output in a patient with decreased IVV.
- Intravenous replacement of potassium should never run at a rate of greater than 10 mEq/h. The oral route of

potassium replacement should be used whenever possible.

- In severe life-threatening hyperkalemia (ECG showing sine waves and broad QRS complexes), patients should first receive 10 mL of calcium gluconate IV for cardioprotective purposes. These patients should receive an amp of D50, 10 U of regular insulin, and 50 mEq of sodium bicarbonate. Subsequently, these patients should then receive 20 to 50 g of Kayexalate every 2 to 4 hours and infusions of glucose and insulin.
- Magnesium metabolism is closely related to potassium and calcium levels. In cases of hyponatremia or hypocalcemia, magnesium and potassium must be checked and corrected accordingly.
- If the patient has significant comorbidities, then transfusion may be considered to achieve a higher hemoglobin level, especially prior to surgery.
- For any acid-base disturbance, it is important to elucidate the underlying cause for both the diagnosis and the treatment to be effective and successful.

Chapter 11

Postoperative Infections: Prevention and Management

W. David Hager
Mark J. Dougherty

DEFINITIONS

Bacteremia—Infection of the bloodstream can complicate any pelvic infection, but is seen most frequently in association with abscesses, peritonitis, and necrotizing fasciitis.

Cuff cellulitis—A soft tissue infection of the surgical margin in the upper vagina where the uterus was removed.

Drug fever—Elevated temperature that is due to an adverse reaction to medications.

Febrile morbidity—A temperature of 38°C (100.4°F) or greater recorded on two occasions, at least 6 hours apart, more than 24 hours after the surgical procedure.

Necrotizing fasciitis—A severe synergistic bacterial infection of the fascia, subcutaneous tissue, and skin that is often caused by group A beta-hemolytic streptococci, often in combination with other bacteria including methacillin-resistant *Staphylococcus aureus* (MRSA), anaerobes, and aerobic, gram-negative bacilli.

P.177

Surgical Site Infections (SSI)—Recent CDC criteria for SSI's have been developed using National Health Safety Network (NHSN) criteria; NHSN data provide regularly updated risk stratified rates of SSI for comparison between individual surgeons and between hospitals. (Edwards and colleagues, 2009).

Urinary tract infection—The criterion for defining a urinary tract infection (UTI) is more than 100,000 colonies/mL of a single pathogen from a clean-catch urine and more than 10,000 colonies/mL from a catheterized specimen.

Vaginal cuff hematoma/cuff abscess—A walled-off collection of blood originating from an oozing vascular pedicle or along the vaginal cuff. If the collection becomes infected, it creates an abscess.

Wound cellulitis—Soft tissue infection localized to the skin and adipose tissue above the fascia that is characterized by erythema, warmth, swelling, and tenderness.

Wound seroma—A collection of serous fluid beneath the skin surface.

Infection complicating surgical procedures has been the consternation of gynecologists since the first operations were performed. Multiple interventions have proven value in reduction of SSI, including appropriate perioperative antimicrobial prophylaxis, avoidance of shaving, appropriate skin preparation (such as with chlorhexidine/alcohol), and monitoring of surgeon-specific infection rates.

It is imperative that the gynecologic surgeon understand basic infectious disease concepts in order to treat infected patients appropriately. Diagnosis and treatment are not guesswork but depend on understanding basic principles.

An understanding of bacteria that are a part of the normal vaginal flora enables the gynecologist to recognize the pathogenic bacteria that contribute to postoperative infection. Certain risk factors play a role in increasing postoperative infection rates. Knowledge of these factors can enable the surgeon to take action to alter those risks, and/or be alert for those who are at increased risk. There are various types of postoperative infection, each with its own unique time of onset and usual bacterial etiology. Knowledge about likely causes of a disorder can facilitate decision making when an antibiotic is empirically selected to treat the patient.

Appropriate patient evaluation, including proper culturing techniques, is critical to this diagnostic process. Steps

to prevent infection must become routine with every surgeon on every case. These steps are necessary not only for the operator but also for all personnel participating in the surgical and medical management of the patient. These steps are described later in this chapter.

FEBRILE MORBIDITY

In the evaluation of patients who have an elevated temperature in the postoperative period, it is important to recognize that all febrile morbidity is not infectious morbidity. Treating a fever without a definite cause of infection will often do more harm than good.

Several different definitions of febrile morbidity have been used, and this may create confusion for the surgeon. The most frequent definition is a temperature of 38°C (100.4°F) or greater recorded on two occasions, at least 6 hours apart, more than 24 hours after the surgical procedure. This excludes a fever during the first 24 hours. Operative site infections during this time are unusual unless there is preexisting infection at the operative site or gross contamination of the site. Some investigators have used a definition of a single temperature elevation of 39°C (102°F) or greater recorded on any occasion in the postoperative period as indicative of febrile morbidity. We prefer the former definition.

Regardless of the choice of definition of febrile morbidity, it is important to treat infection and not fever. Fever may trigger sensitivity to the possibility of infection, but complete assessment of the patient including assessment for UTI, pneumonia, pelvic infection, DVT, intravascular catheter infection, and drug fever should be performed before antibiotic treatment is initiated.

INCIDENCE

New NHSN definitions for SSI have been created and data collected so that hospitals and surgeons can be compared through public reporting. Many states now legally require public reporting of health care associated events, including SSI. The Centers for Medicare and Medicaid Services has initiated “Payfor-performance” programs that include financial penalties/rewards based on provider performance with SSI rates used as part of the formula. National Health Safety Network data provide risk-stratified percentile rates so that, for instance, median abdominal hysterectomy rates for risk class 0, 1, and 2/3 in 2008 were 0.32, 1.61, and 3.41, respectively. Hospitals in the top 25th percentile had zero infections. The U.S. Department of Health and Human Services has set a national 5-year target to reduce SSI by 25% starting in 2012. In order to achieve this goal, risk factors for infection will need to be reduced.

VAGINAL FLORA

The most frequent source of bacteria that cause postoperative pelvic infection among women is the vagina. The vagina is colonized by large numbers of a variety of bacteria that normally exist in a symbiotic relationship. Several factors influence the vaginal flora, including age, sexual activity, stage of the menstrual cycle, use of antibiotic or immunosuppressive agents, and any invasive procedure.

Mean bacterial counts in vaginal secretions are 10^8 to 10^9 bacteria/mL, with three to six different species present. The most frequent aerobic bacteria are *Lactobacilli* sp., *Gardnerella vaginalis*, coagulase-negative *Staphylococcus*, *Corynebacterium* sp., *Enterococcus faecalis* species of *Streptococcus*, and *Enterobacteriaceae*. Anaerobes outnumber aerobes and include *Peptostreptococcus* sp., *Peptococcus* sp., *Prevotella bivia*, *Prevotella disiens*, and members of the *Bacteroides fragilis* group (Table 11.1). These same bacteria are frequently isolated from sites of pelvic infection among women who have undergone gynecologic surgery. This indicates, as Schottmueller proposed at the turn of the century, that pelvic infections are principally a result of endogenous sources of bacteria. The concepts of antibiotic prophylaxis and antiseptic douching before surgery or preoperative placement of antiseptic gel are related to reducing these large numbers of bacteria. Although investigators have found that colonization rates change in relation to the stage of the menstrual cycle, no data have supported the concept that timing of gynecologic

surgery in relation to menses alters infection rates.

Surgery itself alters the numbers and types of bacteria in the vagina and cervix. After vaginal and abdominal hysterectomy, the number of lactobacilli decreases, and the number of facultative gram-negative rods, *B. fragilis* group species, and enterococci increases. Preoperative hospitalization before surgery on a gynecologic ward also alters the vaginal flora in a direction toward more virulent organisms.

P.178

TABLE 11.1 Bacteria Composing Normal Vaginal Flora

AEROBES	ANAEROBES
<i>Staphylococcus aureus</i>	<i>Peptostreptococcus</i> sp.
<i>Coagulase-negative Staphylococcus</i>	<i>Peptococcus</i> sp.
Group B streptococcus	<i>Bacteroides</i> sp.
<i>Streptococcus</i> sp.	<i>Fusobacterium</i> sp.
<i>Enterococcus faecalis</i>	<i>Prevotella bivia</i>
<i>Lactobacilli</i>	<i>Prevotella disiens</i>
<i>Corynebacterium</i> sp. <i>Escherichia coli</i> <i>Klebsiella</i> sp. <i>Gardnerella vaginalis</i>	<i>Bacteroides fragilis</i> group

RISK FACTORS FOR INFECTION

Several factors alter the infectious risk morbidity of postoperative patients ([Table 11.2](#)). Many of these risk factors may be modified by the surgeon. Appropriate use of perioperative antibiotic prophylaxis, including administration within 1 hour of incision, significantly reduces infection risk. Blood glucose control in diabetes and reduction of immunosuppressive medications may decrease risk. Avoidance of hair removal at the surgical site, especially shaving, by the patient or operative team may significantly reduce risk. Skin preparation with chlorhexidine/alcohol or other appropriate antiseptic also reduces postoperative infection rate. Strict adherence to hand hygiene by health care personnel in the preoperative, perioperative, and postoperative period may also play a significant role in SSI risk.

When a hysterectomy is performed through an infected operative site, there is an increased risk of postoperative infection. Likewise, contamination of the operative field by break in sterile technique or injury to the bowel promotes infection. Duration of surgery is considered to be a risk for infection in most studies, but this actually may reflect experience of the operating surgeon, complexity of the case, or inadequate hemostasis. Lack of adequate hemostasis increases the risk of undrained collections of blood and creates an ideal culture medium for contaminating bacteria. Low hemoglobin and hematocrit levels, preoperatively or postoperatively, have been mentioned as factors in increased rates of postoperative infection, especially of abdominal incisions. No data, however, have indicated that raising the volume of red blood cells decreases the rate of infection. Leaving an

excessive amount of devitalized tissue (e.g., large, ligated pedicles) and failure to close dead spaces can predispose to a greater risk of infection. Pedicles should be trim and dry, dead space should be closed, and hemostasis obtained. Lysis of adhesions may increase the risk of infection if a bowel injury occurs.

TABLE 11.2 Risk Factors for Postoperative Infection

Altered immunocompetence
Premenopausal age
Obesity
Radical surgery
Bacterial vaginosis
Prolonged preoperative hospitalization
Excessive intraoperative blood loss
Hematoma or serous fluid collection
Operator inexperience/surgical skill
Lower socioeconomic status
Prolonged operative time
Poor nutrition
Excessive devitalized (necrotic) tissue
Foreign bodies
Diabetes mellitus
Systemic disease
Failure to use prophylactic antibiotics correctly
Shaving of the operative site
Inadequate skin preparation
Surgery in an infected operative site

The use of a vaginal cuff drain has been shown to have a significant beneficial effect on decreasing morbidity but has fallen out of favor because of the simplicity and effectiveness of antibiotic prophylaxis.

Bacterial vaginosis, characterized by increased vaginal concentrations of certain anaerobic and facultative bacteria, has been shown to increase the relative risk of postoperative infection in gynecologic procedures. The presence of increased concentrations of pathogenic bacteria adjacent to the site of incision in the vagina allows for ascending spread of these organisms in a susceptible host. Although treatment of bacterial vaginosis in pregnant women may decrease their risk of preterm delivery and preterm, premature rupture of membranes, no studies have shown a decreased rate of postoperative infection in bacterial vaginosis-positive women treated before gynecologic surgery.

ETIOLOGY

All women have bacteria colonizing the vagina in greater or lesser numbers. Women without symptoms have a mean of 4.2 species present. It is these same bacteria normally existing in a symbiotic relationship that ultimately can invade tissue altered by surgery, leading to clinical infection. The virulence of the bacteria and the volume inoculated are countered by the host's immune defense mechanisms and may be aided by prophylactic antibiotics to combat the occurrence of infection.

The bacteria listed in Table 11.3, which are responsible for postoperative infection after gynecologic surgery, are the same organisms that can be recovered from vaginal cultures of women before hysterectomy, according to Hemsell. The volume of bacteria present and their proximity to the operative site promote a polymicrobial infection in women who experience posthysterectomy infectious morbidity. Aerobic bacteria may initiate the infectious process; as tissue is devitalized and the oxidation reduction potential is altered, anaerobes proliferate and add to the tissue damage. Large, necrotic tissue pedicles and undrained collections of blood are ideal sites for infection to occur. Once the infection has begun, the body's host immune defense mechanisms initiate an inflammatory response, and attempt to wall off and localize the infection. Infected hematomas and abscesses can result when this occurs.

CATEGORIES OF INFECTION

Not all women who have temperature elevation after gynecologic surgery are infected, and not all of those who are infected have the same clinical syndrome. It is important to categorize the infectious process because treatment can vary accordingly.

TABLE 11.3 Pathogens Responsible for Infections After Gynecologic Surgery

Cuff Cellulitis

Cuff cellulitis is an infection of the surgical margin in the upper vagina where the uterus was removed. Symptoms and signs of infection usually begin late in the hospital course or even after discharge from the hospital. These patients' immediate postoperative course may have been completely benign. There is always an element of induration, erythema, and edema in the vaginal cuff immediately after hysterectomy. If the patient becomes infected, she will often have initial symptoms of lower abdominal pain, pelvic pain, back pain, fever, and abnormal vaginal discharge. Examination may reveal persistent hyperemia, induration, and tenderness of the vaginal cuff, and possibly purulent discharge along with fever. The parametrial and adnexal areas are nontender. The white blood cell count usually is mildly to moderately elevated.

Gram-positive aerobes, facultative gram-negative aerobes, and obligate anaerobes can all contribute to the cause of cuff cellulitis. Single- or multiple-agent broad-spectrum antibiotic coverage is effective in treating this infection, although single agents usually are preferred to reduce costs and the likelihood of an allergic reaction.

Infected Vaginal Cuff Hematoma or Cuff Abscess

Hysterectomy can result in small amounts of oozing from vascular pedicles or along the vaginal cuff. This bleeding may result in a walled-off collection of blood called a hematoma. If this localized mass above the vaginal cuff becomes infected, an abscess may result. Bacteria, especially anaerobes, flourish in this environment.

Women with a vaginal cuff abscess present with fever that is usually early in the postoperative period. Other symptoms include chills, pelvic pain, and rectal pressure. Clinical findings include temperature elevation; lower abdominal and vaginal cuff tenderness; the presence of a tender, fluctuant mass near the cuff; and, occasionally, purulent drainage from the cuff. The pain and tenderness is often more predominant on one side.

An infected cuff hematoma actually can present later in the postoperative course than an abscess and usually is associated with a drop in the hemoglobin and hematocrit levels. The hematoma may not be readily palpable but can be delineated on pelvic ultrasound or computed tomographic (CT) scan.

Postoperative Ovarian Abscess

The patient who develops fever and abdominal and pelvic pain late in the postoperative hospital course or after hospital discharge may have a pelvic abscess, possibly of ovarian origin. If there is a sudden increase in abdominal or pelvic pain, a rupture may have occurred. A ruptured abscess should be managed as a surgical emergency, proceeding to a laparoscopy or a laparotomy with excision or drainage of the infected mass. The inciting site for an ovarian abscess is a place of recent follicle expulsion or a site of surgical trauma to an ovary in a premenopausal woman. Ovaries should not be aspirated or probed at the time of hysterectomy for fear that bacteria from the vagina may penetrate the ovary and initiate infection. Once again, anaerobes are the predominant bacteria in an ovarian abscess.

If an ovarian abscess is suspected, then a CT scan should be ordered. The CT scan not only identifies the size and location of the abscess but also allows for visualization and evaluation of the ureters, bladder, and colon. A pelvic ultrasound also may be useful to localize the abscess but does not provide the ancillary information. Many abscesses respond to broad-spectrum antibiotic therapy; but if a tender, fluctuant mass persists, drainage is necessary. A radiologic interventionist may be able to accomplish percutaneous drainage with a needle or catheter using CT or ultrasound guidance, or colpotomy drainage may be possible. For colpotomy drainage to be accomplished safely, the abscess must be fluctuant, fixed in the cul-de-sac, and dissecting the upper third of the rectovaginal septum. With either approach, a closed suction drain should be placed to ensure complete and continued evacuation during the next 2 to 3 days. Some abscesses are amenable to a laparoscopic approach with incision and drainage. Copious irrigation and suctioning are critical if this approach is chosen.

Septic Pelvic Thrombophlebitis

Septic pelvic thrombophlebitis (SPT) complicates gynecologic surgery in 0.1% to 0.5% of procedures. It is usually a diagnosis of exclusion, made when a postoperative patient with febrile morbidity does not respond to appropriate parenteral antibiotic therapy in the absence of an undrained abscess or infected hematoma. The development of SPT is enhanced by venous stasis (e.g., obesity, diabetes), vascular injury, or bacterial contamination of pelvic vessels.

Two forms of SPT have been described. The classic form is seen in association with abdominal surgery. This form occurs 2 to 4 days after surgery and is characterized by fever, tachycardia, gastrointestinal distress, unilateral abdominal pain, and, in 50% to 67% of cases, a palpable abdominal cord resulting from acute thrombus formation. The enigmatic form complicates parturition or pelvic surgery and is characterized by spiking temperatures despite clinical improvement on antibiotics; tachycardia during the temperature spikes; and small, diffusely scattered thrombi in small pelvic vessels. Pelvic findings are minimal in both forms. The diagnosis often may be confirmed by CT scan or magnetic resonance imaging (MRI).

P.180

The traditional mainstay of treatment for SPT is anticoagulation with heparin for 7 to 10 days. Some experts recommend changing antibiotics or extending coverage before heparin is considered. All patients should be treated with antibiotics effective against heparinase-producing *Bacteroides* sp. Longterm anticoagulation is not required unless septic pulmonary emboli have occurred. Lysis of fever may occur 24 to 48 hours after starting heparin, yet other cases may require much longer for complete resolution. Treatment should be continued until the patient is afebrile for 48 hours and clinically well.

Osteitis Pubis

Osteitis pubis rarely complicates gynecologic procedures adjacent to the symphysis pubis, such as retropubic urethral suspension, radical vulvectomy, or pelvic exenteration. Direct or contiguous seeding of the periosteum from pelvic bacteria results in a delayed-onset infection 6 to 8 weeks after the original procedure. Patients report pain and tenderness along the symphysis pubis, especially with ambulation. Low-grade fever, an elevated erythrocyte sedimentation rate, and a moderate leukocytosis have been reported, as well as positive cultures from blood or the

bone itself. Aggressive antibiotic therapy covering *Staphylococcus aureus* and facultative gram-negative bacilli is essential for adequate recovery. If the response is not adequate, surgical debridement of the pubis is necessary.

Wound Infection

Surgical wound infection is possible with any transabdominal gynecologic procedure, but especially with those that are contaminated. Extensive study of the epidemiology of wound infections resulted in a classification of operative wounds in relation to contamination and increasing risk of infection (Table 11.4). Because the vagina is entered during hysterectomy, even an uninfected hysterectomy is classified as a cleancontaminated operation. Fortunately, prophylactic antibiotics and minimally invasive, laparoscopic procedures have greatly reduced the risk of severe, surgical wound infections.

The Centers for Disease Control and Prevention (CDC) definitions of surgical wound infection were modified by Horan et al. This system divides infections into two major categories: (a) an organ/space surgical site infection (SSI) and (b) superficial and deep incision infection. An SSI may be in any anatomic area that was opened or manipulated during a surgical procedure other than the incision itself. This would include most of the infections that develop after hysterectomy. It must develop within 30 days of the procedure and be accompanied by one of the following: diagnosis by a surgeon or attending physician; an abscess or other evidence of infection identified during reoperation or by radiologic or histopathologic examination; aseptically obtained organ/space fluid or tissue, the culture of which resulted in bacterial isolates; or purulent drainage from a drain placed through a stab wound into the organ/space.

Wound Cellulitis

Abdominal wound infections are categorized by their location and severity. The least severe are localized to the skin and adipose tissue above the fascia. Wound cellulitis is characterized by erythema, warmth, swelling, and tenderness. If there is no purulent drainage, antibiotic therapy alone with a cephalosporin or augmented penicillin often is effective. *S. aureus*, coagulase-negative staphylococci, and streptococci cause most of these infections. If wound cellulitis fails to improve, the possibility of resistant organism infection, such as MRSA, or occult abscess should be considered.

TABLE 11.4 Classification of Operative Wounds in Relation to Contamination and Increasing Risk of Infection

Clean
Elective, primarily closed and undrained
Nontraumatic, uninfected
No inflammation encountered
No break in aseptic technique
Respiratory, alimentary, genitourinary tracts not entered
Clean-Contaminated
Alimentary, respiratory, or genitourinary tract entered under controlled conditions and without unusual contamination
Appendectomy
Vagina entered

Genitourinary tract entered in absence of culture-positive urine
Minor break in technique
Mechanical drainage

Contaminated

Open, fresh traumatic wounds
Gross spillage from gastrointestinal tract
Entrance of genitourinary tract in presence of infected urine
Major break in technique
Incisions in which acute nonpurulent inflammation is present

Dirty or Infected

Traumatic wound with retained devitalized tissue, foreign bodies, fecal contamination, or delayed treatment, or wounds from a dirty source

Perforated viscus encountered
Acute bacterial inflammation with pus encountered during operation

Source: Altemeier WA, Burke JF, Pruitt BA, et al. *Manual on control of infection in surgical patients*, 2nd ed. Philadelphia: JB Lippincott, 1984:28, with permission.

Wound Seroma

A collection of serous fluid beneath the skin surface is a seroma. A small amount of serous drainage may be managed with limited opening of the incision, drainage, and cleansing. Larger collections may require more extensive incision and drainage. Antibiotic therapy is not necessary with an uninfected seroma. If a seroma intermittently or continuously leaks, it may become infected and require antibiotic therapy.

Deep Wound Infection

When purulent drainage is noted, the wound should be opened widely to allow drainage and removal of necrotic tissue. The incision should be probed gently to evaluate fascial integrity. If the fascia is intact, healing is hastened by mechanical debridement followed by loose, wet-to-dry packing with gauze moistened with saline; dilute hydrogen peroxide (1:1 mixture with saline) or Dakin's solution, 0.5%. Povidone-iodine is to be discouraged because it does not promote the development of granulation tissue. An antibiotic effective against anaerobes such as piperacillin-tazobactam, metronidazole, or a carbapenem must be used.

P.181

Evisceration of bowel may occur if the infection involves the fascia. This is a surgical emergency requiring identification of the defect, freshening of the fascial edges, placement of intra-abdominal and subcutaneous closed suction drains, and reinforced closure of the fascia. Some surgeons leave the skin open for delayed closure; others close it primarily.

Necrotizing Fasciitis

This severe complication results from synergistic bacterial infection of the fascia, subcutaneous tissue, and skin. This rapidly progressive infection is initially characterized by pain and toxicity out of proportion to physical findings with subsequent development with cutaneous necrosis and hemorrhagic bullae. Perineal necrotizing fasciitis is commonly caused by group A, beta-hemolytic streptococci, but may be a polymicrobial, synergistic infection with anaerobic bacteria or *Clostridium perfringens*. Methicillin-resistant *Staphylococcus aureus* has been increasingly

identified as a causative agent, and empiric IV antibiotics may be needed to cover this organism, pending culture data. Diabetes, alcoholism, and immunocompromise all represent significant risk factors for development of necrotizing fasciitis. Patients usually present with severe pain in the area of involvement; clinical signs of sepsis; and a viscous, cloudy, malodorous drainage. The wound edges may be purple or even necrotic. If gangrene occurs in the area of fasciitis, bullae of the skin and crepitus in the subcutaneous tissue may occur. Necrotizing fasciitis carries a high mortality potential and may be initially difficult to recognize. Therefore, a high index of suspicion must be maintained. Although C/T and MRI scans may be of benefit in the diagnosis of necrotizing fasciitis, aggressive surgical intervention/exploration and antibiotic therapy with activity against beta-hemolytic streptococci, anaerobes, enteric gram-negative bacilli, and MRSA should be initiated.

Urinary Tract Infection

Infection of the lower urinary tract is a frequent complication of gynecologic surgery. The patient may have low-grade fever, dysuria, frequency, and urgency, but in many situations has no symptoms. The criterion for defining a UTI is more than 100,000 colonies/mL of a single pathogen from clean-catch urine and more than 10,000 colonies/mL from a catheterized specimen. Appropriate sterile technique for insertion and management of indwelling catheters is important in preventing UTI. In general, urethral catheters should be removed as soon as possible after surgery unless the surgery has involved the bladder itself. Attachment of the urethral catheter to the leg with a locking device lowers UTI risk by preventing pistoning that leads to secondary urethral trauma. Treatment of a documented UTI should be with an appropriate oral or parenteral antibiotic. Although quinolone antibiotic previously provided antibiotic activity against most urinary pathogens, increasing quinolone resistance has limited quinolone efficacy. Alternate antibiotic choices include trimethoprim/sulfamethoxazole, amoxicillin/clavulanic acid, and cefpodoxime. Some *Escherichia coli* strains with quinolone, trimethoprim-sulfamethoxazole, and amoxicillin/clavulanic acid resistance are still sensitive to cefpodoxime. Some *E. coli* strains are now so highly resistant that only carbapenem therapy is effective.

Bacteremia

Infection of the bloodstream can complicate any pelvic infection but is seen more frequently in association with abscesses, peritonitis, and SPT. Antibiotics effective against the isolated organism should be used. Duration of therapy for gram-negative bacteremia should be 7 to 14 days. Parenteral antibiotics should be used initially but may be converted to oral if improvement has occurred and the patient has been afebrile for 24 to 48 hours. Antibiotic duration for *S. aureus* bacteremia should be 2 to 6 weeks of parenteral antibiotics due to the frequency of metastatic infection with serious sequelae, including endocarditis. Infectious disease consultation should be considered for *S. aureus* bacteremia or fungemia due to the high risk of serious secondary complications. Therapeutic intervention for bacteremia/fungemia includes identification and eradication of the source.

Drug Fever

This diagnosis should be considered when appropriate parenteral antibiotics have been used, and there are no localizing signs of infection, normal or low WBC, eosinophilia, rash, elevated liver enzymes, no undrained fluid collection, and no evidence of SPT. Fevers associated with medications may be unusually high, in some cases greater than 105°F. Medications that are more common causes of drug fever, such as antibiotics, metoclopramide, anti-convulsants, antipsychotics, and allopurinol, should be discontinued.

EVALUATION OF THE PATIENT WITH SUSPECTED INFECTION

Fever is the most common sign of postoperative infection, but it is important to remember that fever is not always caused by infection in the postoperative patient ([Table 11.5](#)). In a large study of 537 women who underwent major gynecologic surgery, Fanning et al. found that 39% developed postoperative fever, but only 17 patients (8%) actually had a documented infection. Other signs and symptoms of postoperative infection can include erythema, induration, and/or tenderness around the incision, drain, or intravenous infusion site; leg pain; tenderness or swelling;

costovertebral angle (CVA) tenderness; cough; or dysuria. When any of these or other signs or symptoms alerts the surgeon to the possibility of a postoperative

infection, an appropriate workup is indicated. A diagnosis of infection should be made or at least a high probability of infection should be present before antibiotics are started.

History

Careful history taking often can be the source of helpful clues to the cause of postoperative infection. The time of onset of the complicating infection is important. Ledger emphasized that the interval between surgery and the onset of fever is helpful in determining the cause of infection. For example, Garibaldi and colleagues suggested that most cases of early postoperative fever are not infectious in origin. Possible noninfectious causes include pulmonary atelectasis, hypersensitivity reactions to antibiotics or anesthetics, pyrogenic reactions to tissue trauma, or hematoma formation. Infectious causes of early postoperative fever include aspiration pneumonia, group A α -hemolytic streptococcal wound infection, or surgery in a previously infected site (e.g., pelvic inflammatory disease or recent D&C or cone biopsy). Other important aspects of history include the surgical procedures performed (e.g.,

abdominal versus vaginal approach, whether ovaries were invaded), risk factors encountered (pelvic abscess, bowel injury), use of antibiotic prophylaxis, symptoms, and whether the patient had any ancillary illnesses (smoking history, history of cardiac valvular disease, immunosuppression).

Physical Examination

Gynecologic surgeons tend to focus on the pelvis as the source of all postoperative infections. Instead, a comprehensive evaluation of the entire patient should be carried out. The upper respiratory tract should be examined to rule out otitis, pharyngitis, and bronchitis and the lower respiratory tract to rule out pneumonia. The gastrointestinal tract should be checked to evaluate bowel function, distention, and tenderness. Breast examination is usually only important in postpartum patients. The urinary tract should be evaluated, and the possibility of pyelonephritis must be considered. Intravenous access, especially central lines or other indwelling foreign bodies, should be carefully inspected and palpated for evidence of infection. The surgical wound must be examined carefully, and if the site of infection has not been identified or symptoms suggest a pelvic infection, a pelvic examination should be carried out. The pelvic examination should evaluate the vaginal cuff for discharge, erythema, and induration. Palpation for tenderness and for masses should be done and cultures obtained if pus is identified.

Laboratory and Imaging Evaluation

In recent years, it has become clear that a routine postoperative “fever workup”—including a variety of studies, such as a complete blood count, urine analysis, chest x-ray, and multiple cultures—is largely unrewarding in identifying the site of postoperative infections. A careful history and physical examination are the best guides to which laboratory tests, if any, are indicated. In a retrospective review of 257 patients who underwent major gynecologic surgery, Lyon et al. found that a urine culture was positive in only 9% of the patients who were cultured and less than 2% of all febrile patients. Fewer chest x-rays were ordered, and they were almost always negative, with only 1.5% of all febrile patients having a significant finding. Similar results were described by Fanning et al., who also noted that none of the 77 blood cultures in their series of 211 febrile postoperative patients was positive.

In a follow-up study, Schwandt et al. outlined a protocol for evaluating postoperative gynecologic patients as follows: (a) record temperatures every 4 hours; (b) for temperatures greater than 38°C (100.4°F), evaluate the patient by history and physical examination; (c) when no significant signs or symptoms are identified, order no tests, and observe the patient. Antibiotics are not started at this point. The authors felt that this protocol of selectively ordering lab tests to evaluate a postoperative fever did not compromise patient care and saved considerable resources. Similar findings also have been reported in a retrospective review by McNally et al.

Although current practice discourages the use of “routine” testing to evaluate a postoperative fever, the clinician must be sensitive to special circumstances, unusual signs or symptoms, or persistent fever or other warning signs. Special circumstances could include a patient who was at high risk for infection because of immunosuppression, gross bacterial contamination at surgery, infection already present before surgery, or a patient in such a frail or unstable condition that any postoperative infection could be fatal. Unusual signs or symptoms, which include evidence of necrotizing fasciitis or gasforming organisms and, most common of all, persistence of fever or other signs or symptoms of infection, definitely warrant a more exhaustive evaluation and, in most cases, prompt aggressive therapy.

A complete blood count with differential usually is indicated, and electrolytes, renal function tests, and liver-associated tests may be useful if sepsis is anticipated, prior damage to these organs exists, and/or antibiotics excreted or metabolized by these organs may be used. Acute pancreatitis can be ruled out by a normal serum amylase and lipase.

Blood cultures are not always indicated. In patients who will receive parenteral antibiotics, those with high fever, with persistent fever despite antibiotics, or who are immunocompromised, they should be drawn. This is particularly true when patients have indwelling central lines for longer than a few days, especially if these lines have been used for several functions (blood transfusions, antibiotics, electrolytes, etc.), and/or the patient had bacteremia that could

seed the tip of the line. In these cases, at least one culture should be taken through the central line catheter. Other cultures of pus from an abdominal incision, the vaginal cuff, an undrained collection, or a drainage tube occasionally may be helpful in a patient who is not responding to antibiotics or in whom an unusual infection (*Actinomyces*) is suspected. Asputum Gram stain and culture is rarely useful but should be considered in a symptomatic, immunosuppressed patient who could have tuberculosis, coccidioidomycosis, or some other atypical pneumonia.

A number of different imaging techniques may be useful in special circumstances. A CT scan of the abdomen/pelvis should identify an abscess; allow evaluation of ureteral and bowel function; and provide information about pulmonary status. In many cases, CT-guided percutaneous catheter drainage in combination with intravenous antibiotics is the treatment of choice. Renal function always should be satisfactory before administering intravenous contrast for a CT or intravenous pyelogram. Ultrasound can be used to scan the abdominal incision and pelvis for an abscess or hematoma. Ultrasound of the heart can diagnose valvular vegetations associated with bacterial endocarditis. It also is useful for evaluation of the leg veins for venous thrombosis. Pelvic or abdominal vein thrombosis can be diagnosed easily in most cases using CT scanning. Radioactive-tagged white blood cell scans can be useful for localizing occult infections, but these have largely been replaced by CT scans.

TREATMENT

The following factors must be considered when making antibiotic choices for the treatment of postoperative infections.

1. Pelvic infections are polymicrobial in etiology.
2. The most frequent causative organisms are aerobic, grampositive cocci (*Streptococci* and *S. aureus*), facultative gramnegative rods (*E. coli*, *Klebsiella* sp., *Enterobacter* sp.), anaerobic cocci (peptostreptococci), and anaerobic rods (*Prevotella* sp., *Bacteroides* sp., *B. fragilis*).
3. Enterococci may occasionally cause sepsis or be a sole isolate but usually accompany other bacteria and are not principal pathogens.
4. The choice of an antibiotic is made empirically before culture results are available.
5. The timing of onset of the infection may be an indicator of a pathogen group.
6. Resistance to frequently used antibiotics is developing.
7. Single agents may be as effective as multiple agents in treating postoperative infections.

The polymicrobial nature of postoperative pelvic infections results in about 20% aerobic gram-positive cocci, 20% gramnegative rods, and 60% anaerobes. Infections that occur in the first 24 hours after surgery usually are caused by gram-positive cocci or occasionally by facultative gram-negative rods. Infections that occur after the first 48 hours more frequently have an anaerobic component often in association with facultative, gram negatives. The effect of timing should be considered in making the initial choice of an antibiotic because an extended-spectrum penicillin or cephalosporin may be the best choice in early-onset infections ([Table 11.6](#)).

The gold standard for treating gynecologic postoperative infections has been gentamicin, 2 mg/kg loading dose, followed by 1.5 mg/kg maintenance dose for patients with normal renal function, plus clindamycin, 900 mg, both administered parenterally every 8 hours. Unfortunately, increasing resistance among anaerobes to clindamycin along with increasing *E. coli* resistance to gentamicin is altering the effectiveness of this regimen. Gentamicin carries potential for nephrotoxicity and ototoxicity, although these are both rare when used for short-term therapy in young, healthy women. Aminoglycoside serum levels should be obtained if the treatment is expected to last more than 72 hours. The addition of ampicillin to the previous combination extends the spectrum of coverage to include many, but not all, enterococci.

Metronidazole has excellent activity against anaerobic bacilli but has minimal activity against anaerobic gram-positive cocci. Metronidazole in combination with levofloxacin has been frequently used as combination therapy;

however, gramnegative resistance to quinolones makes this a less attractive option. The oral absorption of metronidazole is superb, resulting in blood levels that are equivalent to parenteral administration. Metronidazole is only effective against anaerobes and has minimal to no aerobic spectrum.

Investigators have studied various extended-spectrum penicillins and cephalosporins as single agents for the treatment of mild to moderately severe postoperative pelvic infections. These agents have an extended spectrum of in vitro antibacterial activity and β -lactamase stability. Single agents—such as cefoxitin, cefotetan, cefuroxime, ampicillin/sulbactam, and piperacillin/tazobactam—avoid the problems of admixture with multiple agents and the potential for aminoglycoside toxicity. If resistant gram-negative organisms are expected due to prolonged hospitalization or prior antibiotic therapy, a carbapenem antibiotic such as, meropenem, would be a reasonable empiric choice pending culture data. The increasing incidence of resistant organisms elevates the importance of obtaining a deep wound or abscess culture prior to starting antibiotics.

TABLE 11.6 Treatment Choices for Gynecologic Infection

POSTOPERATIVE INFECTION	RECOMMENDED REGIMEN	FAILURES	PENICILLIN ALLERGY
Mild to moderate	Extended-spectrum penicillin or cephalosporin (e.g., piperacillin/tazobactam, 4.5 g/6 h; [this dose goes with pip/tazo] ticarcillin/clavulanic acid, 3.1 g/4-6 h; metronidazole 500 mg/6 h and levofloxacin 500 mg/d ceftriaxone, 2 g followed by 1 g/24 h; cefoxitin, 2 g/6 h; cefotetan 2 g/12 h; cefotaxime, 1 g/8 h [IV doses]).	Clindamycin/gentamicin or metronidazole/gentamicin	Clindamycin/gentamicin
Severe	Metronidazole/gentamicin or clindamycin/gentamicin (e.g., metronidazole, 500 mg/6 h or clindamycin, 900 mg/8 h plus gentamicin, 2 mg/kg followed by 1.5 mg/kg/8 h or a single daily dose of 5 mg/kg [ampicillin, penicillin, or vancomycin may be added to cover enterococci]).	Add ampicillin to clindamycin/gentamicin; imipenem or meropenem	Clindamycin/gentamicin
Pelvic abscess	Meropenem 500 mg-l	Evaluate need for	NA

	g/IV q8h; clindamycin/gentamicin; metronidazole/gentamicin	surgical drainage	
Septic pelvic thrombophlebitis	Meropenem 500 mg-l g/IV q8h; or metronidazole plus heparin		NA
NA, not applicable.			

P.184

If a superficial wound abscess is identified on exam by palpation of fluctuance, a simple incision and drainage should be performed. In patients who have larger abscesses on CT scan (>3 to 4 cm), either surgical drainage or CT scan guided drainage should be considered. Parenteral antibiotics should be continued until the patient is afebrile and otherwise clinically improved for 24 to 48 hours. At that point, antibiotics may be converted to oral, and the patient may be discharged.

If there is not a good response to appropriate antibiotic therapy within 72 hours, the patient should be completely reevaluated. After another review of the history and physical examination, imaging studies should be considered. Perhaps a chest x-ray may indicate new consolidation or an abdominal and pelvic CT scan may identify a fluid collection or abscess, a retained foreign body, or even septic thrombophlebitis. If a fever persists, antibiotics may be discontinued, and the patient recultured/reevaluated before new antibiotics are started. SPT and necrotizing fascitis should be considered.

PREVENTION OF INFECTION

Tremendous potential morbidity and economic burden are imposed by perioperative infections. In a 5-year study of wound infections after abdominal hysterectomy, Kandula and Wenzel found that women with infections were hospitalized an average of 3.55 days longer, resulting in a significant financial impact. It is important to implement specific strategies aimed at preventing postoperative infection and to use these unfailingly with every patient. In doing so, a significant number of infections can be prevented. Identifying risk factors is important preoperatively and intraoperatively. Major risks are obesity, bacterial vaginosis, prior history of wound infection, radical surgery, uncontrolled diabetes, and excessive blood loss (>1,000 mL).

Some guidelines for infection prevention apply to all situations, and some are specific to certain types of infection. Meticulous hand washing before and after any patient contact is particularly important, but unfortunately has poor general compliance. Multiple prior studies have revealed only 40% to 50% physician compliance with hand washing. In our institution, hand hygiene compliance has dramatically improved over the course of the past 5 years through improved access to alcohol hand gels, intensive educational efforts, and use of anonymous observers with feedback to noncompliant medical personnel. Concurrent with an increase in hand hygiene compliance to over 90%, a significant decline in transmission of hospital-associated organisms (MRSA, vancomycin-resistant enterococci, and resistant gram-negative rods) has been documented.

The skin is colonized with bacteria, some of which are transient and reside on the integument for only a short time, and some of which are resident and are present continuously. One can effectively remove the transient microflora with routine hand washing with soap. Alcohol-based hand gels have a more protracted effect in reducing transient microflora, often up to 2 hours. The resident organisms require antimicrobial products for their inhibition of growth or elimination. Hand washing is a cornerstone for preventing the spread of infection ([Table 11.7](#)).

Prevention of Postoperative Pneumonia

All patients who undergo general endotracheal anesthesia are at risk for retention of pulmonary secretions, alveolar collapse, and, in turn, atelectasis and possibly pneumonia. Atelectasis is frequently a cause of immediate postoperative fever. To help prevent this complication, all patients undergoing surgery, and especially those with chronic obstructive airway disease, should be encouraged to discontinue or decrease smoking and have any upper respiratory infections assessed before operation. Postoperatively, coughing, deep breathing, and devices to encourage alveolar expansions should be used. Adequate analgesia to control pain that interferes with respiratory effort should be administered. Early ambulation should be encouraged.

TABLE 11.7 Recommendations for Hand Washing

In the absence of a true emergency, personnel should always wash their hands:

- Before performing invasive procedures (chlorhexidine gluconate 1% solution and ethyl alcohol 61% have been used to replace water-aided hand scrubs with soap in many institutions. We recommend that the initial scrub of the day be with traditional washing for 5 min).
- Uniformly when entering and exiting all patient rooms
- After situations during which microbial contamination of hands is likely to occur, particularly those involving contact with mucous membranes, blood, body fluids, secretions, or excretions. Gloves should be worn in this situation.
- After touching inanimate sources that are likely to be contaminated with virulent or epidemiologically important microorganisms
- After taking care of an infected patient or one who is likely to be colonized with microorganisms of special clinical or epidemiologic significance, such as multiple drug-resistant bacteria. Gloving should be uniformly worn in this situation with hand cleansing prior to placement of gloves and after removing gloves.

Prevention of Urinary Tract Infection

Urinary tract infections can complicate gynecologic surgery because of the proximity of the urethra to the operative site in the vagina. This effect is augmented by the placement of an indwelling urinary catheter. To limit UTIs, appropriate placement and management of catheters is essential. Personnel should be instructed in the proper sterile placement of catheters, maintained as a closed drainage system without traction on the device. Bladder catheters should be placed only when absolutely necessary, should be removed as soon as feasible, and should be maintained with correct fixation to the leg in order to avoid a pistoning effect resulting in urethral trauma. Many of the minimally invasive procedures, including hysterectomy, in our institution have their catheters removed in the postoperative recovery room.

Prevention of Operative Site and Wound Infections

Other Considerations

Multiple studies have demonstrated that antibiotic prophylaxis significantly reduces infectious morbidity following both vaginal and abdominal hysterectomy. These results do not mean that the important surgical principles that have

been shown to reduce morbidity can be ignored, but the use of prophylactic antibiotics in many gynecologic surgical procedures has reduced the incidence of postoperative surgical site infections from 30% to 50% to about 15% in most series.

Theory of Antibiotic Prophylaxis

At the time of hysterectomy, vaginal or cervical bacteria are inoculated into the surgical site, and it is hypothesized that antibiotics in these tissues at this time augment host defense mechanisms to reduce the incidence of clinical infections. For antibiotic prophylaxis to work effectively, several important criteria must be fulfilled. First, the operative procedure must have a significant risk of bacterial contamination and, in the absence of prophylactic antibiotics, an appreciable incidence of operative site infection. Hysterectomy or other gynecologic procedures involving the cervix, vagina, or vulva all meet this criterion. Second, the prophylactic antibiotic administered should be effective against expected pathogens and have a low rate of side effects. Third, the antibiotic should not be one that would be routinely used therapeutically. Although many antibiotic regimens have proven effective in prospective, randomized trials for gynecologic surgery, the first- and second-generation cephalosporins have emerged as the generally recommended antibiotics because of their effectiveness, low incidence of side effects, and low cost. Finally, for effective antibiotics prophylaxis, the tissue levels of the chosen antibiotic need to be optimal at the time bacterial contamination of the surgical site occurs. This means that the antibiotic needs to be administered shortly before the start of surgery, usually at the time the patient is brought into the operating room and anesthesia is induced.

Choice of Antibiotics for Prophylaxis

As noted, the antibiotic selected for a given procedure should be effective, have few side effects, be administered in a way that results in a minimal risk of antibiotic-resistant infections, and be inexpensive. In a meta-analysis of 25 prospective, randomized trials of prophylactic antibiotics for abdominal hysterectomy, Mittendorf et al. reported a reduction of serious postoperative infections from 21.1% to 9%. The most commonly used antibiotic for hysterectomy is cefazolin, because it meets the preceding criteria and has a relatively long half-life of 1.8 hours. Recommended prophylactic antibiotic regimens for various gynecologic procedures are listed in [Table 11.8](#).

Cephalosporins generally should not be given to patients with a history of penicillin anaphylaxis but may be given to patients with milder penicillin allergies. Metronidazole and clindamycin have been particularly effective when anaerobic contamination is anticipated in B-lactam-allergic patients.

In women with damaged or artificial heart valves or others at increased risk for bacterial endocarditis, combination antibiotics such as ampicillin (2 g) and gentamicin (1.5 mg/m²) are recommended. If the patient is allergic to penicillin, vancomycin (1 g over 1 to 2 hours) is substituted for ampicillin. Unlike prophylactic antibiotics given for operative site infections when only a single dose is administered, it is recommended that a second dose be given 6 hours later.

Adverse Reactions

Although reactions to cephalosporins may occur in 1% to 10% of patients, severe side effects such as anaphylaxis have been reported in only about 0.02% of patients. The majority of reactions are skin rashes and urticaria, which usually are resolved by the time the patient has recovered from anesthesia postoperatively. *Clostridium difficile*-related colitis was previously associated

with primarily beta-lactam antibiotics and clindamycin but is now being increasingly induced by quinolone antibiotics, particularly levofloxacin. A new, more potent strain of *C. difficile*, NAP-1, carries a significant morbidity and mortality potential.

TABLE 11.8 Antimicrobial Prophylactic Regimens by Procedure

Miller et al. identified *Clostridium difficile* as the most common hospital-associated infection, superseding MRSA. Although the induction of bacterial resistance to commonly used antibiotics has been a theoretical concern, this has not been a clinical problem when prophylactic antibiotic use is limited to one to three doses of early-generation cephalosporins. More potent broad-spectrum antibiotics should be reserved for specific indications and not used in a prophylactic setting to avoid induction of resistant organisms.

Surveillance for nosocomial infections must be carried out by the hospital infection control program so that surgeons are aware of their individual rates of postoperative infection. Several studies have shown that surgeon-specific wound infection rates can be reduced effectively by such reporting mechanisms.

The classic work of Cruse and Foord helped to delineate specific factors that influence wound infection rates. Others have added to this work so that preoperative and intraoperative management routines can be recommended even though they have not all been confirmed in controlled trials. Preoperative hospitalization should be limited as much as possible. Same-day admission is not just cost-effective for thirdparty payors; it makes good sense from an

infection control perspective. Hair removal should be avoided unless there is an abundance of hair at the operative site. Using a depilatory or clipping the hair is suggested if removal is necessary. Patients should be discouraged from shaving themselves at home before admission, since this results in microtrauma to the skin with a secondary increase in bacterial colonization and infection risk.

Because bowel entry is a major cause of contamination and subsequent wound or surgical site infection, great care should be given to a thorough inspection of the bowel intraoperatively whenever there has been a risk of injury. The use of a povidone-iodine douche or insertion of gel has been recommended for the night before admission or the day of surgery. Although this practice has been recommended for many years, and povidone-iodine solution and gel have been demonstrated to decrease vaginal bacterial counts to undetectable levels 10 minutes after application, the bacterial flora gradually return to approximately one half pretreatment levels in 2 hours. Appropriate preparation of the patient's skin in the operating room is essential to decreasing skin contaminants prior to an incision being made. The benefit of vaginal cleansing with an anti-infective agent the night before, or even immediately before surgery, has not been evaluated in a prospective, randomized trial.

Bacterial vaginosis has been found to be a risk factor for postoperative infection when present before surgery in women undergoing hysterectomy. In a prospective study of 175 women who underwent major gynecologic surgery, Lin et al. found a 36% incidence of postoperative febrile morbidity in patients who had bacterial vaginosis preoperatively and only a 20% incidence of fever among the women who had a lactobacillus-predominant vaginal flora ($P = 0.045$). Although some data support the benefit of treating pregnant women with bacterial vaginosis to decrease the rates of preterm labor, premature rupture of the membranes, and intra-amniotic infection, no data have shown a beneficial effect of preoperative treatment of hysterectomy patients. In light of the obstetric data, some gynecologists recommend screening hysterectomy patients preoperatively and treating those who are infected with metronidazole because anaerobes play such a significant role in postoperative gynecologic infections.

All gynecologists should employ careful hand-washing techniques or Avagard use preoperatively and when seeing patients. Appropriate gowns and eye coverings should be worn. Wearing double gloves is an effective way to decrease the chances of percutaneous injury. Careful surgical technique is essential to minimize postoperative infections. In cases where extensive adhesiolysis is carried out, careful inspection of the bowel should be done. Adequate hemostasis should be obtained whenever possible. The amount of dead space should be limited. Large areas of necrotic tissue should be excised, and vascular pedicles should be short. Closing the subcutaneous space has no benefit, and using suture there can actually increase the rate of superficial wound infection. If the case is dirty, consideration should be given to delayed wound closure. If drains are used, they should be closed suction drains, not gravity drains. Draining the subcutaneous space often is helpful in large patients to eliminate serous and bloody fluid.

UNIVERSAL PRECAUTIONS

The epidemics of acquired immunodeficiency syndrome and hepatitis B viral infection have brought to light the risks of lethal infection of the surgeon or other members of the operative team by blood or tissue fluids in association with surgery. Believing that all at-risk situations can be identified by history, physical examination, or laboratory data is naive and dangerous. To overcome this prevalent thought, universal blood and body fluid precautions were developed. This concept treats all patients' blood and certain other body fluids capable of transmitting blood-borne pathogens as potentially infectious. Universal precautions include the following requirements: (a) the use of gloves when touching blood and body fluids, mucous membranes, or broken skin, or when handling items or surfaces soiled with blood or body fluids; (b) the use of masks and eye protection during procedures that can generate splashing or droplets in the air; (c) the use of a gown or plastic apron if splashing of blood is anticipated; (d) careful hand washing if hands are contaminated with blood or body fluids; (e) extraordinary care in handling needles or other sharp objects, and proper disposal of sharp objects in puncture-resistant containers; (f) the availability of emergency resuscitation devices to minimize the need for emergency mouth-to-mouth resuscitation; and (g) the exclusion from patient care of personnel with exudative lesions or weeping dermatitis until these conditions are resolved.

Assuming that every patient is potentially infected, using specific protocols for the safe use of invasive procedures and taking steps to avoid any and all risk-taking behavior by medical personnel can help to prevent nosocomial infections.

Multiple studies have shown that double gloving significantly reduces the risk of blood contamination to the surgeon and other members of the operative team. In a large study from Finland, Laine and Aarnio reported a 7.4% glove perforation rate for single gloves in 1,020 surgeon uses. When double gloves were used, the inner glove was perforated in only 0.52% of 1,148 uses. Overall, someone in the surgical team had a glove perforation during 18.9% of the operative procedures, and the literature quotes rates of up to 61% in orthopedics and trauma surgery. The most common site of perforation is the index finger of the left hand of the surgeon; but all members of the team are at risk, and gloves can be torn in clamps or retractors as well as punctured by needlestick injuries. Manufacturing defects in the gloves themselves are uncommon but do occur and may go unnoticed until blood is seen on the finger or hand. Although double gloving does reduce dexterity and tactile sensation, it also reduces the potential for blood contamination almost 10-fold. It is a good general practice and always should be used in high-risk situations.

P.187

BEST SURGICAL PRACTICE

- Major risk factors for postoperative infection include immunocompromise, obesity, bacterial vaginosis, prolonged surgery, radical surgery, and excessive blood loss (>1,000 mL).
- Prophylactic antibiotics have been shown to reduce infectious morbidity for most major gynecologic surgery, including hysterectomy. For antibiotic prophylaxis to work effectively, several important criteria must be fulfilled: (a) the operative procedure must have a significant risk of bacterial contamination; (b) the prophylactic antibiotic administered should be effective against expected pathogens and have a low rate of side effects; (c) the antibiotic should not be one that would be routinely used therapeutically; and (d) the tissue levels of the antibiotic need to be optimal at the time surgery occurs.
- Infections that occur in the first 24 hours after surgery usually are caused by gram-positive cocci or occasionally by facultative gram-negative rods. Infections that occur after the first 48 hours more frequently have an anaerobic component. Pelvic infections are polymicrobial in etiology: 20% aerobic gram-positive cocci, 20% gram-negative rods, and 60% anaerobes.
- Rather than routine “fever workup” for postoperative fever evaluation, a careful history and physical examination are the best guides to which laboratory tests, if any, are indicated. Possible noninfectious causes of early postoperative fever include pulmonary atelectasis, hypersensitivity reactions to antibiotics or anesthetics, pyrogenic reactions to tissue trauma, or hematoma formation.
- In order to manage deep wound infection, the incision should be probed gently to evaluate fascial integrity. If the fascia is intact, healing is hastened by mechanical debridement followed by loose, wet-to-dry packing with gauze moistened with saline; dilute hydrogen peroxide (1:1 mixture with saline) or Dakin solution, 0.5%. Povidone-iodine is to be discouraged because it does not promote the development of granulation tissue.
- Careful hand-washing technique is critical to reduction in postoperative infections.
- Evisceration of bowel may occur if a postoperative wound infection involves the fascia. This is a surgical emergency requiring identification of the defect, freshening of the fascial edges, placement of intra-abdominal and subcutaneous closed suction drains, and reinforced closure of the fascia. Some surgeons leave the skin open for delayed closure; others close it primarily.
- The use of universal precautions to minimize the risk of the surgeon, surgical team, or health care worker acquiring a potentially fatal human immunodeficiency or hepatitis B viral infection from the patient is strongly encouraged. Although high-risk patients may be identified, all patients pose a potential risk to the surgeon.

Chapter 12

Shock in the Gynecologic Patient

Addison K. May

DEFINITIONS

Categories of the etiologies of shock—

- Hypovolemic
 - Blood loss, dehydration, and diarrhea
- Distributive
 - Sepsis, endocrine, spinal, and anaphylaxis
- Obstructive
 - PE, tamponade, pericarditis, and pulmonary hypertension
- Cardiogenic
 - MI, myopathy, and valvular lesions

Classification of the severity of hemorrhagic shock—

- Class I—up to 15% of blood volume
Compensation maintains normal cardiac output and blood pressure
- Class II—15% to 30% of blood volume
Compensation cannot maintain normal cardiac output, but systolic blood pressure is maintained; pulse pressure is narrowed (compensated shock)
- Class III—30% to 40% of blood volume
Cardiac output and blood pressure are decreased; significant tachycardia (uncompensated shock)
- Class IV—greater than 40% blood loss
Cardiac output and blood pressure are profoundly decreased; very significant tachycardia

P.189

Compensated shock—A state of global, inadequate organ perfusion, and oxygen delivery with normal blood pressure.

Cytopathic hypoxia—A state of mitochondrial injury and dysfunction resulting from hypoxia and oxidative stress where oxidative phosphorylation is interrupted, thus mandating ATP generation through lactate generation.

Sepsis—The presence of SIRS due to an infectious etiology.

Septic shock—Sepsis advanced to the point of distributive shock.

Severe sepsis—When sepsis has progressed to a severity to manifest organ dysfunction such as delirium, acute lung injury, or acute kidney injury.

Severe SIRS—When SIRS has progressed to a severity to manifest organ dysfunction such as delirium, acute lung injury, or acute kidney injury.

Severe SIRS with shock—SIRS advanced to the point of distributive shock.

Shock—A state of global inadequate organ perfusion and oxygen delivery.

Systemic inflammatory response syndrome (SIRS)—Global activation of the inflammatory cascade, by a variety of stimuli, manifest by two or more of the following:

- Hyper- or hypothermia ($>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$)
- Tachycardia (heart rate >90)
- Increased minute ventilation (respiratory rate >20)
- Leukocytosis or leukopenia (WBC $> 12,000$ or $<4,000$, or $>10\%$ bands)

Shock is defined as a state of global inadequate organ perfusion and may arise from a variety of diverse etiologies. Regardless of the etiology, the shock state will contribute to oxidative stress, cellular injury, and systemic activation of the inflammatory cascade (SIRS) and potentiate or lead to multisystem organ dysfunction syndrome (MODS). Both uncompensated and compensated shock will contribute to cellular changes that potentiate the severity of shock itself. An understanding of the physiologic derangements introduced by shock as well as the therapeutic interventions to mitigate the various etiologies of shock is required to optimally manage patients with this condition. In the chapter to follow, the etiologies, the physiologic cellular and organ derangements caused by the shock state, the interaction with the inflammation and organ injury, and the therapeutic interventions to target each are discussed.

DEFINITION AND ETIOLOGIES OF SHOCK

Shock is defined as a state of systemic or global inadequate organ perfusion and may be caused by a variety of insults. Most commonly, shock is recognized by hypotension, defining *uncompensated shock*. However, inadequate organ perfusion can occur with relatively normal vital signs, as occurs in *compensated shock*. Recognition that shock may exist without significant alterations in hemodynamics is critical to minimizing cellular and organ injury that may be introduced by occult hypoperfusion.

The various etiologies of shock are most frequently classified into four different categories based upon the underlying pathophysiologic alteration: hypovolemic, cardiogenic, obstructive, and distributive. Common causes of *hypovolemic shock* include hemorrhage, dehydration, and diarrheal diseases. *Cardiogenic shock* may be caused by an acute myocardial infarction, valvular lesions, and myopathies induced by ischemia, viral diseases, and inflammatory conditions. Causes of *obstructive shock* include tension pneumothorax, cardiac tamponade, constrictive pericarditis, acute pulmonary embolism, and severe pulmonary hypertension. The various causes of *distributive shock* include sepsis, spinal cord injury with neurogenic shock, adrenal insufficiency, vasopressin deficiency, anaphylaxis, and ischemia/reperfusion. Distributive shock physiologically differs from the other three classifications of shock in that a decline in cardiac output is not universally present. In fact, due to the decrease in systemic vascular resistance, cardiac output is frequently increased unless an underlying cardiac dysfunction also exists.

Appropriate therapeutic interventions for the treatment of shock should be directed toward the underlying pathophysiologic defect, which varies between and within classifications. While shock may be induced by a single etiology, recognizing that multiple etiologies may coexist and that one type of shock may cause or exacerbate a second is crucial to decisions regarding appropriate therapy. Changes induced by shock and the interdependence that may exist are outlined below.

PHYSIOLOGIC RESPONSE

Response to Decreased Cardiac Output

The predominant response to decreased cardiac output is to preserve perfusion to the heart and brain. This

acute physiologic response is best characterized and understood in the context of hemorrhagic shock. Additionally, compensated shock is most easily understood in acute hemorrhagic shock, although inadequate organ perfusion with normal hemodynamics clearly exists in other forms of shock.

Acute hemorrhagic shock may be classified into four classes ([Table 12.1](#)). In *class I* shock, less than 15% of blood volume (approximately 750 mL in a 70 kg individual) has been lost. At this degree of blood loss, an increase in cardiac contractility and heart rate can maintain cardiac output and thus organ perfusion. In *class II* hemorrhagic shock, 15% to 30% of blood volume (approximately up to 1,500 mL in a 70-kg individual) has been lost. At this magnitude of blood loss, the acute compensatory mechanisms of increased heart rate and contractility can no longer maintain cardiac output. To maintain perfusion pressure, vasoconstriction of peripheral and mesenteric vascular beds increases resistance to blood flow, maintaining systolic blood pressure and increasing diastolic pressure (narrowed pulse pressure). While systolic blood pressure is preserved, cardiac output and delivery are decreased. This is the state of *compensated shock*. *Class III* hemorrhagic shock is defined as blood loss at 30% to 40% (approximately >1,500 mL in a 70-kg individual) of total body blood volume. At this degree of blood loss, cardiac output is severely altered and vasoconstriction can no longer maintain systolic pressure. Thus, perfusion pressure of the brain and heart are both now altered. Mental status changes and obvious signs of shock ensue. *Class IV* hemorrhagic shock is defined as greater than 40% of blood volume. At this degree of shock, profound hypotension, tachycardia, and severely depressed level of consciousness are manifested.

TABLE 12.1 Hemorrhagic Shock: Estimated Blood Loss^a Based on Patient's Initial Presentation

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (mL)	<750	750-1,500	1,500-2,000	>2,000
Blood loss (% blood volume)	≤15%	15%-30%	30%-40%	≥40%
Pulse rate	<100	100-120	120-140	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased
Capillary refill	Normal	Delayed	Delayed	Delayed
Respiratory rate	14-20	20-30	30-40	>35
Urine output (mL/h)	>30	20-30	5-15	Negligible
CNS/mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic

Fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood
^a Estimate based upon a 70-kg male.				

It is important to recognize that greater than roughly 1,500 mL of blood in a 70-kg individual must be lost before compensatory mechanisms are overwhelmed and hypotension develops. Significant blood loss with associated hypoperfusion of vital organs may exist prior to the development of hypotension. Inadequate organ perfusion induces cellular insult, as outlined below, regardless of blood pressure and must be recognized and treated.

Cellular Biochemical Changes

Shock, or inadequate perfusion, creates hypoxia of the cells involved, which results in anaerobic rather than aerobic metabolism for cellular functions. This period of anaerobic metabolism produces “hypoxic priming” within the affected cells, characterized by a marked reduction in adenosine triphosphate (ATP) generation by the cell, an increase in oxidative stress, loss of antioxidant potential, and a buildup of acidic by-products, including lactic acid. The decrease in ATP production within hypoxic cells leads to a cascade of events including decreased ion exchange by the sodium-potassium adenosine triphosphatase pumps (Na⁺/K⁺-ATPase), calcium (Ca²⁺), cellular swelling, Ca²⁺ activation of phospholipases with activation of the arachidonic acid cascade, and generation of fatty acid reactive oxidant species. Additionally, cellular hypoxia leads to the ischemic generation of *xanthine oxidase* by irreversible proteolytic cleavage of xanthine dehydrogenase, the enzyme that normally catalyzes the metabolism of hypoxanthine (product of ATP utilization) to xanthine and subsequently uric acid via the generation of NADH from NAD⁺.

Reperfusion of cells following a period of hypoxic priming induces further oxidant injury and activation of the inflammatory cascade through several mechanisms. The xanthine oxidase enzyme, generated during hypoxia, catalyzes the conversion of hypoxanthine and oxygen to xanthine and subsequently uric acid and generating the oxidative species, superoxide (O₂⁻). Additionally, hypoxia followed by reperfusion induces increased activity of nitric oxide synthetase and enhanced production of nitric oxide (NO), another oxidative species. NO and O₂⁻ interact to form yet another oxidative species, peroxynitrite (ONOO). These oxidative species generated by hypoxia and reperfusion directly injure mitochondria, proteins, chromosomes, and membrane structures. In severe shock states, oxidative stress can be greatly potentiated by cellular mitochondrial injury, a condition known as *cytopathic hypoxia*. Oxidative species, such as ONOO, can oxidize the components of the electron transport chain and open pores in the mitochondrial membrane, both contributing to mitochondrial dysfunction and loss of aerobic metabolism by the affected cells. The loss of mitochondrial function mandates anaerobic metabolic pathways by the affected cells, an ongoing reduction of ATP generation, thus further potentiating oxidative stress. The oxidative cellular injury introduced by shock potentiates oxidative injury produced by tissue trauma, infection, and sepsis as shown in **Figure 12.1**.

Global hypoxia and reperfusion directly activates the proinflammatory nuclear transcription factor NF-κB with increased production of cytokines (TNF, IL-1, IL-6, IL-8), chemokines, coagulation factors, adhesion molecules, and activation of tissue macrophages and neutrophils. The shock state also directly activates the innate immune system through the release of a variety of substances (referred to as “damage-associated molecular patterns” or DAMPs) that are recognized by tolllike receptors (particularly TLR4) expressed on endothelial cells, neutrophils, and tissue macrophages. Systemic activation of macrophages and neutrophils results in direct tissue damage and still further cellular oxidant injury. As in the case oxidant generation, activation of the proinflammatory state

and the innate immune system by shock potentiates the activation of the inflammatory cascade caused by other insults such as tissue trauma, infection, and sepsis.

Shock and SIRS

The persistence of the shock state creates a nonlinear increase in oxidative injury and activation of the inflammatory cascade and innate immune system. Increasing severity and persistence of shock will produce systemic inflammatory response syndrome (SIRS) and organ dysfunction, culminating in MODS.

P.191

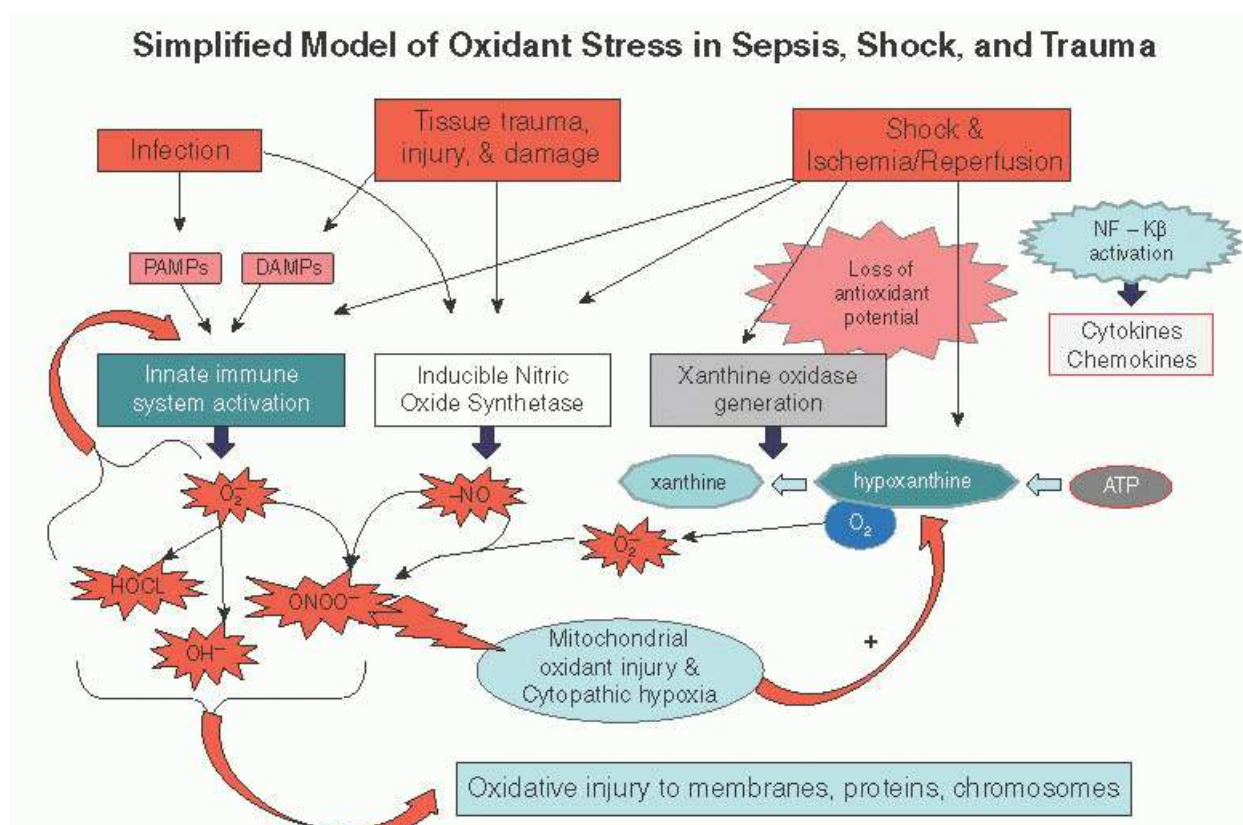

FIGURE 12.1 This simplified model of oxidant stress in sepsis, shock, and trauma demonstrates the overlapping nature of oxidant generation from these insults. Infection, tissue injury, and ischemia/reperfusion injury all activate the innate immune system via the molecular patterns recognized by toll-like receptors on immune cells which in turn produce several oxidative species. Additionally, nitric oxide production is up-regulated. Shock and ischemia/reperfusion injury may also irreversibly cleave xanthine dehydrogenase to xanthine oxidase, increasing the production of oxidant stress. Finally, significant cellular oxidative stress can induce mitochondrial injury and cytopathic hypoxia. PAMPs, pathogen-associated molecular patterns, DAMPs, damage-associated molecular patterns. Oxidative species: HOCl, hypochlorous acid; $O_2^{\cdot -}$, superoxide; NO, nitric oxide; OH^{\cdot} , hydroxide; $ONOO^{\cdot -}$, peroxynitrite.

Additionally, shock also creates and enhances vasodilation resulting in distributive shock. SIRS can result from or be exacerbated by shock. Activation of the inflammatory cascade and the subsequent proinflammatory state outlined above produces physiologic changes in temperature (hyperthermia, temperature $> 38^{\circ}\text{C}$ or less commonly hypothermia, temperature $< 36^{\circ}\text{C}$), heart rate (tachycardia HR > 90), minute ventilation (respiratory rate > 20), and changes in white blood cell count (leukocytosis WBC $> 12,000$, bandemia $> 10\%$ bands, or less commonly leukopenia WBC $< 4,000$), with two or more of these changes defining *SIRS*. As the severity of this process progresses, organ dysfunction will be manifest, thus defining *severe SIRS*. The presence of SIRS and severe SIRS in which the etiology is infectious defines *sepsis* and *severe sepsis*, respectively. In critically ill patients, SIRS and sepsis are very common, occurring in roughly 75% to 80% of this population. However, SIRS

is significantly more common than is sepsis, a fact that should be considered when making decisions regarding empiric antibiotics in response to fever and leukocytosis.

Vasodilation

During shock, vascular smooth muscle function is altered leading to vasodilation. Vascular smooth muscle function is directly altered by a loss of ATP production, decreased cytoplasmic calcium and decreased phosphorylation of myosin, decreasing smooth muscle contraction. The resulting vasodilation is propagated by the up-regulation of nitric oxide synthetase and subsequently increased nitric oxide production, resulting in even greater vascular smooth muscle relaxation. As a result, systemic vascular resistance falls and distributive (or vasodilatory) shock develops. Thus, a distributive shock state may develop secondary to other forms of shock. The vasodilated state may persist for days and may require prolonged vasoconstrictive agents to ensure adequate mean arterial pressure (MAP) to ensure tissue perfusion. Increasing severity and length of hypoperfusion increases the magnitude of this series of events. Thus, hypovolemic, obstructive, and cardiogenic shock may all initiate a state of distributive or vasodilatory shock following resuscitation. After correction of the original underlying physiologic defect (e.g., hemorrhagic shock), subsequent therapy may be required to correct the vasodilatory component rather than continuing pure volume replacement.

Additionally, tissue hypoxia and sepsis both may lead to defects in the production of *vasopressin* by the hypothalamus and *cortisol* by the adrenal glands. Additionally, the use of etomidate as an induction agent for endotracheal intubation is commonly associated with a period of adrenal insufficiency. Deficiencies of either vasopressin or cortisol will produce vasodilation and distributive shock that is refractory to inotropic support. These deficiencies will coexist with the distributive shock resulting from nitric oxide-induced vasodilation and may complicate management of other forms of shock.

Coagulopathy

While large volumes of blood loss may be sustained without the development of coagulopathy if normotension is maintained, coagulopathy develops at much a much smaller volume of blood loss if shock is present. Tissue hypoxia directly potentiates coagulopathy, and on-going shock will worsen derangements that are introduced by blood loss, hypothermia, and infection. Significant overlap of the coagulation system, the anticoagulant and fibrinolytic pathways, and the inflammatory system exists, and hypoperfusion and tissue hypoxia will potentiate alteration in both pro- and

P.192

anticoagulation arms of the coagulation system via multiple mechanisms. Hypoxia may directly alter the release of tissue factor, tissue plasminogen activator, and activation of protein C. These changes overlap and exacerbate those introduced by hemorrhage, hypothermia, and sepsis. Thus, during resuscitation and treatment of patients in shock, recognition that coagulopathy may develop during and be exacerbated by the shock state is important to minimize the chance of potentiation of bleeding and complications related to the derangements in the coagulation system.

Cardiac and Renal Dysfunction

In general, the physiologic response to decreasing perfusion or perfusion pressure is to preserve blood flow and pressure to the brain and the heart. As delivery becomes inadequate, organs that require consistently high levels of ATP production to maintain normal function become altered, specifically the heart and kidney. The alteration in cardiac and renal function following shock complicates the resuscitation of patients with shock, particularly if shock has been prolonged or severe.

Cardiac dysfunction following shock may be quite significant but unrecognized after resuscitation. Cardiac dysfunction may occur even in previously young, healthy individuals and is typically severe in patients who are

elderly or have underlying cardiac disease. At rest, the heart has the highest oxygen extraction ratio of all the organs. The increased heart rate that occurs as a consequence of shock greatly increases oxygen demand by the heart, while decreasing the diastolic perfusion time. In shock states, decreasing perfusion pressure and increasing demands coupled with increasing heart rate quickly create hypoxic conditions, necessitating anaerobic metabolism and a loss of ATP production. Sodium/potassium (Na/K) and sodium/calcium (Na/Ca) ATPase pumps become dysfunctional. Thus, cellular swelling, a loss of contractility, and a decrease in compliance of the heart develop. To achieve adequate filling of the ventricles postshock, higher central venous pressures (CVP) are required, and to achieve adequate contractility, inotropic agents may be necessary. Assessing adequacy of delivery by specific measures of perfusion such as trends in serum lactate, mixed venous or central venous oxygen saturation, and cardiac index or oxygen delivery may be necessary.

Renal function and renal concentrating ability may be significantly altered during periods of either compensated or uncompensated shock. To maintain normal function, the kidneys also require consistent ATP generation. The kidneys concentrate urine by maintaining concentration gradients within the renal medulla; under normal conditions, the renal medulla is relatively hypoxic. During limited perfusion, ATPase pumps cannot maintain adequate concentration gradients; upon reperfusion, urine output may be excessive and dilute. Thus, urine output by the kidney may be a measure of adequate perfusion following periods of shock.

Assessment of Organ Perfusion

The goal of therapeutic interventions for shock, regardless of etiology, is to restore adequate tissue perfusion in order to limit cellular and organ injury because sustained tissue hypoxia is one of the most important cofactors in the development of multiple organ injury. Tissue perfusion is dependent upon forward flow of oxygenated blood and adequate perfusion pressure. As noted in sections above, assessment of adequate organ perfusion during and after resuscitation may be complicated by (a) the presence of compensated shock, (b) changes in cardiac compliance and function, (c) alteration in renal function, and (d) the distributive shock that develops secondary to tissue hypoxia. Unfortunately, no single measure is adequately sensitive or specific in all settings to document adequacy of organ perfusion. Thus, an array of techniques may be required. A brief overview of commonly employed measures is provided below, outlining settings in which measures are adequate and inadequate.

The most commonly used measures of organ perfusion are the assessment hemodynamic parameters and organ function. Significant tachycardia, hypotension, low urine output, cool extremities to physical exam, and alteration in mental status all indicate inadequate perfusion absent conditions that specifically alter each individual measure. However, as noted above, significant limitations to organ perfusion may exist despite all of these being normal. In young, otherwise healthy patients without a period of significant shock, these parameters are most likely adequate, if normal. However, if a period of significant shock is suspected, these measures lose their value. Additionally, in geriatric patients suffering significant stress or insult, these measures are frequently inadequate.

One approach to assessing adequacy of perfusion is to assess the accumulation of by-products of inadequate perfusion through the assessment of either *serum lactate* or *base deficit* (BD). Cells with inadequate perfusion must undergo anaerobic metabolism to continue ATP production. By-products of anaerobic metabolism include the generation of lactic acid as well as the buildup of other acids generated by ATP metabolism and accumulation of acids used in the mitochondrial respiratory process that contribute to BD. While these two measures are similar, they have different characteristics and limitations. Additionally, while these measures may indicate inadequate perfusion, they do not indicate the physiologic defect or defects contributing to the tissue hypoxia such as hypovolemia, cardiac dysfunction, or distributive shock. Thus, they typically must be used in the context of additional information that provides assessment of the underlying defect.

BD can be a sensitive measure of hypoperfusion but, unfortunately, lacks specificity. BD is calculated by the

formula $BD = -[(HCO_3) - 24.8 + (16.2 \times (pH - 7.4))]$ and reflects the buildup of acids within the circulation. In the setting of inadequate tissue perfusion and hypoxia, numerous acids accumulate including lactic acid, by-products of ATP metabolism, and products used by the mitochondria. BD tends to change more rapidly than does serum lactate and may reflect hypoperfusion even when lactate is within normal limits. During pregnancy, recognition that maternal circulation is preserved over fetal circulation and that elevated BD or a decline in serum bicarbonate is important to ensure fetal perfusion. However, numerous therapeutic interventions may alter BD independent of adequacy of perfusion, including the choice of fluid provided to the patient (lactated ringers versus normal saline). Elevated BD predicts poor outcome in acutely injured patients, even in the setting of normal lactate. Thus, this measure can alert the practitioner to occult hypoperfusion but must be interpreted with caution, particularly after resuscitation has been initiated.

Serum lactate is a more specific measure of the adequacy of organ perfusion than is BD but does have significant limitations. Lactate is generated under conditions of anaerobic metabolism to allow ongoing glycolysis and generation of 2 ATP through the conversion of pyruvate by the lactate dehydrogenase enzyme and the generation of NAD from NADH. Serum lactate elevation and its persistence in sepsis and trauma strongly correlate with organ dysfunction and death.

P.193

Studies suggest that resuscitation efforts directed to normalize serum lactate improve outcome, but this remains inadequately studied. Lactate is effectively metabolized and cleared from the serum by the liver; thus, it only rises if hepatic clearance is exceeded and may rise relatively slowly. Metabolic processes that convert NAD to NADH, such as alcohol metabolism, limit the mitochondrial oxidative phosphorylation by consuming NAD and limiting pyruvates conversion to acetyl-CoA and entry into the tricarboxylic acid cycle (TCA or Krebs cycle). Additionally, epinephrine can directly elevate lactate. Other processes that confound the use of lactate as a marker of adequacy of perfusion include hepatic insufficiency and cytopathic hypoxia. In both cases, lactate may be elevated despite normal organ perfusion. In cytopathic hypoxia, the inability of the mitochondria to utilize oxygen mandates ongoing glycolysis and lactate generation.

Venous Oxygen Saturation

Another measure of adequacy of delivery and resuscitation is the use of venous oxygen saturation as a surrogate for the balance between systemic oxygen delivery (D_{O_2}), global oxygen consumption (V_{O_2}), and the fraction of delivered oxygen that is consumed (extraction ratio— ER_{O_2}) in critically ill patients. As oxygen consumption increases relative to delivery, the extraction ratio increases and is reflected as a decline in venous saturation. The most precise measurement of global venous saturation is the mixed venous oxygen saturation (SvO_2), reflecting venous blood from all portions of the body, including the coronary sinus. However, its measurement requires the placement of a pulmonary artery catheter. An alternative is the use of central venous oxygen saturation ($ScvO_2$) via a central line positioned in the superior vena cava or right atria. The two differ slightly, and some data suggest that they may not be interchangeable. The $ScvO_2$ may be up to 6% higher than SvO_2 , but trends in either appear to adequately reflect resuscitation. Generally, values of less than 70% for both measures reflect increased, compensatory extraction. Changes in SvO_2 and $ScvO_2$ occur rapidly; thus, venous saturation can be used as a real-time assessment of resuscitative efforts. The use of venous saturation as a guide to resuscitation in sepsis and other forms of shock has been shown to improve targeted resuscitation and outcomes and may outperform lactate in certain settings.

Limitations to venous saturation include its requiring invasive procedures for placement of either a pulmonary catheter or central line. Additionally, in patients with true shunts (e.g., patients with liver failure) and in patients who have developed cytopathic hypoxia, extraction oxygen extraction will be diminished and venous saturation

may be supranormal.

Assessments of Cardiac Filling and Function

Assessments of cardiac filling and cardiac output are both frequently used to guide resuscitation. To maintain adequate oxygen delivery to tissues, the heart must maintain adequate cardiac output. Output by the heart is determined by heart rate and stroke volume, and stroke volume is determined by filling and contractility. CVP, pulmonary artery pressure, and pulmonary wedge pressure, pulse pressure variation and pulse contour analysis, and ultrasound and echocardiography may all be used to estimate filling. The first three measures all provide an assessment of pressure and one must recognize that pressures do not directly assess volume. With changes in the compliance of the heart, as occurs during shock and resuscitation, the volume for a given pressure changes as well. This is very significant limitation of these values when used to assess adequacy of filling. Ultrasound and echocardiography may be used to provide an estimate of filling but may be technically difficult in many settings of critical illness.

Assessment of cardiac output and function may be determined by pulmonary artery catheter, pulse pressure variation and pulse contour analysis, and transesophageal echocardiography. However, each method has settings in which accuracy of these values may be limited. Additionally, knowledge of the cardiac output does not necessarily equate to adequate oxygen delivery. Tissue perfusion is dependent upon both delivery and perfusion pressure. Oxygen demand by tissues also is not static, and no specific cardiac output is indicative of adequate perfusion in all settings.

Other Assessments of Oxygen Delivery

Research to identify noninvasive measures that can detect occult tissue hypoxia and assure adequacy of resuscitation continues. Additional tools that have been or continue to be investigated include regional capnometry, near-infrared spectroscopy, and sidestream dark-field video microscopy. However, none have achieved widespread acceptance or use.

TREATMENT OF SHOCK

The treatment of shock should be directed toward correcting the underlying physiologic defect or defects that are contributing to inadequate organ perfusion, such as (a) hypovolemia, (b) vasodilatation, or (c) cardiac dysfunction. Both compensated (or occult) and uncompensated shock should be corrected expeditiously to prevent exacerbation of organ dysfunction and propagation of the derangements outlined above. Additionally, during pregnancy, care must be taken to ensure adequate fetal perfusion. While a single underlying insult, such as hemorrhage or infection, most frequently initiates the development of shock, understanding that the physiologic derangements introduced by severe shock frequently include more than one type of shock (i.e., hypovolemic, distributive, and cardiogenic components) is paramount to achieving the best outcome. These secondary components of shock develop as a result of tissue hypoxia; thus, aggressive correction of the underlying primary cause of the shock may fail to improve or even aggravate the other components of shock in the complex patient. The magnitude of each of the various components changes during the course of the illness and recognition of the dynamic nature of the process is important.

While the appropriate treatment of the underlying defect will improve the shock state, incorrectly treating the combination of physiologic defects may worsen hypoperfusion or contribute to other secondary problems such as abdominal compartment syndrome or acute volume overload. For example, treatment of patients with hypotension due to low cardiac output with vasoconstrictive agents will increase systemic vascular resistance, raising blood pressure, but actually decrease cardiac output and delivery. This circumstance may occur when either hemorrhagic shock or cardiogenic failure is treated with high-dose Levophed rather than appropriately treating with either blood products or medications to specifically improve inotropy.

Hemorrhagic Shock

The most common cause of shock in the obstetric and gynecologic patient is hemorrhage. In 2005, hemorrhagic shock was the third leading cause of maternal death due to obstetric factors in the United States. Significant advances in

P.194

our understanding of resuscitation of patients with severe hemorrhagic shock have been made in the past decade, predominately through the trauma literature. The expected signs and symptoms for the degree of shock is provided in [Table 12.1](#), as put forth in the ATLS guidelines. While patients with limited blood loss, class I and class II hemorrhagic shock, may respond to crystalloid resuscitation, patients with larger volume of hemorrhage will require blood and blood component therapy. Goals during the resuscitation of patients in hemorrhagic shock are to achieve replacement of adequate circulating volume while avoiding coagulopathy, hypothermia, progressive acidosis, and excessive crystalloid administration.

Patients with significant hemorrhagic shock may have alterations in their level of consciousness, and an assessment of the safety of their airway and ability to maintain oxygenation should be undertaken and an airway established as required. Two large bore IVs (18 gauge or larger) should be established to ensure the ability to provide crystalloid and blood products without limitation of flow and cell lysis by the catheter. Efforts should be made to maintain patient normothermia. These may include (a) warm fluids, (b) fluid warming devices, (c) heated ventilator circuits with temperature turned to 38°C to 40°C, (d) forced air warming devices, and (e) ambient room temperature set at 26.5°C to 29°C. While beyond the scope of this chapter, prompt intervention to control the source of hemorrhage is required while resuscitative efforts are continued.

As noted in [Table 12.1](#), patients with hemorrhage of up to 30% of their blood volume may be treated with crystalloid resuscitation without necessarily requiring blood products, assuming on-going hemorrhage has been controlled and preexisting ischemic cardiac disease is not present. Patients with blood loss greater than 30% will require blood and blood product administration. The approach to transfusion in a patient with hemorrhagic shock with ongoing blood loss should be different than in those patients with large volume blood loss without shock. Traditionally, resuscitation for hemorrhage has been centered on replacing circulating volume with crystalloid and packed red blood cells (PRBCs). In situations in which blood loss has been matched by fluid and blood replacement without limitations in blood flow (isovolemic blood loss), large volumes of blood may be administered without the development of coagulopathy, and administration of other blood products like fresh frozen plasma (FFP), cryoprecipitate, and platelets should be based upon abnormal laboratory analysis. However, as outlined above, the presence of shock and tissue hypoxia contributes to coagulopathy, and empiric treatment with other components may be indicated. Data predominately from civilian and military trauma literature support an approach in patients with massive hemorrhage which limits crystalloid resuscitation and provides replacement of blood products approximating a 1:1:1 ratio of PRBCs, FFP, and platelets. To achieve this, most centers have developed massive transfusion protocols (MTPs) to provide the correct ratios of products, once activated. An example of the MTP implemented at Vanderbilt University Medical Center is provided in [Figure 12.2](#). Absolute activation points are difficult to establish for all patients. The use of MTPs should be considered in patients with ongoing hemorrhage (or risk of ongoing hemorrhage) and hypotension (systolic blood pressure <90 mm Hg) after initial 2 U of PRBCs. The use of MTPs should be considered in a bleeding patient with severe acidosis, existing coagulopathy, thrombocytopenia, or hypothermia⁴⁴⁴. The use and timing of other products such as cryoprecipitate or recombinant factor VII remains controversial and variable in practice.

Distributive Shock

The most common cause of distributive shock in obstetric and gynecologic patients is sepsis although other etiologies should also be considered such as severe SIRS following ischemia/reperfusion, adrenal insufficiency,

vasopressin deficiency, and anaphylaxis. In all cases of distributive shock, the underlying problem is predominantly vasodilation with inadequate perfusion pressure. Thus, therapy should be directed predominantly to increasing vascular vasomotor tone. The therapeutic agents and approach to achieve appropriate vasoconstriction vary depending on the cause and are discussed below.

Sepsis and Septic Shock

Sepsis is a common problem and is one of the most common causes of critical illness in both obstetric and gynecologic surgery patient populations. The diagnosis of sepsis may be difficult to establish in critically ill patients with insults that may initiate the SIRS. Diagnostic criteria for sepsis, severe sepsis, and septic shock are outlined in [Tables 12.2](#) and [12.3](#). The treatment of *septic shock* involves three critical components: (a) source control, (b) appropriate empiric antibiotic therapy, and (c) restoration of cellular perfusion. While beyond the scope of this chapter, the importance of adequate *source control* cannot be overemphasized. Elimination of necrotic or infected tissues, elimination of infected fluid collections, elimination or control of enteric connections, and reduction of bacterial load are all components of adequate source control. A specific anatomical diagnosis for the source of infection should be sought, either establishing or excluding potential sources within the differential as soon as possible and interventions to establish control within 12 hours after the diagnosis of sepsis as possible. Critically ill patients with previous efforts to establish source control and with an appropriate course of antibiotic therapy who are not responding appropriately should be evaluated for failure of primary source control, typically with diagnostic imaging such as computed tomography.

Empiric Antibiotic Therapy

Timely and appropriate *empiric antibiotic therapy* is also critical in patients with septic shock. Significant observational data demonstrate that inadequate empiric antibiotic coverage (not active against all pathogens) significantly increases mortality, despite altering therapy when sensitivities return. Thus, broad empiric antibiotic coverage targeted to cover all likely pathogens should be initiated and then de-escalated once culture and sensitivity data are available. Additionally, antibiotics should be initiated as soon as sepsis and septic shock is suspected, ideally within 1 hour. In one large observational study of critically ill patients with septic shock, each 1 hour delay in antibiotic therapy from the onset of shock was associated with a 12% increase in mortality. Appropriate culture data should be obtained to allow de-escalation of therapy and the antibiotic regimen narrowed to the least number of agents required to appropriately treat the pathogens involved. As noted above, patients not responding to therapy in an appropriate manner should be evaluated for inadequate source control rather than simply extending antibiotic courses beyond 7 days.

Background: Protocolized transfusion has been shown to improve clinical outcomes as well as transfusion efficiency in patients who require massive transfusion (>10 U in 24 hours). This document provides guidelines for utilization of the massive transfusion protocol (MTP).

1. Patient selection
 - a. Patients with current, ongoing, or impending massive blood loss should be considered for activation of MTP.
 - b. Activation of massive transfusion protocol should be considered for patients who received greater than 2 u of blood in the emergency department (1).
2. Activation
 - a. MTP may be activated by the attending surgeon, intensivist or designated surrogate. If surrogate activates MTP, attending surgeon of record must be provided to blood bank (BB).
 - b. MTP may be activated by trauma/surgical cc faculty, fellows and instructors; anesthesiology faculty; and selected surgical faculty ONLY.
 - c. Upon suspicion of MTP activation, type and screen must be sent to BB as soon as possible.
 - d. To activate MTP, call BB at _____ and provide the following information
 - i. "This is Dr. _____ activating the MTP....."
 - ii. Patient name
 - iii. Patient MRN. This will be repeated by BB personnel for verification purposes.
 - iv. Patient age
 - v. Patient gender
 - vi. Current or intended location
3. Product breakdown
 - a. Each round of MTP provides 6U PRBC, 4U FFP, 1 dose pack of platelets Repeat rounds of MTP contain identical product "doses"
4. Administration
 - a. Products are delivered, and BB calls patient location to verify continuation of MTP. Default is to continue MTP until verbally discontinued by faculty physician.
 - b. MTP boxes are intended to be given in their entirety until completed. If not all products are desired, strong consideration should be given to MTP discontinuation.
5. Endpoints/termination
 - a. When appropriate endpoints are reached, the MTP must be discontinued to limit resource utilization.
 - b. Most reliable transfusion endpoint is a collaborative decision based on operative field examination, laboratory results, and clinical parameters.
 - c. Premature discontinuation of MTP should be avoided to minimize catch-up reactive transfusion.
6. Pitfalls, common errors
 - a. Failure to send type and screen.
 - i. T&S must be sent upon suspicion of MTP requirement.
 - b. Returning platelets on ice.
 - i. Cold temperature destroys platelets. Must be returned in cooler side pouch.
 - c. Failure to identify significant hemorrhage, delayed MTP activation.
 - i. Result in delayed activation, over activation is anticipated
 - d. Premature termination.
 - i. Consider continuing MTP until patient stabilizes in the ICU.
 - e. Failure to provide entire box/dose.
 - i. If not all products are required, d/c MTP and transfuse PRN.
 - ii. Collaborate with intensivist/anesthesiologist regarding transfusion plan.
 - f. Reliability on laboratory tests alone for transfusion indication.
 - i. Laboratory tests are unreliable in the hyperacute setting.
 - g. Inappropriate personnel activating MTP.
 - i. BB personnel are empowered to refuse MTP to callers who are not authorized to activate protocol.

FIGURE 12.2 Massive Transfusion Protocol.

TABLE 12.2 Diagnostic Criteria for Sepsis

Infection, documented or suspected, and some of the following:

General variables

Fever (>38.3°C)

Hypothermia (core temperature < 36°C)

Heart rate > 90/min⁻¹ or more than two SD above the normal value for age

Tachypnea

Altered mental status

Significant edema or positive fluid balance (>20 mL/kg over 24 h)

Hyperglycemia (plasma glucose > 140 mg/dL or 7.7 mmol/L) in the absence of diabetes

Inflammatory variables

Leukocytosis (WBC count > 12,000 μL^{-1})

Leukopenia (WBC count < 4,000 μL^{-1})

Normal WBC count with >10% immature forms

Plasma C-reactive protein more than two SD above the normal value

Plasma procalcitonin more than two SD above the normal value

Hemodynamic variables

Arterial hypotension (SBP < 90 mm Hg, MAP < 70 mm Hg, or an SBP decrease > 40 mm Hg in adults or <2 SD below normal for age)

Organ dysfunction variables

Arterial hypoxemia ($\text{PaO}_2/\text{FIO}_2 < 300$)

Acute oliguria (urine output < 0.5 mL/kg/h for at least 2 h despite adequate fluid resuscitation)

Creatinine increase > 0.5 mg/dL or 44.2 $\mu\text{mol/L}$

Coagulation abnormalities (INR > 1.5 or aPTT > 60 s)

Ileus (absent bowel sounds)

Thrombocytopenia (platelet count < 100,000 μL^{-1})

Hyperbilirubinemia (plasma total bilirubin > 4 mg/dL or 70 $\mu\text{mol/L}$)

Tissue perfusion variables

Hyperlactatemia (>1 mmol/L)

Decreased capillary refill or mottling

WBC, white blood cell; SBP, systolic blood pressure; MAP, mean arterial pressure; INR, international normalized ratio; aPTT, activated partial thromboplastin time.

Adapted from Dellinger RP, et al. Surviving sepsis campaign: international guidelines for management of severe sepsis and septic shock: 2012. *Crit Care Med* 2013;41:580-637. Copyright © 2013 by the Society of Critical Care Medicine and Lippincott Williams & Wilkins.

Restoration of Cellular Perfusion

The third critical component of the treatment of patients with septic shock is the *restoration of cellular perfusion*. Septic patients typically have both volume depletion and vasodilatory components to their shock. Additionally, some patients may also have altered cardiac function. Thus, a quantitative resuscitation managed by a specific protocol should be undertaken. As resuscitation precedes, an evaluation of volume status, blood pressure, organ function, and organ perfusion should be constantly monitored to assess the effectiveness of the resuscitation and provide indicators to adjust therapy. General recommended goals of resuscitation include the following:

TABLE 12.3 Severe Sepsis and Septic Shock

Severe sepsis definition = sepsis-induced tissue

hypoperfusion or organ dysfunction (any of the following thought to be due to the infection)

Urine output < 0.5 mL/kg/h for >2 h despite adequate fluid resuscitation

Acute lung injury with $\text{PaO}_2/\text{FIO}_2 < 250$ in the absence of pneumonia as infection source

Acute lung injury with $\text{PaO}_2/\text{FIO}_2 < 200$ in the presence of pneumonia as infection source

Creatinine > 2.0 mg/dL (176.8 $\mu\text{mol/L}$)

Bilirubin > 2 mg/dL (34.2 $\mu\text{mol/L}$)

Platelet count < 100,000 μL

Coagulopathy (international normalized ratio > 1.5)

Lactate above upper limits laboratory normal (tissue hypoperfusion)

Sepsis-induced hypotension (septic shock)

Adapted from Dellinger RP, et al. Surviving sepsis campaign: international guidelines for management of severe sepsis and septic shock: 2012. *Crit Care Med* 2013;41:580-637. Copyright © 2013 by the Society of Critical Care Medicine and Lippincott Williams & Wilkins.

- a. CVP of 8 to 12 mm Hg
- b. MAP of ≥ 65 mm Hg
- c. Urine output ≥ 0.5 mL/kg/h
- d. Normal assessment of tissue oxygenation
 - Central venous (superior vena cava) or mixed venous oxygen saturation of 70% or 65%, respectively
 - Normalization of serum lactate

Recognition that preexisting comorbidity or other clinical conditions may require an alteration of these end points is important to appropriately target resuscitation. For instance, during the third trimester of pregnancy, the normal values for the end points cited above are altered: CVP 4 to 10 mm Hg, MAP 84 to 96 mm Hg, mixed venous saturation >80%.

An example of an algorithm to direct resuscitation in patients with severe sepsis and septic shock is provided in **Figure 12.3**. Initial therapy is directed at replacing the volume deficits with crystalloid fluid resuscitation in a volume of up to 30 mL/kg. Additional crystalloid may be required based upon the analysis of volume status.

Additional fluid resuscitation should be based upon ongoing assessments of volume responsiveness; excessive crystalloid administration may worsen acute lung injury, edema, and increase the risk of abdominal compartment syndrome. Patients with large fluid requirements may benefit from provision of albumen. Patients with hypotension or hypoperfusion after adequate fluid resuscitation should have vasopressor therapy added. Norepinephrine is the first-line vasopressor of choice, demonstrating better return of splanchnic perfusion than do other agents. Patients with depressed cardiac function may require the addition of an inotropic agent to achieve adequate cardiac output. Epinephrine may be required in addition to or instead of norepinephrine. Alternative inotropic agents may be considered in combination with norepinephrine such as dobutamine or milrinone.

P.197

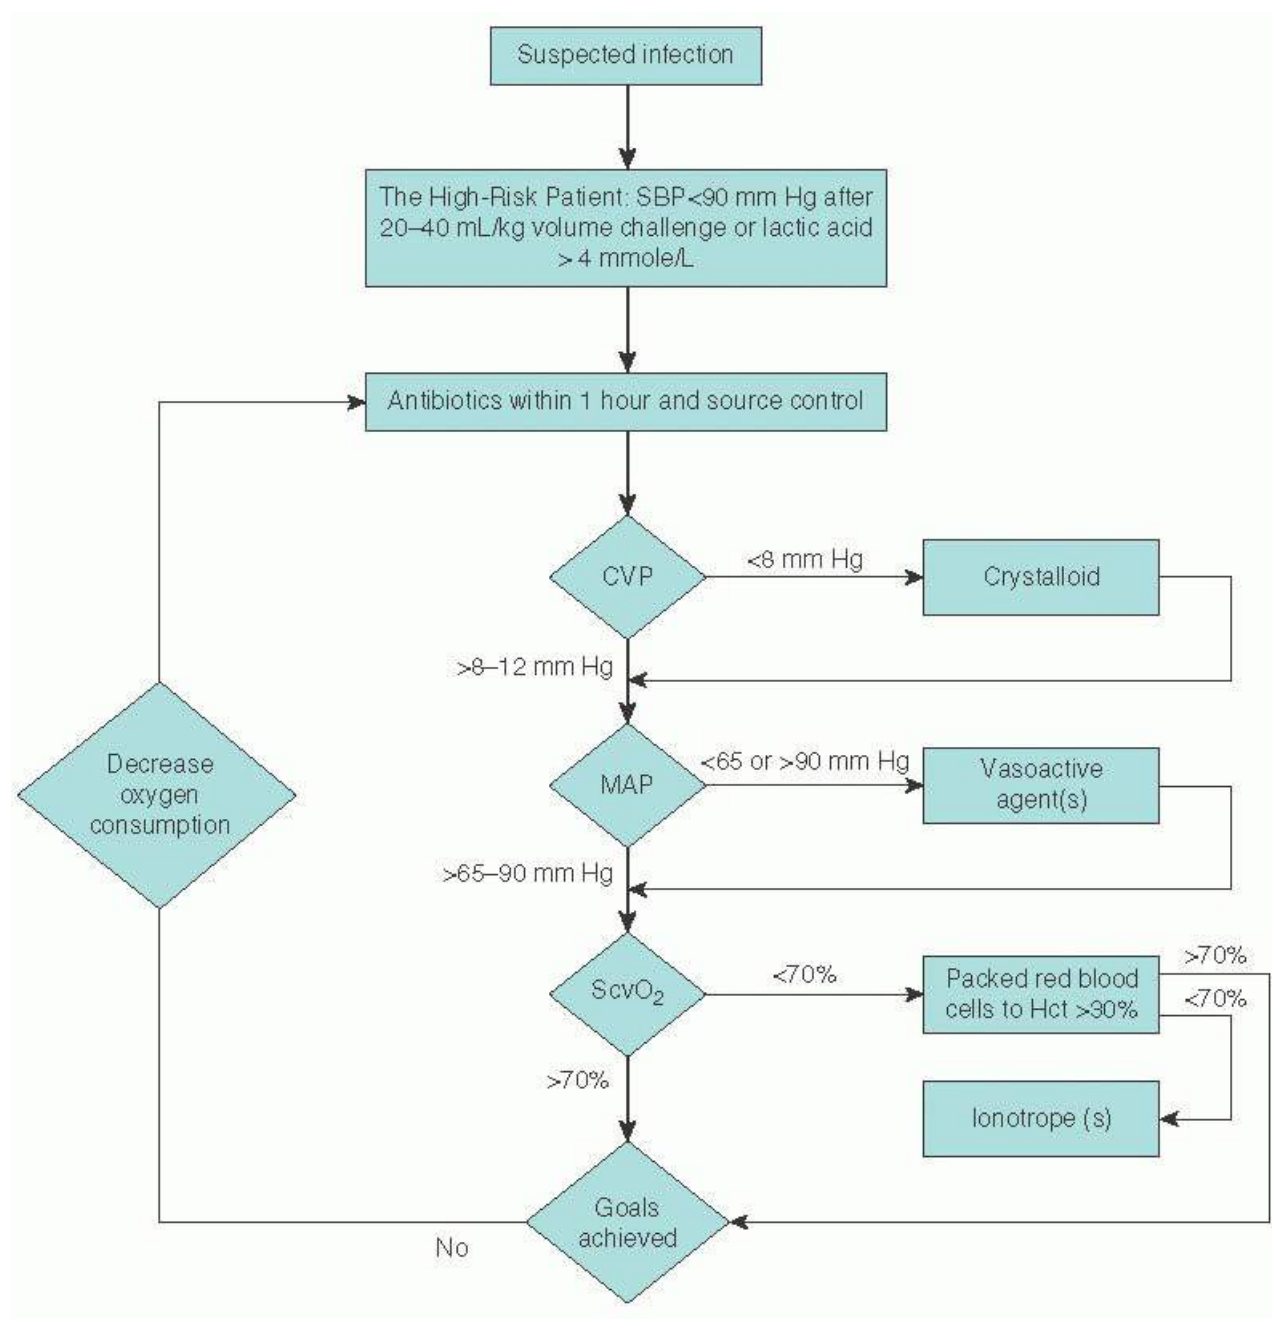

FIGURE 12.3 Algorithm for the goal-directed resuscitation of patients with severe sepsis and septic shock.

Vasopressin and Adrenal Insufficiency

Patients with severe sepsis and septic shock may develop distributive shock related to either vasopressin deficiency or adrenal insufficiency. Patients in whom blood pressure is poorly responsive to or requires high

doses of norepinephrine may be *vasopressin deficient*. The addition of a vasopressin infusion at 0.03 to 0.04 units/min may be initiated with responsiveness determined by a decline in norepinephrine requirements. Due to the pronounced vasoconstrictive effects of vasopressin, this agent should not be used as a first-line agent and the use of doses above the recommended range should only be used as salvage therapy. *Adrenal insufficiency* may also develop as a result of sepsis and be a cause of inadequate response to vasopressor therapy. An absolute value of serum hydrocortisone that indicates either adequate or inadequate production is not currently assessable. Thus, presumptive therapy of adrenal insufficiency is currently recommended in patients who appear unresponsive to vasopressor support. Recommended treatment is with hydrocortisone (50 mg every 6 hours) and tapered when vasoactive support is no longer needed and blood pressure is normal.

Other conditions may lead to either vasopressin or adrenal insufficiency. Tissue hypoxia and severe shock may contribute to both. Assessment of serum cortisol levels in these settings remains controversial as an absolute level of serum cortisol for a given state is difficult to establish.

SUMMARY

An understanding that compensated and uncompensated shock create a nonlinear increase in cellular and organ dysfunction is important for the practicing obstetrician and gynecologist. Persistent shock is a self-replicating process, and prompt, targeted therapy directed toward the appropriate contributing components is paramount. Early correction of cellular perfusion limits organ dysfunction and improves outcomes.

Chapter 13

Wound Healing, Suture Material, and Surgical Instrumentation

Gary H. Lipscomb

DEFINITIONS

Absorbable sutures—Sutures that lose the majority of their tensile strength before 60 days when implanted in body tissues.

Healing by primary intention—Wound healing that occurs if the wound layers are reapproximated following injury.

Healing by secondary intention—Wound healing that occurs if wounds are left open after injury and allowed to close spontaneously from the formation of granulation tissue.

Healing by third intention—Wound healing that occurs when the wound is closed after an initial period of delay of several days also referred to as *delayed primary closure*.

Knot-pull tensile strength—Breaking strength of a suture when tied around a plastic tube using a surgeon's flat knot and stressed from either end.

Nonabsorbable sutures—Sutures that maintain the majority of their tensile strength before 60 days when implanted in body tissues.

WOUND HEALING

Ideally, organic tissue lost by destruction or injury would be replaced with tissue identical in form and function. This process is known as *regeneration*. Although tissue regeneration does occur in lower animals (e.g., salamanders), humans have lost this ability for the most part. With the exception of the epidermis of the skin, mucosa of the intestinal tract, and liver, damaged human tissue heals by the laying down of collagen, a repair process better known as *scarring*. This process is responsible for emergently sealing the wound and ultimately providing longterm structural support for the injured organ but is unable to reproduce other functions of the replaced tissue. As a result, the healing process also leads to disease if an organ becomes unable to function properly owing to extensive replacement of functioning tissue by nonfunctioning scar. Heart failure following a massive myocardial infarction is an example. In other cases, the healing process itself directly produces disease (e.g., postoperative adhesion formation following surgical procedures or tubal occlusion after pelvic inflammatory disease).

Physiology of Wound Healing

The healing of a wound involves several distinct biologic processes: (a) inflammation, (b) epithelialization, (c) fibroplasia, (d) wound contraction, and (e) scar maturation. Although considered distinct, these processes do not occur in a strict sequence but often occur simultaneously with each other. These repair mechanisms are also nonspecific. They are activated whether a wound is made with a surgical scalpel and sutured closed or by trauma and then allowed to heal without surgical closure. However, the nature of the wound influences the degree to which each individual process is involved, and this in turn can affect the ultimate success of the repair.

Inflammation

The inflammatory phase of healing is the initial response to any injury involving more than an epithelial surface. This phase can be divided into two separate but simultaneously occurring responses: a vascular and a cellular

response. Both are initiated by amines, most notably histamine, as well as the kinins and proteolytic enzymes released by the injured tissue. Immediately after injury, a transient vasoconstriction of the local vasculature lasts for 5 to 10 minutes. Vasoconstriction is followed by vasodilatation and an increase in vascular permeability. Edema caused by the escape of plasma through altered vessel walls becomes clinically apparent at this point.

The cellular response is characterized by the migration of leukocytes into the injured area. Although the agents responsible for this active migration of leukocytes remain unclear, chemotactic factors are thought to play a major role. Initially, the polymorphonuclear leukocytes and monocytes in the wound are present in the same concentration as in the systemic circulation. As a result, polymorphonuclear leukocytes predominate for the first 3 days. Because polymorphonuclear leukocytes are relatively short-lived compared with monocytes, the latter stages of the inflammatory phase are characterized by a predominance of monocytes that transform into macrophages. These leukocytes actively phagocytize bacteria, foreign proteins, and necrotic debris. As polymorphonuclear leukocytes die, their intracellular enzymes and debris are released into the wound and become part of the wound exudate. These released enzymes also facilitate the breakdown of material not phagocytized by the leukocytes. This accumulated exudate or pus develops even in the absence of bacteria. Even when this exudate is sterile, the presence of proteolytic enzymes, including collagenase, can interfere with epithelialization and fibroplasia and, thus, interfere with continued wound healing. Poor wound healing, however, is more common in wounds contaminated with bacteria and foreign material. In these cases, the inflammatory response may persist for long periods of time.

Epithelialization

By virtue of their exposed location, the epithelial surfaces of the gastrointestinal, urogenital, and respiratory tract as well as the skin itself are continually subjected to the physical and chemical trauma associated with the activities of daily living. As a result, these surfaces are constantly replacing damaged or destroyed cells through a process known as *epithelialization*. Epithelialization occurs by migration and subsequent maturation of immature epithelial cells from the deeper basal layers of surrounding areas. If the cellular damage is confined entirely to the epithelium, the healing response is merely an exaggerated form of the basic normal replacement process.

If an injury involves the supporting connective tissue beneath the epithelium, however, the other components of the healing processes, in addition to epithelialization, become involved. If the injury severs blood vessels, the vessels retract, and the process of hemostasis is initiated. If bleeding is not too severe, a blood clot soon forms. This clot subsequently contracts, dehydrates, and becomes a scab. Within 12 hours, basal cells from the surrounding epithelial surfaces begin migrating onto the injured surface. Epithelial cells move beneath the scab, detaching it from the wound and sealing the surface. In incised and sutured wounds, epithelialization generally produces a watertight seal within 24 hours of injury. This new layer of epithelial cells is initially thin and poorly attached to the underlying surface, rendering it susceptible to injury from even minor trauma. Final epithelial healing is accomplished by differentiation and maturation of the migrated cells and by scar formation through fibroplasia.

P.200

Fibroplasia

The process by which wounds regain strength is termed *fibro-plasia*. Fibroplasia results in the production of the collagen necessary to form a fibrous scar and ultimately determines the final strength of the healed wound. This process begins with the differentiation of mesenchymal cells into fibroblasts. Fibroblasts then migrate into the wound, apparently along fibrin strands produced during clot formation. Once at the injury site, fibroblasts proliferate and manufacture the glycoproteins and mucopolysaccharides that make up the ground substance of connective tissue. Ground substance is an amorphous matrix that is believed to induce aggregation of collagen

subunits and influences the final orientation of the fibers.

Once the ground substance is produced, fibroblasts begin to synthesize the basic building block of collagen-tropocollagen. Tropocollagen is a stiff elongated macromolecule of three helically intertwined chains of amino acids consisting of two identical $\alpha 1$ chains and one $\alpha 2$ chain. Within the ground substance and at the proper pH, osmolality, and temperature, tropocollagen molecules polymerize into collagen fibrils by forming covalent bonds with their neighbor. These fibrils bond with other fibrils to form collagen bundles. It is not until 4 to 5 days after injury that the wound produces enough collagen to result in a measurable increase in wound tensile strength. Before this time, the wound is held together only by fibrous adhesion. This time frame between wounding and an increase in tensile strength originally was referred to by Howes and Harvey as the “lag period” of wound healing.

Wound Contraction

The manner in which tissue heals is dependent on whether tissue integrity is simply interrupted (as in a surgical incision) or tissue is removed (as in an avulsion injury). In both types of injury, tissue seals itself, begins to reepithelialize, and synthesizes collagen for structural support. However, when large amounts of tissue are missing, the edges of the wound must be brought closer together so that the previously noted tissue responses can repair the defect. This process is known as *contraction*. Contraction of wound margins begins about 5 days after injury and corresponds with the fibroplasia phase of healing. Because this process can be inhibited by cytochrome poisons, such as potassium cyanide, and by smooth muscle relaxants, older theories attributing wound contraction to passive collagen changes have been discarded. Instead, wound contraction appears to be an active process produced by contractile proteins within the fibroblasts. If the area is too large for contraction to bring the edges together, the wound remains covered with granulation tissue, or if small enough, it is covered with epithelium only. Epithelialization of such a wound prevents weeping, but without the normal underlying supporting stroma, it remains too fragile to provide lasting protection. Pathologic progression of skin contraction ultimately may result in restriction of joint or limb mobility. This deformity is termed *contracture* and should not be confused with contraction.

Scar Maturation

The bulky scar formed during the fibroplasia phase consists of randomly oriented soluble collagen fibers. This scar has little tensile strength. During scar maturation, the disordered fibers are replaced with fibers arranged in a more orderly fashion, producing a denser and stronger scar. Collagen fibers also continue to form covalent bonds within fibrils as well as between adjacent fibrils and fibers, resulting in a continued increase in wound tensile strength over time. This maturation process may continue for years.

During scar maturation and remodeling, the breakdown of old disordered collagen slightly exceeds production of new organized collagen fibers. The resulting new scar is softer and less bulky than is the original scar but also is stronger because of its more organized and extensively cross-linked nature. However, if collagen production exceeds breakdown, then a keloid or hypertrophied scar results.

Surgical Wound Healing

Depending on the manner of wound closure, three types of surgical wound healing are recognized: primary, secondary, and third intention. **Figure 13.1** illustrates these types of wound healing.

FIGURE 13.1 Types of wound healing.

P.201

Primary Intention

Healing occurs by primary intention if the wound layers are reapproximated following injury. This apposition of tissue layers allows healing to occur in a minimum of time, with no separation of wound edges and with minimum scar formation. This is the desired mode of healing for surgical incisions.

Secondary Intention

It has been known for centuries that a wound has a higher resistance to infection when left open rather than closed. This was demonstrated experimentally in dogs by Billoth, who applied dressings soaked in liquid feces and pus to wounds. Wounds left open remained healthy in appearance, whereas those that were subsequently closed became infected. As a result, contaminated or infected surgical wounds often are left unapproximated and allowed to close spontaneously. This type of wound healing is referred to as healing by secondary intention. This healing process obviously is more complicated and prolonged than that of primary intention. The wound eventually heals by a combination of contraction and the formation of granulation tissue with the wound gradually filling in from the raw surfaces. This type of healing is slow and frequently characterized by formation of excessive scar tissue. Granulation tissue from the healing wound also may protrude above the wound margin during this process. This can prevent final epithelialization of the surface and require further treatment for complete healing.

Third Intention

Wound healing by third intention, also known as *delayed primary closure*, refers to the technique of wound closure after a period of delay. This method often is used after postoperative wound breakdown or as an alternative to healing by secondary intention of wounds that should not be closed primarily, such as grossly contaminated or infected wounds. The timing of closure is important. After delays of 7 to 8 days, the wound

edges become increasingly difficult to approximate because of the increasing collagen content. Edlich and colleagues have suggested that closure on or after the 4th day appears to be ideal. This concept also is supported by Lowery and Curtis, who showed that wounds closed after a delay of between 3 and 6 days have the lowest infection rates. Furthermore, studies by Fogdestam revealed that wounds closed during this time frame also have greater wound strength at 20 days than do wounds closed primarily.

Methods of Wound Closure

Wound dehiscence with evisceration is a serious complication of abdominal surgery. This complication is associated with prolonged morbidity and high mortality. Published mortality figures range from 18% to 35%, with a mean of 20%. Wound dehiscence occurs in 0.5% to 5% of all abdominal surgeries but is less frequent (0.1% to 0.7%) with gynecologic abdominal procedures. Potential reasons for the decreased rate of dehiscence associated with gynecologic surgery include the use of transverse incisions, healthier patients, lower infection rates, and a lower rate of bowel enterotomies.

Traditionally, gynecologic surgeons have been taught that vertical incisions are associated with a greater likelihood of dehiscence than are transverse incisions. Critical review of the earlier data supporting this conclusion reveals that significant confounding variables often were ignored. In general, vertical incisions often were performed emergently on sicker patients or those who had other risk factors for dehiscence, such as cancer. Transverse incisions typically were performed on relatively healthy patients undergoing elective surgery. At least two randomized studies by Greenall and colleagues and Stone and associates have shown no difference in hernia formation or dehiscence between vertical and transverse incisions.

Proper suture selection is critical in preventing wound dehiscence. The wound may break down if the suture has too little initial tensile strength or if the suture is absorbed too quickly before the wound regains enough strength to resist normal stress. The suture also is only as strong as the knots placed in it. If the knot is tied using an improper technique or too few knots are placed, the knot can slip and the suture line fail. The issues involved with proper suture selection and knot security are discussed in detail later in this chapter. Proper surgical technique is one of the most critical factors in preventing wound dehiscence. Several studies have indicated that the most common cause of wound dehiscence is intact sutures pulling through fascia. Animal studies have confirmed that incisions closed with wide loose fascial bites have greater tensile strength than do those closed using smaller fascial bites. Sanders and DiClementi also have shown that tightly tied fascial sutures result in fascial necrosis beneath the sutures. Thus, the old adage that one should “approximate and not strangulate fascia” is well taken.

Although the use of loose, wide fascial bites appears to reduce the likelihood of suture pull-through, the optimum distance sutures should be placed from the fascial edge is unknown. However, data obtained by Campbell and colleagues can provide some guidelines. When the pullout force and pullout energy of sutures placed in cadaver fascia were plotted against bite size, bites of 0.9 cm yielded the maximum pullout force, but maximum pullout energy was obtained with bite sizes of 1.2 to 1.5 cm. Unfortunately, it is unknown whether pullout energy or pullout force is more clinically relevant.

Tera and Aberg, working with human cadavers, have shown that the strength of a sutured midline incision is approximately doubled if sutures are placed lateral enough to include the edge of rectus muscle. Normally a bite of approximately 1.5 to 2 cm is required to include rectus muscle in a midline closure. From these studies, it appears that fascia sutures should be placed at least 1.0 cm from the fascia edge and that bites of 1.5 cm or larger are probably preferable.

The use of large tissue bites may be responsible, in part, for the success of mass closure techniques, such as retention sutures, or the Smead-Jones closure, in which wide sutures are passed through fascia, muscle, and peritoneum. The Smead-Jones mass closure consists of a combination “far” mass closure bite at least 2.5 cm

from the fascial edge on each side of the incision with a second “near” bite through the fascial edge. This far-far/near-near technique is considered the gold standard for vertical closure because it has been shown consistently to be more secure than simple layered closure.

Unfortunately, the Smead-Jones technique is time consuming and requires a large number of sutures. One solution to this problem has been the use of a continuous running mass closure. In gynecologic surgery, abdominal incisions traditionally have been closed in layers with interrupted sutures. The belief that interrupted sutures provide greater wound security than does a continuous suture is not well documented, and there are several well-performed studies using both general surgery and gynecologic oncology patient populations showing continuous closure to be comparable to Smead-Jones closure provided that adequate tissue bites are taken. A recent meta-analysis of available randomized trials suggests that a continuous technique also is associated with decrease in subsequent ventral hernia formation. The continuous technique not only is the most rapid of all the mass closure methods but also

P.202

is more rapid than are traditional interrupted layer techniques. One theoretical advantage of a continuous suture line is that any stress on the incision is distributed along the entire suture line and not confined to one loop of suture, thereby potentially decreasing the likelihood of suture pullout.

TABLE 13.1 U.S. Pharmacopeia-Required Knot-Pull Tensile Strength (LB)					
ABSORBABLE SUTURES			NONABSORBABLE SUTURES		
SIZE	NATURAL	SYNTHETIC	CLASS I	CLASS II	CLASS III
4-0	1.7	2.4	1.3	1.0	1.8
3-0	2.7	3.9	2.1	1.5	3.0
2-0	4.4	6.2	3.2	2.3	4.0
1-0	6.1	8.8	4.8	3.2	7.5
1	8.4	11.6	6.0	4.0	10.5

Mass closure techniques classically have used a nonabsorbable permanent suture. The use of nonabsorbable sutures occasionally produces painful palpable knots or results in the formation of suture sinuses. The development of slowly absorbed synthetic sutures has allowed the use of these sutures for running continuous closures, thus avoiding the potential complications of nonabsorbable sutures. Several studies are now available showing excellent results using a continuous absorbable suture line for fascial closure even in high-risk patients. Although the use of continuous polyglycolic acid and polyglactin 910 sutures to close vertical midline incisions has been discouraged by some surgeons, others have obtained good results in patients at low risk for dehiscence. Since these initial studies, other synthetic absorbable sutures (polydioxanone and polyglyconate) that retain their tensile strength much longer than polyglycolic acid and polyglactin 910 have become available. Because of this delayed loss of tension strength compared with other absorbable suture material, polydioxanone and polyglyconate sutures are especially well suited for continuous fascial closure and should be considered the

absorbable sutures of choice for mass closure of patients at high risk for dehiscence.

The manner in which the incision is made also may influence the dehiscence rate. Although no good data are available, it has been suggested that the shearing produced when scissors are used to incise the fascia results in increased fascia necrosis and an increased breakdown rate when compared with incisions produced by a scalpel. Likewise, the use of electrosurgery to incise the fascia has been implicated by some data to result in an increase in the dehiscence rate. These factors are magnified if the fascia then is closed improperly. Because such fascia necrosis generally occurs only at the cut edge of the fascia, the use of generous fascia bites during fascial closure probably is more important in preventing fascial dehiscence than is the manner of opening the fascia.

SUTURE MATERIAL

It is unknown when humankind first learned to use strings or animal sinews to ligate bleeding vessels or approximate tissue. Any material used for this purpose is commonly referred to as *suture*, whereas the act of reapproximating tissue with suture is known as *suturing*. The first recorded use of suture and suturing dates to the 16th century bc in the Edwin Smith papyrus, the oldest record of a surgical procedure. Over the centuries, many different materials have been used as sutures. These materials include metals (gold, silver, and tantalum wire), plant material (linen and cotton), and animal products (horsehair, tendons, intestinal tissue, and silk).

The United States Pharmacopeia (USP) is the official compendium that defines the various classes of suture as well as sets standards for dimensions and minimum tensile strength for each class of suture marketed in the United States. Most sutures today significantly exceed the minimum tensile strength required by the USP ([Table 13.1](#)).

Sutures are divided into size categories based on diameter as defined by the USP. Sutures progressively larger than 0 are numbered in increasing numerical order; that is, 1, 2, etc. Sizes progressively smaller than 0 are indicated by an increasing number of zeros; that is, 0, 00, 000. The smaller the suture, the more zeros. For simplicity, the smaller numbers often are written numerically as 1-0, 2-0, etc., where the first numeral refers to the number of zeros.

The USP characterizes sutures based on their rate of absorption by bodily tissues. Sutures initially are classed as either absorbable or nonabsorbable. Absorbable sutures lose the majority of their tensile strength before 60 days when implanted in body tissues. Absorbable sutures are further subdivided by the USP into natural and synthetic sutures. [Figure 13.2](#) illustrates the percentages of tensile strength remaining for common absorbable sutures at various postoperative time intervals.

Nonabsorbable sutures are defined as sutures that maintain the majority of their tensile strength for more than 60 days in body tissue. These sutures are further subdivided by the USP into three classes: class I is composed of silk or synthetic fibers; class II is composed of cotton or linen fibers or coated natural or synthetic fibers, with the coating forming a casting of significant thickness but not contributing appreciably to strength (these coatings typically are added to improve handling characteristics or resist degradation); and class III sutures are composed of monofilament or multifilament metal wire.

Natural Absorbable Sutures

Plain and Chromic Catgut

One of the oldest suture materials is plain catgut. Catgut consists of highly purified strands of collagen obtained from the submucosa of animals. Despite its name, catgut normally is obtained from sheep or cattle intestines. The name is believed to have originated from the Arabic term *kitgut*, which referred to the strings of a musical instrument known as a kit. Kitgut was made from sheep intestines and probably served as a readily available

FIGURE 13.2 Percentage of in vivo tensile strength of absorbable sutures remaining at various postoperative times.

Because plain catgut is a foreign protein, it elicits a marked inflammatory response in tissue. It is rapidly degraded by proteolytic enzymes released by white blood cells. This suture loses more than 70% of its tensile strength in 7 days and is totally digested by 70 days. Plain gut is used in tissue in which strength is needed for very short periods of time. It is ideal for Pomeroy tubal ligations because it dissolves rapidly and thus allows the severed ends to fall apart. Less rapidly absorbed sutures, particularly permanent suture, are associated with higher failure rates, probably because of fistula formation.

Chromic catgut is treated with chromic acid salts that bind to the antigen sites in the collagen. The resulting suture elicits less inflammatory response and subsequently is more resistant to degradation. Chromic catgut maintains more than half of its tensile strength at 7 to 10 days, with some measurable strength up to day 21. It is suitable for tissue in which long-term strength is not needed. Examples of such tissue include serosal, visceral, and vaginal tissues. This suture should not be used in skin because the inflammatory response can cause scarring, and the suture often serves as a nidus for infection. Because natural absorbable sutures are degraded by the proteolytic enzymes released by inflammatory cells, these sutures lose strength more rapidly in infected tissue. Because catgut is derived from animal intestines, primarily cow and sheep, there has been increasing concerns over the possibility of theoretical infection with transmissible spongiform encephalopathies (TSE), such as "mad cow." Intestines are currently classified as tissues of medium infectivity with regard to TSE. Furthermore, because all inactivation processes for TSE cause severe changes to catgut, it is not possible to apply these methods to these sutures to eliminate infectious agents. Risk management is only possible by restricting sources to TSE-free herds. Because of these concerns, catgut sutures have been taken off the market in many countries of Europe as well as Japan. Where available, catgut has become progressively more expensive. Because the primary advantage of catgut over many of the synthetics has been cost, many believe use of catgut sutures will soon become obsolete.

Synthetic Absorbable Sutures

Polyglycolic Acid, Polyglactin 910, Lactomer 9-1, and Glycomer 631

During the 1970s, two synthetic absorbable sutures (polyglycolic acid and polyglactin 910) became available in the United States. These sutures were designed to be stronger, longer lasting, and less reactive than catgut.

Both sutures are composed of braided filaments of a synthetic polymer. Polyglycolic acid (Dexon: Sherwood/Davis & Geck, St. Louis, MO) is a copolymer of glycolic acid, whereas polyglactin 910 (Vicryl: Ethicon, Somerville, NJ) is a copolymer of lactic and glycolic acid. The two sutures have very similar biologic properties. Breakdown is by hydrolysis rather than digestion by proteolytic enzymes. The result is minimal inflammatory reaction and a constant absorption rate. There essentially is no loss in tensile strength in the first 7 to 10 days after implantation. Approximately 50% to 60% of tensile strength remains after 14 days, 20% to 30% after 21 days, and almost no tensile strength at 28 days. The initial tensile strength of both these sutures is significantly greater than catgut suture of equal size. In fact, the tensile strength of the synthetic absorbable sutures is almost equal to the tensile strength of a catgut suture one size larger.

Glycomer 631 (Biosyn: Covidien, Mansfield, MA) introduced in 1995 is a triblock polymer of glycolide, dioxanone, and trimethylene carbonate. Advances in polymer chemistry allowed production of a monofilament suture equivalent to polyglactin 910 and polyglycolic acid. Glycomer 631 maintains its tension strength longer than the two sutures in this class with 75% of the tension strength remaining at 2 weeks and 40% remaining at 3 weeks.

Lactomer 9-1 (Polysorb: Covidien, Mansfield, MA) is a braided absorbable suture composed of glycolide and lactide in a 9:1 ratio. The surfaces of Polysorb have been coated with an absorbable mixture of caprolactone/glycolide copolymer and calcium stearoyl lactylate to decrease their coefficient friction. At 2 weeks, nearly 80% of the tensile strength remains, and approximately 30% of the tensile strength is retained at 21 days. Absorption is essentially complete by days 56 to 70.

One disadvantage of the synthetic absorbable sutures is that they do not handle as well as catgut suture. To counter this difficulty, manufacturers have attempted to enhance the handling qualities of their products by offering versions with various surface coatings or variations with finer and more tightly woven filaments. Although these refinements improve handling characteristics, they increase the tendency of knots to slip. As a result, additional throws may be needed when using these suture versions.

These sutures can be used in most situations in which chromic catgut would be used and have replaced catgut almost entirely for many surgeons. Because they retain tensile strength longer than do natural absorbable sutures, they are acceptable for fascial closure in patients at low risk for fascial dehiscence.

Polyglyconate and Polydioxanone

Sutures of polyglycolic acid and polyglactin are by necessity composed of braided filaments because the inherent rigidity of the polymers produces a monofilament suture too stiff for general

P.204

surgical use. A newer class of polymers, first available in the 1980s, allowed the production of pliable monofilament sutures. This type of suture is represented by polyglyconate (Maxon) and polydioxanone (PDS). Although subtle differences exist between the two sutures, they are similar enough to consider them together when discussing the biologic properties of this suture class.

The initial tensile strength of these monofilament sutures is comparable to that of the multifilament absorbable sutures. However, this class of suture undergoes absorption at a much slower rate than do other absorbable sutures. As a result, tensile strength is maintained for a longer period of time. More than 90% of initial tensile strength is maintained by the end of the first postoperative week, 80% at 2 weeks, 50% at 4 weeks, and 25% at 6 weeks. As with the other synthetic sutures, inflammatory response is minimal. An additional advantage is that these monofilament sutures lack interstices that could serve as a nidus for bacterial infection. As a result, chronic inflammation is rarely seen with this class of monofilament sutures. In comparison, infected absorbable braided sutures have been shown experimentally by Buckall to contain bacteria even after 70 days of implantation.

Because of their delayed absorption profile, both polyglyconate and polydioxanone are excellent choices for

fascial closure. Because these sutures are composed of only one fiber, care must be taken to insure that the strand is not inadvertently damaged by instruments, needles, or other sharp-edged material. Such damage may not be easily recognized in the operating room but can seriously weaken a monofilament suture and may result in suture line disruption postoperatively. This precaution is even more critical when a continuous suture line is used. Additionally, the use of the commonly used loop-to-strand closure to end a suture line produces a very weak knot when monofilament suture is used. The use of two sutures, with each starting at one end of the incision and then tied strand to strand, is recommended when monofilament sutures are used in high load-bearing situations such as fascial closure. A more detailed discussion is provided later in this chapter in the discussion of surgical knots.

Poliglecaprone 25, Polyglactin 910 (Rapide), and Polyglytone 6211

With further advances in polymer chemistry, it is now possible to manufacture the synthetic equivalent of surgical gut. First introduced in 1993, poliglecaprone 25 (Monocryl) has the absorption similar to chromic catgut. Unlike natural collagens, poliglecaprone 25 produces highly uniform and predictable absorption patterns. Like the other synthetic sutures, poliglecaprone 25 is absorbed by hydrolysis and thus does not induce the inflammatory response of catgut. This monofilament suture retains approximately 50% to 60% of its original tensile strength at 7 days postoperatively, 20% to 30% at 14 days, and by 21 days has lost essentially all tensile strength. This particular suture has the advantages of chromic catgut suture but without many of the disadvantages (i.e., intense inflammatory response and somewhat unpredictable absorption rate). Although it is similar to chromic catgut in tensile strength and actually maintains its tensile strength longer than does chromic catgut, it is not recommended by the manufacturer for use for fascial closure or in any tissue in which approximation under stress is required.

Polyglactin 910 Rapide (Vicryl Rapide) released in 1995 is identical in chemical structure to polyglactin 910 but is of lower molecular weight. It has been treated with gamma rays to speed absorption. The result is a braided suture with performance characteristics similar to plain catgut. Absorption is rapid, with 70% of tensile strength lost in the first 7 days. After 10 to 14 days, essentially no strength remains. It is intended for use in the superficial soft tissue where only short-term support is needed. It can be used for skin closure because of its rapid absorption and minimal inflammatory response. The sutures typically begin to fall off at 7 to 10 days. Because sutures remaining in skin longer than 7 days may cause scarring, any suture remaining at this time can be wiped off with sterile gauze or, if necessary, cut. Although this suture does not meet USP strength requirements for synthetic absorbable sutures, its tensile strength exceeds the tensile strength specifications for similar size natural collagen suture.

Polyglytone 6211 (Caprosyn: Covidien, Mansfield, MA) released in 2002 is composed of glycolide, caprolactone, trimethylene carbonate, and lactide. The absorption profile is similar to that of polyglactin 910 Rapide. However, in contrast to polyglactin 910 Rapide, polyglytone 6211 is a monofilament suture.

These sutures are an excellent choice for first- and second-degree episiotomy and vaginal laceration closure. Because of the intense inflammatory response produced, gut sutures are associated with more significantly postepisiotomy pain than are synthetic sutures, whereas long-delayed absorbable synthetic sutures are associated with the presence of unabsorbed suture and knots after the postpartum period.

Nonabsorbable Sutures

By definition, nonabsorbable sutures are suitably resistant to the action of living mammalian tissue. These sutures, however, are not completely resistant to absorption. Over time, these sutures also lose tensile strength, and in the case of natural fiber, sutures eventually are completely absorbed or digested. Despite beliefs to the contrary, the initial tensile strength of many nonabsorbable sutures is less than that of comparable size absorbable suture ([Table 13.1](#)). Nonabsorbable sutures, however, have the advantage of maintaining tensile

strength for long periods of time. Disadvantages of nonabsorbable sutures include the potential suture-related pain, palpable sutures, and occasionally the formation of suture sinuses.

Natural Nonabsorbable Sutures

Modern nonabsorbable natural fiber sutures are composed of either surgical silk or cotton. Silk suture is one of the best handling sutures. The handling and knot-tying characteristics of silk suture remain the standard against which other sutures are judged. This suture has little “memory”; that is, it does not tend to return to its original form after being bent or twisted. As a result, it handles well, ties easily, and possesses excellent knot security. Silk suture loses more than half of its tensile strength after 1 year of implantation and frequently cannot be found after 2 years. In this respect, it can be viewed as a delayed absorbable suture. Because silk is a foreign animal protein, it initiates the greatest inflammatory response of the nonabsorbable sutures. The multifilament nature and the capillary action of this suture make it unsuitable in contaminated tissue or in tissues in which the potential for infection is high.

Cotton is the other nonabsorbable natural suture material still available today. It is rarely used in modern surgical practice. Cotton is the weakest of the nonabsorbable sutures. Cotton loses 50% of its original tensile strength within 6 months of implantation but still has 30% to 40% remaining at the end of 2 years. Unlike silk, which loses tensile strength when exposed to moisture, wet cotton is 10% stronger than dry cotton. Because wet cotton also is easier to handle, it is commonly moistened before use.

P.205

Synthetic Nonabsorbable Sutures

A wide variety of nonabsorbable synthetic sutures exist. Nylon is a synthetic polyamide polymer derived from coal, air, and water. It is available both as a braided polyfilament suture (Nurolon, Surgilon) and as a monofilament suture (Dermalon, Ethilon). Monofilament nylon has slightly greater tensile strength than braided nylon, but braided nylon handles better and has better knot security than the monofilament nylon suture. Monofilament nylon suture incites less inflammatory reaction and is less prone to infection than the braided nylon sutures. However, because nylon is relatively inert, all types of nylon suture produce minimal tissue reaction. Nylon undergoes slow hydrolysis in tissue over extended periods of time. It loses approximately 15% to 20% of tensile strength each year.

Polyester sutures are produced only in braided forms. Most differences in the properties of these sutures are determined by whether they are coated and by the type of coating. The uncoated forms (Mersilene, Dacron) generally offer the best knot security. As with synthetic absorbable suture, coatings can improve the handling characteristics of the polyester sutures. Knot security of coated polyester sutures is generally poorer than that of uncoated sutures. Coatings currently used include polytetrafluoroethylene, also known as Teflon (Polydek, Ethiflex, and Tevdek), polybutylate (Ethibond), and silicone (Ti-Cron).

Polypropylene (Prolene, Surgilon) is a monofilament suture composed of a linear hydrocarbon polymer. It has the least tissue reactivity of all nonabsorbable sutures. Although polypropylene has a high memory, it also exhibits a small degree of plasticity. If it is tied carefully and the knots set firmly, a flattening occurs where the strands cross. This flattening helps lock the knot and thus provides somewhat greater knot security than is possible with many other monofilament nonabsorbable sutures. As with the absorbable monofilament sutures, the same precautions to prevent damage to the suture must be observed with the monofilament nonabsorbable sutures.

Metal Sutures

Although silver wire was used by Sims for closure of vesicovaginal fistulas, metal sutures are rarely used in gynecologic surgery today. Historically, metal sutures have been used in infected sites or for repair of wound dehiscence and evisceration. Stainless steel once was used routinely by the military for closure of battle wounds

of the abdomen. Metal sutures have the highest tensile strength of all suture material. They are also particularly nonreactive. Metal sutures, however, are difficult to handle, require the use of special instruments, and tend to puncture gloves and tissue. With the availability of other nonabsorbable suture materials that also offer high tensile strength and low reactivity but are easier to handle, little reason exists to use these sutures in gynecologic surgery today.

Barbed Suture

The barbed suture is a recent development in sutures. The use of barbed suture has particular advantages in laparoscopy and in dermal closure. Since knots are eliminated and an equal level of tissue approximation is applied throughout tissue closure, these sutures may have advantages over smooth suture in many other surgical applications.

In 2004, the Quill bidirectional barbed suture (Angiotech, Vancouver, British Columbia, Canada) became the first barbed suture to be approved by the FDA. In 2009, the FDA approved the V-Loc barbed suture (Covidien, Mansfield, MA). The Quill system is a bidirectional suture with needles swaged to each end of the suture, while the V-Loc system is unidirectional with only one needle with the other end being a closed loop to avoid the need for a knot to initially anchor the suture. Both sutures are available in a variety of both absorbable and nonabsorbable sutures. The Quill system is available with sutures composed of poliglecaprone 25, polydioxanone, nylon, and polypropylene. The V-Loc system is available as the V-Loc 90 composed of glycomer 631, the V-Loc 180 with polyglyconate, and V-Loc PBT composed of polybutester. The numerical designation of the V-Loc 90 and 180 indicates the time to complete suture absorption.

Because effective diameter of the suture is decreased during the manufacturing process, bidirectional suture is rated one USP size smaller than its equivalent smooth suture, that is, a 2-0 smooth suture and a 3-0 bidirectional suture are actually the same diameter. Unidirectional suture is rated equal to its USP smooth suture equivalent.

Choice of Suture for Fascial Closure

Tensile strength is critical, although many factors are important in choosing a suture for fascial closure. As noted, the most common cause of dehiscence is sutures pulling through fascia. Because a fascial closure can only be as strong as the weakest component, suture for fascial closure should maintain a tensile strength greater than that of the fascia through the critical healing period. Because the incidence of wound infection is related to the amount of suture material placed in the wound, it would also seem reasonable to use the smallest suture able to provide this necessary tensile strength.

All sutures marketed in the United States must meet minimum tensile strength requirements as defined by the USP. The tensile strength measurement required by USP is knot-pull tensile strength. In measuring knot-pull tensile strength, the suture is tied around a plastic tube using a flat surgeon's knot with one end held in place and the opposite end attached to a tensiometer. Although these data are easily obtained from the various suture manufacturers and are frequently used in suture advertisements, knot-pull tensile strength is not particularly applicable to actual surgical situations. A more useful measurement of strength is obtained using the knotted loop model as suggested by Herman. In this model, a loop is formed by tying a suture around a glass rod using sufficient square knots to prevent slippage. The rod is removed and the loop placed over two right angle rods gripped in the jaws of a tensiometer. The jaws are then separated at a constant rate until breakage occurs. This model stresses the material and the knot more comparably to actual in vivo situations and also allows estimation of knot security. Assuming no slippage at the knot, tensile strength calculated using the knotted-loop model is approximately twice the knot-pull tensile strength.

The force required to pull a loop of suture through intact fascia (pullout force) is frequently cited as 8.3 pounds. This figure is derived from work on the fascia of dogs by Howes and Harvey in 1929 and does not necessarily

apply to humans. Fortunately, several studies are now available that have measured the strength of human fascia (Campbell et al., Tera and Aberg, and Boerema). Two of these studies, by Campbell and colleagues and Tera and Aberg, were performed using human cadavers. The third study by Boerema measured the pullout force of fascia at the time of surgery on living patients. All three produced data that indicated the pullout force for human fascia was approximately 15.2 to 24.2 pounds.

Fascial incisions regain their strength slowly, achieving approximately 10%, 25%, 30%, and 40% of original strength by postoperative weeks 1, 2, 3, and 4, respectively. The point at which fascia has regained enough strength to resist the stress of daily activities is unknown. Some

P.206

estimation of this time frame can be obtained from available data on fascial dehiscence. The majority of fascial dehiscence occurs between 2 and 12 days postoperatively, with a mean occurring around days 7 to 8. Dehiscence rarely occurs after postoperative day 12 but has been reported up to day 18. This suggests that in most patients, fascia has regained enough strength by 2 weeks after surgery to resist reasonable stresses but that in a limited number of patients, fascia may not regain sufficient strength to prevent dehiscence until 3 weeks postoperatively.

FIGURE 13.3 The tensile strength of various implanted suture materials over time and the point at which tensile strength is less than fascial pullout strength (14.5 to 24.2 pounds).

Using the fascia pullout data, tensile strength as measured by the knotted-loop model following various lengths of implantation in animals, and dehiscence data, the appropriate size absorbable suture for fascial closure can now be estimated. As can be seen in [Figure 13.3](#), both 1 and 0 polydioxanone and polyglyconate retain tensile strength greater than the fascial pullout force for 4 to 6 weeks, but polyglycolic acid sutures of the same size maintain adequate tensile strength only for 7 to 14 days. Based on this model, a 1 or 0 polydioxanone or polyglyconate suture appears to be the most appropriate absorbable suture for fascial closure. Unfortunately, although these types of data are theoretically appealing, there are little clinical data to support these conclusions. It must be realized that in most healthy patients, fascial dehiscence does not occur, even when rapidly absorbed sutures are used. Before the development of the synthetic absorbable sutures, 1 and 0 chromic catgut sutures were frequently used for fascial closure. In fact, based on a survey of ob/gyn residency programs, chromic catgut still was being used for fascial closure in 16.1% of vertical fascial incisions and 23.4% of transverse fascial incisions as of 1979. Although fascial dehiscence in healthy patients remained uncommon

after fascial closure with chromic catgut, dehiscence rates of up to 11% were reported for other patient populations. Likewise, polyglycolic acid and polyglactin 910 sutures have been used for fascial closure with good success, even in patients at risk for dehiscence.

Surgical Needles

Needles are necessary to carry suture material through tissue. The specific needle required for a procedure is determined by the tissue type, its location and accessibility, and the surgeon's personal preference. All surgical needles have three basic components: the eye, the body, and the point.

The eye of the needle is the point of attachment for suture. Eyes may be classed as closed, French, or swaged. Closed eyes are similar to those on household sewing needles, whereas French eye needles have a slit with ridges inside the slit to catch and hold the suture. Swaged or eyeless needles have the suture mechanically attached to the end of the needle to form a continuous unit. Eyed needles have several disadvantages over swaged needles, including difficulties with threading and the need to pull a double loop of suture through the tissue. Swaged needles are available with either the suture permanently attached or attached in such a manner that it can be removed from the needle by a slight straight tug on the suture. These controlled-release needles, also known as “pop-off” needles, increase the speed at which interrupted sutures can be placed.

The shape of the body or shaft of a needle determines how easily the needle performs in different applications (**Fig. 13.4**). The longitudinal shape of the body may be straight, half-curved, curved, or compound. Straight needles are used commonly when tissue is easily accessible. This type of needle is rarely used by gynecologists except for skin closure. Half-curved, or ski, needles may be used to close skin but have primarily been used in gynecology to facilitate laparoscopic suturing. Curved needles require less space for maneuvering than do other needles, and thus are ideally suited for most surgical procedures. Curved needles are commonly named based on the percentage of a circle they complete; that is, a 1/2 circle needle is one half of a full circle. Curved needles are available in various curvatures, with the 3/8 circle the most commonly used. The less of an arc the needle completed, the more shallow a bite the needle takes. For example, a 5/8 needle is useful in deep wounds in which a deep, narrow bite is required. Compound curve needles were originally developed for anterior segment ophthalmic surgery and are not used in gynecologic surgery.

The point of the needle begins at the widest part of the needle body and extends to the extreme tip. The two types of needle points are the cutting point and the tapered point (**Fig. 13.4**). Tapered points are used in easily penetrated tissue, such as bowel or peritoneum. A variation of the taper point is the blunt point, which has a rounded blunt tip at the end of a tapered shaft. This needle tip was designed for use in friable tissue but has been advocated by some surgeons for use with other tissues because of its reduced likelihood to penetrate the surgeon's gloves or skin. Cutting needles are used in

P.207

tough tissue, such as skin. The most common cutting needle is the reverse cutting needle. Its sharp edge is on the outside of the outer curvature of the needle. Conventional cutting points have the sharp edge on the inside of the curvature. Variations of the cutting point include spatula and lancet points and are used for specialized applications such as ophthalmology.

FIGURE 13.4 Common points and body shapes for curved needles.

Needle Holders

Straight needles can be held and pushed through tissue with the fingers. Straight needles can be used only to sew in a straight line, and only then when the tissue is easily accessible. When straight needles are used, sewing is done in a direction away from the operator.

In the depths of a wound, curved needles are needed. A needle holder is required when curved needles are used. All needle holders have a broad head with a variety of surfaces to prevent the needle from slipping or rotating. Needle holders may be large and heavy, or small and delicate, depending on the size needle to be used. Many needle holders have ring finger grips and locking mechanisms. Two common types of basic needle holders used in gynecology are Wagensteen (straight) or Heaney (angled) ([Fig. 13.5](#)). Curved needle holders are especially useful in vaginal surgery, for which the angled head allows easier needle placement. The needle is loaded so that the angled tip is pointed toward the needle eye and not the tip. Sewing using needle drivers is performed toward the operator.

Surgical Knots

The surgical knot has been described as the weakest link in any knotted suture, regardless of the knot configuration and the type of suture used. If tied improperly, a surgical knot will fail before the tensile strength of the suture is reached. Even when performed perfectly, the mere placement of a knot in suture reduces its overall tensile strength by 30% to 35%. Therefore, some knowledge of surgical knots is imperative for all surgeons.

All surgical knots can be divided into two basic groups: flat knots (square, surgeon's, and granny) and sliding knots

(identical and nonidentical) ([Fig. 13.6](#)). Flat knots are formed with half hitches tied with equal tension on the

ends of the suture. Surgeon's knots are formed by adding an additional loop to the first throw of the half hitch. Sliding knots are two half hitches either nonidentical (square knot) or identical (granny knot), tied with greater tension on one segment than the other.

FIGURE 13.5 Needle holders. (Courtesy of Zinnanti Surgical Instruments, Inc., Chatsworth, CA.)

FIGURE 13.6 Flat and sliding knots.

The term *sliding knot* suggests the tendency of the knot to slip compared with the flat, but this is not completely true. Simple sliding knots of two or three throws do slip often and should not be used as surgical knots. Brouwers and colleagues have shown, however, that flat knots with only two throws also tend to slip rather than break.

The flat square knot is the most secure of all the surgical knots and theoretically the most desirable knot for tying suture. However, according to a study by Trimbos, sliding knots are used more commonly by gynecologists than are square knots. It has been shown also that many surgeons actually tie sliding knots despite being convinced they tie flat knots. Sliding knots frequently are used in actual surgical practice for two reasons. The crossing of the surgeon's hands needed to tie square knots unavoidably releases tension on the knot, and this can lead to knot slippage. The tying of deep ligatures is most easily performed by keeping constant tension on one suture. Thus, sliding knots may be preferable to square knots in certain situations. Whichever knot is used, the operator should be aware of the knot being used and the number of throws needed to obtain maximum knot capacity.

The number of throws required for knot security is frequently debated. Too few throws and the knot is weaker than the suture; additional throws above that needed to equal the suture's tensile strength adds unneeded suture to the wound and may increase the infection rate. When flat square knots are used, Brown has shown that maximum knotholding capacity was achieved with four throws in all noncoated suture tested. In fact, three throws were sufficient to achieve maximum knot-holding capacity except for sutures composed of nylon (both monofilament and braided). The addition of coating to improve handling characteristics also decreases knot security. In a 1983 study, Rodeheaver and colleagues showed that coated suture required two additional flat throws to equal the maximum knot-holding capacity of uncoated suture. In a similar study by Van Rijssel and colleagues, the knot-holding capacity of a sliding knot with one extra throw equaled that of square knots in smaller gauge (3-0) suture. In larger sutures (0), square knots remained stronger than sliding knots with an extra throw, but sliding knots with more than five throws were not tested. From these studies, it appears that a surgical knot of four to six throws is adequate for most sutures. The exact number of throws required, of course, depends on the type of suture and whether a flat or sliding knot is formed.

It is common practice for some surgeons to leave suture tails long to prevent knot disruption should the knot slip. As might be expected, the usefulness of this practice is dependent on the type of suture involved. It has been shown that any knot slippage in nylon, polydioxanone, and polypropylene sutures results in total knot disruption. In other sutures (polyglyconate and polyglactin), initial knot slippage is followed by knot recomposition. The reconstituted knot remains intact until greater force is applied. A long suture tail is only helpful in preventing knot disruption in this latter class of suture.

Knot security is of utmost importance when using a continuous suture line. This is of critical importance if a monofilament suture is used in a strength critical suture line. It is common practice for many surgeons to form the terminal knot in a continuous suture line by tying the ending single strand to the last loop of suture. This "loop-to-strand" knot is a potentially weak configuration. Unlike multifilament sutures that lock in place with each throw, monofilament sutures do not lock and are prone to slippage. Unless multiple square knots are used, the single strand may slip from the knot when placed under tension. As a result, the entire suture line disrupts. At reoperation, the strand may appear broken, but, in fact, one of the three terminal knot ends has slipped through what appears to be an intact knot ([Fig. 13.7](#)). A safer method for tying continuous suture is to run two sutures to the midpoint of the incision and tie the two single strands to each other, thus avoiding the "loop-to-strand" knot. Alternatively, polydioxanone is available in a looped version that eliminates the initial knot and permits ending the suture line in a strand-to-strand configuration. The disadvantage is the large increase in the mass of suture placed into the wound.

SURGICAL INSTRUMENTATION

A multitude of surgical instruments are designed to perform one unique function or slightly improve on the

performance of another instrument. This section is not intended to be a comprehensive list of all instruments available but a review of the basic surgical instrumentation needed for most common gynecologic procedures.

Scalpel

The scalpel is the first instrument used in most surgeries and remains the best instrument for dividing tissue with minimal trauma to surrounding tissue. Scalpel blades come in various sizes and shapes to allow performance of different tasks (**Fig. 13.8**). The basic scalpel blade has a straight ribbed back and an oval cutting surface. This basic blade is commonly available in sizes 10, 15, 20, and 22. The 10 scalpel blade is the most versatile and the most commonly used size. The smaller blades are used for fine dissection and when precise turns are required in making the incision—that is, plastic surgery—although the larger blades are used to rapidly perform an incision. Blades such as the 11 and 12 are designed for specific purposes. The 11 blade is bayonetshaped and used to perform stab incisions for drains and in draining abscesses. The 12 blade is hook-shaped and was originally used for myringotomies. It is infrequently used by gynecologists.

Scissors

The scissors are the second most commonly used instrument to divide tissue. In addition to cutting, scissors also can be

P.209

used for blunt dissection by opening the scissors after the tips have been inserted into a tissue plane. The basic scissors designs used in gynecology surgery are the Mayo, Metzenbaum, and Iris scissors. All come in both straight and curved versions (**Fig. 13.9**). Curved scissors allow horizontal cutting deep in a wound and thus improve visibility. Curved scissors also are used to cut tissue in a smooth curve, such as for incising the vaginal cuff in an abdominal hysterectomy.

FIGURE 13.7 Development of suture line.

Mayo scissors are used when dividing tough tissue, such as the rectus fascia, parametrial tissue, or vaginal cuff. Metzenbaum scissors are more delicate than are the heavier Mayo scissors and are used for cutting thinner tissue, such as peritoneum and adhesions. Metzenbaum scissors are frequently use for retroperitoneal dissection or for developing tissue planes in adhered or distorted tissue.

Iris scissors are small scissors used for delicate dissection. Originally designed for ophthalmic surgery, they are used in gynecology for precise vulvar and vaginal surgery, such as fistula repair or colporrhaphy.

Suture scissors are used only to cut suture and never tissue. Suture scissors are general-purpose scissors with blunt ends to avoid the possibility that the tips will injure structures distal to the suture.

FIGURE 13.8 Surgical scalpel blades.

P.210

FIGURE 13.9 Surgical scissors. (Courtesy of Zinnanti Surgical Instruments, Inc., Chatsworth, CA.)

Tissue Forceps

Tissue or thumb forceps consist of two strips of metal joined at one end ([Fig. 13.10](#)). The opposable ends of the forceps are used to grasp and hold tissue during dissection, suturing, or cutting. These ends are of varying shapes and configuration, depending on the purpose for which the forceps are intended. The most common

alteration to the ends is the addition of teeth. Smooth forceps without teeth are used when handling friable or delicate tissue. DeBakey forceps have long fine smooth tips that provide precise control of small or delicate tissue deep in the wound. They are commonly used in vascular surgery or retroperitoneal node dissection. Toothed forceps bite into tissue, providing a firm grip with minimal pressure. The teeth can vary from one to many and be fine or large. Adson forceps are equipped with fine teeth and are commonly used to approximate skin for staple or suture placement. Ring-tipped and Russian forceps increase the grasping force without using teeth by increasing the surface area of the grasping tips. These forceps are used when a secure hold is needed on structures that would be traumatized by toothed forceps. Bonney tissue forceps are heavy-toothed forceps with serrations along the shaft for maximum gripping power. They are used when sewing fascia.

FIGURE 13.10 Tissue (thumb) forceps. (Courtesy of Zinnanti Surgical Instruments, Inc., Chatsworth, CA.)

FIGURE 13.11 Tissue clamps. (Courtesy of Zinnanti Surgical Instruments, Inc., Chatsworth, CA.)

Clamps

Grasping forceps, commonly referred to as clamps, are designed to grasp and apply traction to tissues ([Fig. 13.11](#)). All have finger rings and a locking mechanism. Babcock clamps have no teeth and are atraumatic. These clamps can grasp and hold delicate tissues such as fallopian tube or bowel without causing damage. Allis clamps have serrated edges with short teeth. This clamp has much more grasping power than does the Babcock clamp. Kocher/Ochsner clamps have transverse ridges along the shaft and interlocking teeth at the tip. Because of their design, tissue within the clamp is unlikely to slip. These clamps are frequently used to grasp heavy tissue such as fascia and occasionally are used as hysterectomy clamps. Ring forceps can be used like ring-tipped

P.212

tissue forceps but more commonly are used to hold folded sponges. In this fashion, they can be used to retract tissue, sponge fluid or blood, or apply solutions to the skin in preparation for surgery. Renal stone forceps were designed to remove stones from the renal pelvis but are commonly used by the gynecologic surgeon to explore the uterine cavity for polyps or retained tissue. When used in this capacity, they are inserted, opened, rotated

180 degrees, closed, and withdrawn.

FIGURE 13.12 Hysterectomy clamps. (Courtesy of Zinnanti Surgical Instruments, Inc., Chatsworth, CA.)

Heaney, Heaney-Ballentine, and Masterson clamps are the commonly used clamps for clamping the parametrial and paracervical tissue during hysterectomy ([Fig. 13.12](#)). Hysterectomy clamps are heavy crushing clamps with ridged shafts. The classic clamps (Heaney, Heaney-Ballentine) also have toothed tips. The more recent Masterson clamp lacks a toothed tip and was designed to generate the least amount of crushing force.

Retractors

Retractors are used to hold tissue out of the operative field to improve exposure during surgical procedures ([Fig. 13.13](#)). Retractors are either held by an assistant (manual retractors) or use counterpressure from other tissue (self-retaining retractors) to hold themselves in place.

Self-retaining retractors frequently are used to hold the sides of the incision apart during gynecologic surgery. Gynecologists seem to favor the O'Conner-O'Sullivan retractor when performing pelvic surgery. General surgeons, on the other hand, prefer the Balfour retractor. The O'Conner-O'Sullivan is a circular retractor with four blades, two permanently attached lateral retractors to retract the sidewalls, and a removable upper and lower blade to retract the bowel and bladder, respectively. This retractor is available with large or small lateral blades, whereas the removable blades come in several sizes. The Balfour retractor also has two lateral blades but only one additional retractor blade. This blade normally is employed as an upper blade with a manual retractor used for bladder retraction if needed. However, if the bowel is carefully packed away with laparotomy packs, the third blade can be used as a bladder retractor. All blades of the Balfour retractor are removable and available in different sizes.

The Bookwalter retractor is the most versatile of retractors, providing excellent exposure to the operative field. It consists of a circular metal ring to which a wide variety of retractors can be attached at any point. Its best use is during radical pelvic surgery or when operating on massively obese patients. In extremely obese patients, it may be necessary to attach the Bookwalter retractor to the operating table.

Manual retractors allow maximum flexibility in providing exposure (**Fig. 13.14**). They can be used alone or as a supplement to self-retaining retractors. Common manual retractors include the Heaney, Deaver, and Richardson retractors. Specialized retractors include the Briesky-Navratil (used during sacrospinous vault suspension), Army-Navy, and Parker retractors (used for skin and subcutaneous tissue).

Dilators

Dilators are metal or plastic cylinders used to dilate the cervical os to sufficient size to admit other surgical instruments (**Fig. 13.15**). Dilators may have tapered (Hank and Pratt) or rounded (Hegar) tips. Dilators with tapered tips require less force to perform dilatation than do dilators with rounded tips. The sizes are measured either by diameter or by circumference. The unit of measurement for diameter is millimeters, whereas the unit of measurement for circumference is in French calibration. The relationship of the two measurements can be calculated by the formula for the circumference of a circle where

P.213

the diameter times pi (3.14) equals the circumference. For comparison purposes, approximately 3 French equals 1 mm of diameter.

CONCLUSION

This chapter has attempted to present an introduction to the mechanisms of wound healing, wound closure, suture material, and instrumentation. It is hoped that this chapter will be a useful resource not only for those embarking on a surgical career but also for experienced surgeons as well.

BEST SURGICAL PRACTICES

- Secondary wound closure should ideally be performed on day 4.
- Proper surgical technique is one of the most critical factors in preventing wound dehiscence.
- Abdominal wall fascia should be loosely closed with suture bites of 1 to 1.5 cm.
- The use of mass closure techniques using long-delayed or permanent suture to close fascia is recommended to reduce fascial dehiscence.

- The use of catgut sutures has been limited in many countries because of increasing concerns over the possibility of theoretical infection with TSE, such as “mad cow” disease.
- Suture knots produced by tying a loop of suture to a single strand are less secure than are those tied using a strand to strand. This is particularly critical when using monofilament suture.

Chapter 14

Incisions for Gynecologic Surgery

James J. Burke II

DEFINITIONS

Arcuate line—The demarcation above which the posterior lamella of the internal oblique aponeurosis fuses with the aponeurosis of the transversalis muscle and passes posterior to the rectus muscles. Below this line, the aponeurosis of the internal oblique passes anterior to the rectus muscles.

Cherny incision—A transverse abdominal incision in which the rectus muscles are transected at their insertion on the pubic symphysis. The fascia may or may not be dissected free from the rectus muscles. Entry into the peritoneum may be vertical or transverse.

Dehiscence—Disruption of a surgical wound, either superficial or deep. Superficial dehiscence is separation of the skin and subcutaneous tissue because of seroma, hematoma, or abscess formation. Fascial dehiscence describes the separation of the fascia without extrusion of the bowel.

Evisceration—Disruption of the fascia with extrusion of the bowel through the wound.

Gridiron incision—A muscle-splitting, oblique incision, useful for a transperitoneal or extraperitoneal approach to pelvic organs; similar to a McBurney incision.

Hernia—A late complication of wound disruption. A fascial disruption occurs with protrusion of the peritoneum, bowel, and omentum. The skin and subcutaneous tissue are intact.

Langer lines—The natural, anatomic tissue lines on the abdominal skin.

Linea alba—Where the aponeurosis of the internal and external oblique muscles insert, anterior to the rectus musculature.

Maylard incision—A transverse abdominal incision in which the rectus muscles are transected after ligation of the inferior epigastric vessels. The fascia is not dissected free of the rectus muscles. The peritoneum is usually entered in a transverse fashion.

Panniculectomy—Surgical removal of the pannus, excess skin, and subcutaneous fat, which hangs like an apron from the abdomen. Removal facilitates gynecologic surgery.

Pfannenstiel incision—A commonly used transverse abdominal incision in which the rectus muscles are not cut and the fascia is dissected superiorly and inferiorly along the rectus muscles. The peritoneum is usually entered vertically.

Schuchardt incision—An incision made in the vagina, along the sulcus of the vagina from the lateral fornix to the introitus and through the perineum. This incision can increase room in the vagina so as to aid in difficult vaginal surgeries.

Smead-Jones closure—An interrupted closure of the anterior abdominal wall using a far-far, near-near approach. The closure includes all of the abdominal wall structures on the far-far portion and only the fascia on the near-near portion.

Although the buzz in gynecologic surgery is a minimally invasive approach, certain benign and malignant gynecologic disease states still require a laparotomy to treat. One of the lasting marks of any abdominal surgery, and most noticeable to the patient, is the scar made by the incision. In selecting an incision, the gynecologist must take into consideration the underlying pathology prompting the surgery, the suspicion of malignancy, the absence or presence of upper abdominal disease, and the underlying comorbid state of the patient. Although there are many types of incisions for gynecologic surgery, selection of any incision must be highly individualized. However, selection of an incision should not be dictated by patient choice to preserve cosmesis if it may compromise the surgical approach. Conversely, unduly large or poorly positioned incisions may increase the likelihood of infection, herniation, or dehiscence, as well as unsightly cosmesis. During the surgical consenting process, the patient should be counseled on the location of the incision, the rationale for the particular incision, and any possible complication that may arise from the planned incision. This chapter presents the classic incisions used by gynecologists to perform most gynecologic surgery. Finally, discussion about the prevention and management of common complications associated with abdominal incisions is presented.

ANATOMY OF THE ANTERIOR ABDOMINAL WALL

To avoid injury to vessels and nerves and to close any incision with minimal chance of dehiscence, abdominal wall anatomy should be thoroughly understood. The abdominal wall protects the visceral organs and vasculature within the abdominal cavity. Cephalad, the anterior abdominal wall extends to the costal margins and the xiphoid process. The costal cartilages of the seventh, eighth, ninth, and tenth ribs form a portion of the cephalad boundary. Lateral boundaries include the iliac crests; inferiorly, the abdominal wall is delineated by the inguinal ligaments, the pubic crests, and the superior border of the symphysis pubis. The principal anatomic structures of the abdominal wall include the overlying skin, subcutaneous tissue, muscles, fascia, and the neurovascular supply to these structures. Many factors—such as age, muscle mass and tone, obesity, intra-abdominal pathology, previous pregnancies, and posture—can result in variation in the contour of

P.218

the abdominal wall. These variations can affect abdominal wall topography and may present impediments to the correct choice and placement of laparotomy incisions.

Skin and Lymphatics

The skin contains small vessels, lymphatics, and nerves. A minimal loss of skin sensation can result from any abdominal incision. Numbness below a transverse incision frequently occurs. As stated in the discussion on nerve supply (below), laterally extended transverse abdominal incisions can result in numbness of the skin on the anterior thigh.

The lymphatic drainage of the upper abdominal wall passes directly to the axillary lymph nodes. The lymphatic drainage of the lower abdomen passes to the inguinal nodes and then to the iliac chain. Some lymphatics around the umbilicus drain toward the liver through the falciform ligament. When an incision is placed transversely in the lower abdomen, lymphatic drainage of the abdominal wall above the incision site is disrupted. Some tissue swelling may develop

temporarily until collateral lymphatic drainage can be established. Patients should be counseled about this possible swelling before undergoing surgery.

In 1861, Austrian anatomist Karl Langer described cleavage lines of the skin while working with cadavers. Langer punctured numerous holes at short distances from each other into the skin of a cadaver with a tool that had a circular-shaped tip, similar to an ice pick. He noticed that the resultant punctures in the skin had ellipsoidal shapes. From this testing, he observed patterns and was able to determine "line directions" by the longer axes of the ellipsoidal holes and lines. These have become known as Langer lines ([Fig. 14.1](#)). Across the abdomen, these lines usually run horizontally, and when making vertical incisions in the skin of the abdomen, cuts perpendicular to Langer lines are made, whereas transverse incisions cut parallel to these. Thus, transverse incisions heal with a relatively fine scar, and vertical incisions can heal with a broad scar, particularly in the lower abdomen.

Muscles and Fascia

The abdominal muscles assist in respiration, defecation, urination, coughing, and childbirth by increasing intra-abdominal pressure. They work synergistically with the muscles of the back to flex, extend, and rotate the trunk and pelvis. There are two groups of muscles that form the musculature of the anterior abdominal wall. The flat muscles include the external oblique, the internal oblique, and the transversalis. These muscle fibers run diagonally or transversely. The second group, composed of the recti muscles and the paired pyramidalis muscles, have fibers that run vertically ([Fig. 14.2](#)). The recti, with their thin investing fascia, are muscles of locomotion and posture. The paired pyramidalis muscles arise from the crest of the pubic symphysis and insert into the lower linea alba. Preservation of the pyramidalis muscles is not essential when making incisions. The integrity of the anterior abdominal wall is not associated with this second group of muscles.

A cross section of the lower abdominal wall shows that the fascia of the abdominal muscles envelops the anterior and posterior surfaces of the rectus muscles and anchors the external oblique, internal oblique, and transversalis muscles to the vertical (rectus) muscles ([Fig. 14.3](#)). There is excellent fascial support anteriorly and posteriorly to the rectus muscles above the arcuate (semicircular) line. In this location, the fascial aponeurosis of the external oblique and the split fascial aponeurosis of the internal oblique fuse together anterior to the rectus muscle and insert in the midline (linea alba). Above the arcuate line, the posterior lamella of the internal oblique aponeurosis fuses with the aponeurosis of the transversalis muscle, passing posterior to the rectus muscle and inserting in the midline. The lower half of the lower abdominal wall is weakened below the arcuate line, at a level about horizontal to the anterior superior iliac spines, where the posterior division of the rectus sheath disappears. In this location, the divided lamella of the internal oblique muscle combines and passes anterior to the rectus muscle. From this lower portion of the lower abdominal wall to the pubic rami, only the attenuated transversalis fascia and the peritoneum lie adjacent to the posterior surface of the muscle. It is in this weakened section of the lower abdomen that most incisional hernias occur after open pelvic surgery through lower midline incisions. In the lower abdomen, the force required to approximate edges of a vertical incision is 30 times greater than the force required to approximate edges of a transverse incision.

FIGURE 14.1 Langer lines run horizontally across the lower abdomen. A transverse incision cuts parallel to the Langer lines and usually heals with a fine scar.

The external oblique muscle and its aponeurosis form the most anterior layer of the flat muscles. The external oblique muscle originates from the lower eight ribs. Superiorly, the fibers of this muscle run transversely; inferiorly, they assume an oblique downward course. A portion of the muscle gives rise

to a broad fibrous aponeurosis, which courses medially, anterior to the rectus muscle. The next posterior fanlike muscle is the internal oblique, which originates primarily from the iliac crest, the thoracolumbar fascia, and the inguinal ligament. The midportion of this muscle runs an upward oblique course and gives rise to the aponeurosis of the internal oblique. As noted, at the lateral border of the rectus musculature, the aponeurosis splits and forms a sheath around the rectus muscle, rejoining medial to the rectus to help form the linea alba. The third flat muscle, the transversus abdominis, arises from the lower six costal cartilages, thoracolumbar fascia, and the internal lip of the iliac crest. This muscle has a truly transverse course. Above the midway point between the umbilicus and pubis, the aponeurosis of this muscle passes behind the rectus muscle and contributes to the posterior rectus sheath. Below this point, the aponeurosis passes anterior to the rectus muscle, contributing to the anterior rectus sheath. Medial to the rectus muscle, the fasciae of all three flat muscles insert to form the linea alba.

FIGURE 14.2 Musculature of the abdominal wall (**left**), showing reflection of external and internal oblique muscles along with the anterior division of the rectus sheath, which exposes the transversalis and rectus muscles. Tendinous inscriptions in the rectus sheath are visible above the umbilicus. The rectus muscle has been reflected (**right**) to demonstrate the posterior rectus sheath and the abrupt cessation of the posterior lamella of the internal oblique at the linea semicircularis (*arcuate line*). Below the *arcuate line*, the intestines are separated from the abdominal wall by the peritoneum and the attenuated fascia of the transversalis muscle.

FIGURE 14.3 Cross section of lower abdominal wall. **A:** The anterior fascial sheath of the rectus muscle from external oblique muscle (1) and split aponeurosis of internal oblique muscle (2). The posterior sheath is formed by aponeurosis of transversalis muscle (3) and split aponeurosis of internal oblique muscle. **B:** Lower portion of abdominal wall below arcuate line (linea semicircularis) with absence of a posterior fascial sheath of the rectus muscle and all of the fascial aponeuroses (1-3) forming the anterior rectus sheath.

The major functions of the flat muscles are to assist with respirations and to assist in increasing intra-abdominal pressure. Each time these muscles contract, they pull at the linea alba. Because the linea alba represents the insertion of six major abdominal muscles (three on each side), cutting it, as with lower midline incisions, actually interrupts the major

P.220

portion of the insertion of these six muscles. Thus, contractions of these muscles in the postoperative period can result in considerable tension on a suture line in the linea alba and can cause considerable discomfort.

The rectus abdominis muscle arises from the pubic crest and courses superiorly, inserting into the xiphoid process with the upper attachments being three times as broad as its pubic insertion. It has three or four fibrous insertions. One is at the level of the umbilicus; two are usually halfway between the umbilicus and the insertions, superiorly and inferiorly, respectively. Of note, the fibrous insertions are tightly adherent to the anterior rectus sheath. These limit the retraction of the muscle when it is cut. Thus, when performing a transverse-muscle-cutting incision, it is not necessary to reapproximate the rectus muscle. The pyramidalis, a triangular muscle, usually lies anterior to the rectus and arises from the anterior portion of the pubic symphysis, inserting into the inferior portion of the linea alba. The midportion of this muscle usually has an avascular raphe, which can easily be incised to adequately expose the space of Retzius.

Blood Supply

The abundant blood supply to the anterior abdominal wall comes from several sources. The main arterial supply consists of the superior epigastric, musculophrenic, deep circumflex iliac, and inferior epigastric vessels. The medial abdominal wall receives blood from the epigastric arteries, whereas the lateral wall is supplied by the musculophrenic and deep circumflex iliac arteries. The lateral wall is also supplied by the lower intercostal and lumbar arteries (T8 to T12 and L1). This freely anastomosing vascular system provides one continuous arterial and venous channel on both sides of the anterior abdominal wall, extending from the subclavian artery and vein (cephalad) to the external iliac vessels (caudad) (Fig. 14.4). Because of the rich anastomosis, vascular deficiency is usually not a complication of abdominal wall surgery. The linea alba is relatively bloodless. The limited vascular supply in this area of fascial fusion can impair wound healing when lower midline incisions are used. Thus, a secure closure is mandatory to avoid dehiscences, eviscerations, or incisional hernias.

Conversely, the epigastric vessels are subject to injury, particularly when a muscle-splitting incision is used. Also, the deep circumflex or musculophrenic vessels can be injured when an extraperitoneal approach is chosen.

The superior epigastric artery is a continuation of the internal thoracic (mammary) artery. This vessel enters the sheath of the rectus from behind the seventh costal cartilage and descends posterior to the rectus muscle. It has multiple branches in the substance of the rectus muscle and anastomosis to the inferior epigastric artery. In the upper abdomen, cephalad to the umbilicus, the main branch of the artery tends to lie posterior to the midportion of the rectus muscle (Fig. 14.5). The inferior epigastric artery arises from the external iliac artery near the midinguinal point. It continues in a cephalad course along the posterolateral portion of the rectus muscle and has an anastomosis with the superior epigastric arteries. The lower a transverse incision is made, the more laterally the inferior epigastric arteries are encountered. Bleeding from branches of the inferior epigastric vessels beneath the rectus muscle can dissect cephalad or caudad along the entire length of the posterior sheath. Below the arcuate line, bleeding can dissect laterally and inferiorly along the retroperitoneal planes and spaces, resulting in extensive hematomas of the abdominal wall and pelvis. Such bleeding can produce confusing acute abdominal signs in the postoperative patient, with large quantities of blood being lost in these loose tissues and spaces.

FIGURE 14.4 The major arterial blood supply of the anterior abdominal wall consists of four major vessels. Two lateral and two medial contribute to the rich anastomosis. (Reprinted from Gallup DG. Opening and closing the abdomen and wound healing. In: Gershenson D, Curry S, DeCherney A, eds. *Operative gynecology*, 1st ed. Philadelphia, PA: WB Saunders, 1993:127, with permission. Copyright 1993 Elsevier.)

The musculophrenic artery, arising from the internal (mammary) thoracic artery, courses along the costal margin posterior to the cartilages. It has an

anastomosis with the deep circumflex artery, which originates from the external iliac at about the same level as the inferior epigastric artery. The deep circumflex courses behind the inguinal ligament and along the iliac crest, eventually piercing the transversalis muscle and digitating between that muscle and the internal oblique. Before its anastomosis with the musculophrenic, this vessel can be relatively large. Care must be taken not to injure this vessel when these muscles are incised laterally.

The venous drainage of the abdominal wall accompanies the arterial supply. The veins of the abdominal wall may be dilated in patients with obstruction of blood flow through the liver and porta hepatis.

Innervation

The nerve supply to the anterior abdominal wall is easily damaged by some incisions. The anterior abdominal wall is supplied by the thoracoabdominal nerves, the iliohypogastric nerves, and the ilioinguinal nerves. The thoracoabdominal

P.221

nerves, which are the 7th to 11th intercostal nerves, leave the intercostal spaces and travel caudad and anterior between the transversalis and internal oblique muscles. These nerves innervate these muscles as well as the external oblique. These nerves enter the sheath of the rectus muscle, and their branches innervate the rectus muscle and the overlying skin. Nerve roots from several vertebrae supply most of the nerves of the abdominal wall, whereby any one nerve will contain fibers from at least two or three intercostal nerves. When incisions are made lateral to the midline, a transverse type is the least likely to cause neural injury. In the upper abdomen, an obliquely caudad and laterally directed incision is least likely to cause significant nerve injury. In the lower part of the abdomen, an obliquely directed cephalad and laterally directed incision is relatively nerve sparing.

FIGURE 14.5 Arterial and venous circulation of abdominal wall. The superior and inferior epigastric arteries provide a rich arcade for the rectus muscles, arising superiorly from the internal thoracic artery and inferiorly from the external iliac artery. The venous system has a similar origin, with the exception that the superficial inferior epigastric vein communicates with the saphenous vein of the leg.

A vertical incision that passes lateral to the rectus muscle or through the muscle itself can denervate medially lying tissue. Depending on the length of the incision, atony or atrophy of the muscle can then occur. A midline incision in the linea alba or a transverse incision (even through the rectus muscle), however, does not interfere with motor innervation of the abdominal musculature.

A minimal loss of skin sensation can result from abdominal incisions and is unavoidable in most cases. The iliohypogastric and ilioinguinal nerves, which are chiefly derived from the first lumbar nerve root, are sensory in function ([Fig. 14.6](#)). Injury to the former, when wide transverse incisions are used, can result in sensation changes in the skin over the mons, whereas injury to the latter can result in sensation changes to the labia majora. A widely placed transverse incision can also result in numbness of the skin over the upper anterior thigh. Although they lie for a distance between the internal oblique and the transversalis muscles, they do not enter the rectus sheath. They do not innervate the external oblique or the rectus muscle. Both nerves supply the lower fibers of the internal oblique and transversalis muscles. If damage occurs to these nerves at the level of the anterosuperior iliac spine, these muscle fibers will be denervated, resulting in weakening of the normal inguinal canal-controlling mechanism and predisposing the patient to an inguinal hernia.

PHYSIOLOGY OF WOUND HEALING

When making a surgical incision, tissue integrity is violated in order to gain access to diseased organs for treatment. These acute wounds heal in a progressive, systematic, and balanced repair process, consisting of four phases: hemostasis, inflammation, proliferation, and remodeling ([Fig. 14.7](#)).

FIGURE 14.7 Orderly steps in wound healing.

The hemostatic phase is initiated immediately upon injury, whereby the intrinsic and extrinsic clotting cascades are activated. When an injury occurs, collagen, von Willebrand factor, and tissue factor are exposed from the subendothelium to the bloodstream, acting as the inciting catalyst for the systemic repair process. A platelet plug forms, composed of platelets and fibrin. Platelets release granules containing multiple growth factors, which act as chemoattractants, and thromboxane A₂, which acts as a potent vasoconstrictor. Transforming growth factor beta (TGF- β) is the key growth factor released, playing a central role in wound healing.

The inflammatory phase occurs from days 1 to 10 and is characterized by an inflammatory cell wound infiltration and initiation of epithelialization occurring at 1 to 2 mm from the wound edges. The ordered cellular influx begins with neutrophils that act as scavengers, cleaning cellular debris through phagocytosis and killing bacteria through oxidative burst. Neutrophils secrete elastase and matrix metalloproteinases (MMPs) to degrade the extracellular matrix, facilitating cellular migration. Monocytes from the blood convert to macrophages arriving at 48 hours, which are the key coordinating cells for transitioning to the proliferative phase by releasing additional growth factors, mediating angiogenesis and fibroplasia, and synthesizing nitric oxide.

The proliferative phase starts when fibroblasts arrive at the wound, usually around day 5. At this time, type III collagen is deposited with neovascularization and initiation of granulation tissue formation. Granulation tissue is perfused connective tissue, which forms the framework for further epithelialization. Fibroblasts in the wound convert to myofibroblasts to allow wound contraction, a key component for healing via secondary intention. Cellular signaling for this conversion is mediated by macrophages through TGF- β . Fibroblasts also secrete MMP, which aids cellular migration.

From day 8 through year 1, wound remodeling and maturation occur. Initial deposition of collagen is disordered, and over time, remodeling of collagen at areas of increased stress allows for increased tensile strength. By the 3rd week, type III collagen has been replaced for type I collagen, which is the most common type of collagen in the human body and provides 30% of its final strength. The maximal tensile strength of the tissue is reached approximately 8 weeks after injury and at a level which is 80% of its original strength.

When this ordered repair process fails, an acute wound is converted into a chronic wound. Factors negatively affecting proper

P.223

wound healing include age; comorbid conditions such as cardiac disease, connective tissue disorders, diabetes, and liver diseases; lifestyle factors such as nutritional status, obesity, smoking, and illicit drug usage; and therapeutic modalities such as prior irradiation, chemotherapy, steroid usage, and NSAID usage. In addition to these factors, bacterial burden can impact wound healing and interrupt the progressive, ordered repair process. Bacteria colonize a wound within 48 hours. Most bacteria have low virulence and do not invade the tissue. The wound relationship with bacteria consists of a continuum from contamination to wound septicemia. Contamination within a wound is defined by nonreplicating bacteria, whereas colonization is defined as replicating bacteria adherent to the wound without tissue damage, both of which do not delay wound healing. However, critical colonization may delay wound healing. In acute wounds, bacteria exist as free-floating planktonic organisms and must be rapidly controlled to prevent tissue destruction and wound sepsis (see below skin preparation for surgery). Bacteria in chronic wounds do not exist as planktonic organisms but rather as biofilms able to resist the host inflammatory cascade and antibiotic therapy.

TABLE 14.1 Wound Classification

CLASS	CATEGORY	DEFINITION	WOUND INFECTION RATE (%)
I	Clean	Wounds are made under ideal operating room conditions. The procedures are usually elective, and no entry is made into the oropharyngeal cavity or lumen of the respiratory, alimentary, or genitourinary tract. Inflammation is not encountered, and no break in technique occurs. The wounds are always primarily closed and seldom drained. Almost 75% of all operations are included in this group.	1-5
II	Clean-contaminated	Wounds occur from entry into the oropharyngeal cavity, respiratory, alimentary, or genitourinary tract without significant spillage. Clean wounds are included in this category when there is a minor break in surgical technique. These procedures include about 16% of all operations.	3-11
III	Contaminated	This category includes open, fresh, and traumatic wounds, operations with a major break in sterile technique, and incisions encountering acute, nonpurulent inflammation, such as in cholecystitis or cystitis.	4-17
IV	Dirty	Old (>4 h) traumatic wounds, perforated viscera, or operations involving clinically evident infections are included in this category. Wounds containing foreign bodies or devitalized tissue are also considered dirty.	5-27

From Ortega G, Rhee DS, Papandria DJ, et al. An evaluation of surgical site infections by wound classification system using the ACSNSQIP. *J Surg Res* 2012;174:33; Cruse PJE, Foord R. The epidemiology of wound infection: a 10-year prospective study of 62,939 wounds. *Surg Clin North Am* 1980;60:27; and Culver DH, Horan TC, Gaynes RP, et al. Surgical wound infection rates by wound class, operative procedure and patient risk index. National Nosocomial Infections Surveillance System. *Am J Med* 1991;91:152S.

The risks of wound infections are directly related to the classification of wounds (Table 14.1). Most of the abdominal procedures performed by gynecologists include a hysterectomy, and whenever the vagina is entered, the procedure is classified as a clean-contaminated procedure. Prevention of surgical site infections (SSIs) is critical to improve quality surgical care and reduce health care costs associated with such infections (see Prevention of Surgical Site Infections).

SUTURES

Many types of sutures have been used throughout the years for closure of wounds, to relieve healing tissues of the disruptive forces. Some of these materials include linen; cotton; silk; wires of gold, silver, iron, and steel; dried gut; animal hair; tree bark; and other plant fibers. In recent years, with advancements in polymer technology, a wide range of synthetic compounds have emerged as suture material. To date, however, no study, or surgeon, has definitively shown there to be a perfect suture for all situations.

The ideal suture material should have the following characteristics: knot security, inertness, adequate tensile strength, flexibility, ease in handling, smooth passage through tissue, nonallergenicity, resistance to infection, and absorbability at a predictable rate. Despite these ideal attributes, the presence of suture material (foreign bodies) in wounds induces an excessive tissue inflammatory response that lowers the body's defense mechanism against infection and interferes with the proliferative phase of wound healing (see above), ultimately leading to inferior wound strength due to excessive scar tissue formation.

Currently available suture material can be classified in many ways: suture size, tensile strength, absorbable versus nonabsorbable, multifilament versus monofilament, stiffness and flexibility, and, finally, smooth versus barbed. Table 14.2 lists the common sutures that are utilized in obstetrical and gynecologic surgical procedures, the relative tensile strength, the type of degradation (if any), and the handling characteristics.

There are two standards to describe the size of suture material: the US Pharmacopeia (USP) and the European Pharmacopoeia (EP). The USP is the more commonly used standard, which was established in 1937 for standardization and comparison of suture materials, corresponding to metric measures. This standardization sets out limits on the average diameter, and the minimum knot pull tensile strengths of the three classes of sutures are collagen, synthetic absorbable, and nonabsorbable. Size refers to the diameter of the suture strand and is denoted as zeroes. The more zeroes characterizing a suture size, the smaller the resultant strand diameter (e.g., 4-0 is larger than 5-0). Intuitively, the smaller the strand size, the less knot pull tensile strength of the suture. However, the tensile strength also is dependent upon the makeup of the suture.

P.226

The tensile strength of a suture will depend upon the diameter of the suture and the material that makes up the suture and is simply the force (measured in weight [pounds or kilograms]) necessary to cause the suture to rupture. This measurement is typically presented in two forms: straight pull and knot pull. A straight pull tensile measurement is the tension that causes rupture of the suture when that force is applied to either end of the suture, where a knot pull measurement is the force necessary to rupture the suture after a knot has been tied in the middle of the suture.

Suture materials are classified as being absorbable or nonabsorbable based upon whether they lose their entire tensile strength within 2 to 3 months or retain their strength for longer than 2 to 3 months. The degradation of suture material depends whether the material is a natural material (such as surgical gut/collagen sutures made from sheep or cow intestines) or synthetic materials (such as polyglactin 910 or polydioxanone), where the former is degraded by proteolysis and the later by hydrolysis. Although both degradative processes cause intense inflammatory responses in tissue, the response to synthetic materials is much less than the response to natural protein analogues.

If a suture is manufactured with more than one fiber, it is deemed a multifilament suture. In regard to wound healing, there are no advantages of a multifilament suture over a monofilament suture or vice versa. However, multifilament sutures inflict more microtrauma to tissue, induce a more intense inflammatory response, demonstrate enhanced capillarity (more crevices and spaces) with an increase in spread of microorganisms, and contribute to a larger knot size than do monofilaments of equal sizes. But the improved handling characteristics and flexibility of multifilament suture material may be more advantageous and outweigh any wound healing detriments as compared to the handling of monofilament sutures.

Suture stiffness and flexibility can be as important, as strength and absorption when it comes to classifying sutures as these traits determine the materials' handling or feel. Stiffness describes whether a suture is soft or hard, gives it memory or recoil, and determines the ease with which knots can be tied. Furthermore, stiffness is associated with the presence or absence of mechanical irritation of the suture due to its ability, or inability, to comply with the topology of the surrounding tissues.

Considering all of the characteristics mentioned above, knot tying of sutures is almost as integral to the surgery as the suture itself. A knot is needed as an anchor to the tissue to avoid suture slippage and acute and chronic wound complications (dehiscence and hernia formation). However, there may be unequal distribution of tension on the knots rather than on the length of the suture line, which may subtly interfere with uniform wound healing and remodeling. Irrespective of the knot configuration and material, the weakest spot along the suture is the knot, and the second weakest point is the portion immediately adjacent to the knot with reductions in tensile strength being reported from 35% to 95% depending upon the study and suture material used. It is these weak areas that generally represent the site of failure of a suture. Finally, knot security will depend on suture size and the tissue needing approximation. Although sliding knots, also known as *nonidentical sliding knots*, can be safely used for pelvic viscera, sutures used to close abdominal wall fascia should be tied with square knots, and the number of throws will depend upon the suture material. Sometimes it is convenient to tie a loop-to-strand knot as a way of terminating a continuous suture rather than tying a single-strand to single-strand knot. Hurt and colleagues eloquently conducted a safety evaluation of tying a loop-to-strand knot with a monofilament suture, poliglecaprone (Monocryl). In these experiments, the authors used 0-0- and 2-0-gauge suture, randomly comparing single-strand with single-strand square knots, loop-to-strand square knots, and loop-to-single-strand, nonidentical sliding knots. A total of 40 knots were tied in each group and evaluated by tensiometry. The major outcome studied was the proportion of knots becoming untied in each group. The authors found that when monofilament sutures were tied loop-to-single strand with nonidentical sliding knots, 85% of the 0-0-gauge suture and 55% 2-0-gauge sutures untied. None of the single-strand to single-strand square knots untied, and only 15% of the 0-0 and 5% of the 2-0-gauge sutures, when tied loop-to-single strand with square knots, untied. Although these conditions were carefully controlled and conducted ex vivo, care must be taken to lay down square knots (six throws) while tying monofilament suture in a loop-to-singlestrand fashion. Van Rissel and colleagues observed poor knot performance when a surgeon's knot plus two square knots was made with monofilament sutures.

In addition to understanding the physical properties and characteristics of the variety of suture material available, the surgeon must consider the tissue and physiologic milieu in which the suture will be placed, before choosing said material. However, since all materials induce some degree of unwanted inflammatory reaction, choosing a balance between strength and inflammation is key to selecting a particular suture for a particular tissue closure. For example, due to the high disruptive forces on rectus fascia, repair of these wounds needs suture material that has relatively longer tensile strength than suture materials used in other areas of gynecology. A recent meta-analysis by Hodgson et al. reviewed absorbable versus nonabsorbable sutures for the closure of rectus fascia and found a statistically significant increase in hernia formation with polyglycolic acid sutures, but no difference in risk with polydioxanone when compared with nonabsorbable nylon and polypropylene. However, there was a statistically significant increase in both suture sinuses and wound pain with nonabsorbable suture compared to absorbable suture. In typical conditions, the reasoned suture selection for closing abdominal fascia for gynecologic operations would seem to be one of the delayed absorption monofilament sutures, such as polydioxanone or polyglyconate, although polyglycolic acid-based sutures are not unreasonable (especially for closure of transverse fascial incisions) given their long safety history in obstetrics and gynecology.

Drains

Sometimes, drainage of the abdominal cavity is appropriate after an operation for a tuboovarian abscess or some other type of pelvic infection. In addition, intraperitoneal drainage may be helpful for oozing peritoneal surfaces after complicated hysterectomies or other pelvic surgery. Although used in the past for prevention of lymphoceles or ureteral fistulae, retroperitoneal drains are not routinely used after radical pelvic surgery.

The use of prophylactic drains in the subcutaneous space to reduce the formation of hematoma and seroma or to reduce abscess and infection remains controversial. Recently, a large meta-analysis of the subject was reported, showing that subcutaneous drains could be omitted after cesarean section, breast reduction surgeries, abdominal surgeries (clean-contaminated wounds), femoral wounds, and hip and knee joint replacement. Furthermore, the authors suggested that drains should not be placed prophylactically secondary to a patient being obese. Farnell and associates, in a prospective study, analyzed 3,282 incisions of the wound varieties listed in [Table 14.1](#). When patients with clean-contaminated or contaminated wounds received subcutaneous closed drainage systems, alone or with antibiotics or saline irrigation, no significant advantage was noted compared with primary closure without

P.227

drainage. However, a trend favoring subcutaneous drainage and antibiotic irrigation was seen in patients with contaminated wounds.

FIGURE 14.8 Cross section of abdominal wall depicting CDC classifications of surgical site infection. (Reprinted from Horan TC, Gaynes RP, Martone WJ, et al. CDC definitions of nosocomial surgical site infections, 1992: a modification of the CDC definitions of surgical wound infections. *Infect Control Hosp Epidemiol* 1992; 13:606, with permission. Copyright 1992, The Society for Hospital Epidemiology of America, Inc. and SLACK Incorporated.)

Drains can be classified into two categories: passive and active. The passive drain functions primarily as an overflow “valve” being assisted by gravity, while the latter drain is connected to some type of suction device. If a drain is used at all, the preferred system is a closed drainage system such as a Jackson-Pratt or a Blake. Both have small reservoirs (100 mL) that are relatively easy for paramedical personnel to manage on the ward and at home. The Blake drain, with its longitudinal ridges, offers less chance of obstruction from small tissue fragments or clots than does the Jackson-Pratt drain. However, no large prospective, randomized trials comparing these two systems have been done to substantiate that claim. To avoid clot formation and subsequent obstruction, the drain is placed on suction early, usually while completing closure of the incision. In addition, the nursing staff (and other caregivers) should be instructed to “strip” the drain catheter each shift (or several times throughout the day) while the drain is in place. Drains in the subfascial or subcutaneous spaces should be removed and not advanced as has been done in the past. Once the drainage is less than 50 mL per 24 hours, usually by postoperative day 2 or 3, it can be safely removed.

PREVENTION OF SURGICAL SITE INFECTIONS

Surgical site infection (SSI) is defined as an infection that occurs at or near a surgical incision within 30 days of a procedure or within 1 year if an implant is

left in place. The Centers for Disease Control further categorize SSIs as being incisional or organ/space. Incisional SSIs are further divided into those that involve only the skin and subcutaneous tissues (superficial incisional SSI) and those involving deeper soft tissues of the incision (deep incisional SSI) (Fig. 14.8). The CDC estimates that approximately 500,000 SSIs occur annually in the United States and account for 38% of all nosocomial infection. Two thirds of these SSIs are confined to the incision and one third involves organs or spaces accessed during the operation. These infections reduce patients' quality of life and account for 3.7 million excess hospital days and more than \$1.6 billion in excess costs annually. Surgical wound classification was introduced in 1964 by the National Academy of Sciences (Table 14.1) and lists estimates of SSI for each class of wound. The rate of SSI with gynecologic operations is typically 8% to 10% and is related to many factors, including surgeon experience, the indication for the procedure, the procedure performed, and the comorbid condition of the patient. In preparation for surgery, there are several patient-centered and operative characteristics that must be considered and completed to reduce the rate of SSI. The CDC recommendations to reduce SSI have been published, and the reader is directed to this reference for the full recommendations. However, a brief synopsis is presented here.

Patient Issues

Several patient characteristics have been associated with increased risk of SSI and include coincident remote site infections or colonization, prolonged preoperative hospital stay, diabetes, tobacco usage, steroid use, obesity (body mass index [BMI] ≥ 30 kg/m²), extremes of ages, poor nutritional status, and perioperative transfusion of blood products.

Preoperative Issues

Although multiple studies have shown that preoperative showers or baths the night before surgery with chlorhexidine gluconate did a better job of reducing bacterial colony counts

P.228

as compared to povidone-iodine or triclocarban-medicated soap, no study has definitively shown that such a practice reduces postoperative SSI rates. A recent, fourth, meta-analysis update on the topic by Webster and Osborne demonstrated (in seven trials included in the analysis, with over 10,000 patients) no conclusive evidence exists that preoperative showering with chlorhexidine over other wash products (iodine or regular soap) reduced SSI. At this time, this issue is still unresolved, and for our patients, we do not recommend the practice.

Traditionally, patients undergoing surgery have hair removed from the site of incision in order to reduce the chance of SSI. Some studies have shown that if hair removal is accomplished by shaving, 24 hours or more, before an operation, microscopic cuts in the skin serve as foci for bacterial multiplication. A recent, large meta-analysis of this practice was completed by Tanner et al. and showed that although hair can be removed by several different methods (shaving, clipping, the use of depilatories to dissolve hair) and at several different time points prior to an operation (the day before surgery versus immediately preoperatively), existing research studies are too small and methodologically flawed to make strong recommendations for or against hair removal or for which technique of hair removal is superior to affect postoperative SSIs. However, the authors' recommendation is that if hair must be removed to facilitate the surgery or application of adhesive dressings, clipping rather than shaving, immediately before surgery, appears to result in fewer SSIs.

There are several antiseptic agents for preoperative preparation of the abdominal skin and vaginal area for gynecologic surgery (Table 14.3). The iodophors, alcohol-containing products, and chlorhexidine gluconate are the most commonly used agents and require various amounts of time to apply and to dry depending upon the agent and the presence of hair on the skin. Darouiche et al. performed a multicenter, prospective randomized trial comparing povidone-iodine to chlorhexidine-alcohol skin preparation for 849 adults undergoing clean-contaminated surgery. These investigators showed that the chlorhexidine-alcohol patient cohort had a significantly lower SSI rate versus the povidone-iodine group (9.5% versus 16.1%, *p* = 0.004). In addition, the chlorhexidine group had fewer superficial infections (4.2 versus 8.6, *p* = 0.008) and deep incisional infections (1% versus 3%, *p* = 0.05). There was no difference in the organ/space infection rate between the two groups. A meta-analysis by Lee et al. included nine randomized controlled trials (inclusive of the study above and a total of 3,614 patients) comparing chlorhexidine preparations to iodine preparations for reduction of SSI. The authors found that chlorhexidine antiseptics significantly reduced the rate of SSIs by 36% (risk ratio 0.64, 95% confidence interval 0.51 to 0.80) across a wide variety of surgical procedures versus iodine antiseptics. It is important to note that when using the chlorhexidine-alcohol (2% chlorhexidine gluconate and 70% isopropyl alcohol, ChlorPrep) preparation of the abdominal skin, the skin must be scrubbed with the preloaded applicator and allowed to dry prior to draping. For preparation of the vagina, currently, no study of sufficient power has been completed that would lead to a strong recommendation for or against chlorhexidine or povidone-iodine cleansing of the vagina to reduce SSI. In our institution, the vagina is cleansed with the povidone-iodine prep routine or chlorhexidine (4% Hibiclens) prep if the patient is iodine sensitive.

TABLE 14.3 Antiseptic Solutions for Operative Preparation of Abdominal Skin

ANTISEPTIC	MECHANISM OF ACTION	ANTIMICROBIAL COVERAGE	ONSET DURATION	APPLICATION	EXAMPLES
Aqueous-iodophor	Free iodine causes protein and DNA damage.	Excellent for gram+ bacteria; good for gram-, fungi, virus, Mtb	Intermediate 2 h	Two-step scrub and paint	Betadine Scrub Care
Aqueous-CHG	Disrupts cell membranes	Excellent for gram+; good for gram- and virus; fair for fungi; poor for Mtb	Intermediate 6 h	Two-step scrub and dry; repeat X1	Hibiclens
Alcohol-iodophor	Ethyl alcohol/ethanol (ETOH) denatures protein. Free iodine	Same as aqueous iodophor, but improved	Rapid 48 h(DuraPrep)	One-step paint <i>Dry time</i> —3 min on hairless surface	DuraPrep solution

	causes protein and DNA damage.	gram and Mtb activity	96 h (Prevail-Fx)		Prevail-Fx
Alcohol-CHG	ETOH denatures protein. CHG disrupts cell membranes.	Same as aqueous-CHG, but improved gram, fungal, and Mtb activity	Rapid 48 h	1-step scrub for dry site—30 s 1-step scrub for moist site—2 min <i>Dry time</i> —3 min on hairless surface	ChloroPrep

The surgical scrub is the process that each member of the surgical team performs by washing the hands and forearms

P.229

prior to donning surgical gowns and approaching the operative sterile field. Recent studies have shown that scrubbing for at least 2 minutes is as effective as the time-honored 10-minute scrub in reducing bacterial colony counts. In addition, the first scrub of the day should include a thorough cleaning under the fingernails (usually with a “pick” and brush). Limited data exist concerning reusable versus disposable surgical attire and different drapes used for different surgeries and the risk of SSI for patients. However, the Occupational Safety and Health Administration does require these “barriers” be present to protect personnel of the surgical team from exposure to body fluids and recommends that surgical attire be changed if visibly soiled.

Most incisions will be closed primarily after the surgical procedure, and a dressing for the incision is applied. Generally, this cover is left in place for 24 to 48 hours prior to being removed. If the incision is left open to be closed at a later time (delayed primary closure) or to heal by secondary intention, then it is packed with sterile dressing. Sometimes, a wound vacuum is placed to aid healing by negative pressure (see below). In general, delayed closure should be used for contaminated or dirty wounds. Alternatively, intermittent staples can be placed in the skin with intervening saline-moistened “wicks” into the subcutaneous spaces. When a bacteria-containing organ is opened (the unprepped bowel or abscessed gynecologic organs) and delayed closure is not used, copious saline irrigation of all layers for closure should be instituted. In addition, a monofilament nonabsorbable or slowly absorbable suture should be used in the fascia closure to further reduce bacterial loads.

Prophylactic antibiotic administration has been shown to decrease SSI in patients undergoing abdominal or vaginal hysterectomy and is aimed at reducing colonization from endogenous bacteria from the skin or ascending, endogenous, pathogenic bacteria from the vagina, opened at the time of hysterectomy. Unfortunately, these antibiotics either are not given or are given at inappropriate times prior to the surgical incision. The theory is that an antibiotic present in tissue will aid the host immune defense mechanism in killing bacteria that are inoculated into the wound (i.e., when a skin incision is made or the vagina opened).

The ideal antibiotic should be of low toxicity, have an established safety record, not be routinely used for the treatment of serious infections, have a spectrum of activity that includes the microorganisms most likely to cause infection, reach useful concentration in relevant tissue during the procedure, be administered for a short duration, and be administered in a fashion that will ensure it is present at the site of surgery, at the time of incision. The American Congress of Obstetricians and Gynecologists has published a practice bulletin covering the topic of antibiotic prophylaxis, and the reader is directed to this publication for a more thorough discussion.

TABLE 14.4 Recommended Prophylactic Antibiotics for Hysterectomy and Urogynecology Procedures

PROCEDURE	ANTIBIOTIC	DOSE (SINGLE DOSE)
Hysterectomy	Cefazolin ^a	1 g or 2 g IV ^b
Urogynecology procedures, including those with mesh	Clindamycin plus gentamicin ^c OR Quinolone ^d OR Aztreonam Metronidazole plus gentamicin OR Quinolone	600 mg IV/1.5 mg/kg IV 400 mg IV 1 g IV 500 mg IV/1.5 mg/kg IV 400 mg IV

^aAcceptable alternatives include cefotetan, cefoxitin, cefuroxime, or ampicillin-sulbactam.

^bA 2 gm dose I recommended in women with a body mass index (BMI) >35 kg/m² or weight >100 kg or 220 pounds

^cAntimicrobial choice in women with a history of immediate hypersensitivity to penicillin.

^dCiprofloxacin or levofloxacin or moxifloxacin.
IV, intravenously.

Adapted from ACOG Committee on Practice Bulletins-Gynecology. Antibiotic prophylaxis for gynecologic procedures. ACOG Practice Bulletin No. 104 American Congress of Obstetricians and Gynecologists. *Obstet Gynecol* 2009;113:180, with permission. Copyright 2009. The American Congress of Obstetricians and Gynecologists.

Although more than 30 prospective, randomized clinical trials and two meta-analyses support the use of prophylactic antibiotics to substantially reduce postoperative infectious morbidity and decrease length of stay in women undergoing hysterectomy, no antibiotic regimen is superior to all others. [Table 14.4](#) shows the acceptable prophylactic antibiotic regimens to be dosed within 1 hour of incision for hysterectomy. First- and second-generation cephalosporins are typically used in patients not sensitive to β -lactam agents. Most patients need only one dose of prophylactic antibiotic; however, for procedures lasting longer than the half-life of the antibiotic, redosing is appropriate (3 to 4 hours for most first-generation cephalosporins). Similarly, if there is a large loss of blood (>1,500 mL), then a second dose of the antibiotic is appropriate. All prophylactic antibiotics need to be stopped within 24 hours of completion of the surgery.

In 2002, the CDC and the Centers for Medicare and Medicaid Services (CMS) collaborated on the Surgical Infection Prevention (SIP) project to develop quality improvement measures, which included the timeliness, appropriate selection and duration of perioperative prophylactic antibiotics, normothermia for colorectal procedures, euglycemia, and appropriate hair removal, in 55 participating hospitals. Investigators found that in the 44 hospitals that reported results, the rate of SSI decreased 27%, from 2.3% in the first 3 months of participation to 1.7% in the last 3 months. In 2006, the SIP evolved into the current Surgical Care Improvement Project with the goal of reducing the rate of surgical complications, and CMS has now tied payment to the hospital based upon participation and reduction of these complications. There are 20 measures covering various discrete elements of patient care; nine of these measures are publicly reported and seven measures focus on SSI reduction, of which five pertain to hysterectomy.

P.230

BEST PRACTICE

- Prophylactic antibiotic administration within 1 hour of surgical incision (within 2 hours if the patient is receiving vancomycin or fluoroquinolones).
- Appropriate prophylactic antibiotic for the specific procedure ([Table 14.4](#)).
- Prophylactic antibiotic must be discontinued 24 hours after surgery end time.
- Surgical site hair removal (clipping or depilation versus no hair removal) if hair interferes with the incision/surgery.
- Urinary catheter removal on postoperative day 1.
- Colorectal surgery patients with perioperative temperature management.
- For cardiac surgery patients, a controlled 6 AM postoperative blood glucose (<200 mg/dL).

Because of concerns about wound complications, a prior dictum was that incisions of the abdominal skin should not be made with electrosurgery. A recent meta-analysis looking at wound complication rates between incisions made with a scalpel or electrosurgery found no difference in wound complications regardless of method of incision creation. The review included nine randomized controlled trials (1,901 participants) and found no significant difference in overall wound complication rates (risk ratio 0.9, 95% confidence interval 0.68 to 1.18) or rates of wound dehiscence (risk ratio 1.04, 95% confidence interval 0.36 to 2.98). No statement could be conclusively made concerning blood loss, pain, or incision time. The authors concluded that current evidence suggests that making an abdominal incision with electrosurgery may be as safe as using a scalpel.

Discarding the skin knife, which continues as an archaic practice to date, has not been shown to reduce wound infection rates but instead leaves an extra “sharp” on the operative field, which may injure members of the health care team. In a randomized prospective study, the rate of postoperative wound infections was not different after the use of one or two scalpels for the incision. The same scalpel used on the skin can be safely used for subcutaneous and deep incisions.

ABDOMINAL INCISIONS

In general, abdominal incisions used for most gynecologic procedures can be divided into transverse or vertical incisions. For extraperitoneal incisions and access to organs not associated with the female genital tract, modifications of oblique incisions are sometimes used. Because of the ease and rapid entry, the abdomen was originally routinely opened by a midline incision in the linea alba. One of the first successful abdominal operations was performed by McDowell in 1809. In the early days of abdominal surgery, transverse incisions were generally avoided because they were more time consuming. Also, an unfounded fear was that transection of the rectus muscle would leave a defect because of retraction of the muscle. As previously stated in the section on anatomy, the adherence of the recti musculature to its anterior fascia by several transverse inscriptions prevents retraction. In the late 1800s and early 1900s, several transverse incisions were developed, such as the Küstner, Pfannenstiel, Maylard, and Cherney incisions. Most of the transverse incisions used for pelvic surgery are identified by the name of the surgeon who first described them, whereas the few vertical abdominal incisions have no such eponyms.

Transverse Incisions

Transverse incisions for pelvic surgery are attractive because they produce the best cosmetic results. Additionally, low transverse incisions are as much as 30 times stronger than midline incisions, are less painful, and result in less interference with postoperative respirations. Wound dehiscence is allegedly more common with vertical incisions. The older literature suggests that wound evisceration was three to five times more common and hernia formation was two to three times more common when vertical incisions were used compared with transverse incisions. Many earlier studies reported an increased incidence of eviscerations with midline incisions that could be associated with inappropriate closures. More recent studies, however, have shown no difference in the risk of wound dehiscence or even a slight advantage for midline incisions. A large study, completed at Hutzel Hospital in Detroit by Hendrix and colleagues, found that there was no difference in fascial dehiscence between transverse (Pfannenstiel) and vertical incisions.

Transverse incisions have certain associated disadvantages. They are relatively more time consuming and relatively more hemorrhagic. Occasionally, nerves are divided, and division of multiple layers of fascia and muscle can result in formation of potential spaces with subsequent hematoma or seroma formation. Ability to explore the upper abdominal cavity adequately is compromised with most low transverse incisions.

Pfannenstiel Incision

Most surgeons would agree that the Pfannenstiel incision provides the best wound security of all gynecologic incisions. The cosmetic results are excellent,

but exposure is limited (especially to the upper abdomen). This type of incision should be used in select patients with certain gynecologic malignancies. It should not be used (or should be used in very select patients) when pelvic exposure is needed in certain nonmalignant conditions, such as severe endometriosis, and large leiomyomata with distortion of the lower uterine segment, or when reoperating on a patient for postoperative hemorrhage.

The original, true Pfannenstiel incision is described as a transverse incision that is slightly curved (concavity upward) and may be made at any level suitable to the surgeon (**Fig. 14.9A**). It is usually 10 to 15 cm long and extends through the skin and subcutaneous fat to the level of the rectus fascia. The rectus fascia is incised transversely on either side of the linea alba, which is cut separately, joining the two lateral incisions but leaving the rectus fascia intact across the midline (**Fig. 14.9B**). The rectus sheath is separated from the underlying muscle by inserting the fingers on either side of the cut edge of the sheath and pulling the fascia in opposite directions, with one hand toward the head and the other hand toward the feet (or alternatively, cutting the attachments in the midline). This maneuver frees the fascia from the anterior surface of the rectus muscle as far as desired between the symphysis and the umbilicus (**Fig. 14.9C**). The rectus muscles are then separated in the midline, and the peritoneum is opened vertically (**Fig. 14.9D**). This procedure avoids the necessity of dissecting the subcutaneous fat away from the anterior rectus fascia, as is done in the Küstner incision. It separates the perforating nerves and small blood vessels, which enter the fascia from the underlying muscles to supply the fascia, although it possibly weakens the incision.

If the Pfannenstiel incision is extended laterally beyond the edge of the rectus muscles and into the substance of the external and internal oblique muscles, injury to the iliohypogastric or ilioinguinal nerves can occur, with resulting neuroma formation. In addition, closure of this extended fascial incision can entrap these nerves in either the closing suture or surrounding scar tissue. To avoid these nerve injuries in laterally extended incisions, including a Cherney or Maylard incision, the lateral extensions should have sutures placed only in the external oblique fascia.

P.231

FIGURE 14.9 A: The skin incision for a Pfannenstiel incision is elliptical just above the symphysis pubis. **B:** The skin, subcutaneous fat, and fascia of the abdominal wall are incised transversely. **C:** The fascia is separated from the rectus muscle superiorly, inferiorly, and laterally. Small perforating vessels require ligation or coagulation. **D:** The rectus muscles are separated, and the peritoneum is incised in the midline.

P.232

The fascia can be closed with a running technique in patients with clean wounds or clean-contaminated wounds. Polyglycolic acid, polyglactin 910, or one of the delayed absorbable sutures can be used. Subcutaneous sutures are usually unnecessary, and the skin is closed with a subcuticular suture (preferably monofilament), reinforced surgical tape (e.g., Steri-Strips), skin glue, or staples.

Küstner Incision

Some surgeons advocate a Küstner incision, incorrectly referred to as a modified Pfannenstiel incision. The slightly curved transverse skin incision begins below the level of the anterior superior iliac spine and extends just below the pubic hairline, through subcutaneous fat, down to the aponeurosis of the external oblique muscle and the anterior sheath of the recti musculature, in the same manner as all other transverse incisions (**Fig. 14.10A**). The superficial branches of the inferior epigastric artery and vein may be encountered in the subcutaneous fat at the lateral margin of the incision. When encountered, they can be ligated or sealed with electrocautery. The fascia is cleaned superiorly and inferiorly until a sufficient area is exposed from the region of the umbilicus

to the symphysis to permit an adequate vertical incision in the linea alba. Excessive separation of the fat from the fascia in the lateral margins of the incision is unnecessary and can provide sites for small postoperative hematomas. Separation of the rectus muscles and entrance into the peritoneum are performed in the same manner in the ordinary midline incision (**Fig. 14.10B**). Because of the importance of obtaining adequate hemostasis in the subcutaneous fat of the skin flaps, this incision is definitely more time consuming than the low midline incision or the Pfannenstiel incision. It offers little or no tensile strength advantage, and its extensibility is severely limited. If this incision is used, strong consideration of subcutaneous, closed suction drainage should be given, due to the large amount of “dead space” created.

FIGURE 14.10 Küstner incision. **A:** Skin incision just below the hairline. **B:** Midline incision through fascia, exposing rectus and pyramidalis muscles. The rectus muscles are retracted laterally, and the peritoneum is incised in the midline.

Cherney Incision

The Cherney differs from the muscle-dividing Maylard incision by the location of transection of the rectus muscles. In both incisions, the skin and fascia are divided transversely as with a Pfannenstiel incision, but Cherney advocated freeing the rectus muscles at their tendinous insertion into the symphysis pubis. The rectus muscles are then retracted cephalad to improve exposure. The transverse Cherney incision is about 25% longer than a midline incision measured from the umbilicus to the symphysis.

The Cherney incision provides excellent access to the space of Retzius and excellent exposure of the pelvic side wall.

P.233

Occasionally, the surgeon who uses a Pfannenstiel incision finds that incision inadequate for exposure for hemostasis or not large enough to expose areas of associated abnormal conditions deep in the pelvis. Under these circumstances, the safe approach is not to transect the rectus muscles halfway, but to perform a Cherney incision. Partial incision of the rectus muscle can lead to injury of the inferior epigastric vessels on the lateral border of the rectus muscles. Also, if conversion to a Maylard is attempted after a previous Pfannenstiel incision, the anterior rectus sheath will have already been widely separated from the rectus muscles. In this case, the ends of the muscle are likely to retract and will not reunite when the edges of the fascia are later reapproximated. In this situation, it may be necessary to reapproximate the rectus muscle ends with horizontal mattress sutures (which may be difficult due to the retraction).

Even if the peritoneum is opened, the space of Retzius can be bluntly dissected (**Fig. 14.11**). The inferior epigastric vessels, which course more laterally on the rectus muscles, are identified. The pyramidal muscles are sharply dissected. The fibrous tendinous rectus muscles are then dissected sharply from their insertion into the symphysis pubis (**Fig. 14.12**). Bleeding is negligible in this area, and the inferior epigastric vessels do not need to be ligated. The peritoneal incision can be extended laterally about 2 cm cephalad to the bladder while the vessels are visualized.

As stated earlier, transverse incisions, particularly the Cherney and the later-described Maylard, can result in nerve injury. The femoral nerve is particularly at risk when a self-retaining retractor with deep lateral blades is used in these widely extended incisions. If a self-retaining retractor is used with either of these incisions, the lateral blades should only be deep enough to fit under the edges of the incision and not rest on the psoas muscles.

In closing a Cherney incision, the ends of the rectus tendons are united to the inferior portion of the lower flap of the rectus sheath with five or six interrupted

delayed absorbable or permanent sutures in horizontal mattress configuration (**Fig. 14.13**). To avoid osteomyelitis, the rectus muscles should not be sutured to the periosteum of the symphysis pubis. Fascial closure is then accomplished with a running continuous suture of No. 0 or No. 1 delayed absorbable material, as in the Pfannenstiel. Although the lines of tension favor transverse incisions as opposed to vertical incisions, running sutures should be placed at least 1.5 cm from the fascial edge and 1.0 cm from one another. The remainder of the closure is similar to the Pfannenstiel closure, depending on the surgeon's preference.

FIGURE 14.11 Developing the space of Retzius. The weight of the hand of the operator easily separates the bladder from the overlying symphysis in the relatively bloodless midline. (Reprinted from Gallup DG. Opening and closing the abdomen. In: Phelan JP, Clark SL, eds. *Cesarean delivery*. New York: Chapman & Hall, 1988:449, with permission; from Taylor and Francis Group LLC, with permission.)

FIGURE 14.12 The finger of the operator is placed posterior to the rectus muscle, and with gentle traction, the muscle is pulled cephalad. The rectus muscle can then be dissected from its insertion at the symphysis by the Bovie device. The peritoneal incision can then be extended laterally, avoiding the inferior epigastric vessels, which are positioned laterally. (Reprinted from Gallup DG. Abdominal incisions and closures. In: Gallup DG, Talledo OE, eds. *Surgical atlas of gynecologic oncology*. Philadelphia, PA: WB Saunders, 1994:43, with permission. Copyright © 1995, Elsevier.)

Maylard Incision

The Maylard incision is a true transverse-muscle-cutting incision in which all layers of the lower abdominal wall are incised transversely. This incision was originally described by Ernest Maylard in 1907. The incision provides excellent pelvic exposure and is used by many surgeons for radical pelvic surgery,

P.234

including radical hysterectomy with pelvic lymph node dissection and pelvic exenteration. Although midline incisions are preferable for patients with suspicious adnexal masses, patients with adnexal masses, which are questionable for malignancy by radiographic and serologic studies, may be candidates for this more cosmetic incision. Patients must be informed that if malignancy is found, the transverse incision will take the form of a “hockey stick” or “J” incision (**Fig. 14.14**), or a separate upper abdominal incision will be used to evaluate the upper abdominal cavity and retroperitoneal paraaortic nodes.

FIGURE 14.13 Reuniting of the rectus tendons to the inferior portion of the lower flaps. The deep inferior epigastric vessels are positioned laterally in the caudad portion of the abdomen. (Reprinted from Gallup DG. Opening and closing the abdomen. In: Phelan JP, Clark SL, eds. *Cesarean delivery*. New York: Chapman & Hall, 1988:449, with permission; from Taylor and Francis Group LLC, with permission.)

FIGURE 14.14 J-shaped incision on the right is shown in relation to deeper structures, the ureter, iliac vessels, and great vessels. It is initiated about 3 cm cephalad to the umbilicus and is carried inferiorly parallel to the round ligament. (Reprinted from Gallup DG. Abdominal incisions and closures. In: Gallup DG, Talledo OE, eds. *Surgical atlas of gynecologic oncology*. Philadelphia, PA: WB Saunders, 1994:43, with permission. Copyright 1995, Elsevier.)

The Maylard-Bardenheuer incision has been modified in several aspects since its original description. Before the skin incision is made, a series of three to four perpendicular markings with a sterile marking pen are made across the planned line of the incision. These markings help later to reapproximate the skin edges. The transverse skin incision is made about 3 to 8 cm above the pubic symphysis, depending on the indications for surgery and patient age and weight. The skin incision should never be made in a deep skin crease or beneath a large panniculus, because of the anaerobic environment

P.235

in this location and increased risk of wound complications. The fascia is incised transversely, and the aponeurosis is not detached from the underlying muscle.

FIGURE 14.15 Maylard incision. The rectus muscles are incised with a knife or a Bovie device. The hand of the surgeon is withdrawn as the muscle is cut. The inferior epigastric vessels were previously isolated, sectioned, and ligated. (Reprinted from Gallup DG. Opening and closing the abdomen. In: Phelan JP, Clark SL, eds. *Cesarean delivery*. New York: Chapman & Hall, 1988:449, with permission; from Taylor and Francis Group LLC, with permission.)

Once the transverse fascia incision has been carried lateral to the borders of the rectus muscles, the inferior epigastric vessels, lying on the posterolateral border of each muscle, are identified. (Some surgeons suggest preservation of these vessels even when the rectus muscles are transected.) The vessels are “teased” away from their attachments by using blunt dissection with an instrument or gentle finger dissection. The vessels are ligated before incising the rectus muscles to avoid tearing of the vessels, vessel retraction, and hematoma formation (Fig. 14.15). The fingers of the surgeon tease the overlying rectus muscle from the peritoneum, and the muscles are sectioned between the fingers by using an electrocautery.

For better approximation of the muscles during closure, suture the underlying muscle to the overlying fascia before entering the peritoneum. A 2-0 delayed absorbable “U” suture is used, and the knots are placed anterior to the fascia. The peritoneum is incised transversely.

Closure of the fascia is similar to the running technique for other transverse incisions. The muscles do not need to be reapproximated with individual sutures (exception noted above), although some surgeons prefer to close the parietal peritoneum with a running polyglycolic suture. Drainage of the subfascial space is the surgeon's prerogative (Fig. 14.16).

FIGURE 14.16 The peritoneum has been closed with 2-0 polyglycolic acid sutures. A closed drainage system is used if hemostasis is not absolute. A running delayed absorbable suture is used, placing the bites about 1.5 cm from the fascial edge. (Reprinted from Gallup DG, Talledo OE, eds. *Surgical atlas of gynecologic oncology*. Philadelphia, PA: WB Saunders, 1994:43, with permission. Copyright 1995, Elsevier.)

Caution should be exercised in using the Maylard incision in patients with impaired circulation to the leg secondary to obstruction of the common iliac arteries or terminal aorta. In this situation, blood flow from the inferior epigastric artery may provide the only additional collateral circulation to the lower extremity. Ligation of this artery could result in lower extremity ischemia and a real vascular surgical emergency. In the gynecologic patient with clinical evidence of impaired circulation in the lower extremity, a midline incision should be used.

Vertical Incisions

Generally, vertical incisions afford excellent exposure, can be easily extended, and provide rapid entry to the abdominal cavity. Whether the incision is made midline or paramedian, the resulting scar may be wide.

Midline (Median) Incision

As stated in the section on anatomy, the midline incision is the least hemorrhagic incision, as well as the incision that affords rapid entry into the abdominal/pelvic cavity. Exposure is excellent, and minimal nerve damage occurs. However, dehiscence and hernias are said to be more common. Abdominal wound disruption is one of the most serious postoperative problems associated with gynecologic surgery. The “burst abdomen,” or evisceration, seen more frequently in general surgery patients, occurs with a frequency of 0.3% to 0.7% in gynecologic patients and is associated with a mortality of 10% to 35%. The type of incision is only one factor associated with evisceration. Mechanical factors—such as wound hematomas, paroxysmal coughing associated with chronic lung disease, and gastrointestinal problems (retching, vomiting, ileus)—can lead to evisceration. However, better perioperative care, newer suture material, and better closure techniques have been shown to lower the rates of wound infection, dehiscence, and hernia formation.

The midline incision is the most easily mastered gynecologic incision because the fascial area is relatively bloodless and the rectus muscles are usually separated in parous women. If the patient has a prior midline incision, the surgeon should incise the skin and peritoneum more cephalad to the earlier incision to avoid injury to possibly adherent bowel. In nulliparous women, the midline separation between the rectus muscles may not be obvious. In these cases, the pyramidalis muscles are useful landmarks in directing the surgeon to the midline separation of the rectus muscles, inferiorly. Because this incision can be extended easily, the midline incision is the most versatile of all incisions used by gynecologists.

Hemostasis of the anterior layers of the abdomen should always be complete before the peritoneum is entered (**Fig. 14.17**). Once the abdomen is explored (in a systematic fashion), the bowel is carefully packed out of the pelvis. Seldom are more than two or three moist laparotomy packs needed to accomplish exposure of the pelvis. If more packs are required or there is a struggle to pack the upper abdominal contents, anesthesia may be inadequate, or in patients with prior abdominal surgery, adhesive disease may be obstructing movement. The more packs used, the more likely small-bowel terminal nerve endings will be damaged, resulting in postoperative adynamic ileus. Use of more modern table-fixed retractors, such as the Bookwalter retractor, not only improves exposure in vertical and transverse incisions but also limits the use of excessive packs.

Paramedian Incision

The true paramedian incision is placed lateral to the midline and splits the rectus muscle longitudinally. Like the midline or median incision, the paramedian incision has excellent extensibility and exposure, particularly on the side of the pelvis where the incision is made. However, because it splits the rectus muscle, the risk of bleeding and nerve injury is increased, relative to the median incision. A modified paramedian incision retracts the rectus muscle laterally before incising the posterior rectus sheath and peritoneum. This approach avoids the potential risks associated with splitting the rectus muscle. Paramedian incisions have been advocated over midline incisions because of alleged greater strength. A recent meta-analysis, comparing outcomes of midline incisions with transverse and paramedian incisions, showed that midline incisions had higher hernia rates as compared to transverse incisions (risk ratio 1.77, 95% confidence interval 1.09 to 2.87) and paramedian incisions (risk ratio 3.41, 95% confidence interval 1.02 to 11.45).

Fascial Closure of Vertical Incisions

Although midline incisions allow quick entry into the abdomen and provide excellent exposure to abdominal and pelvic anatomy, the relatively avascular nature of the anatomy, as well as the lateral pulling forces, make these types of incisions weaker and prone to early (see SSIs above and evisceration below) and late postoperative complications. Incisional hernia is a frequent complication of midline abdominal surgery with a reported incidence of 3% to 13% and typically results in some future surgical intervention, increasing patient morbidity and decreasing patient quality of life. Most incisional hernias seem to develop during the early postoperative period and are related to early separation of the fascial edges. Because the regenerative capability of fascia is limited, the ability of the closing suture line to hold these edges together during the early postoperative period is paramount. The fascia heals quite slowly and needs to have support from the suture utilized for at least 6 weeks to reduce the risk of incisional hernia formation. The surgeon can control several variables (e.g., reducing SSIs [as discussed above], choosing an appropriate suture for closure, employing proper suturing technique) to reduce the rate of hernia formation.

Selecting a suture to close midline abdominal incisions is the prerogative of the surgeon; although a myriad of options exist, no consensus on the choice of suture material (or even technique of closure) exists. Over the last two decades, multiple prospective randomized clinical trials have been completed comparing one suture to another and evaluating for wound complications, such as evisceration, hernia formation, wound infection, suture sinus formation, and wound pain. Although some classes of suture outperformed others, to date, no single suture has emerged as the sole superior choice for closure of midline incisions. However, several types of nonabsorbable and slowly absorbable suture material have come to the forefront for closure of midline incisions with resulting reduction of hernia formation versus closure with quickly absorbing suture material. As mentioned above, one of the most important factors of closure of the midline incision is that the fascial edges need to be approximated for at least 6 weeks to reduce hernia formation. Nonabsorbable monofilament and slowly absorbable (e.g., **PDS**; see **Table 14.2**) suture material produce low rates of incisional hernia, as compared to fast-absorbing suture, which support the fascia for less than 6 weeks. In addition, the rate of SSI is lower with monofilament suture compared to multifilament material, owing to the interstitial spaces where bacteria can evade phagocytosis. Diener et al. recently performed a meta-analysis of midline laparotomy closure, reviewing the literature, including five systematic reviews (dating from 1998) and 14 trials (published between 1981 and 2009), and including 7,711 patients (6,752 midline incisions). The authors reported that the five systematic reviews contained significant heterogeneity and did not meet their criteria for analysis. However, the 14 trials included in their review demonstrated no statistical heterogeneity for patients undergoing elective midline laparotomy closure. Their findings showed that hernia rates were significantly lower with absorbable suture versus nonabsorbable suture (odds ratio 0.41, 95% confidence interval 0.43 to 0.82, $P = 0.001$) and slowly absorbable versus quickly absorbable sutures (odds ratio 0.65, 95% confidence interval 0.19 to 0.88, $P = 0.02$). No statistical differences were noted among the secondary end points of wound dehiscence, suture sinus formation, wound infection, and wound pain, whether wounds were closed with nonabsorbable versus slowly absorbable or slowly absorbable versus quickly absorbable suture material. The authors concluded that for elective primary or secondary laparotomy through midline incisions, the abdominal fascia should be closed with slowly absorbable (monofilament) suture material in a continuous fashion. The authors had no recommendation for closure of the abdominal fascia in emergency setting.

Suturing technique goes hand in hand with the suture material used for midline laparotomy closures. Several meta-analyses have been performed assessing outcome after

continuous closure (with varying types of suture material) versus interrupted closures (with various types of suture material). In general, these reviews showed that incisional hernias, wound dehiscence, suture sinus formation, wound infection, and wound pain were less for continuous closure as compared to interrupted closure. In addition, the continuous closure technique is significantly easier and faster than interrupted closure (**Fig. 14.18**) Further, closing

the wound in one single layer has produced lower dehiscence rates than closure with several layers, and including the peritoneum in the suture line does not contribute to the tensile strength of the wound.

FIGURE 14.17 **A:** Cutting of linea alba in low midline incision with scalpel. **B:** Cross section of abdominal wall showing skin, subcutaneous fat, anterior and posterior rectus sheaths, and underlying peritoneum. **C:** Opening of peritoneum with knife, and demonstration of small bowel protruding into peritoneal opening. **D:** Enlargement of peritoneal opening to the region of the umbilicus with Mayo scissors.

Standardizing the tension applied on sutures in the clinical setting during closure of the abdomen is difficult. However, higher tension is correlated with higher rates of SSI than with

P.238

lower tension. This may be due to soft tissue that is included in the stitch, which gets compressed and devitalized, leading to tissue necrosis and increasing the rate of SSI. For continuous closure, the *suture length to wound length* (SL-to-WL) ratio is directly correlated with incisional hernia formation (fewer hernias with SL-to-WL ratio of 4 or higher) but depends upon the number of stitches, the size of the stitches, the tension on the suture line, and the length of the wound.

FIGURE 14.18 Closure of a midline incision using a No. 2 polypropylene, running mass closure. The anterior fascia, muscle, posterior fascia, and peritoneum are included in the bites (**inset**), which are taken 1.5 to 2 cm from the fascial edge and about 1 cm apart. With permanent polypropylene suture, a hemoclip can be used on the short end to avoid suture unraveling.

Calculation of SL-to-WL ratio: $(A - [B + C]) / D$

A = length of suture used

B = length of suture remnants at the starting knot

C = length of suture remnants at the finishing knot

D = length of skin incision

High SL-to-WL ratio can be accomplished with large stitches or with small stitches placed at closer intervals. For several decades, it had been recommended to place large stitches at least 1 to 1.5 cm from the wound edge and 1 cm apart. This surgical dictum was purely based upon experimental data. However, recent experimental data from Cengiz et al., and taking into account SL-to-WL ratio, showed that smaller stitches, placed 5 to 8 mm from the wound edge and at close intervals of 4 to 5 mm, resulted in a stronger wound 4 days after closure compared to wounds closed with larger stitches, placed 10 mm from the edge and 10 to 15 mm apart. More recently, Millbourn et al. showed that keeping the SL-to-WL ratio at 4 or greater, but using smaller stitch sizes as described above, resulted in an incisional hernia rate significantly lower than if large stitches were used to maintain the same SL-to-WL ratio (5.6% versus 18.0%, $P = 0.001$). In addition, SSI rates were less with small stitch size versus larger stitches (5.2% versus 10.2%, $P = 0.02$).

Although interesting from a historical perspective, the interrupted Smead-Jones closure technique (**Fig. 14.19**) has not been shown to be superior to a continuous closure technique in patients at high risk for wound disruption. However, this technique is a far-far, near-near, interrupted, mass closure technique. The first (far-far) bite includes both the fascia and peritoneum on each side, and only the anterior fascia is included in the near-near bite. The widely spaced initial pass takes the tension off the healing incision, while the carefully placed near-near bites approximate the fascial edges. A nonabsorbable or slowly absorbable suture is used, with the key to the success of this closure being widely spaced far-far bites (at least 1.5 to 2 cm from the fascial edges).

FIGURE 14.19 Smead-Jones layered closure. This is a far-far, near-near suturing technique, with the anterior fascia being included in the near-near bite. A No. 1 nylon or No. 1 polypropylene suture (or some other delayed absorbable suture) is used, with the key to the success of this closure being widely spaced far-far bites (at least 1.5 to 2 cm from the fascial edges). This closure technique may be performed in an interrupted fashion or as running suture. (Reprinted from Morrow CP, Curtin JP. Incisions and wound healing. In: *Gynecologic cancer surgery*. Churchill Livingstone, 1996:152, with permission: from

BEST PRACTICE

- Use a monofilament suture material, slowly absorbable or nonabsorbable.
- Use a continuous suture technique.
- Close the wound in one layer.
- Avoid high tension on the suture—adapt but do not compress the fascia edges.
- Place the stitches in the fascia only, 5 to 8 mm from the wound edge and at close intervals 4 to 5 mm apart.
- The SL-to-WL ratio should be 4 or greater.

Oblique Incisions

Oblique incisions can be used for a transperitoneal or an extraperitoneal approach.

Gridiron (*Muscle-Splitting*) Incision of McBurney

The McBurney incision is an excellent choice for an uncomplicated appendectomy and can be used for the extraperitoneal drainage of an abscess from pelvic inflammatory disease. In pelvic inflammatory disease, when drainage becomes necessary for an indolent broad ligament abscess that does not respond to antibiotics and does not point into the cul-de-sac for drainage, drainage through a gridiron incision is most effective. The incision is constructed as for an appendectomy, except that it is made a little lower, and the peritoneal cavity is not entered. Similarly, if drainage of the pelvis is required during a pelvic laparotomy, the drain should not exit through the midline incision but rather through a small gridiron (stab wound) incision in the lower abdomen. In treating a large tuboovarian abscess that extends out of the pelvis and does not respond to antibiotic therapy, extraperitoneal drainage through a McBurney incision is also possible by approaching the abscess laterally. This permits entrance into the site of infection without soiling the peritoneal cavity.

FIGURE 14.20 Gridiron incision. **A:** Position of incision. **B:** Fibers of external oblique have been split. **C:** Internal oblique muscle being split with a Kelly clamp. **D:** In closing, internal oblique fibers are approximated with figure-of-eight No. 0 delayed absorbable sutures. **E:** Aponeurosis of external oblique is closed with continuous or interrupted No. 0 delayed absorbable sutures.

The gridiron incision is made obliquely downward and inward over the McBurney point (**Fig. 14.20A**). The location can be varied when the incision is performed for appendectomy during pregnancy or when it is used for abscess drainage, as mentioned above. The incision in the skin can be made at a lower

level to preserve the cosmetic appearance of the abdominal wall. The incision is carried through the skin and subcutaneous fat to the external oblique muscle. The fibers of the muscle are separated in the direction in which they run (**Fig. 14.20B**). The internal oblique and the transversus abdominis are separated in the line of their fibers (**Fig. 14.20C**). At this point, the internal oblique and the transversus abdominis course in the same direction and are

closely fused. Retractors are avoided, if possible. Instead, the peritoneum should be gently reflected away from the abdominal wall inferiorly and the abscess entered beneath the round ligament for extraperitoneal drainage. Thickened indurated tissue may make this step difficult. If the parietal peritoneum is adherent to the peritoneal surface of the abscess, drainage still may be possible without transversing free space in the peritoneal cavity. The surgeon should avoid contaminating the peritoneal cavity with pus, if possible.

The gridiron incision can be used in the left lower quadrant to drain an abscess on the left side of the pelvis as well as to perform sigmoid colostomy. Closure is depicted in [Figure 14.20D, E](#) and is best made with a monofilament slowly absorbable suture.

Rockey-Davis Incision

An alternative to the McBurney incision is the Rockey-Davis (or Elliot) incision. It is a transverse incision placed at the junction of the middle and lower thirds of a line extending from the anterosuperior iliac spine to the umbilicus. Medially, the incision extends to the border of the rectus muscle. The aponeurosis of the external oblique muscle is split in the line of its fibers. The internal oblique and transversus muscle fibers can be separated by blunt finger dissection. The peritoneum is incised transversely. This incision has provided satisfactory exposure to pathology in either lower abdominal quadrant. A similar incision made lower on the abdomen preserves the cosmetic appearance of the abdominal wall.

Incisions for Obese Patients

The prevalence of obesity is increasing in the United States, with 30% of adults being classified as being obese ($\text{BMI} \geq 30 \text{ kg/m}^2$) and 20% as being classified as extremely obese ($\text{BMI} \geq 40 \text{ kg/m}^2$). Obesity is a recognized risk factor for postoperative wound infections, and thus, placement of an abdominal incision can be challenging in these patients. Pitkin first observed increased operative and postoperative risks when abdominal hysterectomy is performed on obese patients. He noted significantly more postoperative fever in the obese patients versus nonobese (59% versus 36%) and a significant difference in wound complications for obese patients over nonobese (29% wound complication rate versus 4%). Krebs and Helmkamp reported a wound infection rate of 24% in massively obese patients when a periumbilical transverse incision was used. Because muscle cutting is needed for this transverse incision, entry time can be lengthy and relatively hemorrhagic. If any transverse incision is chosen for obese patients, it should be far removed from the anaerobic moist environment of the subpannicular fold ([Fig. 14.21](#)).

FIGURE 14.21 Midline incision in an obese patient. The panniculus is retracted inferiorly, and the incision avoids the moist anaerobic environment (*inset*) beneath the subpannicular fold. (Reprinted from Gallup DG. Opening and closing the abdomen. In: Phelan JP, Clark SL, eds. *Cesarean delivery*. New York: Chapman & Hall, 1988:449, with permission; from Taylor and Francis Group LLC, with permission.)

In 1977, Morrow and colleagues suggested modifications of preoperative care, intraoperative techniques, and postoperative care in obese gynecologic patients and observed only a 13% wound infection rate. Gallup subsequently modified Morrow's techniques. He reported his experience in a group of 97 obese patients, comparing them to obese patients not operated on by the modified protocol. Obese patients who were managed with the modified protocol had a wound infection rate of 3% versus 42% in those patients not operated on by protocol.

In the obese patient, the umbilicus is deviated caudally on a vertical axis in the supine and dorsal lithotomy positions. When relating the position of the umbilicus to the pubic symphysis, it can sometimes be at or below the level of the pubic symphysis, depending upon the size of the panniculus. Any incision should not be performed in the suprapubic fold after lifting the fat pad because of the poorly vascularized skin, which is typically thin and submitted to intense maceration due to the moist warm anaerobic environment that promotes the proliferation of numerous organisms ([Fig. 14.21](#)).

Several options for incisions on the obese abdomen exist. Querleu described a transverse incision, similar to the Maylard incision described above. But the midline incision seems to be the incision of choice for most surgeons. This incision is made by first retracting the panniculus caudad, below the inferior margins of the symphysis ([Fig. 14.21](#)). The skin incision is a periumbilical incision because it is usually extended around the umbilicus and more cephalad due to the caudally deviated position of the umbilicus. The fascial incision is always extended to the symphysis. A supraumbilical longitudinal

incision, as described by Greer and Gal, is a variation, where the entire incision is above the umbilicus, in the flat area of the abdomen above the panniculus.

After the operation is completed, the abdominal fascia is closed with a monofilament slowly absorbing (or occasionally monofilament nonabsorbable) suture

in a continuous closure. Subcutaneous sutures and or drains are not used. The skin is closed with staples, which are left in place for 2 weeks.

Panniculectomy and Abdominoplasty

An alternate surgical approach in the massively obese patient is to remove the large panniculus before the intended pelvic surgery. As observed by Kelly in 1910, wound complications can be avoided and cosmesis can be achieved by this procedure. Exposure to the pelvic organs is certainly improved. In 1978, Pratt and Irons reported on 126 panniculectomies, and 85 of these were performed to facilitate exposure to the surgical field. The average hospital stay was only 14 days, but 34.5% of the patients had some degree of morbidity. In the series by Voss and colleagues, 5 of 76 (6.6%) patients undergoing panniculectomy and hysterectomy developed pulmonary embolism. In another series, investigators encountered excessive blood loss and acknowledged the need for transfusion in combined surgery. More recently, several series have noted the relative safety of combining abdominoplasty with other surgical procedures. Hopkins and colleagues performed a retrospective review of patients who underwent panniculectomy at the time of gynecologic surgery. They identified 78 patients (average weight 278 pounds) on whom the procedure was performed. Their infection rate was a laudable 2.6%, with an equally impressive average blood loss of 71 mL. Four of the patients had minimal incisional separations.

As more sophisticated monitoring, better antibiotics, better suture material and techniques, and a safer blood supply have become more available, selective use of combined gynecologic procedures and plastic surgical removal of the panniculus is increasing. Extended antibiotic prophylaxis to prevent SSI in morbidly obese patients who do have the combined hysterectomy and medically indicated panniculectomy may be indicated. In a cohort study conducted at the Mayo Clinic, investigators showed that morbidly obese women who received standard prophylactic antibiotics and continued oral ciprofloxacin until drains were removed, had fewer SSIs compared to morbidly obese women who received only standard prophylactic antibiotic treatment (5.9% for extended antibiotics versus 27.9% in the standard treatment group). In a study of patients who had a mean weight of 261 pounds, Morrow et al. found no operative mortality and a mean hospital stay of 8.2 days. Only 11% of the patients required transfusion. The investigators in this series emphasized that the panniculectomy should be performed first to improve exposure.

Although removal of a large panniculus results in better exposure, patient selection for this potentially morbid procedure should be carefully considered. Also, the patient must be counseled and must be strongly motivated to lose weight and change her nutritional habits. If the patient is not committed to these lifestyle changes, it seems impractical to perform an extensive abdominoplastic procedure and incur the associated morbidity. If the surgical procedure is not urgent, an alternative would be to defer the procedure until the patient has achieved 40% to 50% of the planned weight loss.

Of the various operative techniques available for panniculectomy and abdominoplasty, the elliptical transverse incision, originally described by Kelly, has proven to be the procedure of choice. Two modifications of the transverse panniculectomy can be useful. The most common procedure includes an elliptical “watermelon” incision ([Fig. 14.22A](#)), extending from the lateral aspect of the lumbar regions to about 3 to 4 cm above the umbilicus. If the patient requests the preservation of the umbilicus, it can be excised and transplanted to the upper pedicle of skin. However, as shown by Cosin and colleagues, this transplantation can lead to increased wound complications. Inferiorly, the transverse incision follows the concave skin fold that separates the overhanging panniculus from the suprapubic skin. The underlying fat is excised deeply in a slightly wedged manner, with the deep portion of the fat extending outward and slightly beyond the skin margin to avoid ischemia of the skin edge. Meticulous attention must be given to absolute hemostasis (a time-consuming procedure) to avoid postoperative hematoma formation and infection. The excessive use of cautery, which produces a favorable environment for bacterial growth in devitalized tissue, should be avoided. The lateral angles of the incision may require separate “V” incisions to avoid the unsightly folds of redundant fat ([Fig. 14.22B](#)). When these V-shaped wedges are closed, the angle of the incision is converted into a

P.242

Y-shaped configuration, which eliminates the excessive skin in the lateral aspects of the abdominal wall. After the removal of the large panniculus, the abdomen can be opened either transversely or vertically. A vertical incision has been advocated to improve exposure.

FIGURE 14.22 Panniculectomy incisions. **A:** Elliptical transverse incision extending from the region of iliac crest passes above and below the umbilicus. **B:** V-shaped incision in lateral angles eliminates folds of skin in abdominal wall. **C:** W-shaped incision over the mons pubis extends along the inguinal ligament to the iliac crest. **D:** The upper incision passes above the umbilicus. Wide mobilization of the upper skin flap is carried to the sternum and rib margins. **E:** After removal of panniculus and skin, the upper skin flap is sutured without tension to the lower skin margin. **F:** A firm elastic dressing is crisscrossed over the abdominal wall for abdominal support and prevention of seroma formation.

DELAYED PRIMARY CLOSURE AND SECONDARY CLOSURE

The value of delayed primary wound closure in managing possible contaminated wounds has been recognized by military surgeons for many years. In 1968, Grosfeld and Solit reported that patients with perforating appendicitis had a reduction in wound infection rates from 34.1% to 2.3% when delayed closure was used. Similarly, in a high-risk group of patients—which included patients with obesity, cancer, possible contamination from above-and-below procedures, infection, and bowel content contamination—Brown and colleagues found a marked reduction in wound infection rates when delayed primary closure was used compared with immediate closure in matched patients. The infection rate for the former group was 2.1%; for the latter, 23.3%. Possible candidates for such a closure include patients with ruptured appendicitis, ruptured tuboovarian abscess, extensive bowel injury, or diverticulitis with contamination.

After closure of the fascia, the wound is irrigated with copious amounts of saline and then packed with 0.1% Dakin solution (sodium hypochlorite). The wound dressing sponges are changed two to three times a day with a wet-to-dry technique, using sterile saline or 0.1% Dakin solution. Once the signs of infection are gone, the Dakin solution should be stopped, as it can impede epithelialization. In 4 to 5 days, depending on the appearance of granulation tissue in the subcutaneous tissues, the previously placed sutures are tied to approximate the skin edges. Tincture of benzoin is placed at the lateral edges of the closed incision, and Steri-Strips are used to approximate uneven skin edges.

Alternatively, the skin edges of the incision can be closed with widely spaced staples, “wicking” the intervening spaces with saline-soaked (Dakin solution in the face of infection) gauze (e.g., Nu Gauze or Kerlix strips). Once adequate granulation tissue is present, the skin edges can be reapproximated with nonabsorbable monofilament sutures and local lidocaine at the patient’s bedside before discharge from the hospital.

Superficial separation of layers anterior to the fascia is usually associated with wound infections, seromas, or hematomas. Many centers suggest opening the wound, usually the entire length, obtaining appropriate cultures for antibiotic choice, and allowing healing by second intention, with once- or twicedaily wound dressing changes. Although most cleansing in a second-intention scenario is accomplished by home health care personnel, patients are inconvenienced by this method. A trend in many centers and practices has been to perform delayed closure after a period of 2 to 5 days. In 1988, in a prospective randomized study, Hermann and associates found that secondary closure, performed 2 days after wound drainage had ceased, resulted in a significant reduction in healing time when compared with healing by second intention.

In a larger series of patients on an obstetrics and gynecology service, Walters and colleagues found a similar advantage in delayed closure of wounds. In 35 patients who underwent reclosure, 85.7% had their wounds successfully closed. Patients in this study had abdominal incisions that had been opened owing to infection, hematoma, or seroma. The fascia was intact in all patients, and all patients had wound debridement and cleansing for a minimum period of 4 days. All patients in this series had reclosure performed in the operating room and received three doses of cefazolin. The closure was done by an en bloc technique, using No. 2 monofilament nylon sutures. In a series from the University of Mississippi (Dodson et al.), patients with superficial wound dehiscence

were randomized to en bloc closure with No. 1 polypropylene versus a superficial closure through the skin using No. 2 polypropylene vertical mattress sutures. There was no statistical difference in the number of days needed to complete wound healing. However, the en bloc group required longer time for closure, and these patients experienced more pain. Of note, none of these patients received prophylactic antibiotics, and all wounds were reclosed under local anesthesia in the patient care area 2 to 6 days after reopening the wound.

Our technique for reclosing wounds is similar to that reported by Dodson and associates. After reopening the wound in patients with superficial wound dehiscence, the subcutaneous tissues are debrided daily, and wet-to-dry dressings using sterile saline are placed in the wound two to three times daily. Antibiotics are generally not used unless the patient has a concomitant infection (e.g., cellulitis or cuff infection). The wound is closed when a healing bed of granulation tissue without exudate or necrotic debris is present. Many wounds require sharp debridement, but most can still be closed within 5 days of reopening.

Wounds are closed in the treatment room on the ward or in the office with local 1% lidocaine anesthesia after premedication with anxiolytics and narcotic pain medication. The skin is then prepped with a povidone-iodine solution, and the sutures are placed 1 cm from the skin edges and 2 cm apart. The suture of choice is a No. 0 polypropylene suture or a similar permanent or delayed absorbable suture. We leave the sutures in for 2 weeks.

An alternative to secondary closure with suture is negative pressure wound therapy (NWPT). Since the first reports of this type of therapy for chronic wounds in 1997, NWPT has overwhelmed the wound healing world, including treatment of postoperative wound complications. This method utilizes a pump to produce subatmospheric pressures (50 to 125 mm Hg), a polyurethane foam (which is black in color) with pore sizes ranging from 400 to 600 μ m or polyvinyl alcohol foam (which is white) (both of which can be cut to conform to the wound), tubing to connect the foam to the pump and to the fluid reservoir, and occlusive material to create a seal to maintain negative pressure. The mode of the pump is either intermittent or continuous. The mechanism of action is that the foam occludes the wound, allowing for quicker epithelialization, and drains away any exudates. In addition, the subatmospheric pressure creates tissue strain, stimulating cellular proliferation, angiogenesis, and growth factor elaboration. Further, inflammation and edema is reduced, with all the associated mediators, and the bacterial load in the wound is reduced. The black foam, which has the larger pores, is considered most effective at stimulating wound contraction and formation of granulation tissue. The white foam has a smaller pore size and is utilized to restrict granulation tissue growth. Contraindications to NWPT include exposed vessels, anastomotic sites, organs, nerves, malignancy, untreated osteomyelitis, nonenteric and unexplored fistulae, and necrotic tissue. The presence of necrotic tissue requires aggressive debridement prior to NWPT. It is important to note that no randomized clinical trial comparing NWPT to delayed closure has been done despite a robust use of this technology for disrupted, postoperative wounds.

P.243

COMPLETE WOUND DEHISCENCE AND EVISCERATION

Technically, wound dehiscence means separation of all layers of the abdominal incision, but wound dehiscence has been subdivided based on the layers of tissue that have separated. Incomplete or partial dehiscence (superficial dehiscence) means separation of the skin and all tissue layers posterior to the skin, sometimes including the fascia. However, if the disruption includes the peritoneum, the disruption is called a complete dehiscence. Should the intestine protrude through the wound, the term *evisceration* (also a burst abdomen) is used. The frequency of fascial dehiscence ranges between 0.3% and 3% of all cases of pelvic surgery.

Evisceration is one of the most feared and dangerous postoperative complications, with a reported incidence of 0.4% to 3.5%, rates that have remained constant over the last several decades despite advances in perioperative care, surgical techniques, and materials. The mortality rate associated with evisceration has been reported to be as high as 35% and is usually associated with other complications, such as sepsis. However, Helmkamp's 10-year study noted a mortality rate of only 2.9% in 70 cases, which may reflect improved supportive care available for these patients in recent years. Evisceration is less likely to occur in gynecology patients than in general surgery patients.

Older studies reported that the type and location of the incision and the type of suture used were major causative factors in evisceration. However, many of the predisposing factors for complete wound disruption or evisceration are metabolic and include malnutrition, poorly controlled diabetes, corticosteroid use, and older age. Mechanical factors associated with dehiscence and evisceration include obesity, intra-abdominal distention (including rapid postoperative reaccumulation of ascites), infection, retching, and coughing. In addition, any process that can impair wound healing, such as radiotherapy or chemotherapy, can contribute to an increased risk for wound disruption.

Complete wound dehiscence and evisceration are usually problems associated with tissue failure and not suture failure, with the main mechanism being suture cutting through the suture holding tissues. If the suture holding tissues disintegrate due to a necrotizing infection, this usually occurs 7 to 10 days after wound closure, as it takes time for an infection to develop. However, rates of severe SSI causing dehiscence or evisceration are quite low (0.1%). The most common cause for wound dehiscence is most likely the quality of the suture technique (see above). Maintenance of a SL-to-WL ratio over 4 and utilizing a continuous closure versus interrupted are both associated with low rates of dehiscence and evisceration.

Rollins and associates noted that about half of their patients with serious wound complications had prior abdominal or pelvic surgery. In the series reported by Jurkiewicz and Morales, 88% of eviscerated wounds had tearing of suture through the fascia, with knots and suture intact. Thus, large loose sutures with secure knots are always preferable to tight strangulating sutures that cause ischemia of the incision margin.

Eviscerations usually occur from day 5 to 14 after operation, with a mean of about 8 days. One of the early signs of complete dehiscence and impending evisceration is the seepage of serosanguineous pink discharge from an apparently intact wound. It can be present for several days before evisceration occurs and occurs in 23% to 84% of cases. Although occult hematomas are usually the cause of such discharge, these wounds need to be examined carefully by probing with a cotton-tipped swab to assess the integrity of the fascial closure. Frequently, the patient is conscious of something giving way, "tearing," or "popping" immediately before the burst abdomen becomes clinically apparent.

With few exceptions, complete dehiscence or eviscerations should be closed as soon as they are recognized. In case of evisceration, when a delay of several hours is anticipated because of a recent meal, the bowel can be replaced by using sterile gloves, gently packing it in place with lap pads soaked in saline, and securing it with an abdominal binder. Broad-spectrum antibiotics should be initiated, and baseline blood counts and serum electrolyte studies should be obtained.

Closing an evisceration should be performed in the operating room (never on the floor) and always under general anesthesia so that the extent of the dehiscence may be determined. Necrotic tissue clots and suture material should be removed, and aerobic and anaerobic cultures should be obtained. The

bowel and omentum should be inspected and thoroughly cleansed with several liters of warm normal saline. If the fascial margins can be located and are not ragged, a continuous, mass closure technique with a slowly absorbable monofilament suture, achieving an SL-to-WL ratio of 4 or more, is advised. When completing the closure, it is unknown whether small or large stitch size is better, but the SL-to-WL ratio can be maintained with either. The subcutaneous tissue and skin are packed open for later delayed closure or NWPT placement.

If the wound edges are ragged or the patient's condition is poor, a through-and-through retention suture of No. 2 nylon or polypropylene is used. The sutures are placed at least 2.5 to 3 cm from the skin edges and are passed through all layers. To allow for edema, they are placed 2 cm apart (**Fig. 14.23**).

P.244

To prevent inclusion of the underlying intestine in a suture, all sutures are held up before the first one is tied. Skin edges unopposed between the through-and-through sutures can be approximated with interrupted 3-0 polypropylene. The through-and-through sutures should be left in place for 3 weeks. A nasogastric tube should be used in the immediate postoperative period to avoid abdominal distention, and broad-spectrum antibiotics should be continued and modified according to culture results.

FIGURE 14.23 A: Secondary closure of an evisceration with retention sutures (usually No. 1 polypropylene sutures—rubber dams can be included) and preferably No. 2 polypropylene sutures. **B:** All layers are incorporated.

INCISIONAL HERNIA

Incisional hernia is a frequent complication after midline incisions (and less frequently in transverse incisions) of the abdominal wall. In this situation, the peritoneum remains intact, and the fascial margins and adjacent muscles separate, leaving a defect beneath the subcutaneous tissue into which the bowel and omentum may herniate.

Causes of herniation are similar to those of evisceration; however, the skin, subcutaneous tissue, and peritoneum remain intact. Most cases of ventral hernia follow an incisional infection, weakening the supporting tissues. Increased intra-abdominal pressure from coughing and vomiting, along with necrosis of the fascial margins, permits the sutures to pull through the edge of the fascia. These changes result in separation of the wound edges and failure of fibroblastic bridging of the fascia. This complication occurs more frequently in lower abdominal incisions because of the anatomic deficit of the posterior fascial sheath beneath the rectus in the area inferior to the semicircular line. Ventral hernias occur after low midline incisions in about 0.5% to 1% of all gynecologic operations, with the incidence rising to about 10% after a wound infection. Similarly, reclosure after dehiscence increases the chance of hernia formation to about 25%.

Although the initial fascial defect may be small, the size of the resultant hernia can assume varying proportions and involve the entire length of the lower abdominal wall. The size of the hernia depends on the mobility of the bowel and omentum and the final aperture size of the ventral defect. A large amount of small bowel and omentum can escape from a small fascial defect into an easily expandable subcutaneous space. The smaller the fascial defect through which small bowel can herniate, the greater the frequency of incarceration, obstruction, and infarction.

Patients with ventral hernias often report lower abdominal discomfort, and with large ventral hernias, the abdominal wall is distended to varying degrees. Patients with large hernias may note bowel peristalsis beneath the skin and report that the bulge becomes smaller when they are in a recumbent position. The hernia is more noticeable during coughing and straining and can increase in size over time because of enlargement of the hernial ring or incorporation of additional segments of bowel into the hernial sac. Rarely, a ventral hernia produces acute symptoms of visceral torsion, incarceration, and infarction. Repair of the hernia is preferably done on an elective basis.

Advances in the technique of hernia repair as well as the materials (synthetic and biologic meshes) to repair such hernias have made a thorough discussion of the topic here, beyond the scope of this chapter.

PERINEOTOMY INCISIONS

Adequate exposure is just as important with vaginal surgery as it is with abdominal surgery. When exposure is not adequate with abdominal operations, the incision is extended, or some other measure is used to improve exposure. Certain measures also can improve exposure with vaginal operations. A tight vaginal introitus may restrict exposure of the upper vagina but can be enlarged at the beginning of the operation by making a midline or mediolateral episiotomy incision. A mediolateral incision can be made on one or both sides of the vaginal introitus. If a midline episiotomy is made and closed transversely, the vaginal introitus can be made larger than before, if that is deemed advisable. These incisions can be closed with 2-0 or 3-0 delayed absorbable suture.

Sometimes, the entire vagina is small in caliber because of virginity or nulliparity, atrophic shrunken vaginal mucosa, previous colporrhaphy, or previous irradiation or disease. The vaginal vault may be fixed in a relatively high position, with relatively little descensus. Because adequate exposure through the vagina may be impossible, some operations may require an abdominal approach. On the other hand, required exposure may be obtained by making a Schuchardt incision. The entire vagina can be enlarged with this incision, achieving remarkable improvement in exposure of the upper vagina. Therefore, a patient whose problem might otherwise have necessitated an abdominal approach can have the advantage of a perfectly satisfactory vaginal operation if a Schuchardt incision is made.

According to Speert (1958), Langenbeck made a deep relaxing incision into the perineal body in attempting vaginal hysterectomy for uterine cancer in 1828. Similar incisions were used by Olshausen in 1881 and Duhrssen in 1891. Karl Schuchardt described his incision in 1893:

to make more accessible from below a uterus whose mobility is limited.... With the patient in the lithotomy position and her buttocks elevated, a large, essentially sagittal incision is made, somewhat convex externally, beginning between the middle and posterior third of the labium majus, ...extending posterior toward the sacrum, and stopping two fingerbreaths [*sic*] from the anus. The wound is deepened only in the fatty tissue of the ischiorectal fossa, leaving the funnel of the levator ani muscle, the rectum behind it, and the sacral ligaments intact. Internally, the sidewall of the vagina is opened into the ischiorectal fossa and the vagina divided in its lateral aspect by a long incision extending up to the cervix. There thus results a surprisingly free view of all the structures under consideration.

The incision is ordinarily made on the patient's left side by a right-handed operator (**Fig. 14.24**). A left-handed operator may find it technically easier to make the incision on the patient's right side. Bilateral incisions have been advocated in extreme cases. The side on which the incision is made may be dictated by the location of the pathology to be removed. Injection of the tissues to be incised with sterile saline solution can be helpful, especially beneath the vaginal mucosa in the line of the incision. The assistant pulls upward to the left with the index finger placed as deep as possible in the vagina just to the left of the urethra. The operator makes countertraction by placing two fingers in the vagina and pulling downward to the right. This pull and counterpull in opposite directions stretches the left vaginal wall. The incision is made with the electrosurgical unit beginning at the 4 o'clock position at the introitus and extending downward in the skin of the buttock to the level of the anus. The incision is then carried upward through the vaginal mucosa into the upper third of the vagina. As the incision is deepened, the fingers of the operator's left hand are used to displace the rectum medially to protect it from injury. The ischiorectal fossa fat is visible

P.245

below the puborectalis muscle, which is incised with the electrosurgical knife (**Fig. 14.24**). If necessary, the left paravesical space can be developed. For the best possible exposure, the apex of the vaginal incision should intersect any incision made around the cervix, achieving hemostasis by coagulation or ligation.

FIGURE 14.24 A: The Schuchardt incision begins at the 4-o'clock position in the vaginal introitus and extends into the buttock and up the posterolateral wall of the vagina to the cervix. **B:** The ischiorectal fossa fat is exposed. The puborectalis muscle is divided. The left paravesical and pararectal spaces can be exposed through the incision.

At the end of the operation, the Schuchardt incision is closed with 2-0 and 3-0 delayed absorbable sutures, attempting to reapproximate the puborectalis muscle edges and to obliterate the dead space in the ischiorectal fossa. Drainage of these incisions is usually not necessary.

The Schuchardt incision most often is used for extensive vaginal hysterectomy for early invasive cervical cancer. We also have used it when performing extensive dissections to remove endometriosis in the vaginal vault, to gain better exposure for difficult vaginal hysterectomy or vesicovaginal fistula repair, to repair injuries to the lower ureter, to remove organized hematomas just above the puborectalis muscle, to drain lymphocysts vaginally, or to remove benign cystic teratomas in the lower presacral area behind the rectum. It can convert a technically difficult, complicated, and dangerous vaginal operation into one that is simple, easy, and safe. It is difficult to understand why perineotomy incisions are so quickly performed for obstetric operations and so reluctantly for gynecologic operations.

BEST SURGICAL PRACTICES

- During counseling for surgery, location of the incision, rationale, and any potential complications must be presented to the patient.
- Fascial closures (of midline and some transverse incisions) should be accomplished with delayed absorbable monofilament suture (see above). Plain catgut or chromic catgut should *never* be used for fascial closures.
- Closed drainage systems (i.e., Jackson-Pratt or Blake) should be used when drains are considered. Passive drains, such as Penrose drains, should not be used.
- Monofilament sutures should be tied with either three square knots (six throws) or one surgeon's knot and two square knots (four throws).
- For superficial dehiscence, consider delayed closure or NPWT over secondary-intention closure with wet-to-dry dressing changes for improved patient healing. Delayed closure in the office may be less expensive and more convenient for the patient compared to NPWT.

Chapter 15

Principles of Electrosurgery and Laser Energy Applied to Gynecologic Surgery

Ted L. Anderson

May S. Thomasee

DEFINITIONS

Active electrode—The electrode in monopolar circuits that carries the radiofrequency energy to the patient operative site.

Active electrode monitoring—A system with a sleeve placed around the active electrode to detect stray energy and to carry the induced energy to ground. Stray energy generally occurs from breaks in insulation or capacitive coupling.

Alternating current (AC)—Sinusoidal energy waveform (60 Hz) used in household electrical appliances and in electrosurgery.

Ammeter—Device that measures the amount of current flowing through a conductor at a specific moment.

Ampere—Quantity of electrons that move through a conductor over time (coulombs per second).

Bipolar—Closed circuit system where the active and passive electrodes are located within the energy device. This system does not use the patient as part of the circuit.

BLEND—Variation of electrical “on” and “off” time, where the current is interrupted at a variation of time, other than the standard CUT and COAG settings. (The current is “on” usually between 25% and 50% and varies with each BLEND setting.)

Capacitance—The buildup of electrical charge surrounding the active blade or even insulator of an electrosurgical device.

Capacitive coupling—Occurs when two conductors are separated by an insulator. Is always present, but not always dangerous. Becomes dangerous when the discharge of electrical energy occurs outside of the surgeon's field of view or when it is not recognized as conducting energy to nearby tissue through electromagnetic current.

Circuit—An electrical network that has a closed loop giving a delivery and return path for electrical current, accomplishing work by routing electrons.

COAG—Function on electrosurgical unit to describe interrupted, modulated, or damped current. The voltage of this waveform is always, higher than it is with CUT waveforms, given the same power output.

Coulomb—Measure of a quantity of electrons.

Current (power) density—Total amount of energy output per unit area of tissue. Affected by size of active electrode, shape, and power output (settings) of electrosurgical generator. Measured in watts (W). The smaller the spot of contact, the greater the density (current concentrated at the surface area of an electrode in contact with tissue during electrical flow) and the greater the heat effect for the same amount of time. Related to the square root of the area of contact.

Current (amperes)—Flow rate of a quantity (coulombs) of electrons.

CUT—Function on electrosurgical unit to describe uninterrupted, unmodulated, or undamped current in a continuous sinusoidal waveform. At the same power settings, the voltage of the waveform is always lower than it is with COAG or BLEND waveforms.

Desiccation—A form of coagulation achieved by “drying out” tissue through making contact with the active electrode. Either CUT or COAG waveforms may be used, but CUT waveform is preferable to reduce depth of penetration. Intracellular temperature stays below 100°C, which leads to cell shrinkage and dehydration.

Direct coupling—Occurs when two conductive materials in the same circuit touch during electrical activation or are close enough that arcing can occur. This can be intentional or unintentional. A break in the insulation of an active electrode that allows sparking to tissue is an example of unintended direct coupling.

Dwell time—Length of time an activated electrosurgical device is held at a specific tissue location.

Edge density—Affinity of electrons to concentrate at the edges of flat or irregularly shaped electrodes as they exit the electrode. This feature enhances the cutting ability of blades shaped electrodes.

Electricity—Movement of electrons between two oppositely charged poles, positive and negative.

Electrocautery—Use of electricity to heat an object with subsequent direct transfer of energy by heat, such as a hot iron. Electrons do not move into the affected tissue; only heat is transferred.

Electrosurgery—Concentrated transfer kinetic energy (via electrons) from an active electrode to tissue creating a passive transfer of heat, using an electrosurgical generator.

Energy (joules)—Quantity of work produced over time. Energy (joules) equals work (watts) multiplied by time (seconds).

Faradic effect—Stimulation of tetanic muscle contractions, including cardiac muscle, when using electrical current with radiofrequency less than 100,000 cycles per second.

Fulguration—A form of coagulation achieved by arcing or spraying of “sparks” to tissue surface using high-voltage, damped, or interrupted (COAG) function with active electrode not touching tissue. Immediately causes charring and carbonization of the superficial tissue. Used to coagulate bleeding vessel or for treatment of endometriosis.

Heat (thermal energy)—Produced as electrons move from the low resistance of an electrosurgical probe to the high resistance of tissue. This energy may boil (vaporize) or denature (coagulate) tissue, depending on the extent and rapidity with which heat is generated.

Hertz (Hz)—Unit of measurement of electromagnetic sine wave. 1 Hz = 1 cycle per second.

Hybrid laparoscopic trocar sleeve—Conductive trocar sleeve used in laparoscopy that is covered by an outer nonconductive locking sleeve. Not used often anymore.

Impedance (ohms)—Resistance to flow of electrons through a conductor. Although resistance refers to direct current through a uniform wire, such as copper, it is generally substituted for impedance. Impedance is correctly applied with changes in voltage (alternating or fluctuating), frequency (modulating or demodulating), or tissue type (lipid membranes, soft tissue, fibrous tissue, fat, muscle, bone, or artificial appliances). It can measure the combination of tissue resistance and capacitance. Impedance in human tissue is generally 100 to 1,000 V; in the fallopian tube, it is 400 to 500 V.

Isolation ground circuitry—Safety feature that uses transformers not in contact with the parent generator so that the induced flow “floats” its own separate circuit. If a break in the floating circuit occurs, all energy within that circuit stops and does not seek ground.

P.250

Kilohertz (kHz)—Equal to 1,000 cycles of electromagnetic radio waves per second.

Kinetic energy—The energy that an object possesses due to its motion.

Monopolar—Type of electrode or electrical system in which the active electrode is small (high current density) and the passive electrode is large (low current density), and they are located remotely from each other. Most monopolar generators are calibrated against a 500-V load of resistance.

Open circuit (open “activation”)—State when the electrosurgical instrument is activated prior to touching the tissue. A charge density can build up at the tip of the electrode and spark or stray to an unintended site if activated for a prolonged period of time remote from the site of intended effect. Open circuitry is used to start fulguration.

Return electrode (passive or dispersive electrode)—Large conductive pad (low current density) placed on the patient to complete an electrosurgical pathway and return electrosurgical energy to the generator.

Return electrode monitoring—A system of modern electrosurgical generators whereby the return electrode consists of a dual pad system with internal monitoring capabilities to sound an alarm on the generator if not placed properly.

Radiofrequency—High-frequency electrical current in the range of 3 kilohertz (kHz) to 300 gigahertz (GHz), or 3,000 to 3 billion cycles per second.

Sparking (arcing)—Transmission of electrical energy through gas (air, argon). Used in a noncontact technique with COAG interrupted waveform for tissue fulguration.

Vaporization—Raising the cellular temperature rapidly above 100°C, which causes cell wall rupture, releasing steam. CUT mode is preferred for this with a noncontact technique.

Voltage (volts)—Electromotive force (pressure) that drives current.

Watts (work)—Amount of work produced by electron flow (current). Work (watts) equals force (volts) multiplied by current rate (amperes).

Waveform—The pattern of sinusoidal oscillation of an alternating electrical current from positive to negative.

Waveform frequency—Number of oscillations of an alternating electrical current, usually between 350,000 and 4 million cycles per second in electrosurgery.

INTRODUCTION

The practice of medicine and surgery has increasingly relied on applications of energy since the late 1800s. Indeed, the majority of gynecologic surgical procedures performed today incorporate some form of applied energy. However, the underlying physical principles that govern the desired biologic effects remain marginally understood by most surgeons. The typical resident graduating from an obstetrics and gynecology program has received limited formal training concerning the principles and application of electrosurgery, as was often the case for his or her faculty mentors. Importantly, these limitations in a surgeon's knowledge of electrosurgical principles can permit delivery of unintended energy, resulting in immediate or delayed complications.

Over the past decade, electrosurgical instruments and generators have evolved into complex systems that can interact with biophysical properties of tissues to modulate, limit, and even discontinue energy delivery in response to measured parameters. In some cases, multiple energy modalities can be delivered by the same instrument. Thus, it is imperative that the contemporary gynecologic surgeon has a comfortable working knowledge of energy generation, delivery, and tissue effects in order to use these devices and systems effectively and safely.

Our goal in this chapter is to provide the basic fundamental principles of electrosurgery and laser technology. More specifically, we wish to provide a very practical approach that illustrates how these are applied within the field of gynecologic surgery to promote safe use of the available instruments.

HISTORY AND THE DEVELOPMENT OF ELECTROSURGERY

As early as the 4th century BC, the Egyptians described the treatment of wounds using a device called a “fire

drill,” which turned rapidly to produce heat along its shaft. In the early writings of the Hippocratic Corpus (approximately 400 BC), followers of Hippocrates described the treatment of various tumors, as well as hemorrhoids, through direct application of heat. During this period, the use of heat was frequently accomplished through specific heating of a metal device and placing it directly on the wound, essentially inflicting third-degree burns without the ability to modulate tissue effect. Accordingly, the word “cautery” arose from the Greek term *kauterion*, meaning “hot iron.” Around 1600, the English physician and scientist William Gilbert introduced the term *electricus* meaning “like amber” as he discovered attraction of objects to each other after rubbing them against an amber rod. Once electricity was widely available, this concept was further expanded to “electrocautery.” *Electrocautery* is the use of electricity to heat the metal tip of a device and subsequently apply direct heat to the tissue. Thus, up until this point, all applications of heat to medicine were in the form of cautery or electrocautery.

It was actually Benjamin Franklin's eighteenth century experiments with electricity that led to the idea that direct application of electrical current to tissue might be used to advantage in medicine. While John Wesley (England), Johann Kruger (Germany), and Jean-Antoine Nollet (France) experimented with paralytic conditions, Franklin and his Dutch colleague Jan Ingenhousz described a “highly elated state” after several unintended nonlethal shocks to the head and proposed this as therapy for melancholy.

Two significant discoveries paved the way for modern application of electricity in medicine. First was the recognition of electromagnetic induction by Michael Faraday and Robert Todd, leading to the ability to harness and store electrical energy reliably. This gave rise to a pathway for development of electrosurgical generators. The second was an extension of the work of Luigi Galvani, who demonstrated that electricity applied to frog legs induced muscle contraction, when William Morton and Arsenne D'Arsonval recognized application of electricity at a frequency of greater than 100 kHz allowed electricity to pass through the body without inducing pain or burn and without inducing muscle (including cardiac) spasm, the so-called faradic effect. D'Arsonval further noted that the current directly influenced body temperature, oxygen absorption, and carbon dioxide elimination, increasing each as the current passed through the body. Of note, the temperature was determined to increase proportionally to the square of the “current density.”

The French surgeon Joseph Rivière in the early 1900s was perhaps the first to use electricity clinically, in the form of an electrical shock to treat a hand ulcer. However, in the 1920s, it was Grant Ward who demonstrated that a continuous sinusoidal electrical waveform was superior for cutting tissue, and an interrupted electrical sinusoidal waveform resulted in more effective coagulation. This led to the now infamous collaboration between Harvey Cushing and physicist William Bovie to

P.251

produce an electrosurgical unit (ESU) (generator) designed to achieve intraoperative hemostasis during neurosurgical procedures. They published the results of a case series of intracranial tumor excisions in 1928, with an excerpt by Dr. Bovie describing the principles of superficial dehydration (desiccation), cutting, and coagulation as they applied to the tissue. These landmark events led to the era of modern applications of electricity in medicine.

BASIC PRINCIPLES OF ELECTROSURGERY

Electrocautery and electrosurgery are not synonymous. We distinguish between the two terms electrocautery and electrosurgery based on many differences as described in this chapter. *Electrocautery* refers to the application of electric current to an instrument of high resistance, resulting in heating, and then applying this hot instrument for direct transfer of heat to destroy tissue, without the ability to modify the depth of tissue penetration or tissue effect. For example, as described earlier, this would be like burning the skin with a hot iron. Conversely, *electrosurgery* is the employment of kinetic energy in the form of alternating current (AC) radiofrequency to

transfer energy to tissue, raising intracellular temperature, which can be modulated to achieve desired tissue effects.

In order to achieve electrosurgery, there are three specific elements we must have. First, there must be a generator or ESU to accept electricity delivered from the electrical outlet on the wall of the operating room, modulate it to a higher frequency, and deliver it in the required conformation. Second, there must be an active electrode to deliver electricity to the tissue of interest in the form required. Third, there must be a return electrode to deliver the electricity away from the tissue to complete the electrical circuit.

The flow of electricity from an ESU through tissue follows the basic principles of physics. Particles of energy (*electrons*) are forced through tissue in a maximal direction from a positively charged pole to a negatively charged pole, in a sinusoidal waveform. The term circuit is used to describe the path the electrons take. In electric circuits, electricity is typically carried through conductors such as wire. However, electricity can also be carried through ion-containing substances like living tissue. Electron flow through cells creates changes in polarity of the cellular electrolytes (Na^+ , Ca^{++} , K^+ , Cl^- , etc.). Electromagnetic energy causes the anions to migrate toward the positive electrode and cations toward the negative, which is referred to as the galvanic effect. Importantly, the high-frequency flow of electrons in the radiofrequency spectrum surpasses that required for cellular membrane depolarization and does not affect the opening of sodium or calcium channels. Rather, the frictional forces of these charged intracellular ions create kinetic excitation and subsequent intracellular thermal heating as a result of thermodynamic changes.

The flow of electrons through a conductor is called *current*, which is governed by two opposing forces, namely *voltage* (the force pushing electrons along a circuit) and *resistance* (opposition to the free flow of electrons). This relationship is defined by Ohm law, which is depicted in [Figure 15.1](#). You can see from this relationship that in order to increase electron flow (current), you must either increase the electromotive force (voltage) or decrease the impedance to free flow (resistance). It may help to think of this in terms of water flowing through a hose in your garden. If you kink the hose (increase resistance), your water flow (current) is going to decrease. The only way to accommodate for this is to increase the water pressure (voltage) proportionally.

$$\text{Current (I)} \begin{matrix} \text{(amps)} \end{matrix} = \frac{\text{Voltage (V) (volts)}}{\text{Resistance (R) (ohms)}}$$

FIGURE 15.1 Ohm law describes the flow of electrons through a circuit.

We can further explore the relationship between resistance and voltage by examining the concept of *power*, defined as the instantaneous energy required per unit time to perform a function, measured in watts. Specifically, power is defined by the electromotive force (voltage) times the flow of electrons (current), or $W = V \times I$. With mathematical substitution of Ohm law ($I = V/R$), we can derive that power (watts) is related to the voltage squared divided by resistance, or $W = V^2/R$. In practical terms, this means that as resistance increases, in order to maintain the power required to perform a function, the electromotive force (voltage) must increase exponentially. As we shall see, it is the voltage that we must harness and control to accomplish electrosurgical tasks effectively and safely. If we go back to our hose analogy, this means that if you increase resistance (kink the hose), in order to maintain the watts or instantaneous energy required per unit time to perform a function of work (to water the garden), the voltage (water pressure) must increase. Therein, we have the basic mathematical and physical basis for applied electrosurgery.

ELECTROSURGICAL GENERATORS

Generators of ESUs deliver AC the surgical field carried by an electrosurgical instrument (active electrode). More specifically, the ESU must take the electrical current supplied from the wall outlet and change it to direct current.

Then, through the use of oscillators, it must be modulated back to AC with higher frequency and the appropriate characteristics needed to produce the desired effects on tissues. The frequency delivered is between 500,000 and 5 million cycles per second and is sufficiently rapid to avoid stimulation of muscle contraction by surpassing the threshold for calcium and sodium channel depolarization. Because this frequency is in the range of AM radio waves, it is often referred to as radiofrequency (RF) current. Frequencies below 100,000 cycles per second are capable of causing tetanic muscle contraction, which is referred to as the *faradic effect*. On occasion, harmonic demodulation can occur, which produces small amounts of RF at less than 100,000 Hz presumably by alteration of current through interactions with the biophysical environment, which produces minor muscle twitches or nerve stimulation. Conversely, usual household appliances, such as hair dryers or blenders, use 60 cycles per second (or 60 Hertz, Hz) and are at much lower frequency than that of electrosurgical instrumentation (**Fig. 15.2**).

Most modern solid-state ESUs are capable of producing over 8,000 V, which is capable of pushing electrons up to 3 mm in room air under standard atmospheric conditions. However, more common outputs in typical use are in the 1,000 to 3,000 V range with a frequency upward of 350,000 Hz. Further, most generators today are calibrated to power output, with the power set reflecting the power available at the start of the electrosurgical application. As tissue impedance increases with heating in response to applied energy, we know from our prior calculations that power decreases. Additionally, many modern ESUs are best described as adaptive generators. Often designed to work in concert with specific instruments, they have the ability to adjust computer-controlled output in real time. They measure tissue impedance at the operative site and modulate output accordingly. Additionally, there are features for limiting maximum voltage, thereby reducing unintended effects of “stray energy.”

P.252

FIGURE 15.2 Radiofrequency spectrum. The frequency produced by electrosurgical generators overlaps with the range of AM radio waves and is thus referred to as “radiofrequency” (RF).

Three fundamental principles that have guided the evolution of the modern ESU are “electricity must complete a circuit or it will not flow,” “electricity goes to ground,” and “electricity follows the path of least resistance.” Older generator models were ground referenced, which means that a “grounding pad” was required to return the electrical current delivered to the patient (complete the electrical circuit). However, given the other principles just mentioned, currents often traveled through alternative grounding pathways, including EKG clips, creating unintended patient thermal injury. Isolated ESUs were introduced in the late 1960s, whereby current delivered by the ESU was returned to the ESU, not to ground, to complete the circuit. Further, the current delivered to the patient was generated in transformers insulated from the ESU frame. Thus, when the electrical circuit is interrupted, the electrons do not seek ground; no current flows. This introduced the concept of “return electrode” rather than “grounding pad,” although the two terms are often (incorrectly) used interchangeably. This advancement dramatically reduced thermal injury hazards associated with earlier grounded systems. However, if return electrodes were not properly or completely placed, or if they began to peel off intraoperatively, burns could

occur at these sites due to electrical arcing and increased charge density.

Return electrode monitoring was introduced in the 1980s. In this system, still used today, return electrodes consist of two side-by-side conductive pads. Built-in monitors measure integrity of pad contact with skin and balance of contact between the two pads through a low-impedance feedback with the ESU. If there is an imbalance, poor contact, or a breach in contact, an alarm sounds and generator output is automatically discontinued. It should be noted that for these return electrodes to function effectively, both pads should be equal distance from the operative field with the largest edge facing the site.

FIGURE 15.3 Monopolar electrical circuit. RF is delivered from the ESU through an active electrode to the patient, is dispersed through the patient, and is returned to the ESU via a remotely placed return electrode to complete the circuit.

MONOPOLAR AND BIPOLAR

All modern ESUs offer the ability to modulate electrical current output. The radiofrequency output can be delivered in *monopolar* or *bipolar* circuits (see [Figs. 15.3](#) and [15.5](#) below). Further, radiofrequency can be delivered by providing a continuous or interrupted pattern RF energy. By convention, we typically refer to these two patterns as *CUT* and *COAG* (respectively) in homage to the description of tissue effects by Ward and Bovie in the 1920s.

Of course, *monopolar* current is a misnomer, as all electrical circuits must be bipolar. The more appropriate distinction would be the location of the active and return electrodes with respect to each other. With monopolar circuits, the active electrode (instrument delivering RF energy) and the return electrode (sometimes called dispersive or passive electrode) are located remotely from each other. Thus, the RF energy enters the body (conductor) through the active electrode and is dispersed through a myriad of pathways following the path of least resistance to the return electrode to complete the electrical circuit ([Fig. 15.3](#)). The concentration

P.253

of RF energy at the active electrode is responsible for local tissue effect (e.g., burn) at that site. Conversely, the dispersed nature of RF energy through the body and at the site of the return electrode explains why there is minimal, if any, recognizable effect. This concept is known as “current density.” You may notice this concept readily when comparing the tissue effect using a standard electrocautery spatula electrode with the edge versus the wide face of the blade facing the tissue. This is further illustrated by the increased tissue effect when using a

needle tip electrode without decreasing the ESU output (**Fig. 15.4**).

FIGURE 15.4 Current density. The higher concentration of RF energy at the active electrode is responsible for the tissue effect achieved at that site. Increasing the electrode size decreases charge density and lessens the local effect. Further, as electrical current radiates away from the active electrode, the tissue effect is dramatically decreased.

In bipolar circuits, the active and return electrodes are components of the same instrument. The charge density is basically identical at both electrodes. The only part of the patient involved in the circuit is that tissue directly located between the electrodes (**Fig. 15.5**).

In monopolar circuits, RF energy may be delivered either in a continuous waveform or in interrupted pulses electrical current, referred to as *CUT* or *COAG*, respectively, in deference to tissue effect described by Grant Ward in the 1920s. In *CUT* mode, there is delivery of a continuous uninterrupted sinusoidal waveform through the active electrode (continuous duty cycle). Alternatively, in *COAG* mode, the RF energy is delivered in pulses whereby over a given time RF energy is only delivered approximately 4% of the time (interrupted duty cycle). During the “off time,” desiccated, cooled, and coagulated tissue with denatured proteins increases resistance and thus increases voltage required for energy delivery. Most ESUs offer a “BLEND” mode in which the duty cycle is increased to 40%, but off 60% of the time, allowing for a mixture of cutting and coagulation properties (**Fig. 15.6**).

FIGURE 15.5 Bipolar electrical circuit. RF is delivered from the ESU through an active electrode to the patient and is returned to the ESU via return electrode located in the same instrument to complete the circuit. Only the tissue located between the electrodes is involved in the circuit.

In bipolar circuits, RF energy is delivered by the ESU in CUT setting, which is a continuous sinusoidal waveform with low voltage. Modern instruments available to use in the bipolar mode also employ use of compressive force to reduce vascular pulse pressure and subsequently blood flow through the intervening tissue. This further helps the energy to remain concentrated between the electrodes in order to achieve maximal desired tissue effect. Further, there is often the incorporation of feedback mechanisms to determine when the intervening tissue is sufficiently desiccated. This feedback allows an adaptive ESU to recognize increased tissue resistance and discontinue energy delivery when complete tissue effect has been achieved.

P.254

FIGURE 15.6 Continuous (CUT) versus interrupted (COAG) duty cycles differ in the duration that RF energy is delivered over time and by the voltage required to deliver that energy. Most generators offer a BLEND mode that offers some features of both extremes by varying the duration of the duty cycle.

TISSUE EFFECTS

Although the terms “CUT” and “COAG” have become ingrained in our electrosurgical lexicon, it is more useful to think of waveform and technique with respect to the tissue effect achieved. RF energy may be used to cut through tissue via rapid increase in temperature in a noncontact mode (vaporize) or coagulate tissue through slow deep dehydration and denaturation of proteins (desiccate) or by the superficial spray of electrons (fulgurate), often resulting in tissue carbonization ([Table 15.1](#)). Temperature changes have been identified with each of these effects. Normal resting human physiologic temperature is 37°C. Irreversible damage in tissue occurs at $\geq 50^{\circ}\text{C}$ by intracellular protein denaturation and coagulation. Cellular dehydration (evaporation of water) occurs when tissue is heated to $\geq 90^{\circ}\text{C}$, which is referred to as *desiccation*. Rapid temperature rise to $\geq 100^{\circ}\text{C}$ will cause cell walls to rupture as liquid water changes to steam by a process known as *vaporization*. At temperatures $\geq 250^{\circ}\text{C}$, tissues begin to char and carbonize leading to a *fulguration* effect.

As mentioned earlier, the CUT mode delivers a continuous sinusoidal waveform alternating from positive to negative at the frequency output of the ESU. This RF, delivered through a small active electrode (high current density), generates rapid and intense intracellular heat, which vaporizes the surrounding cells. The steam vapor occupies a space much greater than the water of the cell, creating two effects. First, it literally explodes the cells. Second, and equally importantly, it dissipates the heat generated to reduce thermal damage to adjacent tissue. Consequently, there is little or no coagulation effect. This mode is used to maximal advantage if the RF energy is

engaged immediately before touching the tissue. If the active electrode is moved too slowly, or allowed to dwell in one spot too long, the tissue becomes dehydrated, resistance is increased, and tissue is more slowly dehydrated (desiccated). Therefore, for efficient and effective cutting of tissue, the surgeon should use a continuous waveform (CUT) with a small or thin active electrode that is activated just prior to tissue contact. With a peak voltage of about 200 V, the ionized air facilitates a layer of steam as the electrode glides by exploding cells with minimal surrounding heat or tissue coagulation.

TABLE 15.1 Tissue Effect Can Be Altered by Altering the Waveform and using the Active Electrode with a Contact or Noncontact Technique

	NO CONTACT	CONTACT
CUT (continuous)	Vaporization	Desiccation
COAG (interrupted)	Fulguration	Desiccation

In the COAG mode with a frequency of 500 kHz, bursts of RF energy occur over 31,000 times per second. However, this accounts for less than 5% of the time in pure COAG mode. It is during the “off” intervals that tissue is cooled and denatured (coagulated), which increases resistance. If the COAG waveform had the same peak voltage as the CUT waveform, the average power delivered per unit time would be less because the RF energy is off the majority of the time. In order to deliver the same power, the COAG waveform must deliver the same average voltage as the CUT waveform. To do so, there must be large peak voltages during the percentage of time that the RF energy is being delivered ([Fig. 15.7](#)). The high-voltage sparks created are more widely dispersed, and, due to the intermittent heating effect, cellular temperature does not increase rapidly or sufficiently to vaporize. Consequently, cells are more slowly dehydrated and do not explode to create an incision in tissue, but greater tissue resistance is the result. Because of the higher peak voltage (greater electromotive force), COAG waveforms can drive current through higher resistances, which permit fulguration (superficial), even after dehydration has occurred, and deeper desiccation of tissue. Fulguration and desiccation are both forms of tissue coagulation. With desiccation, concentration of current is related to the area of tissue contact with the active electrode. This creates deep penetration of heat and minimal charring of the tissue surface. On the other hand, fulguration occurs when (noncontact) superficial sparking occurs. Due to the high peak voltage at high current density, the sparks are sprayed in a random fashion in repeated intermittent cycles, resulting in tissue necrosis and charring. Given equal current density, noncontact fulguration is more efficient at creating surface necrosis and charring. However, contact desiccation yields a greater depth of tissue dehydration.

Coaptive coagulation is a term that refers to grasping of a bleeding vessel with a conductive metal instrument using sufficient pressure to stop blood flow. Subsequently, the active electrode is used to transfer energy through the instrument, causing coagulation and protein denaturation of the tissue. The surface of the tissue is coagulated first, with subsequent desiccation of the deeper tissue. The CUT waveform should always be used during coaptive coagulation since it has lower voltage and will reduce the chance of desiccation of the surrounding tissue.

Desired tissue effects can vary based on multiple factors and are not as simple as using CUT current when “cutting” is needed and COAG current when “coagulation” is needed. In 1928, Bovie described three distinct

tissue effects of electrosurgery: *superficial dehydration, cutting, and tissue coagulation*. Superficial dehydration involves using the active electrode at a very short distance above the tissue, not in contact with, and causing electron “spraying” across the surface for dehydration of a thin layer of tissue. The cutting mechanism involves using current to separate the tissues ahead of the active electrode without using the electrode as a manual cutting device. This technique relies on an arc of electrons ahead of the electrode tip, prior to contacting the tissue. This method can be altered to perform coagulation by “damping” or interrupting the waveform to produce a coagulation effect in highly vascular tissue, while current remains the same. Lastly, he described tissue coagulation (“electrocoagulation”) in which an electrode cannot perform the same effects as that of cutting. This type of tissue manipulation is based on two factors, the current density at the electrode tip and the dwell time of the activated instrument. The larger the area of tissue to be

P.255

coagulated, the weaker the current needed with a longer dwell time. If a stronger current is used, the superficial tissue becomes quickly dehydrated or carbonized, causing cessation of flow to the surrounding tissue. If the dwell time is activated for longer than necessary to achieve the desired effect, there is possibility of unintended stray current to nearby tissues.

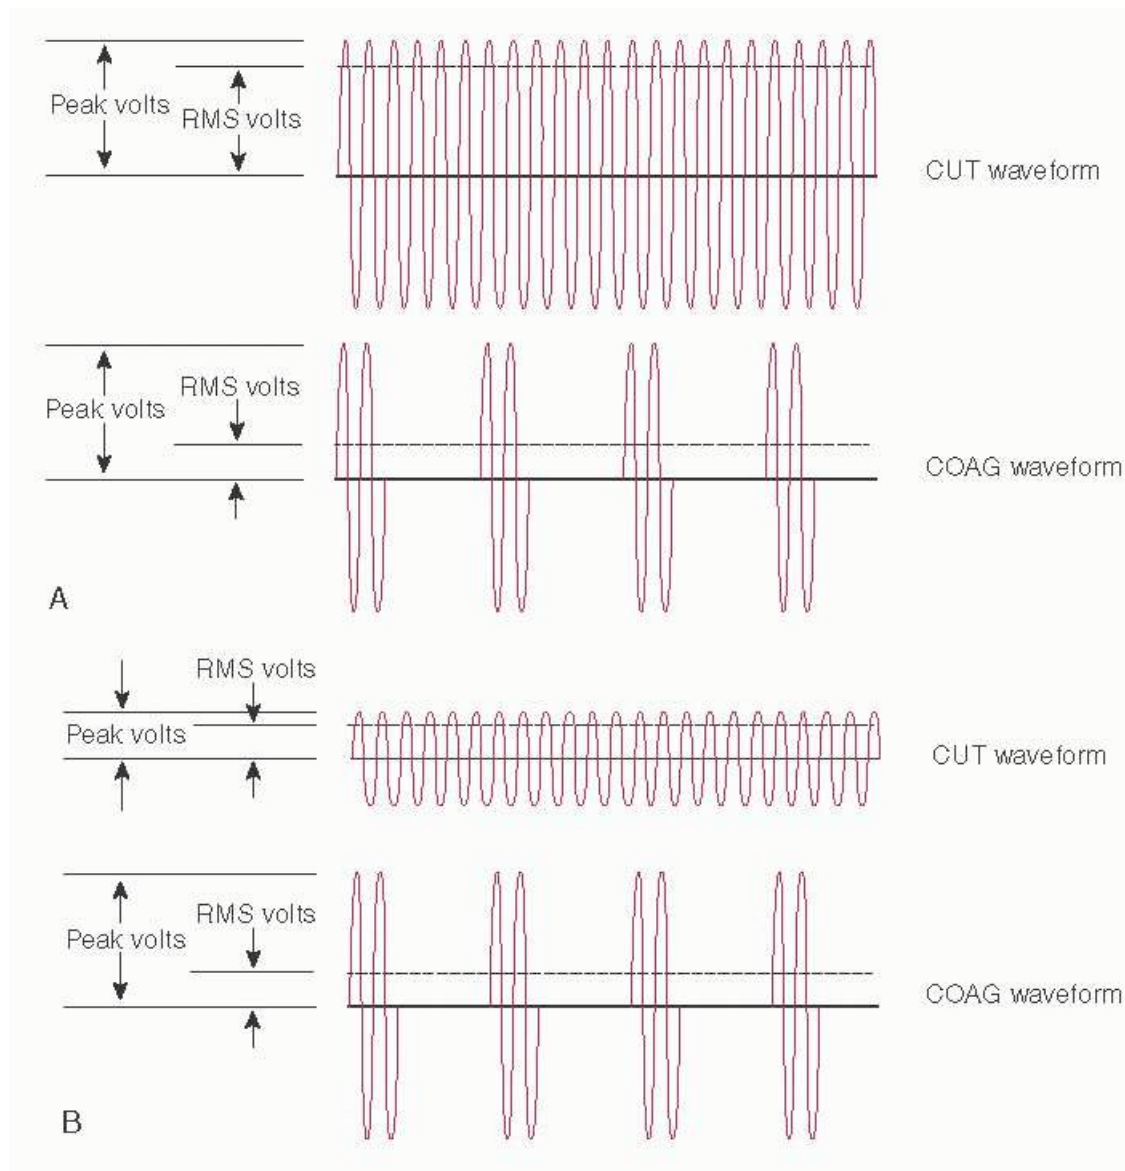

FIGURE 15.7 When the voltage is the same between pure CUT and pure COAG current, the amount of power delivered in COAG is only one third that of CUT. Conversely, when the power is the same between pure CUT and pure COAG current, the peak voltage of COAG is about three times greater than that of CUT. (RMS, root mean square.)

To achieve numerous desired tissue effects, the surgeon can use a combination of waveforms, current waveforms, active electrode characteristics, and surgical technique (**Fig. 15.8**). We have already discussed the effects achieved by electrode contact versus noncontact (**Table 15.1**) and different waveforms (**Figs. 15.6** and **15.7**). Additional manipulation of tissue effects may be accomplished by altering the size of the electrode, which controls current density. A needle tip electrode will yield greater current density than the broad surface of an electrosurgical bladed electrode. Therefore, at a given power using a continuous waveform, the needle tip electrode will produce quicker higher temperatures favoring vaporization (cutting), whereas the broad blade will result in a lower current density and slower and lower rise in temperature, favoring tissue desiccation. The speed with which the active electrode is moved can also contribute significantly to tissue effect. Recall that at an ideal speed, the active electrode glides through a path of vaporizing cells to cut tissue with minimal collateral effects. On the other hand, moving the electrode too slowly (increased dwell time) will generate increased heat in surrounding tissues resulting in a proportional degree of tissue coagulation. Once the superficial tissue is fulgurated, it acts as its own insulator. Dwelling over the same tissue longer than is required for the fulguration effect has potential to cause deeper tissue injury with potential for stray paths of electron flow. Similarly, moving the active electrode too fast will result in a continuous waveform contact mode (desiccation) as it overshoots the microenvironment of ionized air that creates a layer of steam from vaporized cells.

FIGURE 15.8 Variables that moderate tissue effects include electrode manipulation (contact versus noncontact), waveform (CUT versus COAG or BLEND), size of electrode (current density), and speed of active electrode movement.

Finally, in order to achieve a desired tissue effect, the surgeon must take into consideration the constitution of the target tissue.

P.256

Tissue impedance (resistance), which primarily depends on water content, will also affect the electrosurgical outcome. Impedance is high in desiccated tissues, moderate in adipose tissues, and very low in vascular tissues with higher water content. The impedance of tissue is dynamic during electrosurgery. Moreover, the power needed to accomplish a particular electrosurgical effect may vary from one patient to another. Lean, muscular patients are better overall conductors of electricity. Obese or emaciated patients may provide more tissue impedance to the electrical current and so may require more applied power to achieve the same effect. Power requirements to achieve a given electrosurgical effect will be higher whenever an electrode is applied to an area of higher impedance. With higher resistance, there is increased possibility of stray current seeking alternative sites of action. For example, as water evaporates and tissue coagulates, impedance rises—at times to the point that current is inhibited from flowing through the tissue. If the surgeon reflexively increases the power setting and consequently the output voltage, the current is more likely to overcome the tissue resistance and seek an alternative pathway of least resistance to the ground, which may lead to unintended thermal injury. Therefore, it

is always advisable to use the lowest power setting to achieve the desired tissue effect.

ELECTROSURGERY AND PATIENT SAFETY

As we have seen, the principles of Ohm law along with the rules “electricity must complete a circuit or it will not flow,” “electricity goes to ground,” and “electricity follows the path of least resistance” provide the basis of predictable use of RF energy in surgical applications. However, these same principles illustrate the potential dangers of unintended energy paths. Complications arise when electrosurgical principles are not thoroughly understood and devices are not properly used. Injuries from electrosurgical devices have been reported anywhere from 2.2 to 5/1,000. Of note, these are recognized injuries at the time of surgery. Electrosurgical injuries do not always present at the time of surgery and can frequently present complications between 3 and 7 days postoperatively. It is believed that there are a larger number of unrecognized injuries, some of which do not become substantial and are thus underreported. Unintended thermal injury to tissue can be related to many factors, including direct and indirect application of energy. We discuss here examples of the most common sources of unintended energy application, potentially leading to patient injury.

Open Activation

Intentionally activating the active electrode prior to contact with tissue (open activation), the surgeon can create a fulguration effect (discussed earlier). Perhaps the best example of this is the use of a ball electrode to fulgurate the bed of a cervical loop electrosurgical excision procedure (LEEP). However, this becomes a potential hazard when the active electrode is at a sufficient distance away from the target tissue (e.g., activating the RF energy in a laparotomy incision when the active electrode is a few inches away from the target). The energy charge builds up at the tip of the electrode as it encounters the very high resistance of air. With sufficient power, the electromotive force (voltage) can cause the RF energy to discharge the energy across the resistance of the insulator to the nearest (often unintended) site, much like a lightning bolt discharge.

Direct Coupling

Direct coupling occurs when an active electrode comes into contact with a conductive instrument that channels RF energy to another site (tissue) with which it is in contact. An intentional use of this principle would be passing current from an active electrode through a pair of forceps that is grasping a vessel at the operative site. A common example of unintended direct coupling in laparoscopy occurs when activated monopolar scissors touch adjacent bowel graspers, causing direct transfer of RF energy to the unintended site (bowel). Alternatively, this may occur when the active electrode touches the laparoscope, which is in contact with bowel.

Insulation Failure

This type of “stray energy” perhaps occurs more frequently in laparoscopy than in laparotomy. It is frequently unrecognized, owing to the fact that less than 15% of the operative field is typically seen when using a video camera and laparoscope. Laparoscopic instruments are covered by an insulator to direct current to the active electrode at the tip of the instrument. When there is a break in the insulated shaft of an instrument, which can occur through a variety of mechanisms such as moving the instrument repeatedly through a trocar or when cleaning and processing for reuse, RF energy can discharge through these breaks with effects like that described in open activation. The bowel is a frequently affected target of stray RF energy from insulation failure. Usually, blanching of sigmoid wall (or other tissue) occurs, and the surgeon should assume that tissue destruction is deeper than is visible. This type of tissue injury (pale, blanching) has a higher likelihood of breaking down in the future. However, this may be more indirect if, for example, the RF discharge were to the laparoscope, which is in turn in contact with bowel. Should such injury to the bowel occur, the correct method of action for the bowel is excision or resection and reanastomosis.

Capacitive Coupling

Capacitance refers to the ability of an object to store an electrical charge. Capacitance coupling may occur when two conductors in proximity to one another are separated by an insulator. It is best described as a mechanism whereby electrical current in the active electrode induces a current in another nearby conductor (unintended) despite otherwise intact insulation. For example, when using an operative laparoscope, the insulated active electrode (scissors, for example) is passed through a channel within the operative scope. This produces the ideal situation for capacitive coupling of the laparoscope by the active electrode (**Fig. 15.9**).

Some degree of capacitive coupling occurs with all standard monopolar electrosurgical instruments, but it is not always

P.257

a hazard. Whether the “stray energy” of capacitive coupling causes clinical injury depends on (a) the total amount of current transferred, (b) the ability to prevent arcing discharge of the built-up energy to an unintended tissue target, and (c) concentration of the current (i.e., the current density) as it makes its way back to the patient return electrode. Higher voltages increase capacitive coupling. The low-voltage CUT mode exhibits less capacitive coupling than COAG does. Thin insulation decreases the effective separation of the electrode from the surrounding conductor and will increase the amount of induced current.

FIGURE 15.9 Capacitance coupling is the induction of electrical current between two conductors separated by an insulator. The active electrode carries active current and induces a separate current in the nearby conductor.

Common conditions exist where capacitive coupling can cause sufficient current to cause an injury. When a metal trocar is used, it can be capacitively coupled to the active electrode. Additionally, when a conventionally insulated electrode is passed through a metal suction-irrigator, approximately 70% of the current may be induced in the suction-irrigator. The same situation can occur when an active electrode is passed through the operating channel of a laparoscope. An all-metal cannula through the abdominal wall will “bleed off” stray current through the abdominal wall as the RF energy is discharged over a larger surface area on its way to the return electrode with minimal or no effect. However, if the metal trocar is anchored by a plastic sleeve in the first example, or if a plastic trocar is used, then RF energy can build up until it overcomes the impedance of surrounding air to discharge through the path of least resistance to an often unintended tissue target. Another common and rarely recognized example occurs when the wire of a monopolar electrosurgical instrument is wrapped around a hemostat attached to a surgical drape for stabilization. With prolonged use of the electrosurgical instrument, the hemostat may become charged through capacitive coupling and that electrical energy may discharge seeking ground through the path of least resistance causing a drape fire or a burn to the patient (**Fig. 15.10**).

FIGURE 15.10 Securing the wire of an electrosurgical instrument to the drape with a hemostat provides an opportunity for capacitive coupling and discharge of built-up energy to create a drape fire or a patient burn.

Bipolar Instruments

Bipolar electrosurgical instruments became popular in the mid-1970s as an alternative to monopolar instruments with hopes to avoid complications of stray current as described above. Although bipolar electrosurgical instruments are safer than monopolar instruments with respect to stray RF injury, they are not without possibility of complication. It is important to remember that the zone of thermal damage may extend beyond that of the electrodes at the instrument tip. Once the tissue is sufficiently desiccated, further application of electricity can propagate heated water and subsequent steam to adjacent tissue, causing a thermal spreading effect. In order to reduce this potential, the surgeon should cease desiccation once vapor is no longer visualized and when the tissue becomes white in color.

Excessive desiccation can cause stickiness of the tissue as a result of carbonization, often referred to as an “amalgam.” Additionally, the active electrode can become adherent to the tissue, due to molecular breakdown of the cellular contents into sugars if the COAG function is used improperly or for a prolonged period of time. When deep tissue desiccation is required, the CUT function should be used to ensure deep penetration of tissue. If the COAG function is used instead, in tubal sterilization for example, it can cause immediate surface char and cessation of the flow of electrons while increasing tissue impedance, increasing lateral thermal spread, and preserving patency of the underlying tubal lumen. Use of the CUT mode allows a more precise and controlled spread of energy within the tissue due to its continuous, low-voltage waveform.

When using bipolar instruments, the use of an “in-line ammeter” is recommended to help monitor the increase in tissue resistance indicating complete tissue desiccation.

ADVANCED MONOPOLAR AND BIPOLAR DEVICES

Unique instruments are now widely available that dramatically reduce the potential for injury though unintended RF energy discharge in monopolar instruments. Further, with the advent of bipolar electrosurgical devices in the

mid-1970s, there came a recognized need for more versatile instruments, including the ability to offer both tissue desiccation and cutting abilities in the same instrument. Having these functions within one instrument provides more efficiency to the surgeon and avoids the need to change out surgical instruments for various tissue effects. There was a simultaneous desire to reduce the thermal spread, tissue carbonization resulting in instrument sticking, and increased “plume” formation of conventional bipolar instruments. Several instruments are now available that can be used to grasp, dissect, seal vessels up to 7 mm in diameter, and transect tissue. These tissue-sealing devices all employ the three components of pressure, temperature, and time to coapt tissue; denature and mobilize collagen and other proteins within the tissue at elevated temperatures; and fix or reorganize the collagen fibers to form a tissue seal. Then, some mechanism is used to transect the sealed tissue.

Active Electrode Monitoring

The potential for injury from capacitive coupled currents can be reduced with an understanding of the biophysics but can be eliminated by active electrode monitoring systems that “collect” stray current and confine capacitive coupling to the surgical instrument. Such a device is commercially available that eliminates the risk of capacitance regardless of the type of trocar sleeve used (Encision, Inc., Boulder, CO). This device

P.258

consists of a shroud over the active electrode shaft that shunts all capacitance-coupled current back through a return electrode to the electrosurgical unit, which avoids unintentional RF energy discharge. Additionally, if there is any breach in the insulation of the active electrode that could promote direct coupling to other metal instruments or adjacent tissue, the surgeon is alerted with an audible alarm (Fig. 15.11).

FIGURE 15.11 The Encision (formerly Electroshield) system eliminates the threat of unintentional capacitance injury when using monopolar instruments during laparoscopy by returning capacitance-induced current back to the generator. If an insulation breakdown occurs, the surgeon is alerted.

Argon Beam Coagulator

The argon beam coagulator is a monopolar active electrode housed inside an insulated cannula through which argon gas is dispelled at up to 12 L per minute (laparotomy) or 4 L per minute (laparoscopy). This instrument is superior for controlled noncontact superficial fulguration of tissue, owing to two unique properties of argon gas. First, electrons prefer to follow a stream of argon gas rather than pass through room air or carbon dioxide (CO₂), as each of the latter has a higher resistance to electron flow. Accordingly, because electrons choose to flow the

path of least resistance, they stay collimated (parallel alignment) in the flow of argon, so sparks can be directed with efficiency. Second, the ionization properties of argon gas flowing over the active electrode enhance the distance the spark can travel to complete the circuit to the tissue surface. These properties create a bright bluish hue to the sparks, which makes them easy to see and aim at the bleeding surface (**Fig. 15.12**). The gas, expelled under pressure, blows the pooled blood away from the surface bleeders, making coagulation more discrete and efficient. To create the planned fulguration effect, the wand must move like a paintbrush to prevent deep tissue damage.

Plasma Kinetic Technology

The PlasmaKinetic platform (Olympus America, Center Valley, PA) employs an advanced solid-state adaptive generator with software to deliver pulsed RF energy with continuous tissue impedance. This vapor pulse coagulation generates less

P.259

heat overall but ensures reaching temperature for effective collagen denaturation without rapid desiccation. As the generator delivers a pulse of RF energy, tissue impedance is measured and voltage is altered (decreased) to match the impedance. In between pulses, the tissue cools, allowing for renaturation (fixing) of the collagen. This cycle continues until complete tissue sealing and desiccation has been accomplished. Instruments for use with laparoscopy, laparotomy, and vaginal surgery are available with this technology. Several related devices are available using this platform. The HALO device (Olympus America, Center Valley, PA) includes a knife blade that can be advanced after desiccation to cut the tissue. The newest device in this line (ThunderBeat) offers the option of advanced bipolar technology or a combination of advanced bipolar together with ultrasonic technology for simultaneous sealing and cutting of tissue.

FIGURE 15.12 Argon beam coagulator. The ionized gas has its own unique blue hue that makes the sparks easily visible for accurate fulguration. **A:** The argon beam coagulator at work. **B:** Sparking effect of standard electrode (**left**) compared with argon beam coagulator (**right**).

LigaSure

The LigaSure device (Covidien, Boulder, CO) achieves true tissue fusion using a combination of pressure and pulsed energy to denature collagen and elastin in tissue bundles, vessel walls, and lymphatics to reform into a permanent plastic-like seal that resists deformation with tensile strength up to three times the normal systolic pressure. The tissue to be sealed is grasped in the jaws of the instrument, and a calibrated force is applied to the tissue during energy delivery. Using proprietary adaptive generator technology and software, the type of tissue held in the forceps is recognized and tissue impedance is monitored while delivering the appropriate amount of RF energy required to seal the tissue. During the process, elastin and collagen are denatured, creating a permanent seal that resists deformation. A cutting blade is then deployed to cut the sealed tissue. Instruments for use with laparoscopy, laparotomy, and vaginal surgery are available with this technology.

EnSeal

The EnSeal Laparoscopic Vessel Fusion System (Ethicon Endo-Surgery, Cincinnati, Ohio) uses a set of high-compression plastic jaws embedded with nanometer-sized spheres of nickel through which the temperature of the tissue pedicle is predetermined by local conductivity. A patented positive temperature coefficient system utilizes a carbon crystalline matrix to limit tissue temperature along the seal line. This creates a conductive polymer chain at temperatures less than 100°C that dissociates at temperatures greater than 100°C, thus limiting

energy delivery and lateral thermal spread. The device has a central mechanical blade used to compress the tissue to force water out of the cells and reduce lateral thermal spread by reducing excess steam within the tissue being desiccated. This feature also serves as the cutting function of the tool.

ULTRASONICS

Ultrasonic devices generate tissue effects similar to advanced bipolar devices. However, the source of thermal energy generation is ultrasonic vibration of the active shaft of the device at greater than 20,000 vibrations per second. An ultrasonic generator delivers AC to the handpiece to achieve excitation in pizelectrodes interspersed between metal cylinders. This process results in mechanical energy by vibrating the cylinders at frequencies between 23 and 55 kHz. The shaft of the instrument, which is the active element or nonarticulating jaw, is in contact with the cylinders and oscillates linearly at the same frequency.

Different tissue effects can be achieved by variation in the oscillation distance of the shaft. The higher setting (100 μ) is better for rapid tissue transection while minimizing lateral thermal spread, but the effectiveness in coagulation of tissue and vessels is decreased. Alternatively, a shorter oscillation (50 μ) is superior for tissue and vessel sealing, yet results in greater potential for lateral thermal spread and cavitation. Cavitation occurs when steam released from vaporized cells expands tissue planes. Although this does occur to some extent with monopolar vaporization, it occurs at lower temperatures with ultrasonic energy due to the oscillating tip. Thus, ultrasonic devices are similar to advanced bipolar devices in that they both sequentially convert electrical energy to mechanical energy to thermal energy to facilitate tissue effects. However, with bipolar devices, the source of friction is intracellular (molecular), whereas ultrasonic devices create extracellular friction from the oscillating shaft followed by intracellular heating without the passage of electrical current through the tissue.

There are multiple ultrasonic devices currently available, including the Harmonic Scalpel and Harmonic ACE (Ethicon Endo-Surgery, Cincinnati, OH), Autosonix and Soncision (Covidien, Boulder, CO), and SonoSurg (Olympus America, Center Valley, PA). A recently available device by Olympus, ThunderBeat, combines both advanced bipolar and ultrasonic technology in the same device in a manner, allowing the surgeon to use the different energy sources independently or sequentially.

SPECIAL SURGICAL SITUATIONS

Pregnancy

No data indicate that using electrosurgical techniques in a pregnant patient has any untoward effect on the fetus at any stage of development. Owing to the dispersion effect, the fetus, bathed in electrolyte-rich amniotic fluid, is protected from any concentration of electrical current. Just as the output frequency of all electrosurgical generators is above the faradic effect (the level that stimulates muscle contraction) for adult electrosurgery, the same is true for the fetus.

During a cesarean section, the only concern is the accidental touching of an activated electrode to the fetus, which causes tissue heating. This does not mean that the usual technique of making an incision in the uterus would preclude using an electrosurgical incision, but rather that a “backstop” under the incision line, between the amniotic membrane and the muscle wall, should be in place. Although using a nonconductive material, such as a plastic suction tip, may seem wise, a metal ribbon retractor also can be used because it has a large surface area serving to diffuse the current density. Caution should be exercised when using the gloved finger of the surgeon as a backstop because if open activation is used, the increased voltage may create a hole in the glove.

Body Piercing and Prosthetic Implants

There have been no documented electrosurgical injuries reported in the literature in relation to body piercing. Nonetheless, faulty instrument insulation can theoretically transmit current from the surgical active electrode to

the metal object, causing a skin burn. Therefore, conventional wisdom indicates that removal of umbilical and labial piercings prior to a surgical procedure is prudent when possible. It is not necessary to remove piercings or other metal jewelry distant from the operative site. These objects are too far away from the active electrode to receive substantial electrical current. If removal of rings and/or piercings is

P.260

not desired or possible, then taping the metal object down to the skin to create the greatest surface area contact will decrease current density and minimize any potential risk.

The same principles apply to metal-implanted prosthetic devices. The large surface area would minimize the potential of patient burn, and there have been no reported adverse patient events related to prosthetic devices and electrosurgery. It is noteworthy that the overlying scar has more potential for affecting the electrical circuit through increased resistance, and that is minimal as well.

Implantable Devices

Any implanted cardiac pacemaker, implantable cardioverter-defibrillator, resynchronization device, or ventricular assist device is referred to as a cardiac implantable electronic device (CIED). The nature of any device type and patient reliance on that device must be investigated preoperatively. Failure to do so can lead to adverse outcomes. The potential for electromagnetic interference with CIEDs depends upon the distance from the active and return electrodes, the RF frequency used, and the current pathway. Attention must be paid to place the return electrode in a location so that the path between the active and return electrodes does not travel near the CIED generator or leads. If so, then the risk of interference is low, although there is at least some potential for interference as the RF circuit does not travel linearly between the active and return electrode.

Possible adverse effects of CIEDs with electrosurgery include permanent damage to the device, inability of the device to function properly, resetting of the device, or inappropriate delivery of implantable cardiac defibrillator (ICD) therapy leading to patient effects of hypotension, tachyarrhythmia or bradyarrhythmia, myocardial tissue damage, and myocardial ischemia or infarction. When planning a surgical procedure in a patient who is heavily dependent on the CIED, alternative monopolar instruments should be replaced whenever possible with bipolar instruments where current is limited to tissue between the tips of the forceps and stray RF energy is rare.

Preoperative management of the CIED may include reprogramming or disabling algorithms and suspending antitachyarrhythmia functions. Clinical magnets positioned over the CIED can change pacing to an asynchronous mode in pacemakers and suspend tachycardia therapies in implantable cardiac defibrillators. However, magnets should not be routinely used over an ICD. Temporary pacing and defibrillation equipment should be immediately available before, during, and after the procedure.

Although continuous monitoring by EKG is critical, that signal can also be subject to electromagnetic interference, which can complicate detection of CIED malfunction. Thus, peripheral perfusion by pulse oximetry or invasive arterial waveform should also be monitored.

There are noncardiac devices using electric current that could potentially be affected by RF energy during electrosurgery. These include neural stimulators and gastric neurostimulators used to treat gastroparesis. Minimizing interference with these devices is desirable. However, the consequences of malfunction are not immediately life threatening, as with CIEDs.

ELECTROSURGICAL APPLICATIONS IN OPERATIVE HYSTEROSCOPY

The same electrosurgical principles that have been discussed previously in this chapter apply to hysteroscopy as well, with one notable exception, that is, the need to create distension of the uterine cavity and provide an electrically insulated environment (replacing the insulation of air during laparotomy or CO₂ gas during laparoscopy). This is accomplished through the use of nonionic fluids such as glycine, mannitol, or sorbitol.

These media are absorbed to varying degrees, depending on factors such as operative time, intracavitary pressure, and vascular nature of the resected tissue. With excessive absorption come the hazards of fluid and electrolyte imbalances and complications from metabolism of the medium itself (e.g., glycine is metabolized to water and ammonia). However interesting and important, these issues are beyond the focus of this chapter.

Some surgeons employ endometrial loop resection, some use ball ablation, and some employ both techniques sequentially. Further variability is noted in watts used, speed of the electrode, and even pressure applied by the rollerball to the uterine lining (more pressure results in greater active electrode contact and decreased current density). Some surgeons use only COAG waveform, while others use CUT or even some sequential or spatial combination of the two. However, we do know that by using the CUT waveform, there is less bubble generation and accumulation on the anterior surface of the cavity. At the end of the ablation procedure, some surgeons switch to a COAG waveform at 75 W. With the increased peak voltage of this waveform, electrons driven by higher electromotive force “seek out” undertreated areas of lower impedance, ensuring complete tissue coagulation.

There are three common, if not unique, electrosurgical complications associated with operative hysteroscopy, aside from the fluid management issue described briefly above. The first is due to uterine perforation by an active electrode during RF energy application. This can be minimized by (a) never advancing the hysteroscope with the active electrode extended and (b) only energizing the active electrode while retracting the active electrode toward the hysteroscope. If this type of complications does occur, then laparoscopy or laparotomy (depending on skill level) must be undertaken to evaluate possible pelvic or abdominal organ injury. The second is accidental burns to the vagina or perineum through capacitive coupling of the outer sheath of the resectoscopic hysteroscope. Because the inner and outer sheaths of the resectoscope (conductors) are separated by air (insulator), capacitive coupling can occur. Relatively high current density in the outer sheath touching small areas of genital tissue can create a burn injury. Finally, injuries can also occur from defects in electrode insulation, especially when interrupted COAG current is used and the cervix is overdilated and is in contact with less than 2 cm of the outer sheath. The high electromotive force created by prolonged activation along already desiccated tissue (increased resistance) and subsequent current diversion is responsible for this type of injury.

BIPOLAR HYSTEROSCOPIC SURGERY

A family of instrumentation is available for hysteroscopy that uses bipolar technology to attain the desired electrosurgical effect. Two advantages of bipolar electrosurgery include the ability to use in a saline environment, mitigating the potential hazards of nonionic fluid absorption. Additionally, isolation of the electrical circuit occurs between a set of closely separated electrodes separated by a ceramic insulator. Performance is similar to its monopolar counterpart, providing tissue vaporization and desiccation while retaining all of the inherent safety features of bipolar electrosurgery.

The VERSAPOINT system (Ethicon Women's Health and Urology, Somerville, NJ) consists of a dedicated bipolar electrosurgical generator and a variety of specialized hysteroscopic bipolar electrodes for different tissue effects. A key feature of the system is its ability to adjust automatically to an optimal power setting depending on the type of electrode.

P.261

The VERSAPOINT adaptive generator varies the output power in response to local impedance changes at the active electrode. A high-impedance vapor pocket is created that surrounds and insulates the active electrode from completing the circuit through the normal saline until tissue contact is made. Once contact occurs, current flows through the tissue and, by seeking the path of least resistance, returns through the saline to the proximal return electrode and finally back to the generator. Similar bipolar resectoscopic systems are also available

through Karl Storz Endoscopy America (El Segundo, CA) and Richard Wolf Medical Instruments (Vernon Hills, IL).

BIPOLAR ENDOMETRIAL ABLATION

Nonresectoscopic bipolar endometrial ablation is possible using the NovaSure Global Endometrial Ablation System (Hologic, Marlborough, MA). This system includes a single-use, three-dimensional bipolar device and adaptive RF generator that produces a controlled destruction of the endometrium in an average of 90 seconds. After inserting the device transcervically into the uterine cavity, it is seated by retracting a protective sheath to deploy a fan-shaped bipolar electrode that conforms to the uterine cavity. During deployment, the measured endometrial cavity length and width are entered into the generator, which calculates the power output required to ensure ablation of the uterine cavity. During activation, a vacuum is used to ensure good electrode tissue contact, as well as to remove blood, endometrial debris, and steam, eliminating any uncontrollable steam ablation effect. The term “global” refers to the fact that the entire cavity is treated simultaneously (**Fig. 15.13**).

FIGURE 15.13 The NovaSure Global Endometrial Ablation System is a bipolar device for endometrial ablation using a metalized mesh electrode, vacuum for firm tissue contact, and an impedance-controlled generator

designed to create a shallower depth of desiccation at the cornual area and lower uterine segment, with a deeper ablation in the uterine midbody. (Courtesy of HOLOGIC, Inc. and affiliates.)

Using a constant power output generator, the maximum power delivered is 180 W. The depth of ablation is controlled by monitoring tissue impedance during the procedure. A

P.262

shorter center-to-center distance between electrodes provides a more shallow depth of desiccation at the areas and lower uterine segment. A wider center-to-center distance between electrodes provides for a deeper ablation in the uterine corpus. The endometrium does not require pretreatment or thinning prior to treatment. RF energy delivery continues until monitored tissue impedance reaches 50 ohms (representing a distinction between the lower resistance of the endometrium and the higher resistance of the myometrium) or after 2 minutes, at which time the NovaSure System discontinues energy delivery.

LASER TECHNOLOGY

Historical Perspective and Background

Although the basis of laser technology was first described by Albert Einstein in 1917, working lasers did not appear until 1960 and were not applied to medicine until about 5 years later. LASER is actually an acronym for “light amplification by stimulated emission of radiation.” Energy from lasers is derived by the ability to generate light emissions that are both highly collimated (parallel rays) and coherent (in phase, noninterfering wavelengths) and that can be delivered to the surgical site by a series of mirrors or fibers without measurable degeneration of these properties. In doing so, virtually any surgical procedure requiring vaporization, cutting, or coagulation of tissue can be performed using lasers. Laser energy can destroy tissue layer by layer, without touching it, with minimal thermal damage.

Lasers generate light energy through the release of photons from excited atoms in a medium contained within an optically resonant chamber. The nature of the active lasing medium, a collection of atoms usually in the form of crystals or gas, is how the type of laser derives its name. When the medium is stimulated by an external source (e.g., electricity), the atoms circulating the nucleus of the medium are stimulated into a higher energy orbit. As the electrons decay to resting levels, light energy in the form of a photon is released. This process is known as spontaneous emission. Not only can electrons be stimulated by an external energy source, they can be bombarded by photons, which causes decay and emission of a photon that is identical in phase (coherent), in wavelength, and in color (monochromatic) and travels in the same direction without divergence (collimated). This process is called stimulated emission.

The optical cavity in which the electrons reside, and where the photons are produced, is lined by mirrors. All of the mirrors are completely reflective, except for a semitransparent mirror at one end of the linear axis of the optical cavity. The direction in which photons are emitted is totally random. They are focused by the mirrors so that most resonate back and forth along the axis of the optical chamber. Photons that are aligned with the optical axis of the chamber are released when the laser is “fired,” emerge through the semitransparent mirror, and are emitted from the laser as the monochromatic parallel coherent laser beam.

Laser generators have focusing attachments for delivery of the light energy for superficial use (e.g., colposcopy or lower genital tract), for laparotomy, and for laparoscopy. Historically, all lasers have been able to transmit energy via a flexible quartz fiber except for the CO₂ laser, which was transmitted along rigid tubes reflected by mirrors. However, a hollow-core flexible fiber delivery system recently has been developed for delivery of CO₂ laser energy (OmniGuide, Cambridge, MA) with adapters for external, laparoscopy, and robotic use.

Laser Tissue Interactions

Just as the surgeon can manipulate the active electrode to modify the effects of RF energy at the surgical site, there are three parameters that impact the amount of laser energy delivered. The first variable is wattage. For most applications, energy in the order to 5 to 10 W is sufficient; it is rarely necessary to exceed 20 W.

The second parameter is time. Simply put, the longer the laser remains focused on one spot, the more energy is applied to that area. This can be modified either by moving a continuous wave beam around within the desired treatment area or by delivering the laser energy in pulses. In pulsed modes, laser energy can be delivered as a single pulse or a series of pulses. Generally, a single pulse is less than 0.25 second. Timed pulses of short duration can be useful in controlling delivery.

The third parameter that can be controlled is the spot size of the beam. This is analogous to altering the current density of RF energy at the tip of the active electrode to alter tissue effects. Power density, expressed in watts/cm^2 , is inversely proportional to the area of the spot size, such that doubling the beam diameter reduces power density to one fourth. Conversely, decreasing spot size in half results in a fourfold increase in power density.

As previously mentioned, laser energy emerges from the generator in a coherent and parallel fashion. This could hypothetically travel in this form to infinitely. However, the laser light is focused to a fixed focal length, depending on the application of the device (external, laparotomy, or laparoscopy use). The surgeon can further alter the focus with additional lenses or mechanical devices. By focusing or defocusing the laser energy, it is used as a cutting or coagulating tool.

Applications of Lasers

The first gynecologic application of laser technology was reported in 1973 when Kaplan and colleagues used CO₂ laser to treat cervical lesions. Potassium titanyl phosphate (KTP) and neodymium:YAG (Nd:YAG) lasers became increasingly popular for laparoscopic applications, especially related to treatment of endometriosis and infertility patients, partially because of their specific properties but equally because a flexible fiber delivery system was comparatively easier to use than the rigid mirrored system of the CO₂ laser. However, because of increasing cost consciousness and availability of superior advanced RF-based devices in the late 1990s, laser technology for all but external lower genital tract disease dramatically decreased.

There are three zones of laser tissue damage: (a) the area vaporized, (b) the area of tissue death that results from the heated tissue short of vaporization, and (c) the area of tissue damage caused by conduction of the heat away from the lased site. Because it removes tissue with vaporization and evacuation, the suctioned plume allows the tissue base to heal without a devitalized tissue covering. Postoperative pain is reduced because nerve endings are sealed by the beam.

In gynecologic surgery, the most commonly used lasers are CO₂, argon, KTP, and Nd:YAG ([Table 15.2](#)). The argon and KTP lasers produce light waves of a specific wavelength, giving a characteristic color. The Nd:YAG and CO₂ lasers have wavelengths in the nonvisible spectrum. Accordingly, a helium-neon laser (632 nm, red) is typically coupled with them to use as a beam aiming guide and to aid in focus.

CO₂ Laser

The CO₂ laser is the most versatile and most widely used laser. Laser energy is absorbed, scattered, or affected by the thermal conductivity and local circulation of the tissue. Soft tissue is about 80% water by volume, which absorbs CO₂ laser energy readily, limiting penetration. Indeed, it has a shallow depth of penetration (up to 0.5 mm), and minimal lateral thermal damage is limited to about 0.5 mm. The CO₂ laser is therefore relatively safe and can be used in critical areas where RF energy application would be more dangerous, such as near

the bladder, on the lateral side wall near the ureter, and on the bowel serosa. A sharply focused laser beam produces narrow tissue vaporization comparable to an incision made by a scalpel. However, defocusing the beam enlarges the spot, and using the same settings, power density is reduced to treat a thin surface rapidly. The CO₂ laser provides excellent vaporization and cutting by increasing the power density and excellent coagulation with slight defocusing of the beam. The amount of damage caused by heat conduction is directly proportional to the amount of time spent in lasing.

TABLE 15.2 Laser Characteristics

TYPE	LASING MEDIUM	WAVELENGTH (NM)	COLOR	DEPTH OF PENETRATION
Argon	Argon gas	488-512	Blue-green	0.5 mm
KTP	Potassium titanyl phosphate	532	Green	1-2 mm
Nd:YAG	Neodymium-doped yttrium aluminum garnet	1,064	Near infrared	3-4 mm
CO ₂	CO ₂ gas	10,600	Infrared	0.1 mm

Disadvantages of the CO₂ laser include focusing of the helium-neon beam as well as production of smoke referred to as “plume,” which needs frequent evacuation to allow adequate visualization of the target.

Nd:YAG Laser

Similar to CO₂ lasers, Nd:YAG lasers emit an invisible beam requiring a helium-neon spot for guidance. However, this energy penetrates tissue to greater depths of 3 to 4 mm, and, because the Nd:YAG energy scatters in tissue, its thermal damage is greater than that of CO₂. Poorly absorbed by water, it is not as good for vaporization, but it has much better coagulation properties. Because of its depth of penetration and its performance in a liquid environment, it was used to advantage in the early days of hysteroscopic procedures, including endometrial ablation. Although this laser fiber is typically used in a noncontact technique, adding a sapphire tip to the end of the fiber, the laser energy can be focused and converted into heat and used in a contact mode. This improves its vaporization abilities, but the tips need to be cooled with gas or liquid through the fiber.

KPT and Argon Lasers

The KTP and argon lasers have similar wavelengths in the visible light spectrum and are delivered via a fiberoptic fiber. The advantages of these lasers over the CO₂ laser include selective absorption by hemoglobin and other pigmented tissues and less plume production. These lasers produce a moderate scatter, 100 times that of the CO₂ laser, resulting in significantly reduced cutting ability but substantially increased coagulation effectiveness.

The main disadvantage is the need to wear special glasses that distort the view of the pelvis and make it difficult to visualize small implants of endometriosis.

LASER SAFETY

Lasers have been used in gynecologic surgery for nearly 40 years. Although there has generally been good safety record, there is great potential for injury. It is recommended that surgeons wishing to use laser technology undergo both didactic and practical training in laser use. There are also a few guidelines that should be kept in mind related to use of laser technology:

- Place an appropriate warning sign on the door of the operating room indicating when lasers are being used.
- All operating room personnel should wear protective safety glasses, matched for the wavelength of the laser used.
- When the laser is not actively being fired, it should be placed in standby mode.
- Drapes near the operative field should be flame resistant and kept wet if possible.
- Adequate suction should be available to collect all plume produced by laser use. Understand their specific tissue interactions of the laser being used. It is much easier to cause damage to a vessel or ureter when using deep penetrating energy such as that produced by the Nd:YAG laser than when using the CO₂ laser energy.
- Fibers used to transmit laser energy are delicate and can break, deliver laser energy at the break point, and potentially injure the patient and/or operating room personnel.

SUMMARY

When electricity is used in surgical applications, it follows Ohm law and three general rules: (a) Electricity must complete a circuit or it will not flow, (b) electricity goes to ground, and (c) electricity follows the path of least resistance. An understanding of these concepts, continuous and interrupted waveforms produced by electrosurgical generators and electrical circuits, and the tissue effects produced by active electrode characteristics and manipulation, the surgeon can use radiofrequency energy to advantage in the operating room. Conversely, a lack of understanding by the surgeon can result in poor surgical outcome and unnecessary complications. Just as physicians are expected to understand and prescribe drugs in a precise and logical manner, so should they have a working knowledge of the energy sources they choose to use in surgery.

BEST SURGICAL PRACTICES

Fundamental Principles of Electrosurgery

- Ohm law describes the underlying electrical principle of electrosurgery. Current (flow of electrons) is directly related to voltage (electromotive force) and inversely related to impedance (resistance to flow of electrons).
- Three rules explain the flow of electrons in tissue: (a) Electricity must complete a circuit or it will not flow; (b) electricity goes to ground; and (c) electricity follows the path of least resistance.

P.264

- An electrosurgical generator produces sinusoidal waveforms, variants of current, and voltage as a continuous (undamped) output current called CUT, a highly interrupted (damped) output called COAG, or a moderately interrupted (damped) output called BLEND.
- Electrosurgery creates a desired tissue effect by delivering high-frequency AC with active electrodes that

manipulate electrons to sufficient concentration (current density) in living tissue.

- In most circumstances, the CUT waveform should be used to cut and desiccate tissue, reserving the COAG waveform for surface fulguration to control small open bleeders and for superficial coagulation.
- Specific tissue effects can be achieved by using specific waveforms, using contact or noncontact techniques, altering the size and shape of the active electrode, and altering the movement speed of the active electrode (dwell time). The educated surgeon can integrate these variables to achieve the desired result.
- The lower-voltage CUT waveform should be used to incise tissue and for coaptive sealing of larger blood vessels. The higher voltage of the COAG current produces rapid tissue desiccation and carbonation, resulting in increased tissue resistance limiting coagulation to superficial small vessels. The BLEND current may provide a satisfactory combination for cutting through fatty tissues, such as the subcutaneous tissue or omentum.
- Coaptive sealing of the uterine and ovarian vessels using any type of monopolar current may be ineffective if the blood flow remains uninterrupted. Unless a vessel is sufficiently squeezed before electricity is applied, current density is dramatically reduced by conduction in blood, as any heat is dissipated by convection. Bipolar cautery is recommended for these larger pedicles.

Fundamental Principles to Reduce Risk during Electrosurgery

- Place electrode pencils in their safety holster when not in use. This will avoid accidental activation delivering unintended RF energy.
- Inspect each instrument's insulation before use.
- Any alcohol preparation near the field of surgery should be completely dried before initiation of an electrosurgical device to avoid fire.
- With monopolar systems, use a monitored return electrode system (frequently referred to as a REM system). Place return electrodes close to the operative site on a clean, dry, shaved area, avoiding bony prominence and scar tissue. The longest edge should face the operative site, and REM pads should never be cut.
- Cords to electrosurgical devices should be secured using a nonconductor (or plastic) clamp. The cord should never be wrapped around a metal clamp, as this has potential for direct coupling with high output of power or if there is an insulation failure in the device cord.
- Activate CUT for all desiccation-coagulation procedures; use COAG for fulguration procedures.
- Activate the electrode in short bursts (about 3 seconds) to minimize capacitive coupling. Use the manufacturer's recommended connection cables. Inspect instrument insulation before each use. If the usual power settings seem inadequate, do not increase the power until the circuit is checked, especially the return electrode.
- Select the lowest voltage that will create the desired effect. For any given power setting, CUT current produces a lower peak voltage than COAG current.
- If open activation occurs at a site remote from the intended area, the charge has potential to build at the tip of the instrument and discharge via arcing to an alternate site. Moreover, this can cause unrecognized injury out of the operative field of view if performed during laparoscopic procedures. If the surgeon desires true fulguration or vaporization of tissue, the instrument should be activated as near to the tissue as possible without actually touching it.
- Consider using bipolar methods. Bipolar systems deliver current as an uninterrupted CUT waveform calibrated

against a lower resistance than monopolar systems. As such, it is wise to use a current flow meter to confirm complete desiccation of tissue, especially during tubal sterilization. In some tissues, the thermal effect will be limited such that monopolar application will be preferable.

- Consider using bipolar energy for patients with pacemakers and other implanted cardiac devices. If monopolar must be used, follow safety advice from the implant manufacturer.
- The degree of thermal necrosis on tissue that is electrically incised is dependent on the velocity of passage as well as electrode size and shape and the electrosurgical waveform.
- As one electrode is changed to another, the surgeon should keep charge density, waveform, and electrode characteristics in mind and adjust the generator output to match the task at hand.
- The most common complication during electrosurgery is return electrode burns, owing to improper application of the electrode. Prophylactic measures include proper skin preparation and site application. Alternate site burns, such as to cardiac leads, usually result from improper grounding, use of too much power, and high-voltage application.

Fundamental Principles of Electrosurgery Techniques

- Before taking any electrosurgical action, determine the source of bleeding and its proximity to vital anatomy using mechanical tamponade with active hydrolavage. If the bowel, bladder, or ureter is in close proximity to the bleeder, mobilize that structure sufficiently before applying energy.
- Because the output voltage of COAG current is very high, contact coagulation is generally limited to superficial layers. That is because of the accelerated buildup of tissue resistance from rapid desiccation and superficial carbonization. Conversely, electrode contact using the lower-voltage CUT current heats tissue more gradually, leading to deeper and more reliable penetration.
- Preferentially use BLEND or COAG current for a wider zone of hemostasis during incision of vascular tissues and to facilitate dissection of tissues with greater impedance, such as fatty or desiccated pedicles and adhesions. On the other hand, it is more prudent to use the lower-voltage CUT current via the edge of an electrode whenever lateral thermal spread may pose extra liability to adjacent tissues.
- If bleeding in the vicinity of the bowel, bladder, or ureter cannot be controlled with pressure alone, carefully direct short bursts of noncontact COAG current with a broadsurface electrode to attain hemostasis with the least possible amount of electrosurgical penetration. Still, visceral bleeding is best controlled by mechanical means, using the patience of pressure or suture ligation.
- Although the flow of current is restricted to the tissue between the poles during bipolar electrosurgery, this does not eliminate the risk of thermal injury to tissue that is distant from the site of directed hemostasis. As current is applied between the poles, the intervening tissue gradually desiccates until it becomes thoroughly dehydrated.

P.265

- Unwanted thermal damage can be minimized by terminating the flow of current at the end of the visible vapor phase, applying current in a pulsatile fashion to permit tissue cooling, and securing pedicles by a stepwise process that alternates between partial desiccation and incremental cutting.
- Because the rate of temperature generation is a direct function of the volume of tissue being desiccated, thermal spread can also be reduced by using the sides or tips of a slightly open forceps to press or lift, rather than coapt for hemostasis.
- As with contact monopolar coagulation, tissue between the electrodes of a bipolar instrument may become

adherent during desiccation. Repeated attempts to shake the tissue free may lead to traumatic avulsion of a key vascular pedicle. A stuck vascular pedicle can usually be unglued by energizing the opened device while immersed in a conductive irrigant, such as saline.

Chapter 16

Diagnostic and Operative Laparoscopy

Howard T. Sharp

Marisa R. Adelman

DEFINITIONS

Aqua dissection—The use of fluid, most often sterile water or saline, under force, to separate one anatomical plane from another. Laparoscopic suction-irrigators are an excellent tool for performing aqua dissection.

Chromopertubation—A procedure in which a colored dye is passed through the fallopian tubes to confirm patency.

Colpotomy—A surgical incision in the vagina. The *-tomy* part of the word is from the Greek word *tome*, meaning cutting.

High definition—A term initially introduced in the 1930s to define the then-new technology that replaced the experimental systems ranging from 15 lines to about 220 lines of resolution. High-definition television is now defined as resolution 1,080 or 720 lines. HD is broadcast digitally and consequently produces a more vivid and realistic picture.

Morcellate—To divide into small portions.

Reposable—A trocar/sleeve kit in which disposable trocars are used with reusable sleeves in an effort to reduce the cost of disposable products while ensuring sharp, undamaged instruments more commonly found in the disposable kits.

Veres needle—A spring-loaded needle designed to allow entry into body cavities without trauma to underlying organs during laparoscopy.

Laparoscopic surgical advances have accelerated remarkably over the past decades. What was initially a primitive tool for diagnostic purposes and simple procedures such as tubal sterilization has evolved into a more coordinated system for the repair or removal of diseased abdominal and pelvic organs. As operative laparoscopy has become more complex and technology has continued to advance, new challenges and complications have been recognized. The proper use of equipment and techniques can greatly add to patient safety and satisfaction. To this end, the purpose of the chapter is to review contemporary equipment, commonly used surgical techniques, and strategies to avoid and manage complications associated with laparoscopic surgery.

HISTORY

The first description of endoscopy is attributed to Phillip Bozzini in 1805, as he attempted to view the urethral mucosa with a simple tube and candlelight. Hysteroscopy was the first gynecologic endoscopic procedure performed when Pantaleoni used a cystoscope to identify uterine polyps in 1869. Laparoscopy was first performed by Jacobaeus of Sweden in 1910, wherein a Nitze cystoscope, composed of a candle and a hollow tube, was used to illuminate the peritoneal cavity. Kalk of Germany was instrumental in developing laparoscopy into a diagnostic and surgical procedure in the early 1930s. By the end of the 1930s, laparoscopy was being used in the diagnosis of ectopic pregnancy and the performance of tubal sterilization. Raoul Palmer

of France reported the use of gaseous distention with lithotomy-Trendelenburg positioning in 1947. The use of “cold light” and fiberoptics were landmark innovations credited to Fourestier, Gladu, Valmiere, and Kampany and Hopkins, respectively. Monopolar electrosurgery for tubal sterilization was popularized in the 1960s. Semm of Germany reported advanced operative laparoscopic procedures such as salpingectomy, myomectomy, oophorectomy, ovarian cystectomy, and salpingostomy in the 1970s. These pioneers of endoscopic surgery and many others have laid the crucial groundwork that has enabled modern gynecologic surgeons to perform advanced operative laparoscopy on a routine basis, with a variety of energy systems under increasingly ergonomic and efficient conditions.

INDICATIONS FOR LAPAROSCOPY

Diagnostic Laparoscopy

Laparoscopy can provide valuable clinical information in a number of circumstances. It can aid in the evaluation of patients with acute pelvic and abdominal pain, including ovarian torsion, ovarian cyst rupture, ectopic pregnancy, appendicitis, and pelvic inflammatory disease. In the evaluation of less emergent conditions, such as chronic pelvic pain and infertility, it is useful to identify pelvic adhesions, endometriosis, hernias, uterine fibroids, and adnexal masses. Before performing diagnostic laparoscopy, a thorough history, detailed physical examination, and appropriate imaging studies should be completed.

Operative Laparoscopy

Most surgeries traditionally performed by the abdominal or vaginal approach can now be performed laparoscopically. Studies are still needed to better define which advanced procedures are most appropriate to perform laparoscopically from an economic and safety vantage point. Operator experience is a critical factor that must be considered. Commonly performed laparoscopic procedures include adhesiolysis, treatment of endometriosis, tubal sterilization, ovarian cystectomy, oophorectomy, salpingectomy, salpingostomy, and hysterectomy. More advanced procedures include repair of pelvic organ prolapse, tubal reanastomosis, myomectomy, radical hysterectomy, and lymphadenectomy.

EQUIPMENT

Contemporary laparoscopy equipment consists of an imaging system comprising a telescope (laparoscope) and video camera system, an insufflation or abdominal wall lift system, and specialized surgical instruments. Digitization and robotics are areas that continue to evolve.

Imaging Systems

Imaging systems consist of a laparoscope, light source, fiberoptic cord, camera unit, and monitors. High-definition digital cameras are compatible with the increased resolution capabilities of high-definition flat screen monitors. Most imaging systems are also equipped with a printer, video recorder, or DVD recorder for documentation.

The laparoscope in its basic form is a telescope. Laparoscopes range from 1.8 to 12 mm in diameter, with a distal end (objective) available in varying viewing angles ([Fig. 16.1](#)). The 0-degree deflection-angle telescope is most commonly used and provides a straightforward view, whereas a 30-degree foroblique lens allows for visualization in a large frontal view but must be continuously directed to maintain field orientation. Operative laparoscopes are equipped with a central channel that allows laser, electrosurgical, or mechanical instruments to be introduced into the abdomen. Light is introduced through the laparoscope with a fiberoptic cable powered by a light source. It is important that the light source has sufficient power to deliver adequate light through the fiberoptic cable. Ideally, high-intensity light sources that use xenon or halogen are used. Though a significant amount of original light is lost from the original hot light source, the

fiberoptic cable is able to transmit enough heat to burn paper drapes as well as patient's skin; therefore, caution should be used to avoid inadvertent contact with drapes or the patient.

FIGURE 16.1 Telescopes used in laparoscopy. **Top:** 5-mm, 45-degree viewing angle laparoscope. **Middle:** 5-mm, 0-degree viewing angle laparoscope. **Bottom:** 10-mm, 0-degree viewing angle laparoscope.

The camera unit consists of a camera head, cable, and camera control. The camera head attaches to the eyepiece of the laparoscope and captures images transmitted by the laparoscope. Camera/laparoscopes are now available as combined, fused units that are fully autoclavable, with push-button zoom and autofocus features. The basis of laparoscopic cameras is the solid-state silicon computer chip or charge-coupled device (CCD). This is composed of silicon elements, which emit an electric charge when exposed to light. Each silicon element contributes one pixel unit to the image produced. The image resolution is dependent on the number of pixels on the chip. CCDs are housed within the camera head of rigid scopes, in comparison to complementary metal oxide semiconductors, which are located at the tip of flexible scopes. Most laparoscopic cameras have 250,000 to 2,073,600 pixels. Three-chip CCDs provide better image quality but are more expensive, as they have a separate chip for each primary color, as opposed to the single-chip CCD. High-definition displays, with 1,080 lines, are needed to provide optimal visualization. Newer developments include the use of wireless systems, designed to provide central control over operating room devices, using either a microphone or a movable touch-pad screen.

Abdominal Lifting Systems

Insufflation systems allow gas to fill the abdominopelvic cavity to optimize visualization. Insufflators are designed to deliver gas at low rates during initial Veres needle insertion, but are also able to provide high flow rates when gas is lost to maintain a relatively constant, set intra-abdominal pressure during surgery. Insufflation may be achieved with a Veres needle or the Hassan trocar, filtered tubing, an insufflator, and gas tanks. Insufflation tubing with a 0.3-micron filter is recommended to prevent intraperitoneal contamination with bacteria, microparticles, and debris from the insufflator and gas tank. A Veres needle is often used to create a pneumoperitoneum, although other methods, such as direct trocar insertion and open laparoscopy, will be discussed. The Veres needle is available in reusable or disposable

P.267

models containing a spring-loaded tip that retracts as it pierces the abdominal wall, allowing a blunt tip to engage on entry to the peritoneal cavity (Fig. 16.2). This is designed to avoid damaging the bowel or other intra-abdominal organs. Though filtered room air has been used, carbon dioxide is most commonly used today. Carbon dioxide has the advantage of being rapidly absorbed by blood. However, it is converted to carbonic acid on moist peritoneal surfaces, which can cause pain. For this reason, nitrous oxide or helium is preferred by some, especially in cases using local anesthesia or conscious sedation. Some have advocated the use of heated or hydrated gas to prevent hypothermia during laparoscopy. A Cochrane review concluded that during laparoscopic abdominal surgery, heated gas insufflation, with or without

humidification, had minimal benefit on patient outcomes. Specifically, there was no effect on postoperative pain, changes in core temperature, or length of hospitalization observed. This is partly because insufflators that contain a heating unit will ultimately have little or no effect on temperature by the time the gas has traveled 50 to 100 cm in tubing. In longer surgeries, prevention of hypothermia is better achieved by using a heated body surface blanket or a device that delivers heated and hydrated gas. Gasless laparoscopy can also be performed with the use of a mechanical lifting arm that attaches to a fanlike retractor along the peritoneal surface of the abdominal wall, obviating the need for gas distension. Some favor this approach in patients with cardiopulmonary risk factors.

FIGURE 16.2 Disposable Veres needle.

Surgical Instrumentation

Trocars and sleeves are used to pierce the abdominal wall for placement of the laparoscope and surgical instruments (**Fig. 16.3**). Trocar sleeves range from 3 to 15 mm in diameter and are available as reusable, disposable, and reusable systems. Disposable systems consist of completely disposable trocars and sleeves. They offer the advantage of consistent sharpness but are more expensive. Reusable trocars offer the advantage of being the most cost effective, but they must be maintained for sharpness. Reusable systems are composed of a disposable bladed or nonbladed trocar with a reusable sleeve. All are acceptable for use. Most sleeves contain a Luer-Lok port that attaches to insufflation tubing. Trocar tips may be pyramidal, conical (reusable), bladed, or blunt tipped or have optical access (disposable). Conical and blunt-tipped trocars have the advantage of making smaller fascial defects but require greater force to place. Optical access trocars enable the surgeon to visualize the layers of the abdominal wall during placement. Expandable trocar sheaths are available that are initially placed through the abdominal wall with a Veres needle and then expand to accept a 5- to 12-mm port. These offer the advantage of creating smaller abdominal wall defects and thereby reducing the risk of hernia formation and injury to the inferior epigastric vessels.

FIGURE 16.3 Trocars and sleeves. Shown from left to right: 12-mm blunt optical tip, 12-mm Hasson blunt tip, 12-mm shielded tip, 5-mm pyramidal tip, and 5-mm bladeless tip. (Courtesy of Genicon.)

Ancillary instruments may be placed through secondary trocar sleeves to aid in diagnostic and operative laparoscopy (Figs. 16.4 and 16.5A, B). These include blunt probes; a variety of graspers, including toothed and atraumatic graspers; scissors; needle drivers; knot pushers; biopsy forceps; suction-irrigators; energy delivery tools; specimen retrieval bags; and tissue morcellators. A uterine manipulator may be used to improve access to the uterus, fallopian tubes, ovaries, and the posterior and anterior cul-de-sacs. These are available in reusable and disposable models (Fig. 16.6A-C). Some manipulators are inserted in a fixed position and allow limited uterine mobility, whereas others are hinged and allow the uterus to be moved anteriorly, posteriorly, and laterally. Many of these also offer the ability to perform chromotubation for evaluation of fallopian tube patency. Colpotomizer cups are included, or can be attached to most uterine manipulators, and engulf the cervix, allowing the surgeon to cut against it when resecting the uterus and cervix from the vagina during laparoscopic hysterectomy. The colpotomizer delineates the vaginal fornices, allowing for maximal preservation of vaginal length, and optimizes separation of the ureters from the uterine arteries, in order to avoid injury. At least one of the current cups on the market utilizes light, in order to better identify the cervicovaginal junction. The same device may also include a balloon that is inflated to prevent the pneumoperitoneum from escaping through the

P.268

vagina (pneumoooccluder) once the colpotomy has been made. Though these instruments can significantly facilitate the hysterectomy, they are more expensive than other manipulators, and the time required to insert them can potentially contribute to the overall anesthesia time. An alternative to a colpotomizing cup is a sponge-stick or EEA sizer.

Energy and Hemostasis

The application of energy systems to laparoscopy has expanded laparoscopic surgeons' ability to perform complex surgeries with the capability to rapidly divide tissues and maintain hemostasis. This technology has also introduced a new set of complications, such as unrecognized bowel burns from inadvertent direct and capacitive coupling. In an effort to reduce risks associated with monopolar electrosurgical devices, several options are available. One is the use of endomechanical energy; a second is the use of bipolar electrosurgery, laser, or ultrasonic energy; and a third is the gaining of a better understanding of electrosurgical principles. Though our understanding of laparoscopically applied electrophysics has improved, gynecologic surgeons often have no formal electrosurgical training or credentialing, in contrast to the once-common laser safety courses.

Endomechanical Energy

Endomechanical energy can be used for tissue division and hemostasis in a number of ways, including suturing, stapling, and the application of vascular clips.

Suture

The simplest laparoscopic ligature to apply is the pretied loop, available as a slip knot on a push rod that is used to push a suture loop around a tissue pedicle for hemostasis. The Roeder loop, which was modified by Kurt Semm for laparoscopic use, can also be tied in the operating room using standard suture.

Laparoscopic suturing can be performed using stock suture, ideally 36 to 48 inches in length ([Fig. 16.7](#)). Needle drivers are used to drive needles through tissue, and knots may be tied outside the laparoscopic

port (extracorporeal knot) or within the body (intracorporeal knot). Extracorporeal knots are usually performed as sliding square knots, pushed through the trocar sleeve to the tissue by multiple passes of a knot pusher, which serves as the surgeon's finger (**Fig. 16.8**). Intracorporeal knots are tied within the abdomen by looping the suture material around the laparoscopic needle holders using the same technique as an "instrument tie" (**Fig. 16.9**). Laparoscopic suturing requires considerable practice to confidently load the needle into the needle driver and place sutures accurately. To this end, the Endo Stitch (Covidien) was developed, wherein the needle is preloaded and the suture is passed through tissue up to 2 cm thick by closing a handle and a toggle switch. Interrupted or continuous suturing can be accomplished. The Endo Stitch is a 10-mm disposable instrument, which uses device-specific suture cartridges. There are several other automatic suturing devices, both disposable and reusable, some of which are able to articulate. Both absorbable clips and titanium knots are available to secure the ends of suture, obviating the need for knots. In an effort to accommodate surgeons desiring to use the laparoscopic needle driver and suture, self-righting needle drivers were designed, which automatically fix the needle at a perpendicular or oblique position to the needle driver. Such devices can facilitate suturing laparoscopically.

Staplers

The Endo GIA, originally designed for gastrointestinal anastomosis, can be used in gynecologic laparoscopy as a stapling device for securing and dividing tissue. After placing and firing the preloaded device, six staggered rows of staples, 3 cm in length and 1 cm in width, are left behind. A knife blade simultaneously divides the tissue, leaving three rows of staples on each side of the incision.

P.269

FIGURE 16.7 Extracorporeal knot tying with slip knot. **A:** With both suture ends outside the body, the suture is cut below the needle. A single throw is made. **B:** With the free end of the suture, three revolutions are made around both suture strands. **C:** The tail of the suture is inserted through the lowest loop. **D:** The tail is pulled to tighten the knot, the suture is cut above the knot, and the slip knot is pushed with a closed-nose

knot pusher to the desired position. (Modified from Murphy AA. Operative laparoscopy. *Fertil Steril* 1987;47:1, with permission. Copyright © 1987 Elsevier.)

FIGURE 16.9 Intracorporeal knot tying. **A:** The needle is passed through the tissue. **B:** A surgeon's knot is made with the instruments and pulled tight.

P.270

Vascular Clips

Endoscopic vascular clips may be used to achieve hemostasis for bleeding vessels or pedicles. These offer the advantage of being used near vital structures, where the use of other forms of energy may otherwise result in lateral thermal damage.

Laser Energy

The term *laser* is an acronym for *light amplification by spontaneous emission of radiation*. Surgical lasers available for gynecologic use include CO₂, argon, potassium titanyl phosphate, and neodymium:yttrium-aluminum-garnet. These have the ability to vaporize, cut, and, to varying degrees, coagulate tissue (see [Chapter 15](#)).

Ultrasonic Energy

The HARMONIC ACE Scalpel (Ethicon) uses vibration at a rate of 55,000 cycles per second, as an energy source to break hydrogen bonds in tissue, resulting in cutting or coaptation of vessels. The Harmonic devices are available for use in vaginal, abdominal, and laparoscopic procedures. The laparoscopic device, termed the Harmonic Ace ([Fig. 16.10](#)), is approved for sealing vessels up to 5 mm in diameter. It can be used to grasp, seal, and incise structures, or the active blade can be used alone for dissection and transection of tissue. This modality results in minimal lateral thermal spread of energy, and there is no risk of electrical injury.

Electrosurgery

Monopolar and bipolar electrosurgical instruments are frequently used to perform tubal sterilization and to obtain hemostasis. Monopolar instruments use current that flows from an active electrode through a

patient's tissue, and exits by way of a return electrode plate (usually placed on the patient's thigh), to the electrosurgical unit (ESU). Needlepoint electrodes, L-hooks, and most endoscopic scissors are examples of monopolar electrosurgical instruments. Bipolar instruments, such as the Kleppinger forceps and the newer impedancecontrolled bipolar systems, use current that flows from an active electrode through tissue and returns back to the ESU through a return electrode within the same instrument. With bipolar energy, a return electrode plate is not necessary. Both monopolar and bipolar electrosurgery can be used for cutting or coagulating (see [Chapter 15](#)).

Electrosurgical instruments conduct high-frequency alternating current (AC), which forces electrons through the tissue and accomplishes resistive heating. With AC, electrons flow back and forth between positive and negative poles, as compared with direct current, in which electrons only flow in one direction. Household electrical outlets conduct low-frequency AC, at 60 cycles per second (Hz). Electrosurgical generators convert low-frequency AC to high-frequency AC, in the range of radiofrequency (300 to 600 kHz). The waveform of radiofrequency current is continuous and sinusoidal. The waveform can thus be interrupted to produce different effects ([Fig. 16.11](#)).

FIGURE 16.10 HARMONIC ACE. (Courtesy of Ethicon.)

FIGURE 16.11 Coagulating and cutting waveforms.

Cutting mode utilizes continuous uninterrupted low-voltage energy, inducing resistive heating and causing cells to vaporize at their boiling point of 100°C. There is very little elevation in surrounding tissue

temperature, therefore minimizing the amount of lateral thermal damage. Modifications in the waveform refer to blend 1 (80% on, 20% off), blend 2 (60% on, 40% off), blend 3 (50% on, 50% off), and coagulation (6% on, 94% off). Electrosurgical generators will maintain a constant power output; therefore, when the highly interrupted waveform of *coagulation mode* is utilized, and current is reduced, a higher output voltage will be generated ($\text{watts} = \text{voltage} \times \text{current}$). These “bursts” of high voltage increase the temperature of surrounding tissues, resulting in denaturation and charring, giving the effect of coagulation and hemostasis, rather than cutting. Understanding the concepts of cutting and coagulation is clinically relevant when bleeding is encountered. For example, when there is surface oozing, fulguration is used to achieve enough superficial lateral thermal spread to cause hemostasis. Fulguration is superficial coagulation, which uses the coagulation mode to achieve high-voltage sparking. The highly interrupted, high-voltage current causes random sparks to arc between the electrode and tissue, rapidly elevating superficial tissue temperatures, in order to achieve hemostasis. Vessels up to 2 mm in diameter can be controlled in this manner, although it is ineffective in wet surgical fields, as the current is conducted and the energy is widely disbursed. Conversely, in the case of a larger bleeding vessel or pedicle, it is best to desiccate the tissue by applying pressure (coaptation) and cutting current. This causes fibrous bonding of the dehydrated cells of the endothelium without significant lateral thermal spread. It also decreases the risk of thermal bowel injury from capacitive coupling (see [Chapter 15](#)), as lower voltage is used. Conversely, when the coagulation waveform is used in this scenario, instead of causing bonding inside the vessel, superficial lateral thermal spread is more likely to occur along the tissue surface, resulting in eschar formation and subsequent bleeding. Current density refers to the amount of current flow per cross-sectional area, described in amps per meters squared.

P.271

This concept has several direct applications to the use of electrosurgical energy in laparoscopy and is used to safely return current from the patient to the ESU. Because current density is described in terms of current per meter squared, applying energy to a small area of bleeding or to a bleeding tissue pedicle will result in an intended thermal effect, inversely related to the electrode size. For example, the use of a needlepoint electrode will have high-current density, compared with a much larger spatula tip, resulting in greater energy applied to a small surface in the former. The current density principle is used to allow current to exit the body without causing injury, as it exits through a relatively large surface area of the return electrode, usually placed on the patient's thigh. This does not cause an exit site burn because of low current density. Exit site burns have typically occurred when part of the return electrode has peeled away from the patient, resulting in a smaller area of surface contact, thus creating high current density at the exit site. Newer systems have a built-in fault, whereby the active electrode will not deliver current if the pad is no longer in complete contact with the patient.

Bipolar instruments have undergone significant transformation in recent years. Simple bipolar systems, such as the ESU with a Kleppinger forceps, have evolved to devices that provide bipolar energy that senses tissue impedance to perform controlled energy delivery. The LigaSure Vessel Sealing Device (Covidien) ([Fig. 16.12A](#)) applies high coaptive pressure at temperatures below 100°C, to denature and reform hydrogen cross-links, forming a vascular seal. Tissue fusion and vessel sealing use the body's own collagen and elastin to create a permanent fusion zone. Hemostasis is achieved by reforming the collagen and elastin in vessel walls to form an autologous seal. Tissue impedance is monitored 3,333 times a second, in order to provide real-time adjustment of energy output. The EnSeal Laparoscopic Vessel Fusion System (Ethicon) ([Fig. 16.12B](#)) is also able to produce high-coaptive pressures and does so uniformly across the length of the jaw, as a mechanical blade is advanced. The plastic jaws are thermoelastic and contain conductive carbon spheres. When the temperature exceeds 100°C, the polymer of the jaws expands, and the spheres are separated such that they cannot conduct current. Tight temperature

regulation is thus maintained, avoiding elevation in temperature of surrounding tissue. Additionally, the offset electrode configuration, whereby the positive electrode is located within the nonhinged lower jaw and all jaw components serve as the negative electrode, is designed to minimize thermal spread. The combination of coaptive pressure and heat results in a tissue seal. PlasmaKinetic technology (Gyrus ACMI, a division of Olympus) makes two laparoscopic instruments, both of which deliver pulsed, ultra-low-voltage, high-current radiofrequency energy and utilize continuous impedance feedback. The HALO PKS Cutting Forceps (**Fig. 16.12C**) uses a mechanical blade, while the PKS Omni delivers both bipolar coagulation and cutting. The newest device on the market, the ThunderBeat (Olympus) (**Fig. 16.12D**), combines bipolar and ultrasonic energy. Sealing can be achieved alone by applying bipolar energy, or sealing and cutting can occur simultaneously with a combination of bipolar and ultrasonic energy. Bipolar energy is applied laterally, while ultrasonic energy is applied centrally. All of these devices are approved to seal vessels up to 7 mm in diameter.

In several comparative studies between the HARMONIC ACE, LigaSure, and EnSeal, failure rates and mean burst pressure tended to increase for all instruments with increasing vessel diameter, but the lowest burst pressures measured were still three times higher than that of normal systolic pressure. EnSeal and LigaSure had less radial adventitial collagen denaturation than the Harmonic ACE. Representative histologic samples were found to have less than 3 mm of coagulative necrosis for all instruments; therefore, 5 mm is likely a safe margin of distance from an instrument, in order to avoid histologic damage. When change in temperature was measured at varying distances, no changes were recorded at distances greater than 1 cm from the tips of monopolar, bipolar, Harmonic, and LigaSure devices in a porcine model. It is worth noting that the maximum temperature during and after activation is approximately 200°C for ThunderBeat and Harmonic, and that those devices require almost twice the time to cool to less than 60°C, as compared to LigaSure. The maximum temperature during and after activation therefore requires some caution, in order to avoid inadvertent thermal damage to surrounding structures.

Energy systems are commonly used for making the colpotomy, although there are reports of introducing a scalpel laparoscopically. Monopolar hooks, bipolar hooks, spatulas, lasers, and the active ultrasonic blades of the Harmonic and ThunderBeat devices run the gamut of what is available

and typically used. Several companies manufacture monopolar loops for assisting in performance of supracervical hysterectomy. They typically operate at high wattages (100 to 130 watts), using moderately

interrupted current (20% coagulation, 80% cut), and can transect the uterine corpus from the cervix in approximately 5 seconds. The loops may also assist in transection of broad-based pedunculated myomas, especially when visualization of the stalk is obscured. It is important when using a monopolar loop, however, to ensure that no viscera are entrapped prior to activation. Many other monopolar, bipolar, and ultrasonic devices can accomplish the same tasks, but not with the same degree of efficiency. The time saved in the operating room must be balanced by the cost of additional instrumentation.

Robotics

In 1994, the first U.S. Food and Drug Administration-approved robotic surgical device called AESOP (Automated Endoscopic System for Optimal Positioning, Computer Motion, Inc.) was introduced. With this system, the surgeon could control the orientation of the laparoscope through voice commands. The da Vinci Robotic Surgical System (Intuitive Surgical) and Zeus Robotic Surgical System (Computer Motion) allow the surgeon to operate from a remote station with hand controls that can provide increased dexterity and minimize fatigue, tremors, or incidental hand movement (see [Chapter 17](#)).

POSITIONING THE PATIENT FOR LAPAROSCOPIC SURGERY

The patient should be placed on the operating table in the low lithotomy position with the buttocks at or slightly over the table's edge to allow placement and use of an intrauterine manipulator and to have access to the perineum if needed during surgery. The patient's thighs should be in the same plane as the abdomen to allow freedom of motion for laparoscopic instrumentation. When the knees are bent and elevated above the plane of the abdominal wall, it is difficult to gain access to the upper abdomen and pelvic brim without bumping into the legs because of the fulcrum effect of instruments placed into lower ports. Stirrups should have ample padding to support the lower leg without creating pressure points. Particular attention should be given to preventing injury to the peroneal nerve, which is especially vulnerable to compression injury. It is preferable to use a stirrup that can be elevated without undraping the patient so that a high lithotomy position can be used for easier vaginal access if needed. To avoid stretch injury to the femoral, sciatic, or obturator nerves, the thigh should be flexed no more than 90 degrees, and the hips should be abducted no more than 45 degrees. External rotation should be avoided.

Systems to prevent slippage while in steep Trendelenburg include nonslip pads, beanbags, and shoulder braces. Nearly all of these setups require that the arms be tucked to the side. Caution should be exercised when using shoulder braces, as brachial plexus injuries can result when placed too medially.

Surgical Suite

Efficient orientation of the surgical suite is critical for efficient laparoscopic surgery. In general, a right-handed surgeon stands on the patient's left side with the surgical assistant on the patient's right; however, some surgeons prefer the patient's right side. The monitor is usually placed between the patient's legs if only one is available. In the case of two monitors, these are usually placed near the patient's lower legs in the direct line of vision of the surgeons. Newer surgical suites have done away with towers and have ceiling-mounted, movable flat screens, which are highly ergonomic ([Fig. 16.13](#)). The insufflation monitor is usually placed across from the surgeon so intra-abdominal pressure can be viewed. Insufflation tubing, light cords, electrosurgical cords, and suction-irrigation tubing should be out of the surgeon's path if perineal access is necessary. Knowledgeable operating room personnel are likewise critical to the laparoscopic mission. The scrub technician usually stands caudad to the surgical assistant. A circulating technician assists in troubleshooting equipment and obtaining supplies and equipment.

FIGURE 16.13 Ergonomic surgical suite with ceiling-mounted, movable flat screens.

ENTERING THE ABDOMINAL CAVITY

The abdominal cavity may be initially entered at the umbilicus or alternative sites by Veres needle, open laparoscopy, or direct trocar insertion.

Umbilical Site Veres Needle Technique

When the umbilical site and Veres needle technique is used, the Veres needle is first placed into the abdominal cavity to establish a pneumoperitoneum, and a trocar is subsequently placed into the pneumoperitoneum. A meta-analysis of methods used to establish pneumoperitoneum compared open access (Hasson type) with closed access (needle/trocar) and two types of closed access techniques (direct trocar versus needle/trocar). It was noted that deaths were only reported in the needle/trocar group. However, because of the rarity of death as an outcome, the statistical risk could not be compared meaningfully. The meta-analysis was underpowered to adequately compare the two closed techniques. Therefore, the question of which technique for initial port placement is safest has not been definitively answered to date.

A scalpel is used to make a small skin incision in accordance with the size of the trocar to be placed at the umbilicus or in the left upper quadrant (discussed later in Alternatives to Umbilical Entry). The skin should be elevated in the case of umbilical entry, and the scalpel should be held parallel to the long axis of the patient, to avoid incidentally lacerating the great vessels, which lie in close proximity to the umbilicus. Having the anesthesiologist decompress the stomach with a nasogastric tube will decrease the risk of inserting the Veres

P.273

needle or trocar into an overdistended stomach, especially in the case of a left upper quadrant entry. The patient's abdomen should be relaxed by neuromuscular blockade if general anesthesia is being used to allow adequate elevation for Veres needle and trocar insertion. The patient should be lying in a flat or neutral position on the operating table, because the use of Trendelenburg positioning may cause the trajectory of the Veres needle or trocar to be closer to the great vessels rather than the pelvic cavity. In the thin patient, the Veres needle or trocar should be directed toward the hollow of the sacrum to avoid the great vessels (**Fig. 16.14**). In the obese patient, the aorta is typically above the level of the umbilicus; therefore, the Veres needle or trocar may be inserted vertically (90 degrees to the long axis of the patient), as long as the abdominal wall has been elevated adequately (**Fig. 16.15**). Placing the Veres needle close to the base of the umbilicus takes advantage of the thin natural confluence of tissue planes at the umbilicus. Separate clicks can be heard or felt as the needle traverses the fused fascia of the rectus muscles and then peritoneum.

FIGURE 16.14 Insertion of the Veres needle.

Correct placement of the Veres needle into the abdominal cavity can be assessed by several techniques. The hanging drop technique is used by placing a small amount of sterile saline in the top of the Veres needle to verify a negative intraabdominal pressure as it descends into the abdominal cavity. Alternatively, the syringe barrel test can be performed by watching the column of saline descend the barrel of a syringe attached to the Veres needle. Aspiration of a syringe attached to the Veres needle can test for blood or gastrointestinal contents. Low-flow insufflation should be performed at a flow rate of approximately 1 L/min, until further signs of intra-abdominal needle placement are confirmed, such as low intra-abdominal pressure (<10 mm Hg) or loss of dullness to percussion over the right upper quadrant. If the “intraabdominal” pressure reading is higher than 10 mm Hg, the probability of extraperitoneal insufflation is high, and the approach should be reassessed. A prospective, observational study of four tests to ascertain Veres needle placement compared the double click test, the hanging drop test, the aspiration test, and the initial five insufflation pressures in 345 women. High insufflation pressures were the most sensitive for preperitoneal insufflation. Occasionally, high insufflation pressures may be encountered with correct intra-abdominal entry, such as in the case of morbid obesity or when the omentum is in close proximity. Often, the abdominal wall can be lifted, allowing the omentum to dislodge from the Veres, and an appropriate opening pressure will be observed. If elevating the abdomen does not result in a more appropriate pressure within several seconds, it must be assumed that the Veres needle is in the incorrect space and must be reinserted. High-flow insufflation may occasionally be used in the presence of reassuring signs of correct needle placement. During insufflation, intra-abdominal pressures should not exceed 20 to 25 mm Hg to avoid interfering with diaphragmatic excursion and central venous return from caval compression. After an adequate pneumoperitoneum has been established, ranging from 1 to 5 L depending on body habitus, a trocar is inserted at the umbilicus, paying attention to the angle of insertion based on body habitus, as discussed. Once the trocar is placed, the bladed or central portion is removed, and the laparoscope is placed through the trocar sleeve to ensure correct placement before attaching the insufflation tubing to the trocar sleeve.

FIGURE 16.15 The location of the umbilicus in relationship to the major vessels in nonobese, overweight, and obese patients. (Modified from Hurd WW, Bude RO, DeLancey JO, et al. The relationship of the umbilicus to the aortic bifurcation: implications for laparoscopic technique. *Obstet Gynecol* 1992;80:48, with permission. Copyright © 1992, The American Congress of Obstetricians and Gynecologists.)

Alternates to Umbilical Entry

When Veres needle insufflation is not successful, or in patients who are at risk for adhesions near the umbilicus, placing the Veres needle at a site other than the umbilicus is usually successful. Two commonly used sites are Palmer point and the left ninth intercostal space. Palmer point is located 3 cm from the midline and 3 cm below the left rib cage. The needle is directed 15 degrees cephalad after the skin has been stretched caudally. This will help direct the Veres needle at a 90-degree angle to the peritoneum, facilitating entry. If the ninth intercostal space is used, the Veres needle should be placed between the ninth and tenth rib, grazing the top of the tenth rib. This grazing minimizes the risk of damaging the intercostal neurovascular bundle. The rib cage provides a natural elevation of a space devoid of bowel regardless of patient weight. There is a remote chance of pneumothorax with this technique. Before performing either of these techniques, palpation for splenomegaly should be performed. After Veres needle placement, a 5-mm trocar is usually placed at Palmer point.

Open Laparoscopy

Hasson described the technique of open laparoscopy in 1971 as a way of avoiding blind trocar placement. A small incision is made at the umbilicus. Allis clamps are used to grasp the fascia, which is incised, and the peritoneum is entered directly. A Hasson-type cannula is used that can be anchored to sutures in the rectus fascia. In a review of more than 5,000 cases over nearly three decades, this technique has been shown to be associated with a low complication rate.

P.274

Direct Trocar Insertion

Direct trocar placement has also been described by placing the trocar through the umbilicus initially, rather than using the Veres needle.

SECONDARY TROCAR PLACEMENT

One or two secondary ports are usually adequate for most laparoscopic procedures. More complicated surgeries may require up to five. These may be placed lateral to the inferior epigastric artery or in the midline above the bladder. The size and number of trocars will depend on the procedure and equipment to be used. A 3- to 5-mm trocar may be used for diagnostic laparoscopy to maneuver pelvic organs for adequate visualization. Most instruments for tissue manipulation will fit through a 5-mm port. Some energy delivery systems and tissue retrieval systems require the use of larger ports (8 to 15 mm). Anticipating the need for larger ports can lead to significant cost savings when disposable trocars are used.

The placement of lateral trocars can be associated with injury to the inferior epigastric vessels. Before lateral

trocars placement, these vessels can usually be seen along the anterior abdominal wall, as they branch off the external iliac vessels. They can also be found in the anterior abdominal wall triangle, delineated medially by the medial umbilical ligament and laterally by the insertion of the round ligament (**Fig. 16.16**). Laparoscopic visualization of the inferior epigastric vessels has been shown to be successful in 88% of normal weight women, decreasing to 63% in obese women. The ability to visualize the superficial epigastric vessels with transillumination, however, is much more dependent upon weight, with 84% identified in normal weight women and only 23% identified in obese women. Insertion of a spinal needle through the anterior abdominal wall at the intended site of trocar insertion can help find a safe trajectory away from the inferior epigastric vessels. If the vessels cannot be seen, a safe location can usually be found by measuring 5 cm superior to the pubic symphysis and 8 cm lateral. In a study in which ultrasonography was used to measure the distance between the inferior epigastric artery and the umbilicus, a median of 4.75 cm was observed. Additionally, the distance from the midline at the levels of the umbilicus and the ASIS never exceeded 6 cm. Six centimeters should therefore be considered the minimum safe distance from the midline. Secondary trocars should be inserted in a controlled fashion, under direct vision. Placement of suprapubic secondary trocars should be placed well above the bladder. Two fingerbreadths measured above the pubic symphysis has been standard terminology for midline trocar placement. Because of the significant differences in finger widths among surgeons and considering the increased risk of bladder injury using the suprapubic location, it is also worth placing a spinal needle through the anterior abdominal wall in the midline to ensure that the port is well above the bladder. If the patient has had a prior laparotomy, the bladder may be tented superiorly, and it may be necessary to place the trocar higher.

FIGURE 16.16 Note the relationship of the inferior epigastric vessels to the medial umbilical ligament and the insertion of the round ligament.

TISSUE REMOVAL

Small tissue fragments, such as peritoneal biopsy specimens, may be removed through 5-mm trocar sleeves. Large, dense specimens, such as leiomyoma fragments, require larger ports (10 to 15 mm). Fluid-filled specimens, such as ovarian cysts, may be placed in a plastic specimen removal bag (**Fig. 16.17**) and drained while in the bag to avoid spillage. A posterior colpotomy can also be performed for specimen removal. Colpotomy may be performed vaginally, as one would when performing vaginal hysterectomy, or laparoscopically. Laparoscopic colpotomy is performed by first inserting a lubricated sponge stick into the posterior vaginal fornix for cul-de-sac elevation. An incision is then made between the uterosacral ligaments into the posterior vaginal fornix, using the sponge stick as a backstop. Laser, unipolar scissors, or the Harmonic Scalpel may be used as

an energy source. An endoscopic specimen bag may be removed through the colpotomy incision. A wet lap pad may be placed vaginally to allow optimal pneumoperitoneum for laparoscopic closure of the colpotomy, or the colpotomy may be closed vaginally. Alternatively, morcellation may be performed with an electromechanical or bipolar morcellator (**Fig. 16.18A-D**). There are several electromechanical morcellators, both disposable and reusable, which either are battery powered or utilize a generator. They range 12 to 15 mm in diameter, although the disposable units are typically only available in a 15-mm diameter. The blades are single use and can be retracted during specimen retrieval, when the morcellator function is not needed. A bladeless morcellator is now available, which uses bipolar energy, and a product line-specific generator. For safety reasons, it is important that the tip of the morcellator be in view at all times. Keeping the cutting tip elevated and parallel with the abdominal wall adds to visualization and decreases the risk of inadvertently injuring bowel and other vital structures, as severe injuries have been reported, including injury to the pancreas. The specimen should be drawn up into the morcellator rather than pushing the morcellator into the specimen.

FASCIAL CLOSURE

Fascial defects should be closed when measuring 10 mm or greater. This can be done directly, by visualizing the fascia, and securing it in an interrupted or figure-of-eight fashion, utilizing a UR6 needle. Alternatively, a fascial closure device can be used and is especially helpful in patients with a thick anterior abdominal wall, when the fascia is difficult to visualize (**Fig. 16.19A-D**). These closure devices are used under direct laparoscopic visualization. Some designs require the retrieval of a suture loop, while others are designed to autoretrieve the end of the suture. Additionally, certain designs will allow for any width of fascial closure, while others secure a predetermined width of fascia. Whether performed abdominally or laparoscopically, it is important to secure an appropriate width of fascia to avoid tearing and subsequent herniation.

DIAGNOSTIC LAPAROSCOPY

A systematic approach to diagnostic laparoscopy, like checklists for pilots, can help ensure thoroughness in what

is regarded as a routine surgery. After insertion of the laparoscope, the abdomen should be carefully examined, particularly the area in the trajectory of the Veres needle or trocar, to ensure that inadvertent bowel or vascular damage was not caused. Trendelenburg positioning should then be used to view the pelvic cavity and organs.

With the assistance of a uterine manipulator, the uterus can be anteverted to visualize the posterior aspect of the uterus, from the fundus to the posterior cul-de-sac. This should begin with a panoramic view and proceed with a close-up magnification view to detect subtle findings, such as atypical manifestations of endometriosis. The presence of peritoneal windows or defects in the posterior cul-de-sac should be noted if present.

P.276

The posterior cul-de-sac should also be probed with an instrument such as a blunt probe or atraumatic grasper to palpate any hidden endometriotic nodules that may be imbedded within the rectovaginal septum. Anytime a shallow posterior cul-de-sac is noted, this should be considered, as an obliterated endometriotic posterior cul-de-sac can have a deceptively normal-appearing peritoneal surface. The uterosacral ligaments should have the appearance of a "V" with the apex at the cervix. If peritoneal fluid is obscuring the posterior cul-de-sac, the fluid should be removed by suction. The broad ligaments should be inspected for the presence of endometriosis, adhesions, or fibroids.

FIGURE 16.19 Fascial closure devices. **A:** Endo Close. (Courtesy of Covidien.) **B:** Weck EFX. (Courtesy of Teleflex.) **C:** Carter-Thomason. (Courtesy of CooperSurgical.) **D:** Carter-Thomason II. (courtesy of CooperSurgical.)

The ovaries should be viewed globally. This can be accomplished by simply flipping the ovary superiorly with a probe or other blunt instrument, or the utero-ovarian ligament can be grasped with an atraumatic grasper from the contralateral port and rotated by twisting the grasper clockwise for the left ovary and counterclockwise for the right ovary. This provides an excellent view of the undersurface of the ovary that can be easily held in place for inspection of the ovarian fossa and pelvic sidewall. With the ovary lifted up away from the sidewall, the transperitoneal course of the ureter can usually be seen. The ureter is optimally visualized by looking for peristalsis as it

P.277

crosses the common iliac artery at the pelvic brim. One advantage of identifying the ureter early during surgery is that the peritoneal surface can become edematous as the case proceeds, likely from prolonged carbon dioxide exposure and manipulative contact. The fallopian tube should be handled with care. Fallopian tube forceps are available that allow the tube to be grasped at the mesosalpinx while surrounding the tube. The proximal portion of the tube should be examined for nodules, which may be indicative of salpingitis isthmica nodosa. The fimbria should be examined delicately, looking for any sign of phimosis. Anterior to the fallopian tubes, the round ligaments should be viewed and traced laterally to identify the presence of hernia. The anterior cul-de-sac is best seen by using the uterine manipulator to place the uterus in a retroverted position. In this position, the anterior surface of the uterus and the bladder parietal peritoneum can be seen well. The anterior abdominal wall should be viewed for the presence of endometriosis or hernia.

The appendix should be viewed for any sign of inflammation, endometriosis, or fecalith. This is best performed by using an atraumatic bowel grasper. The upper abdomen should also be inspected, taking note of the liver, gallbladder, and diaphragmatic surfaces. If needed, the large and small intestine can also be inspected by “running” the bowel with two atraumatic bowel graspers. A panoramic, 360-degree evaluation is helpful to ensure that no upper abdominal adhesions have been missed that may have caused the intestine to be adherent to the anterior abdominal wall. It is possible in the presence of such adhesions to place a trocar through and through the intestine unknowingly. This condition can be ruled out by placing the laparoscope through one of the lower ports for visualization of the umbilical port. Chromopertubation may be performed by instilling a diluted indigo carmine solution through the uterine manipulator. Lack of spill may be due to obstruction, tubal spasm, or leakage from the cervix. It is therefore important to have a tight uterine cannula seal at the cervix.

OPERATIVE LAPAROSCOPIC PROCEDURES

Adhesiolysis

Pelvic adhesions have been associated with infertility and chronic pelvic pain. It should be recognized that chronic pelvic pain is often a complex condition, and in the absence of gastrointestinal obstructive symptoms, adhesiolysis is usually often not curative of pain. To better understand the nature of symptomatic adhesion, pain mapping under conscious sedation may be a useful technique. In performing adhesiolysis, optimal results depend on the use of microsurgical technique, gentle tissue handling, and meticulous hemostasis with minimal tissue fulguration. Adhesiolysis can be performed by a number of techniques, including blunt and sharp dissection, electrodissection, aquadissection, and laser dissection.

Blunt dissection is the most rudimentary form of adhesiolysis. Although not recommended, this technique is usually used in treating thin, avascular adhesions. Virtually any type of laparoscopic instrument can be used to place traction on an adhesion to cause separation. If bleeding or significant resistance is encountered, this

technique should be abandoned.

Sharp dissection is the preferred method for dealing with all adhesions, especially thick avascular adhesions. The advantage of sharp dissection over electrodissection is the decreased risk of inadvertent electrosurgical injury. This is performed in a similar fashion to laparotomy. The adhesion is held on tension with an atraumatic grasper, and scissors are used to lyse the adhesive band. It is important to turn the tip of the scissors toward the optical viewing angle to avoid vascular or bowel injury.

Aqua dissection can be used to free adhesions from the pelvic sidewall to avoid injury to ureter or the great vessels. It is also a useful technique in removing endometriotic nodules. With this technique, the peritoneum is grasped, and an incision is made large enough to place the tip of a powered suction-irrigation device. Irrigation is used to force fluid under the peritoneum, causing it to balloon out from deeper tissues. The adhesion or peritoneum can then be dissected free.

Monopolar energy and *bipolar energy* are frequently used to lyse thicker vascular adhesions. When using electrosurgery, care must be used to avoid injury to bowel. It is always best to start from known to unknown. As known areas are freed from adhesions, unknown areas become recognizable. Monopolar instruments, like scissors and needlepoint electrodes, are ideal for these adhesions. Bipolar instruments, such as Kleppinger forceps, bipolar scissors, or newer tissue-controlled bipolar energy instruments that seal vessels, can be used.

Laser dissection has been used in laparoscopy with great success as a result of minimal lateral thermal spread, as compared with most forms of electrosurgery. However, it should be noted that this form of energy is indeed still an energy source and obtains hemostasis through lateral thermal spread. The small spot size of laser makes this a useful tool for precision adhesiolysis. The CO₂ laser has a depth of penetration of 0.1 mm and is excellent for cutting. With the adhesion on tension, the CO₂ laser is introduced through the operating channel of the laparoscope or through a secondary port.

The Harmonic Scalpel is used with a technique similar to both bipolar and monopolar dissection, depending whether tissue is grasped or the active blade is used alone. This technique does not use electrosurgery. Ultrasonic energy has the advantage of limited lateral thermal spread, similar to the newer bipolar electrosurgical instruments.

Sidewall and Retroperitoneal Space Dissection

It is often necessary to identify the course of ureter and iliac vessel in cases of pelvic sidewall adhesions or endometriosis. If the ureter is able to be identified at the pelvic brim but then is obscured by adhesions, endometriosis, or an ovarian mass along its caudad course, the peritoneum overlying the sidewall can be grasped and opened with scissors (**Fig. 16.20**). A Maryland dissector can be used to gently

P.278

spread the peritoneum to view the ureter. If the anatomy is distorted, it may be necessary to start the dissection at the pelvic brim or by opening the round ligament. If the round ligament is to be opened, it should be divided with an energy source as lateral as possible, and a blunt grasper can be used to dissect the retroperitoneal space, watching for the ureter on the medial leaf of the broad ligament and avoiding the iliac vessels. Developing the pararectal space can help to define anatomic landmarks to avoid inadvertent vascular or ureteral injury. Once the ureter and uterine artery are located, adhesions can be lysed with an energy system of the surgeon's choice.

FIGURE 16.20 Pelvic sidewall dissection. The peritoneum has been incised so that the retroperitoneal structures can be visualized.

Posterior Cul-De-Sac Dissection

When endometriosis or pelvic adhesions partially or completely obliterate the posterior cul-de-sac and are associated with pelvic pain or infertility, a surgical approach is usually indicated. Cul-de-sac obliteration secondary to endometriosis often involves deep fibrotic endometriosis that may involve the rectum, rectovaginal septum, or uterosacral ligaments. Dissection of the posterior cul-de-sac may be necessary and can be performed laparoscopically by skilled surgeons. The goal is to lyse adhesions, excise large or deep endometriotic lesions, and resect or vaporize small superficial lesions.

The patient should undergo a bowel prep before surgery. A uterine manipulator is used to antevert the uterus, and a rectal probe is placed in the rectum to delineate and retract the rectum posteriorly. A sponge stick placed in the vagina can further delineate the rectum from the vagina (**Fig. 16.21**). The anterior rectum is carefully dissected from the posterior aspect of the uterus or vagina with scissors, laser, Harmonic Scalpel, or tissue-controlled bipolar energy system. The use of monopolar and traditional bipolar energy can result in significant thermal injury to the rectum. Aquadissection may also be useful. Dissection should continue until the loose areolar tissue of the rectovaginal space is reached. If a ureter is near the site of dissection, the position of the ureter should be confirmed before any dissection takes place. The fibrotic endometriosis can then be excised from the posterior vagina or uterosacral ligaments. If endometriosis extends to the vaginal mucosa, this is excised, and the posterior vagina is closed vaginally or laparoscopically. Palpation of the endometriotic nodule before and after removal is helpful to ensure complete excision.

FIGURE 16.21 Dissection of the posterior culde-sac. Instruments in the uterus, posterior fornix of the vagina, and rectum help define the anatomy.

Oophorectomy and Salpingo-Oophorectomy

STEPS IN THE PROCEDURE

Salpingo-Oophorectomy

- Ensure that the tube and ovary are free of all adhesions.
- Identify the ureter. If it is not possible to visualize the ureter through the peritoneum, incise the peritoneum, and identify the ureter by dissecting the pararectal space.
- The infundibulopelvic ligament is isolated and sealed with either bipolar or ultrasonic energy and transected. The utero-ovarian ligament is sealed and transected.
- The intervening mesosalpinx is incised parallel to the round ligament.
- All pedicles are inspected for hemostasis.

Several techniques for laparoscopic oophorectomy or salpingo-oophorectomy have been described. One procedure involves the placement of three loop ligatures around the ovary and adnexa. Before placement of the loops, the structures must be free of adhesions. Incisions in the mesosalpinx are sometimes necessary to facilitate placement. The ovary or adnexa is cut distal to the three loops. Small bleeding points can be coagulated on the stump, but care must be taken not to coagulate the suture.

Alternatively, the peritoneum is opened, and the ureter is identified by dissecting the pararectal space (**Fig. 16.22A, B**). Lactated Ringer solution or saline can be injected into the retroperitoneal space to push the ureter away from the site of coagulation and increase the margin of safety. The uteroovarian ligament is coagulated or sealed with bipolar energy or ultrasonic energy and transected, and the infundibulopelvic ligament is then coagulated or sealed and transected. If the fallopian tube is to be removed with the ovary, the proximal fallopian tube and utero-ovarian ligament are coagulated or sealed before transection (**Fig. 16.23A-C**). The intervening mesosalpinx is similarly transected. Pedicles are examined for hemostasis, and the ovary is removed by one of

the described methods of tissue removal. Laparoscopic stapling devices can also be used on the pedicles, but care must be used to avoid the ureter.

FIGURE 16.22 Dissecting the retroperitoneal space. **A:** The peritoneum overlying the pelvic sidewall is incised. **B:** The peritoneum is opened, and the ureter and vessels are identified.

FIGURE 16.23 Oophorectomy with the use of bipolar coagulation. **A:** The utero-ovarian ligament is coagulated and then transected. **B:** The infundibulopelvic ligament is coagulated with bipolar forceps and then cut. **C:** An Endoloop may be placed on the infundibulopelvic ligament after transaction for added hemostasis.

P.280

LAPAROSCOPIC MYOMECTOMY

STEPS IN THE PROCEDURE

Myomectomy

- A hemostatic agent, such as dilute vasopressin, is injected into the myometrium, either through a port or transabdominally.
- The uterine serosa is incised with a laser, needle electrode, or ultrasonic energy.
- A myoma screw is introduced into the fibroid, or a tenaculum is used to grasp the fibroid.
- The fibroid is enucleated with a combination of traction and countertraction, as well as electrosurgery where indicated.
- The defect is closed in two to three layers.

Laparoscopic myomectomy is a heterogeneous procedure that can range from a simple procedure to one of the more difficult laparoscopic surgeries requiring expert laparoscopic suturing skills. For example, large pedunculated fibroids (8 to 10 cm) can be detached in a few minutes. Large intramural fibroids may take several hours to remove and repair in the hands of expert laparoscopic surgeons. Two case-control studies comparing open with laparoscopic myomectomy have both demonstrated significantly longer mean operating room time and shorter hospital stays with the laparoscopic group. The use of a preoperative gonadotropin-releasing hormone (GnRH) agonist may be considered in patients who are anemic. A prospective randomized study using leuprolide acetate in patients undergoing laparoscopic myomectomy also demonstrated significantly lower blood loss and operative times in the treatment group. The authors of this study noted increased operative time in the subset of markedly hypoechoic fibroids because of increased fibroid softness. Other studies have shown longer operative times and a higher conversion to laparotomy rate associated with the use of GnRH agonists in laparoscopic myomectomy because of difficult cleavage planes.

FIGURE 16.24 Excision of a pedunculated myoma. The base is thoroughly coagulated and cut.

FIGURE 16.25 Myomectomy. **A:** The leiomyoma is grasped with forceps or a corkscrew and is dissected from the myometrium with careful blunt and sharp dissection. **B:** The defect, if large, is closed with sutures in two layers.

Pedunculated myomas can be resected by coagulating and transecting the base, and the defect does not typically require suturing (**Fig. 16.24**). Intramural and subserosal fibroids require an incision to be made with scissors, laser, needle electrode, or Harmonic Scalpel. Before incising the uterine serosa, it is advisable to inject hemostatic agents into the serosa and myoma. A dilute vasopressin solution or bupivacaine plus epinephrine may be injected transabdominally into the myometrium through a spinal needle. A randomized placebo-controlled trial demonstrated significantly lower blood loss, total operative and enucleation time, and degree of surgical difficulty associated with bupivacaine plus epinephrine compared with saline. When the whorled white appearance of the myoma is seen, the edges of the uterine serosa are held open with atraumatic graspers, and a corkscrew retractor is screwed into the myoma. Using upward traction with the corkscrew retractor, the myoma is peeled away from the uterine corpus (**Fig. 16.25**). Hemostasis is

P.281

achieved with electrosurgery or Harmonic Scalpel. The defect is sutured closed in two or three layers, depending on the depth of the defect, using a delayed absorbable suture as described previously. In order to close a defect under tension, an intracorporeal cinch knot, an extracorporeal sliding knot, or a barbed suture can be used. Another option is to perform uterine closure through a minilaparotomy if the fundus or area to be sutured can be delivered through a small incision. Morcellation can be performed, or smaller specimens can be delivered through a posterior colpotomy. It is best to avoid losing myoma pieces that become detached, as there have been reports of specimens becoming infected, parasitic, or continuing to grow at the trocar incision site. Loss of tissue, however, is not necessarily an indication for laparotomy, as a case series of 12 retained specimens, three of which were myomas, resulted in no sequelae with 2-year follow-up. Uterine rupture has been reported in patients undergoing laparoscopic myomectomy, and pregnancy should be monitored with the same caution given to patients who have undergone abdominal myomectomy. It is not known whether laparoscopic repairs are equivalent to repair by laparotomy, although healing time is certainly improved.

FIGURE 16.26 Acesa System. (Courtesy of Halt Medical.)

A radiofrequency ablation system, which utilizes an electrode array to accommodate fibroids of varying size, can now be delivered laparoscopically. The Acesa System (Halt Medical) ([Fig. 16.26](#)) uses monopolar radiofrequency, with real-time temperature feedback control, to achieve a target temperature of 100°C. The electrosurgical probe contains a needle electrode array, consisting of seven straight electrodes, which is inserted percutaneously through a 2-mm skin incision. The procedure is performed in conjunction with real-time laparoscopic ultrasound. In a 12-month prospective follow-up study, mean uterine volume decreased by 25.1%, mean fibroid volume decreased by 44.3%, and a clinically significant reduction in menstrual bleeding was observed in 68.8% of subjects. A median of 5 days was missed from work, return to normal activities occurred at a mean of 9 days, and 95% of patients reported being satisfied with the treatment at 12 months. A total of 674 fibroids were treated, with a mean of five fibroids per patient. There were four device-related adverse events and one surgical reintervention.

LAPAROSCOPY USING LOCAL ANESTHESIA OR CONSCIOUS SEDATION

Laparoscopy can be performed under conscious sedation in the operating room or in a nonhospital environment, such as physician's office. Microlaparoscopy is often used with 2- or 3-mm instrumentation. Local anesthesia and conscious sedation has long been used to perform tubal ligation. The use of microlaparoscopic instrumentation has assisted in performing laparoscopy under conscious sedation in the office setting for pain mapping in chronic pelvic pain patients. Pain mapping may be useful in patients with chronic pelvic pain of uncertain etiology, as this enables the patient to participate in the evaluation of the pelvis, and to decipher between incidental versus painful adhesions and endometriosis. If conscious sedation is to be performed in the office without the presence of an anesthesiologist, it is important to follow state guidelines. The American College of Surgeons has developed guidelines that have been endorsed by the American Congress of Obstetricians and Gynecologists, which detail requirements for an optimally safe environment and resuscitation.

Laparoscopy under conscious sedation is usually performed by combining local anesthesia with intravenous sedation. Proper patient selection is important, as patients must be able to withstand lifting the abdomen at the umbilicus for trocar insertion and tolerate local infiltration at the umbilicus. The umbilicus is infiltrated at the skin and then down through the fascia with a 25-gauge needle, using approximately 10 mL of 1% lidocaine or 0.25% bupivacaine. If conscious sedation is used, short-acting narcotics, such as remifentanyl, are ideal if pain mapping is to be performed, so that the patient is able to respond to intraperitoneal stimuli. If tubal sterilization is to be performed, an anxiolytic drug such as midazolam is useful.

COMPLICATIONS

Nerve Injury

Most nerve injuries occurring during laparoscopic surgery are neurapraxia or nerve contusion and will usually resolve within 6 weeks. Neurotmesis, or complete division of the nerve, is the most severe form of nerve injury, often resulting in permanent disability. Proper preoperative and intraoperative patient positioning—as well as knowledge of known risk factors associated with mononeuropathies—is an important part of providing a safe environment for laparoscopic surgery. Femoral neuropathy occurring during laparoscopy can be associated with excessive hip flexion or abduction or long operating times. When the lithotomy position is used in patients undergoing vaginal or laparoscopic surgery, the thigh should be flexed no greater than 90 degrees and abducted no greater than 45 degrees. If a patient's position is changed intraoperatively from low lithotomy to high lithotomy, these relationships should be maintained. Obturator neuropathy is most commonly associated with direct injury during radical pelvic surgery or lymphadenectomy, but can also occur as a result of excessive hip flexion. As the obturator nerve leaves the obturator foramen, it lies directly against bone and can become acutely angulated and deformed if the hips are excessively flexed, particularly during prolonged surgery. The obturator neurovascular bundle is also vulnerable during laparoscopic retropubic dissection, particularly during the paravaginal repair of lateral defects of the anterior vaginal wall. Surgeons who operate in these spaces should be well versed in the anatomy of the obturator nerve.

The iliohypogastric and ilioinguinal nerves can be injured from lateral trocars with subsequent suture ligature and fibrotic entrapment. Care should be taken to avoid extreme lateral trocar placement; however, there is considerable anatomic variation in the course of these nerves, and injury cannot always be avoided. Mapping of nerves in fresh frozen cadavers revealed that the ilioinguinal nerve enters the abdominal

P.282

wall with an average of 3.1 cm medial and 3.7 cm inferior to the ASIS and that the iliohypogastric nerve enters the abdominal wall with an average of 2.1 cm medial and 0.9 cm inferior to the ASIS. Placement of trocar sites 2 cm above the level of the ASIS, at any point medially, would avoid almost all of the ilioinguinal and iliohypogastric nerves identified in the study, although such placement may not always be practical.

Sciatic neuropathy during laparoscopic surgery can be a result of nerve stretching. Injury to the sciatic nerve has been reported in procedures lasting as short as 35 minutes in freehanging stirrups. The peroneal division of the sciatic nerve is under the least amount of tension when the knee and hip are flexed, as the nerve is fixed at the sciatic notch and the fibular head. Tension along the nerve is increased with hip flexion when the knee joint becomes straightened or externally rotated. Patients at increased risk of sustaining sciatic nerve injury are long legged, obese, or short in stature. In hangingtype stirrups, long-legged or obese patients have a tendency for external hip rotation, and shorter patients have less flexion at the knee. In such cases, stirrups that support the ankle and calf may be more appropriate.

In a large retrospective study, at a single institution, a total of 19,461 cases were reviewed, encompassing 56 surgical procedures performed in the lithotomy position. Fifty-five patients were found to have persistent neuropathy of the lower extremity, defined as a motor deficit if at least 3 months' duration. The majority were neuropathies of the common peroneal nerve, of which there were 43. The remaining neuropathies included eight sciatic and four femoral. At 12 months, approximately 50% of patients with common peroneal and femoral neuropathies had regained complete motor function, while none of the patients with sciatic neuropathies had regained complete motor function. The most important risk factor, found to have a relative risk of 100, was each hour spent in lithotomy. Decreasing the amount of time spent in the lithotomy position

should therefore be the primary preventative strategy.

The incidence of brachial plexus injuries is 0.16% and can be particularly devastating, especially when bilateral. The brachial plexus arises from the anterior nerve roots of C5-T1; passes behind the clavicle, over the first rib; and is partially fixed to the fascia of the upper arm. The upper roots can be stretched when a patient is positioned in steep Trendelenburg, and the body slides relative to outstretched arms, or when shoulder braces are positioned too medially. This results in weakness of the upper arm and a constellation of sequelae termed Erb palsy. The lower roots can be compressed between the clavicle and first rib when the arms are abducted greater than 90 degrees. This results in weakness of the distal forearm and hand and a constellation of sequelae termed Klumpke paralysis.

Vascular Injuries

Of all the injuries associated with laparoscopy, vascular injuries are the most acutely life threatening, particularly in the case of injury to the aorta, vena cava, or iliac vessels. Injury can occur during Veres needle placement, during trocar insertion, or during tissue dissection. Injury to the great vessels requires immediate laparotomy, manual compression, repair, and usually transfusion. Injury to smaller vessels can usually be rendered hemostatic with the use of bipolar electrosurgery, hemostatic clips, or laparoscopic suturing techniques. Injury to the inferior epigastric vessels can occur during placement of the lateral trocar. The inferior epigastric artery can usually be seen as it branches off the external iliac artery running cephalad along the abdominal wall peritoneum. If it is injured, a bipolar forceps can be placed through the contralateral port in an attempt to coagulate. Alternatively, endoscopic fascial closure devices can be used to place suture on either side of the vessel for vascular occlusion. Hemostasis can usually be immediately achieved by placing a 30-mL Foley catheter through the trocar site and inflating the balloon for tamponade. The Foley catheter can then be secured with an 8-inch clamp. This injury can also be managed by enlarging the trocar site to visualize, clamp, and ligate the bleeding vessel.

Gastrointestinal Injury

Gastrointestinal injury is the most lethal injury associated with laparoscopy, with a mortality rate reported as high as 3.6%. Injury may occur from Veres needle placement, trocar insertion, adhesiolysis, tissue dissection, devascularization injury, or thermal injury. As a general rule, Veres needle injuries need no repair as long as the puncture is not associated with bleeding or a subsequent rent from additional tissue manipulation. In the case of colonic puncture without tearing, nonoperative management with antibiotics, copious irrigation, and suction has been suggested. There has been little evidence-based literature published about stomach injury during laparoscopy, but it is estimated that gastric perforation occurs in approximately 1 in 3,000 cases. Risk factors for stomach injury include a history of upper abdominal surgery and difficult induction of anesthesia, as a gas-distended stomach can distend to below the level of the umbilicus. Orogastric or nasogastric suction before Veres needle or trocar placement can help lower this risk. Trocar injury to the stomach requires repair by laparoscopy or laparotomy. The defect may be oversewn with a delayed absorbable suture in layers, and the abdominal cavity should be irrigated and suctioned, being sure to remove any food particles as well as gastric juices. Nasogastric suction is usually maintained postoperatively until normal bowel peristalsis occurs.

Veres needle and trocar injury to the small intestine may not be obvious because of small-bowel redundancy and a tendency for small bowel to fall out of view. Furthermore, a through-and-through trocar injury may be hidden from laparoscopic view. Potential injury should be investigated when multiple anterior abdominal wall adhesions are present. A lower quadrant secondary port can be used to view the umbilical port site. If there are no abdominal wall adhesions but a bowel injury is suspected, the bowel should be run with laparoscopic bowel graspers, or manually by standard laparotomy, until an injury is satisfactorily ruled out. A full-thickness injury to the small bowel of 5 mm or greater should be repaired in two layers with an

interrupted layer of 3-0 delayed absorbable suture to approximate the mucosa and muscularis and a serosal layer of 3-0 interrupted silk suture placed perpendicular to the long axis of the intestine to avoid stricture formation. This is usually performed by laparotomy or by minilaparotomy at the umbilical site, where the injured bowel loop is pulled through to the skin surface and repaired. Laparoscopic repair has also been reported as effective by surgeons with advanced gastrointestinal surgical skills. If the laceration to the small bowel exceeds one half of the luminal diameter, segmental resection is recommended.

Trocar injury to the colon is reported to occur with a frequency of approximately 1 per 1,000 cases. Undetected injury to the large intestine can be associated with significant morbidity, compared with injury to the small intestine and stomach, because of the high concentration of coliform bacteria. Therefore, if injury to the colon is suspected, the area should be inspected carefully, using atraumatic bowel graspers, or laparotomy may be performed. The management of large intestinal injuries depends on size, site, and length of time from injury to diagnosis. In general, once the diagnosis of colonic

P.283

injury is made, broad-spectrum antibiotics should be administered, and consultation should be sought with a surgeon who has experience with bowel injury. In the case of a small rent with minimal soilage, the defect can be closed in two layers with copious irrigation. When a larger injury has occurred and the bowel has not been prepared with a mechanical or antibiotic regimen, or when the injury involves the intestinal mesentery, a diverting colostomy is usually necessary. In the case of delayed (postoperative) diagnosis, a diverting colostomy should be performed. If injury to the rectosigmoid colon is suspected, filling the posterior cul-de-sac with normal saline, injecting air into the rectum through a catheter-tipped bulb syringe, and looking laparoscopically for bubbles may aid in detection (flat tire test). Alternatively, proctosigmoidoscopy may be performed or used to inject air into the rectum.

Thermal injuries are histologically different from traumatic injuries and therefore must be treated differently. Thermal bowel injuries can be differentiated histologically from traumatic injury by the presence of coagulation necrosis and the absence of capillary ingrowth and white cell infiltrate in the former. Because of this coagulation necrosis, thermal injuries require wide resection, even though the bowel may still have a normal appearance adjacent to the injury, as it may take days for the extent of the injury to become apparent.

Trocar Site Hernia

In a retrospective review of more than 3,500 laparoscopies in 1993, the frequency of incisional hernias was reported to be 0.17%. The fascia should be closed in trocar sites that are 10 mm and larger. Although there are case reports of hernia occurring at 5-mm trocar sites, closing 5-mm trocar sites usually requires enlarging the skin incision, or using laparoscopic fascial closure devices, which may not be warranted in this rare possibility. Closing the fascia may not entirely prevent hernia formation. A survey of more than 3,200 gynecologists noted that 18% of hernias occurred despite fascial closure and appeared to be related to the number of laparoscopies performed, rather than the length of the surgeon's career. Trocar site hernias can present as occult or incarcerated hernias. A defect is usually palpable over the trocar site incision with Valsalva, or a mass can be seen. If the patient presents with signs of bowel obstruction, the bowel must be inspected carefully, and if there is evidence of necrosis or vascular compromise, the bowel should be resected.

Urinary Tract Injury

Bladder injury during laparoscopy is estimated to occur 1 in 300 cases. Higher injury rates have been reported with laparoscopic hysterectomy and bladder neck suspension. Risk factors for bladder injury include a distended bladder during suprapubic trocar insertion; previous surgery with distortion of bladder anatomy, causing it to be pulled cephalad with the parietal peritoneum; and endometriosis obliterating the

anterior cul-de-sac. Inserting a Foley catheter into the bladder before trocar placement, and using lateral trocar sites, will lessen the risk of bladder injury. In cases when a midline, suprapubic trocar is used, and the superior aspect of the bladder cannot be deciphered, filling the bladder with 300 mL of water or saline will define the bladder margins. Intraoperative signs of bladder injury include clear fluid in the operative field, visible bladder laceration, and gas distention of the Foley bag. To adequately make the diagnosis, the bladder wall can be inspected directly, or methylene blue or indigo carmine, diluted with 200 to 300 mL of sterile normal saline, may be instilled retrograde through the Foley catheter. Intentional cystotomy or cystoscopy may be performed to inspect the extent of the injury and to ensure that there is no ureteric involvement.

Recommendations for repair of bladder injuries have been reviewed in a consensus statement of the International Society of Urology (Société Internationale d'Urologie). In the acute setting, bladder injuries can be treated with catheter drainage alone if the injury is small, uncomplicated, and isolated. A cystogram should be performed on the 10th day of drainage, when more than 85% of bladder injuries will be healed. A surgical repair should be performed if the Foley catheter is unable to provide adequate drainage because of blood clots or persistent extravasation or if there is concomitant injury to the urethra or ureter. Cystotomy closure should be performed using a watertight, multilayered repair, with absorbable suture. Laparoscopic repair may be performed in the case of a small injury with adequate exposure and surgical expertise, as long as the ureters and bladder neck are not compromised.

According to a nationwide Finnish record linkage study, although the overall complication rates for laparoscopy are decreasing, the rate of ureteral injury has remained steady at 1%, with the greatest risk associated with laparoscopic hysterectomy. A review of the world literature through 2003 concluded that laparoscopically assisted vaginal hysterectomy was the most frequently performed surgery associated with ureteral injury. The usual time to diagnosis in postoperative patients with ureteral injury is typically between 2 and 7 days, but has been reported as late as 33 days after surgery. Patients often present with symptoms of abdominal pain, fever, hematuria, flank pain, or peritonitis. Leukocytosis is a common finding. Management of ureteral injury should be undertaken in collaboration with a surgeon trained in ureteral injury repair. In the majority of cases, percutaneous or cystoscopic stenting techniques can be used. Laparotomy is usually performed for end-to-end anastomosis or reimplantation of the ureter into the bladder, but in experienced hands, repair may be performed laparoscopically. The literature is growing in favor of intraoperative diagnostic cystoscopy after complex vaginal, laparoscopic, and abdominal pelvic surgery, in an effort to avoid delayed diagnosis of injuries to the urinary tract. It appears that cases in which the diagnosis is delayed are most likely to result in the greatest morbidity and legal repercussions.

CONCLUSION

Laparoscopy has become a mainstay of gynecologic surgery. Laparoscopic technology continues to evolve, requiring continual education and research. The main benefits of laparoscopic surgery have been shorter hospitalization, improved cosmesis, and, in some cases, improved safety and cost. Evidence-based surgical studies are difficult to perform but will be required to fully understand the role of each laparoscopic procedure in terms of long-term outcomes and cost.

BEST SURGICAL PRACTICES

- A good laparoscopic surgeon should know his or her limitations and not hesitate to call for help.
- Conversion to laparotomy is not considered failure.

- Careful selection of patients is the first key to success in any surgery.
- Preparation is essential in laparoscopic surgery and may include a “pilot’s checklist” and/or “dress rehearsal” to avoid being caught with too few inappropriately sized trocars.
- “Shortcuts,” which modify a surgical procedure, “change” the procedure. Once the surgical technique has been

P.284

changed, success rates obtained from literature or prior experience cannot be attributed to the new procedure.

- Careful positioning of the patient can help avoid nerve injuries, as can minimizing operative time.
- Traction-countertraction and exposure are important in both open and laparoscopic surgeries. To maximize these, an additional trocar port is often helpful.
- Consider intraoperative cystoscopy with indigo carmine in complex pelvic surgery.
- Understand your energy source.

Robotic Surgery

Jed Delmore

Kevin E. Miller

DEFINITIONS

Learning curve—Defined as the length of time or number of cases to reach a predictable operating time, the fewest complications, or lowest blood loss.

Patient-side cart—A mobile cart composed of a camera arm and three operating arms that attach to the laparoscopic ports.

Robot—A machine capable of carrying out a complex series of actions automatically, especially one programmable by a computer.

P.285

Surgeon console—A mobile cart composed of a stereoscopic viewer, master controllers, and a series of foot pedals.

Uterine manipulator—One of several instruments inserted in the uterus with an attached colpotomy ring to facilitate movement of the uterus and visualization of the vaginal fornix.

Vision cart—A mobile cart containing the vision system for image processing, light source, carbon dioxide insufflator and energy sources, and usually a video monitor.

INTRODUCTION

History

The technologic advances in minimally invasive surgery, specifically gynecologic surgery, over the past 50 years are staggering. Using monocular laparoscopes with continuous carbon dioxide insufflation of the peritoneal cavity, most gynecologists in the United States in the early 1970s were performing diagnostic laparoscopy and tubal sterilizations. Within a short period of time, video laparoscopy allowed a rapid expansion in procedures performed by the minimally invasive approach. Salpingectomy, oophorectomy, myomectomy, resection and ablation of endometriosis, hysterectomy, and a long list of other procedures, are now commonly performed. Until recently, most technologic advances in laparoscopy have involved video equipment, instrumentation, and newer energy sources. A combination of astounding technologic advances has resulted in the introduction of robotic or robotically assisted surgery in gynecology, and astute, aggressive marketing to physicians and the public has resulted in the rapid assimilation of robotic surgery into today's surgical practices. However, controlling the application of robotic technology and teaching the procedures seem to lag behind the marketing.

According to the Oxford Dictionary, "robot" is derived from the Czech word *robota* meaning "forced labor." The term was introduced in Karel Čapek's play "*Rossum's Universal Robots*" in 1920. A robot is defined as a machine capable of carrying out a complex series of actions automatically, especially one programmable by a computer. The history of robotic surgery is best described as a convergence of research performed in multiple locations in the 1980s. Expanding on the technique of stereotactic brain biopsies, Kwoh and colleagues modified an industrial robot, the Unimation PUMA (Programmable Universal Machine for Assembly) 200, for the biopsy of brain tumors in 1988. In 1991, Davies et al., at the Imperial College of Science, Technology, and Medicine in London reported the use of a modified PUMA 560 robot, which later became PROBOT, for transurethral resection of prostatic tumors. During the 1980s and early 1990s, researchers at the National Aeronautics and Space Administration Ames Research Center were working on virtual environments while researchers at the Stanford Research Institute were working on robotics and a telemanipulator system for hand surgery. As described in a review by Satava, the Department of Defense and the Defense Advanced Research Projects Agency funded research directed toward the concept of telepresence surgery for combat casualty care. This culminated in the demonstration of a telepresence vascular anastomosis in the swine model in 1996 by Bowersox and telesurgical laparoscopic cholecystectomy in 1998 by Himpens. In 1993, Yulun Wang, PhD, formed Computer Motion, which developed a robotic camera holder for laparoscopy called Automated Endoscopic System for Optimal Positioning (AESOP) and ultimately created an integrated robotic system that attached to the operating table called ZEUS. In 1995, Frederic Moll, MD, acquired the license for the telepresence surgical system and created Intuitive Surgical. In 2003, Computer Motion and Intuitive Surgical merged into a single entity, Intuitive Surgical. Presently, da Vinci is the only robotic surgical system approved by the U.S. Food and Drug Administration (FDA) (Intuitive Surgical, Sunnyvale, CA). As a result, any reference to robotic surgery or robotic platform in the remainder of this chapter pertains to the Intuitive, da Vinci system. This is not meant to be an endorsement of this or any other product; it simply reflects the fact that there are no other commercially available robotic platforms at present.

Advantages and Disadvantages

The November 2009 American Congress of Obstetricians and Gynecologists Committee Opinion concerning types of hysterectomy concluded that vaginal hysterectomy is the approach of choice whenever feasible, on the basis of its well-documented advantages and lower complication rates. Laparoscopic hysterectomy is an alternative to abdominal hysterectomy for those patients in whom vaginal hysterectomy is not indicated or feasible. "The experience with robot-assisted hysterectomy is limited at this time; more data are necessary to determine its role in the performance of hysterectomy." The advantages of robotic surgery include those experienced by the patient, the hospital, and by the surgeon. The advantages to the patient include smaller incisions compared to laparotomy, shorter hospital stay, less blood loss, and a more rapid return to normal activity. Laparoscopic surgery provides the same benefits; but because of technical considerations noted below, the range of surgical procedures is greater with robotic surgery. The advantages to a surgeon include enhanced visibility with a three-dimensional (3D) view, enhanced image magnification, and stable camera platform devoid of first-assistant fatigue that can result in an unstable field of view with camera motion. The instruments utilized by the surgeon are wristed to allow a full range of motion and angles similar to an open procedure. In distinction to conventional laparoscopy, which relies on a fulcrum effect and requires movement of the handle of the instrument in the opposite direction to the desired movement of the tip, robotic surgery allows hand and instrument movement in the same direction. Surgeon hand tremor is minimized, and the ratio of hand motion to robotic instrument motion can be adjusted. Sarlos reported that fatigue and back discomfort may be reduced by a more ergonomically correct position at the surgeon console. This benefit may be the greatest during longer cases. Robotic suturing may be considerably easier for most surgeons compared to laparoscopic suturing in studies reported by Andenberg and Chandra. For instructing resident physicians and fellows-in-training, the video monitor on the vision cart allows the educator to draw on the monitor that can be seen by the trainee at the console. Sonographic or computed tomographic images from

preoperative studies can be projected onto the surgeon console screen for viewing during surgery. The newest da Vinci Si model allows surgeons at two separate consoles to operate simultaneously on the same patient, or it allows a mentor to intervene during a trainee's procedure. The potential advantage to the hospital or institution is a shorter patient hospital stay for procedures that historically resulted in a longer stay if performed by laparotomy. Potential disadvantages to the patient include a longer operative time and facial edema from protracted Trendelenburg position.

The major disadvantage to all parties is the cost of the robot, associated instruments, drapes, and maintenance contracts. The cost of a da Vinci robotic system varies between \$1,000,000 and \$2,300,000. Wristed robotic instruments, which have a limit of 10 uses, cost approximately \$1,300.

P.286

For point of reference, the 2011 purchase price paid by one of our community hospitals for typical laparoscopic instruments utilizing different energy sources ranges from \$350 to \$450. Annual maintenance costs for the robotic system are estimated at \$150,000 (Intuitive Surgical, Second Quarter Investor Presentation, <http://phx.corporate-ir.net/phoenix.zhtml?c=122359&p=irol-IRHome>).

Because of the size of the entire robotic system, larger operating rooms (ORs) are required for optimal efficiency and may add expense to the institution. Size and position of the robotic arms when docked may cause difficulty for the bedside assistant when passing sutures, retracting tissues, or manipulating the uterus with a vaginal manipulator.

From the surgeon's standpoint, the major disadvantage is the lack of haptic or tactile sense with the instruments. Those surgeons accustomed to blunt dissection of tissues will be required to enhance their sharp dissection skills and rely on anatomic landmarks. Those in residency training may suffer from diminished experience with traditional open procedures and operative technologies as more and more gynecologic surgical procedures are done using minimally invasive and robotic techniques.

ROBOTIC TRAINING

In 2007, Javier Magrina explained that robotic surgery "... is nothing more than an enhancement along the continuum of laparoscopic technologic advances and represents only the beginning of numerous more forthcoming advances."

Obstacles and Challenges to Teaching and Learning

Currently, there is no standardized training model or validated method to teach robotic surgery. Two notable obstacles to teaching the application of this new technology result from the unique features of robotics. Until recently, a single surgeon controlled the robotic operation without the use of a second set of independent controls for the assistant or trainee. The teacher/instructor had no ability for immediate hands-on correction as he or she would have had with traditional teaching. Thus, potential patient safety issues become a concern with implementation of robotics. The situation is likened to a student pilot on final approach without the flight instructor being able to take control of the airplane's pitch and power controls to avoid a potentially dangerous landing. The robotics instructor must correct the trainee with prompt, understandable, and verbal commands. However, dual consoles are now available, although they are expensive and not widely available. These dual consoles allow cosurgeons to work on the same patient with three moving instruments controlled by the cosurgeons in contrast to two moving instruments with a single console. Additionally, a mentor and a trainee can operate on the same patient simultaneously. The single-surgeon console in use at most facilities is a "resident-unfriendly" platform. The resident initially functions as a table-side assistant or observer, which is quite different from the usual hands-on learning experience. Hanly suggested that wider availability of mentoring consoles will likely improve resident and nonresident learning experiences and enhance patient safety. The telestration feature enables the teacher/mentor to point, draw, or illustrate directly on the video touch screen monitor as the surgeon sees this on the surgeon console screen in real time.

Another obstacle to learning robotic surgery is the lack of tactile sensation and feedback to the surgeon. Palpation of the tissues is not translated to the surgeon in the same way as one "feels" the tissues with open procedures or conventional laparoscopy. This lack of tactile sensation or haptics presents an initial challenge to learning until one is conditioned to develop a "sensation of feel" on the basis of the visual cues as proposed by Hagen and colleagues. This may be likened to an experienced pilot transitioning to flying a remote-controlled drone aircraft from a virtual cockpit far from the area of flight. Despite these obstacles, Dharra and Falcone, Stefanidis et al., and Suh et al. suggest that the robotic features of instrument motion comparable to open procedures, tremor reduction, 3D high-definition image, wristed instrument articulation, and downscaling movements have made more difficult advanced laparoscopic surgical cases with steep learning curves easier to learn and apply to patient care.

Training Methods

Initially, most robotic training regimens were developed and sponsored by Intuitive Surgical, Inc., the maker of da Vinci Surgical System. The manufacturer has been active in developing training methods and recommendations to introduce the techniques of robotic surgery to potential customers. However, with increased experience of surgeons and institutions, locally developed training protocols have placed less emphasis on the manufacturer to provide training. Initial training protocols incorporated a combination of "on-site" (hospital) training, "off-site" (laboratory) hands-on courses, as well as Internet-based modules and surgical videos. All OR team members require basic training on mechanical and technical aspects of robotic system functions (*system training*). This specifically includes learning the components of the system, how to dock, set up, and insert instruments, implement safety features, and troubleshoot malfunctions. The second aspect of training deals with acquiring the technical skills to perform surgery (*procedure training*). Training modules and videos may be accessed at <http://www.davincisurgerycommunity.com>.

Since there is only one commercially available robotic surgical system available in the United States today, the technical system training is still largely provided by the manufacturer. This system training can be completed with the Internet-based Intuitive Surgical curriculum including system overview, setup/docking, surgeon console functions, and safety features. The setup module instructs on port placement, camera arm positioning, instrument arm positioning, docking, endoscope insertion and removal, and instrument insertion and removal. The surgeon console module instructs on system setup and vision, ergonomic, and instrument control. The safety features module teaches how to troubleshoot fault messages, emergency switch location and use, energy source control, and procedure conversion to open or standard laparoscopy.

Procedure training is surgeon and procedure specific and directed at acquiring the needed technical skills. For the gynecologist/pelvic surgeon, a sample of the procedures performed robotically include hysterectomy, adnexal surgery, lymphadenectomy, radical hysterectomy, myomectomy, sacrocolpopexy, Burch retropubic urethropexy, endometriosis resection, and ureteral and fistula repairs. Commercially produced and Web-based surgical videos provided by surgeons are available. Inanimate simulator training, live animal models (pig lab), and case observation have been required of surgeons learning robotic techniques before being proctored by an experienced surgeon. After certification of completion of both system and procedure training, experienced gynecologic surgeons desiring to obtain robotic surgical privileges are commonly proctored at their home institution with a minimum of two to five cases before independent-use

and procedural training within their institution. Completion of a procedure training program described by Geller and associates at the University of North Carolina is required before residents or fellows performing robotic surgery. This "System Skills Practicum" includes developing proficiency in four surgical skills: (a) "manipulation drill" that requires transfer of rubber rings from tower to tower to learn wristed instrument movements and camera manipulation (clutching), (b) "dissection drill" that requires dissection of a vessel encased in gelatin using scissors and grasping instruments, (c and d) "suturing drills." The "suturing drills" are timed and involve reapproximating linear and jagged lacerations on an inanimate model to teach needle-driver use and intracorporeal knot tying with camera and instrument clutching. These suturing drills are the most difficult to master. Surgical training programs such as residency and fellowship also typically require involvement in a minimum number of case observations in addition to working as first assistant with progressive hands-on experience.

The simulation training module connecting to the da Vinci Si model functions the same as a flight simulator or video game box. The surgeon works directly at the console on a series of exercises to learn and maintain proficiency skills in manipulation of the robotic controls. The simulation unit scores and records each exercise to allow quantification of progress. Manipulation skills of the wristed instruments, camera control, clutching, dissection, energy control, and needle driving are performed in various combinations. Surgical facilities responsible for credentialing may be able to utilize this module to assess surgeon skill retention and possibly to maintain privileges.

Does Previous Experience with Operative Laparoscopy Matter?

Several studies have evaluated experienced surgeons and inexperienced/novice surgeons with regard to skill development when learning simple and complex robotic techniques. Stefanidis and Suh found that previous experience as an assistant surgeon on robotic surgical cases shortens the learning curve, and all trainees have lessened physical demands and decreased workload with improved accuracy and precision in comparison to standard laparoscopic techniques. They also reported that surgical novices seem to learn difficult tasks such as robotic suturing more easily than experienced surgeons. Interestingly, other high-intensity hand-eye coordination activities, such as prior high-volume video game experience, were found to have a negative impact on learning robotic suturing in a study by Harper. Overall, it appears that lack of previous laparoscopic experience does not seem to be a major obstacle in learning the technical aspects of the robotic platform.

Experience with Various Energy Sources

As with standard operative laparoscopy, the surgeon performing robotic surgery should be familiar with the various energy sources, as the power settings and depth of thermal spread may be new or different from what they are accustomed to with standard laparotomy, vaginal, or laparoscopic procedures. Energy sources used with the da Vinci system include bipolar cautery, monopolar cautery (scissors), PlasmaKinetic (PK), and harmonic energy sources. If bedside assistants will be operating conventional laparoscopic energy sources, adequate education and experience are required.

What Is the Learning Curve for Robotic Surgery?

Operating time may represent an indirect measure of the learning curve for a specific surgical procedure. An efficient OR team should lead to decreased operating times. Because of the significant technical training robotic surgery requires of the entire surgical team, safety and efficiency in robotic surgery require a well-trained, experienced team, which is used to working together. The importance of the same team working together frequently with the same surgical procedures cannot be overemphasized. Several components contributing to operating times include OR personnel, surgeon, and patient factors. First, efficiency is dependent upon the OR personnel for room turnover, equipment processing and setup, and assisting the surgeon in positioning and draping the patient. Second, surgeon factors depend on his/her learning curve or experience performing the particular operation. As with any other surgical method, operating times decrease and technical proficiency increases as the frequency and volume of cases increase to a certain number. Third, patient-dependent factors that increase the difficulty of the surgery, such as morbid obesity, previous surgeries, and presence of extensive adhesions, are to be considered. The patient factors should be considered especially when selecting initial cases and will depend on the surgeon's experience and skill level. A study by Hoekstra and colleagues found a learning curve of 5 to 10 cases to demonstrate proficiency in simple hysterectomy, cuff closure, and pelvic lymph node dissection for gynecologic oncology fellows. Useful methods of teaching were verbal feedback, telestration teaching, and demonstration of a portion of the procedure after a first attempt by the fellow. Looking at hysterectomy performed in a community-based practice, Lenihan and associates found that surgical time stabilized at a total time of 95 minutes after 50 cases.

In a recent study of gynecologic surgeons learning robotic surgery skills, Woelk et al. concluded that "surgical proficiency" with the new techniques required performing many more robotic procedures than previously thought. A total of 325 robotic hysterectomies were done by eight different gynecologic surgeons over a 3-year period at the Mayo Clinic. Operative time and intraoperative and postoperative complications were recorded for each surgeon, and results were analyzed in 6-month blocks of time. Operative time and postoperative length of hospital stay declined significantly over the 3-year study, but complications did not change significantly, although there was a trend toward fewer complications as surgical experience accumulated.

The risk of complications and length of surgery continued to decline and did not level off for any of the surgeons over the 6 to 36 months of evaluation, which included up to 150 hysterectomies for one of the surgeons. None of the surgeons monitored had a complication rate of greater than double the local benchmark rate for abdominal hysterectomy (11.4%), but only one surgeon, the most experienced, was able to achieve a complication rate of less than the abdominal hysterectomy benchmark (5.7%)—and this was finally achieved after 91 robotic hysterectomies. This was the only surgeon who actually did over 90 robotically assisted hysterectomies during the course of the study.

Credentialing Requirements

Credentialing and granting hospital privileging vary throughout the United States. Individual institutions may rely on recommendations from local or national experts for guidelines regarding robotic surgical privileges. The robotic platform is a complex surgical tool, and surgeons should be expected to be specifically credentialed to perform each operation, for example, hysterectomy, using robotic techniques. Credentialing in basic operative laparoscopic skills makes sense, as robotics is an adaptation of laparoscopy. However, advanced laparoscopic skills are not necessarily required or helpful for the robotic surgeon. For experienced surgeons, two to five proctored robotic surgical procedures are usually required

before independent robotic privileges are granted. Residents and fellows will likely have a more protracted exposure to robotics and may require performance or significant involvement in more cases before showing proficiency.

In our institution, credentialing criteria for robotic surgery include core privileges in the specialty (gynecology, urology, general surgery, etc.) with documented attendance at a basic certified course in robotics and observation of a minimum of two full robotic cases before being granted temporary privileges. Documentation of robotic training during residency or fellowship may satisfy the above requirements. Before performing proctored procedures, the surgeon must perform a minimum of two documented simulated runs with OR staff and the robotic instrument specialist. After this, two proctored cases are observed by a physician with robotic privileges. Surgeons are then able to operate independently and must perform a minimum of eight procedures within the next year to maintain robotic privileges. The Department of Obstetrics and Gynecology places the surgeon in a period of focused review for ongoing evaluation of outcomes and patient safety.

How Will Resident Training Be Altered with the Advent of the Robotic Platform?

As the technologic advances in minimally invasive surgical procedures increase, the demands placed on resident training are in constant flux. During the late 1980s, vaginal, simple laparoscopic, and open surgery progressed to incorporate more advanced hysteroscopic and laparoscopic techniques. Eventually, this led to the more common use of total and subtotal laparoscopic hysterectomy. Twenty years later, in an era of robotic surgery, the gynecologic surgeon in training has a wider spectrum of procedures to master in the same 4-year time frame. Will resident physicians graduate with an adequate number of each type of hysterectomy to be proficient? Will it become rare to perform the traditional open abdominal hysterectomy? Will the vaginal hysterectomy be utilized less frequently? How do we teach patient selection for robotic surgery? While robotic surgery may replace abdominal hysterectomy for many indications, vaginal hysterectomy is associated with low morbidity, short operating time, rapid postoperative recovery, and low cost, so it should remain the technique of choice when technically possible.

With regard to resident training in hysterectomy, in the United States, obstetrics and gynecology residents perform an average of 120 hysterectomies during their training. This is an overall decrease in the total number of hysterectomies compared to years past, with a notable decrease in the number of vaginal hysterectomies as reported by Pulliam. Now, with robotic training, there is the potential for a significant decrease in the number of abdominal hysterectomies performed by the average gynecologic surgeon as well as the resident-in-training. In our community, we found that abdominal hysterectomies decreased significantly after robotic surgery became available, but no decrease in vaginal and/or laparoscopic-assisted vaginal hysterectomy was detected.

ROBOT COMPONENTS AND INSTRUMENTATION

Although the da Vinci robotic system is currently the only FDA-approved robotic system for surgery, there are three models currently in use: the original standard unit, the S model, and the Si model. The models vary in instrument length, camera capability, presence of a third operating arm, and the availability of high-definition video capability. Each system consists of the patient-side cart, the surgeon console, and the vision cart/console.

FIGURE 17.1 Binocular, 3D laparoscope.

Vision Cart

A 12-mm endoscope (Fig. 17.1) that is passed through the camera port in the patient is internally composed of two 5-mm lenses attached to the camera head, all of which are on the sterile field. The camera cables are passed off the field and attached to the vision system, which processes the images from the two 5-mm lenses and produces the 3D stereoscopic view. In addition to the vision system, the vision cart/console also contains the light source, heated carbon dioxide insufflator, and cautery unit or another energy source (Fig. 17.2).

The vision console is usually equipped with a video monitor that provides a 2D view of the operative field and allows telestration. The touch screen monitor allows the table-side assistant, educator, or colleague to draw on the monitor, which projects over the field visualized by the surgeon at the surgeon console. This allows for education of the surgeon, trainee, or members of the surgical team (Fig. 17.3). The vision cart is mobile and pulled adjacent to the operating table once the surgical procedure has begun.

Patient-Side Cart

The patient-side cart (Fig. 17.4) is placed immediately next to the operating table by either straight docking between the patient's legs or side docking at the level of the right or left hip. The standard system was designed with a camera arm and two operating arms. The S and Si systems have three operating arms and a camera arm. Positioning of the camera arm and operating arms varies with the procedure to be performed. The arms are attached to laparoscopic ports through which the wristed instruments or camera is placed. Without a second surgeon console, only two of the robotic operating arms are

P.289

capable of movement at any point in time. If the third arm is docked, one of the arms can serve as a retractor while the surgeon utilizes the other two arms for surgery. The surgeon may alternate or toggle between the available robotic operating arms. Instruments are interchangeable between all three operating arms. Most surgeons will use monopolar scissors for dissection in one arm and a grasper utilizing bipolar cautery, PK, or harmonic shears for hemostasis in the opposite hand.

FIGURE 17.2 Vision cart.

FIGURE 17.3 Telestration monitor.

FIGURE 17.4 Patient-side cart.

FIGURE 17.5 S model surgeon console.

Surgeon Console

The surgeon console (Fig. 17.5) is composed of a stereoscopic viewer through which the surgeon views the surgical field: two master controllers used to manipulate instruments and move, rotate, and focus the camera and a series of foot pedals. Foot pedals on the right side are used to activate the energy sources for the two operating instruments. A camera pedal on the left side allows movement of the camera. The S system has a pedal to focus the camera and a separate pedal on the left side to switch between two operating arms (Fig. 17.6). The Si system does not have a foot pedal to focus the camera, as that function is accomplished with the master controllers. A toggle switch is built into the side of the Si unit that is foot-activated to alternate operating instruments (Fig. 17.7). As mentioned earlier, the Si system allows a second surgeon at a separate console to

P.290

operate in parallel with the primary surgeon by controlling the third operating arm. In addition, the Si system allows visualization of radiographic images by the surgeon in the surgeon console display. While the surgeon sees intraoperative images in high definition and three dimensions, the OR staff sees conventional images on the accessory monitors. The Si unit also allows for a teaching/simulation unit to be attached and operated from the surgeon console.

FIGURE 17.6 S model foot pedals.

FIGURE 17.7 Si model foot pedals.

Instruments

A variety of interchangeable instruments (**Fig. 17.8**) specific to robotic surgery are available for use. As mentioned previously, most surgeons will utilize scissors with monopolar cautery in one operating arm and a grasper with attached energy source for hemostasis in the opposite arm. A fenestrated grasper is available for the third arm. Additional instruments include vascular forceps, a single-tooth tenaculum, a monopolar spatula, and several types of needle drivers. Each da Vinci-specific instrument may be reused up to 10 times. The table-side assistant may use a laparoscopic atraumatic grasper, irrigator/aspirator, energy source, and needle driver through the right or left upper quadrant assistant port. If a hysterectomy is performed for reasons other than cervical cancer, most surgeons will utilize a uterine manipulator. Two popular manipulators are the RUMI system (CooperSurgical, Trumbull, CT) with Koh ring or a VCare Manipulator (ConMed EndoSurgery, Utica, NY). If manipulating the cervix is contraindicated, the Apple vaginal probe (Apple Medical Corp, Marlborough, MA) is helpful (**Fig. 17.9**).

FIGURE 17.8 Commonly used robotic instruments.

FIGURE 17.9 Uterine and vaginal manipulators.

Energy Sources

The use of an energy source for tissue dissection and cutting will usually involve monopolar electrocautery with a da Vinci scissor or spatula. Bipolar cautery may be applied with a fenestrated forceps or Maryland dissector. Additional energy sources used with robotic instruments include Harmonic ACE (ultrasonic shears) (Ethicon Endo-Surgery, Cincinnati, OH) and the Gyrus PK dissecting forceps (advanced bipolar) (Gyrus ACMI, Maple Grove, MN).

OR AND TABLE SETUP

If possible, the largest available OR should be assigned as home for the robotic system. Sufficient room must be allowed for the operating table to be positioned for a variety of cases involving the pelvis, upper abdomen, thorax, and head and neck region. The patient-side cart and vision cart are mobile and parked away from the operating table until needed. Once needed, they are positioned adjacent to the operating table for surgery. Gynecology cases will involve two operating table setups: one for placing vaginal instruments and one larger table for the abdominal portion of the procedure (**Figs. 17.10** and **17.11**). Most operating tables currently in use will allow for patient weight in excess of 600 pounds and 30 degrees of Trendelenburg position. To avoid movement of the patient in steep Trendelenburg position, the table should be equipped with a warmed gel pad allowing for friction with the patient's bare skin or a beanbag device, which molds to the patient (**Figs. 17.12** and **17.13**). Another option is an inverted egg

P.291

mattress taped to the bed for bare skin contact (**Fig. 17.14**). The patient's arms are padded with foam, tucked to her side, and secured with bedsheets. Shoulder braces may be used with care to prevent movement of the patient (**Fig. 17.15**). If not positioned carefully, the shoulder braces may put the patient at risk for nerve injury. Adjustable stirrups in standard and bariatric sizes are needed to allow placement of vaginal instruments. With motion of the camera arm, there is risk of contact with the patient's face, resulting in injury. Padding of the patient's face will be addressed in the anesthesia section.

FIGURE 17.12 Beanbag restraint.

FIGURE 17.13 Gel pad restraint.

FIGURE 17.14 Inverted egg crate mattress restraint.

FIGURE 17.15 Shoulder brace.

Anesthetic Considerations

Anesthetic concerns regarding OR procedures for robotic surgeries include the use of steep Trendelenburg, tucking and padding both arms, covering both legs, and padding and covering the patient's face. Airway pressures may be elevated due to increasing patient size and steep Trendelenburg positioning. Intra-abdominal pressures created by carbon dioxide insufflation and intestines resting on the diaphragm can create an anesthetic challenge. Over time, surgeons and anesthesiologists have become more comfortable with these challenges. When our program started, all patients had two large bore intravenous (IV) sites, and in many cases, an arterial line was placed. Currently, invasive monitoring is seldom needed, and in most cases, a single IV site is utilized. We have made an effort to assess all patients in the preanesthesia clinic several days prior to surgery, therefore providing the safest possible surgery and anesthetic experience. Many gynecologic procedures will involve placing a laparoscopic port in the left upper quadrant of the abdomen for use by the first assistant. We routinely place an orogastric tube to decompress the stomach and avoid gastric trauma from port placement. An important anesthetic consideration is knowing that gastric secretions may track along the orogastric tube to fill the mouth or stain the patient's face. As mentioned earlier, the camera arm of the robot is in constant motion and may come in contact with the patient's face, especially when the camera port is placed well above the umbilicus or a 30-degree, downward lens is used. To prevent trauma, eye shields are placed on the patient; followed by foam padding; and then a face shield allows egress of the endotracheal tube, esophageal stethoscope, and orogastric tube ([Fig. 17.16](#)). In cases of lymphadenectomy, the IV fluid rates are kept at a minimum by anesthesia to avoid venous distention.

The Dedicated OR Team

As the surgeon is sitting at the surgeon console without patient contact, he or she relies exclusively on the dedicated OR team to be the hands and eyes at the table. Dedicated

P.292

implies two definitions: team members who are personally committed to the most efficient and safe robotic procedures possible, and OR management that will assign the same skilled staff for all cases rather than rotating multiple OR staff. Members of our team include a circulating registered nurse familiar with the variety of robotic procedures, driving the patient-side cart and troubleshooting any problems with console error messages and instrument needs. In addition, we utilize two table-side assistants, one of whom will provide retraction, pass instruments or suture, irrigate the field when needed, and address any conflicts between robotic arms. The second table-side assistant is responsible for uterine manipulation and specimen retrieval ([Fig. 17.17](#)). Both assistants drape the upper abdomen while the surgeon places the uterine manipulator. The two bedside assistants may be surgical scrub technicians, certified surgical first assistants, physician assistants, nurse practitioners, or resident physicians. The most efficient operations will be associated with the most experienced table-side assistants.

FIGURE 17.16 Eye protection and facial padding.

The Surgeon

In addition to operating the instruments, the surgeon has several other important perioperative responsibilities. The surgeon is responsible for assuring a reasonable period of time for the initial learning curve, appropriate patient selection, preoperative preparation of the patient, and calm leadership of the rest of the team. There are several possible definitions of the “learning curve” for robotic surgery. It may be defined as the length of time or number of cases to reach a predictable operating time, the fewest complications, or lowest blood loss. It is not in the patient or surgeon’s best interest to start with the most complicated procedures. Dealing with a morbidly obese patient, multiple previous abdominal procedures, large fibroid tumors of the uterus, or severe pelvic endometriosis while still learning to effectively manipulate the robotic instruments will result in more complications, unnecessarily long surgical times, and surgeon frustration. Accommodating to the use of different surgical instruments and the lack of haptic sensation is best dealt with by scheduling less complicated cases at the onset of training. Once appropriate patient selection has been completed, the surgeon should explain the aspects of surgery and provide detailed postoperative instructions in advance of the surgery. We have been emphatic about the need to avoid straining or Valsalva maneuvers in the first 2 weeks postoperatively and avoiding any vaginal sexual intercourse for 6 weeks following surgery. On the basis of the type of procedure planned, the surgeon will decide on placement of the camera port, first-assistant port, and two or three operating ports. The operating table will be positioned to allow either side docking or docking between the patient’s legs. The surgeon will place the uterine manipulator and, in many cases, place sutures in the cervix if a hysterectomy is planned. The surgeon will tell the table-side assistant which instruments and energy sources will be needed. Once the patient is in Trendelenburg position and ports are in place (Figs. 17.18 and 17.19), the robot is docked and instruments are placed.

P.293

At that point, the surgeon assumes control of the surgeon console and initiates the internal portion of the procedure. Once the procedure is complete, the robot is undocked, the abdomen is deflated, and port site skin incisions are closed. Using noncutting trocars, for the 8-mm and 12-mm ports, we have not routinely closed the fascial incisions. All incisions are injected with local anesthetic.

FIGURE 17.17 Surgical assistants' positioning.

FIGURE 17.18 Patient positioned and padded.

FIGURE 17.19 Ports in place and 30 degrees of Trendelenburg.

Postoperative Care

One of the greatest advantages of minimally invasive surgical procedures, whether laparoscopic or robotic assisted, is the early mobility and dismissal of patients. At the completion of the procedure, if renal function is normal and the patient is well hydrated, IV ketorolac is given before leaving the OR. A 1- to 2-L bolus of intravenous fluids is given in the recovery room, and the Foley catheter is removed prior to discharge from the recovery room. Regular diet, oral analgesics, and IV ondansetron are part of the routine postoperative orders. Patients are discharged home once they are able to tolerate a liquid diet, demonstrate adequate pain control, and void without difficulty. More than 50% of patients can be dismissed the day of surgery and more than 95% dismissed in less than 24 hours after the surgery is complete.

GYNECOLOGIC PROCEDURES PERFORMED ROBOTICALLY

Although many types of gynecologic procedures have been performed, we will focus on the five most common: robotic hysterectomy, robotic hysterectomy and staging lymphadenectomy, robotic radical hysterectomy, robotic myomectomy (RM), and robotic sacrocolpopexy (RSCP). The first report of uterine horn reanastomosis in an animal model was reported by Margossian in 1998, followed by a pilot study by Falcone and colleagues applying robotic surgery for tubal reanastomosis in humans in 2000. In 2002, Diaz-Arrastia and colleagues at the University of Texas Medical Branch in Galveston reported 11 patients undergoing robotic hysterectomy and bilateral salpingo-oophorectomy. Blood loss ranged from 50 to 1,500 mL, and operative times ranged from 4.5 to 10 hours. By 2006, Reynolds and Advincula reported their experience with 16 patients: 12 undergoing robotic-assisted laparoscopic hysterectomy and 4 treated with supracervical hysterectomy. Blood loss ranged from 50 to 300 mL, and operative times ranged from 170 to 432 minutes. Following these initial publications, multiple institutions and investigators have reported their experience with robotic hysterectomy or comparisons among robotic hysterectomy, laparoscopic hysterectomy, and abdominal hysterectomy. These experiences will be listed in detail later. To date, no randomized trials have compared these techniques, although a multi-institutional, international trial to compare abdominal radical hysterectomy to laparoscopic or robotic radical hysterectomy for early-stage cervical cancer has been proposed by Obermair.

Hysterectomy for Benign Indications

Following the initial feasibility studies noted previously, a 2007 study by Kho and associates reported the initial experience with 91 patients undergoing robotic-assisted hysterectomy with or without removal of adnexa, appendix, and lysis of adhesions. Estimated blood loss was 78 mL, mean operating time was 127 minutes, average length of stay was 1.35 days, and a complication rate of 8% was reported. A study by Matthews and another by Landeen compared robotic hysterectomy to laparoscopic hysterectomy and open hysterectomy. Reports by Payne, Shashoua, Nezhat, and Giep have compared robotic hysterectomy to laparoscopic hysterectomy. **Table 17.1** summarizes several published reports of robotic hysterectomy for benign indications. In general, robotic hysterectomy was associated with a longer operating time, lower blood loss, similar to shorter length of stay, and similar complication rates when compared to laparoscopic hysterectomy. When compared to abdominal hysterectomy, surgery times were longer, blood loss was lower, length of stay was shorter, and complication rates were lower for patients treated with robotic hysterectomy. It should be noted that all of these studies were retrospective in design. Open hysterectomy and laparoscopic hysterectomy used for comparison were performed prior to the introduction of robotic hysterectomy.

In a study of 256 patients undergoing robotic hysterectomy with uteri weighing 250 to 3,020 g, with the median weight at 453 g, Payne et al. reported median operating times of 167 minutes for women with uteri weighing 500 g or greater, compared to 126 minutes for women with uteri weighing less than 500 g. Blood loss increased as uterine size increased, hospital length of stay was 1 day, and a major complication rate of 2% was reported.

Surgical Technique of Robotic Hysterectomy

P.294

STEPS IN THE PROCEDURE

Robotic Hysterectomy with or without Bilateral Salpingo-oophorectomy

- Preoperative assessment including history and physical examination with review of indications for surgery. Assessment in the preanesthesia clinic if indicated. Equally important is the assessment for the robotic approach, including patient size; associated medical conditions, which may impact the ability to tolerate steep Trendelenburg positioning; and ventilation.
- Following induction of anesthesia, placing a temporary Foley catheter, cervical sutures, and uterine manipulator if planned for use will complete the vaginal portion.
- Camera port positioning well above (25 cm) the fundus of the uterus to allow an unobstructed field of view is essential. Operating ports and first-assistant ports are placed after insufflation with CO₂ to assure there is no external conflict/contact between arms.
- The patient is placed in the maximum Trendelenburg position required for the procedure, and the patientside cart is docked.

- The retroperitoneum is developed on each side to allow optimal visualization of the ureters. If salpingo-oophorectomy is planned, the ovarian vasculature is coagulated/sealed and divided. If the adnexa are to be preserved, the utero-ovarian ligaments are coagulated and divided.
- The uterus is placed under traction to one side, and the peritoneum of the anterior and posterior broad ligament is incised to skeletonize the uterine vasculature adjacent to the cervix.
- The anterior peritoneum and bladder are dissected away from the cervix and bladder to allow visualization of the impression of the colpotomy ring of the uterine manipulator distending the anterior vaginal fornix.
- The uterine vessels are coagulated/sealed at the level of the colpotomy ring with the bladder gently displaced distally.
- An anterior colpotomy is created on top of the colpotomy ring and extended circumferentially around the vaginal fornix allowing the uterus and cervix to be detached from the vagina and delivered through the colpotomy.
- A damp laparotomy sponge is placed in the vagina to prevent loss of CO₂, and the field is assessed for hemostasis.
- The vaginal angles are secured, and the vaginal cuff is closed with running or interrupted absorbable suture placed 1 cm back from the edge of the vagina to minimize cuff dehiscence.
- After the abdominal incisions are closed, the vaginal pack is removed and the vagina is inspected for evidence of any lacerations or bleeding.
- Orders are placed to remove the Foley catheter in the recovery room and start the patient on oral analgesics, regular diet, and most will be dismissed the same day.
- Patients are instructed to avoid vaginal intercourse for seven weeks postoperatively.

On the day prior to surgery, we have requested patients limit themselves to a full liquid diet and take one bottle of magnesium citrate at noon.

EBL, estimated blood loss; LOS, length of stay.					

Prior to induction of general anesthesia, the patient is positioned on the operating table utilizing a gel pad, inverted egg crate mattress, or beanbag positioner. Depending on the patient's size, shoulder braces may be needed but used with caution. Once the patient is anesthetized, prepped, and draped, an indwelling catheter is placed in the bladder and sutures of size 0 polyglactin are placed at the 3 o'clock and 9 o'clock positions in the cervix. The cervix is dilated,

P.295

and a uterine manipulator is placed. We prefer to use the VCare Manipulator (ConMed EndoSurgery, Utica, NY). The sutures are brought through the colpotomy ring for traction to allow removal of the uterus later. The abdomen is then approached, and a decision regarding camera port placement is made. In virtually all cases, the camera port is above the umbilicus; however, the distance from the umbilicus depends on the uterine size. A distance of 20 to 24 cm above the uterine fundus is ideal. Once the abdomen is insufflated, sites are marked for the additional ports. Eight-millimeter ports for the operating arms are usually placed 10 cm lateral to the midline at or just below the level of the umbilicus. A 12-mm port is placed for the first assistant in the left upper quadrant, and an additional 8-mm port for the third operating arm of the robot is placed in the right lower quadrant (Figs. 17.20 and 17.21). The patient is placed in 30 degrees of Trendelenburg, and the bowel is displaced from the pelvis. Conventional laparoscopic instruments may be needed for dissection of omental and bowel adhesions to enhance port positioning and visualization. The robotic arms are then docked to the ports, and instruments are placed. We usually use a fenestrated bipolar grasper in one operating port and monopolar scissors in the opposite port. A Prograsp forceps is frequently placed in the third operating port. The first assistant uses an atraumatic grasper, bariatric needle driver, and irrigator/aspirator through the 12-mm port in the left upper quadrant.

FIGURE 17.20 Port site marking.

FIGURE 17.21 Ports in place.

FIGURE 17.22 Incising the posterior broad ligament.

The technical steps in a hysterectomy follow those of a standard abdominal hysterectomy except for entry into the vagina. The uterus is grasped at the cornua and displaced to one side with the Prograsp forceps that runs parallel to the anterior abdominal wall. Once the ureter is identified in the retroperitoneum (**Fig. 17.22**), the round ligament is coagulated and divided. If salpingo-oophorectomy is planned, the ovarian vasculature is coagulated and divided at this time (**Fig. 17.23**). The anterior and posterior broad ligaments are incised, and uterine vasculature is then skeletonized and coagulated (**Fig. 17.24**). The uterine artery can be coagulated at the level of the hypogastric artery to minimize bleeding if extended dissection of the uterus due to leiomyoma or endometriosis is anticipated (**Fig. 17.25**). Once the above procedures have been completed on both sides, the bladder is dissected clear of the uterus and cervix, allowing identification of the colpotomy ring distending the anterior vaginal fornix (**Fig. 17.26**). With the bladder well dissected and displaced inferiorly, the anterior colpotomy is made and carried circumferentially around the vaginal fornix on top of the colpotomy ring (**Fig. 17.27**). When completely detached, the uterus and cervix (and adnexa if included) are delivered through the vagina. At this point, the bedside assistant will place a dry laparotomy sponge within a sterile surgical glove to occlude the vagina, thus preventing

P.296

loss of carbon dioxide (**Fig. 17.28**). Monopolar scissors are replaced with a needle driver, and the vaginal cuff is closed. A 0 polyglactin suture in either an interrupted figure-of-eight placement or running from each angle to the midline is used to close the vaginal apex (**Fig. 17.29**). Support is provided by incorporation of the cardinal and uterosacral ligaments into the angle closure. In the case of uterine leiomyomata, which prevents delivery of the uterus through the vagina, we secure the uterus with the third operating arm while bivalving or quartering the uterus with monopolar cautery. Once all vascular pedicles are inspected, the instruments are removed, the robot undocked, the abdomen deflated, and ports removed. As we use only noncutting trocars, none of the fascial incisions are closed. All incisions are injected with 0.25% bupivacaine with epinephrine following subcutaneous closure and before applying a liquid skin adhesive. In the absence of contraindications, we will give 15 to 30 mg of ketorolac intravenously at the end of the case and 1 to 2 L of IV fluid in the recovery room. Oral analgesics are prescribed once dismissed from the recovery room. Most patients will be discharged home within 24 hours with instructions to ambulate frequently, avoid straining for 2 to 3 weeks, and avoid sexual intercourse for 6 weeks.

FIGURE 17.24 Coagulation of uterine vessels.

Robotic Hysterectomy and Lymphadenectomy for Endometrial Cancer

Perhaps, the area of gynecologic surgery most enthusiastically adopting robotic techniques is in treatment of endometrial cancer. Because of age, health issues, and size, this group of women represents the highest risk for surgical complications. **Table 17.2** represents most of the available literature regarding the application of robotic surgery for treatment of uterine cancer. Studies by Boggess, Bell, and Lim compare hysterectomy and staging lymphadenectomy performed robotically, laparoscopically, or as an open procedure. In general, blood loss and length of postoperative hospitalization were the lowest in the robotic group. Operating times were shortest in the open group and comparable in the robotic and laparoscopic groups. Complications were lowest in the robotic group. Lymph node counts were similar across all three groups. Studies by Seamon, Holz, and Cardenas-Goicoechea compare hysterectomy and staging lymphadenectomy performed robotically with those performed laparoscopically. Surgical time was shorter, and length of stay for robotic surgeries was shorter in two of the three studies. Estimated blood loss was lower for robotic surgery in all three studies. Node counts were higher in the robotic group in one study and comparable in the other two studies. Conversion to an open procedure was less likely in the robotic group compared to the laparoscopy group. Studies by Veljovich and DeNardis comparing robotic hysterectomy and staging lymphadenectomy to an open procedure confirm that operating times are longer, blood loss is less, and length of stay is shorter in the robotic group. Node counts are comparable in both groups.

FIGURE 17.25 Visualization of uterine artery.

FIGURE 17.26 Bladder dissection.

Because of the association between obesity and endometrial cancer, the role of robotic surgery in that patient group is of great interest. Gehrig and colleagues reported on 49 obese patients with endometrial cancer treated robotically compared to 32 matched patients treated laparoscopically. Robotic surgery was associated with a lower estimated blood loss, shorter operating times, shorter hospital stay, and increased node counts. When comparing robotic surgery for endometrial cancer in the obese patient to an open procedure, Seamon and colleagues demonstrated lower blood loss, fewer complications, shorter length of stay, and comparable node counts with robotic surgeries. However, longer operating times were also reported for the patients treated robotically. To date, there are no prospective studies comparing robotic hysterectomy and staging lymphadenectomy to laparoscopic or open approaches.

P.298

Surgical Technique for Lymphadenectomy

We prefer to perform the pelvic lymphadenectomy prior to the hysterectomy and the aortic node sampling after the hysterectomy. By developing the retroperitoneum, including the paravesical and pararectal spaces, the medial leaf of the broad ligament serves as a barrier between the node-bearing tissues and the rectosigmoid. The extent of the lymph node dissection in the pelvis includes the distal common iliac nodes, the nodes surrounding the external iliac artery and vein, and the obturator lymph nodes (**Fig. 17.30**). At the completion of the pelvic lymphadenectomy, all nodal tissues from both sides are placed in a sterile plastic pouch to be delivered through the vagina at the completion of the hysterectomy. The hysterectomy is performed as described previously. Once the vaginal cuff is closed, the monopolar scissors replace the needle driver and the right-sided aortic node sampling is performed. The peritoneum overlying the right common iliac artery is incised to the level of the lower aorta and inferior mesenteric artery. The nodal tissue overlying the lower aorta and distal vena cava is dissected clear of those vessels while retracting the right ureter laterally (**Fig. 17.31**). The right-sided aortic nodes are placed in the thumb of a sterile glove and brought out through the first-assistant port. The left aortic lymphadenectomy is similar but less difficult because there is no vena cava on the left side. The left ureter should be identified and carefully avoided.

Since less IV fluid is given intraoperatively to minimize venous filling, extra fluid is given in the recovery room prior to transfer. As with the patients undergoing robotic hysterectomy for benign conditions, many patients can be dismissed on the day of surgery and more than 90% of patients are dismissed in less than 24 hours of surgery.

FIGURE 17.30 Pelvic lymphadenectomy.

FIGURE 17.31 Aortic node sampling.

Robotic Radical Hysterectomy and Pelvic Lymphadenectomy

Table 17.3 lists 13 studies published since 2008 with a total of 432 patients treated by robotic radical hysterectomy and pelvic lymphadenectomy. Studies by Fanning, Kim, Persson, and Lowe describe the experience of the authors performing the robotic procedure. Five studies by Boggess, Ko, Maggioni, Geisler, and Cantrell compare robotic radical hysterectomy to abdominal radical hysterectomy. Nezhat and Tinelli compared robotic radical hysterectomy to laparoscopic radical hysterectomy. Finally, studies by Magrina and Estape compare robotic radical hysterectomy to laparoscopic radical hysterectomy and abdominal radical hysterectomy. In the study by Magrina, robotic surgery resulted in a decreased length of stay compared to open procedures and comparable length of stay compared to laparoscopic procedures. Operating times for robotic surgery were similar to open procedures but shorter than the laparoscopic approach. Blood loss was greatest in the open group when compared to robotic and laparoscopic techniques. There was no difference in lymph node counts or complications between the three groups. The results reported by Estape differ somewhat in that robotic surgery was longer than open procedures but comparable in length to the laparoscopic approach. Robotic surgery resulted in a higher lymph node count when compared to open and laparoscopic approaches. When looking at the comparative studies of robotic radical hysterectomy to open procedures by Geisler, Maggioni, Cantrell, and Ko, estimated blood loss and length of stay are shorter, operating times in general are longer, and lymph node counts and complications are comparable. There are no prospective studies comparing robotic radical hysterectomy to laparoscopic or open procedures, although an international phase III randomized trial comparing the three approaches has been proposed by Obermair.

Robotic Radical Hysterectomy Technique

Patient positioning for robotic radical hysterectomy is the same as described earlier in the chapter. Uterine manipulators are usually replaced with a Lucite vaginal probe to facilitate dissection of the bladder and to assess the length of the vaginal cuff. Depending on the patient preference, age, and gross appearance, the ovaries may be preserved or removed. Paravesical and pararectal spaces are developed, and the uterine artery is coagulated and divided at its origin from the hypogastric artery. The ureter is then dissected from the medial broad ligament, and the ureteral tunnel is exposed. The anterior vesicle ligament is cauterized and divided, thus unroofing the ureter from the cardinal

P.299

ligament all the way to its entry into the bladder. Once this has been accomplished on both sides, the bladder is dissected away from the upper third of the vagina, and the posterior vaginal wall and uterosacral ligaments are exposed. The uterosacral ligaments are divided at the level of the anterior rectum. At this point, an upper vaginotomy is performed, and adequate vaginal margin is determined on the basis of the size of the cervical cancer. The specimen is removed through the vagina, and a dry laparotomy sponge in a sterile glove is placed in the vagina to maintain the pneumoperitoneum. Bilateral total pelvic lymphadenectomy is then performed. Common iliac nodes are removed through the first-assistant port and labeled separately. The pelvic nodes are placed in a sterile pouch and brought out through the vagina. The vaginal cuff is closed with interrupted or running 0 polyglactin sutures. Patients are usually dismissed the following morning with an indwelling catheter with plans for a voiding trial in 1 week.

Robotic Use in Reconstructive Pelvic Surgery

Robotic Sacrocolpopexy

The primary application of robotics in reconstructive pelvic surgery has been sacrocolpopexy. Sacrocolpopexy has been the most important operation in the abdominal approach for repair of enterocele and vaginal vault prolapse. It may also be utilized for apical support with concurrent hysterectomy. The procedure is reported by Nygaard as a durable repair with approximately a 90% long-term success rate. Permanent synthetic graft material, usually type I macroporous polypropylene mesh, is used most commonly. In the mid-1990s, the laparoscopic approach to perform this operation was reported by Nezhat and colleagues. However, this was a technically difficult operation to learn with a steep learning curve. Laparoscopic sacrocolpopexy offers similar success rates as open abdominal surgery with the benefits of minimally invasive surgery, such as shorter hospital stay, more rapid recovery, and possibly less morbidity. However, those benefits are associated with longer operating times. Because of the technical difficulties associated with the learning curve and maintaining proficiency as well as the benefits of the vaginal reparative approach, this technique has not been widely adopted. The availability of robotics is changing the trend from the open and laparoscopic approaches.

Several retrospective reports on RSCP or sacrohysteropexy are presented in [Table 17.4](#). Akl and associates evaluated 80 patients treated with RSCP and followed them for 1 to 24 months. Five percent of patients required conversion to an open procedure, and a 6% graft exposure rate was reported. Operative time decreased by 25% after the first 10 cases. In three separate studies, Daneshgari, Göçmen, and Kramer describe case series of 12 to 21 patients with overall low blood loss, comparable operative times, and short hospital stays. Kramer described 21 patients who underwent RSCP, with 12 patients requiring additional repairs at a later date.

P.300

Reported complications include small bowel obstruction, ileus, pelvic abscess, bladder injury, ureteral injury, and conversion to an abdominal approach. The overall complication rate appears to be no higher than abdominal sacrocolpopexy (ASCP). Geller and colleagues in 2008 reported the largest series but only compared RSCP to ASCP. Geller and colleagues found a significantly longer operating time, shorter length of hospital stay, and lower blood loss for RSCP compared to ASCP. At 6-week follow-up, they reported similar pelvic organ prolapse quantification point C improvement in both groups. Geller and associates treated 28 patients with RSCP at a mean follow-up of 14.8 months. They found improved pelvic floor function with stable support and sexual function. Two patients with graft exposures and two recurrent prolapse were reported. Acknowledging the small volume of published reports, these initial data and unpublished experiences seem to indicate safe and reliable use of the robotic platform for sacrocolpopexy.

TABLE 17.4 Robotic Sacrocolpopexy

AUTHORS	NO. OF SUBJECTS		FOLLOW-UP DURATION	EBL (ML)	OPERATIVE TIME	LOS (DAYS)	OUTCOME
Geller (2008)	73	RSCP	6 wk	103 ± 96	328 ± 55 min	1.3 ± 0.8	Comparable point C improvement
	105	ASCP		255 ± 155	225 ± 61 min	2.7 ± 1.4

RSCP, robotic sacrocolpopexy; ASCP, abdominal sacrocolpopexy; EBL, estimated blood loss; LOS, length of stay.

Surgical Technique

The initial technical aspects are similar to preparation for hysterectomy as described above. Either a straight or side dock technique is utilized. Port placement for the camera is usually above the umbilicus approximately halfway or higher between the pubic symphysis and xiphoid process (12-mm dilating trocar). Two 8-mm da Vinci dilating trocars are placed approximately 10 cm or greater, lateral to midline at a level usually between the anterior superior iliac spines and umbilicus (below the level of the camera port). The assistant 12-mm port is placed in either the left or right upper quadrant. The third da Vinci robotic arm is not usually required but is prepared for possible additional retraction on more challenging cases. The upper pelvis and abdominal wall are cleared of omental and bowel adhesions with laparoscopy before docking, at which point further adhesions deeper in the pelvis are cleared with the monopolar shears. If the sigmoid colon is excessively redundant or unruly due to poor bowel preparation, it may be retracted to the left anterior abdominal wall with a traction suture to be released at completion of the case. Usually, the assistant is required to retract the sigmoid colon to the left. The vagina is distended with a Lucite probe or large stainless steel bowel sizer (or two as needed) for vaginal manipulation. The rectum also may be stented with a probe to aid in the deep posterior dissection. Other instruments such as Breisky-Navratil retractors may be placed vaginally as needed to improve visualization of dissection planes and suture placement. We will frequently place an Allis clamp in the midline vagina anteriorly and posteriorly where we anticipate placing the most distal aspect of the mesh arms. Placement of the Allis clamps is dependent upon the patient's anatomic defects. Placement of the Allis clamps also helps in identifying how far to extend the dissection in the vesicovaginal and rectovaginal spaces. The upper pelvic structures including the aortic bifurcation, right common iliac artery, right ureter, and sacral promontory are identified. Care is taken to identify the left common iliac vein as it crosses the field. The peritoneum over the first sacral joint (S1) is opened, and the areolar, fatty, and lymphatic tissues are carefully cleared to expose the anterior longitudinal ligament and middle sacral vessels while keeping clear of the left common iliac vein ([Fig. 17.32](#)).

FIGURE 17.32 Exposing anterior longitudinal ligament.

P.301

FIGURE 17.33 Exposing anterior vagina.

The middle sacral vessels may be coagulated once skeletonized. A 30-degree downward-directed scope may be helpful for this dissection in some patients. The line of dissection is then carried over the peritoneum and the underlying fatty tissue to the right of the sigmoid colon and medial to the ureter to the pelvic floor and vaginal apex. Care is taken to avoid trauma to the presacral, lateral sacral, and hypogastric veins. Next, the peritoneum over the vagina is opened to develop the rectovaginal and vesicovaginal spaces ([Figs. 17.33](#) and [17.34](#)). The table-side assistant is instructed to manipulate the vaginal stent to assist the

dissection. Once these spaces are opened and the bladder and rectum are mobilized, an assessment is made of length for the mesh arms. A self-constructed or prefabricated type I macroporous, polypropylene Y-shaped mesh with two arms and a width of 4.5 to 5 cm is cut to the desired length (usually 4 to 8 cm) with a tail for attachment to the sacrum. The mesh is applied over a wide surface area with multiple placements of permanent suture through the full thickness of the vaginal wall. The mesh is attached to the anterior vagina and then the posterior vagina (Figs. 17.35 and 17.36). The 30-degree upward directed scope may be useful for placement of the low posterior sutures. The vagina is then elevated toward S1, is taken off of tension, and marked for attachment to the anterior longitudinal ligament with a permanent suture placed transversely, usually under the middle sacral vessels. The tail is secured with two or three sutures (Fig. 17.37). The peritoneum is then closed over the mesh with a delayed absorbable suture to cover the bridge of mesh between vaginal apex and sacrum in an attempt to decrease the risk of adhesions and bowel obstruction. We close the peritoneum from distal to proximal, taking care not to kink or damage the ureter during the closure. A vaginal pack may be used to keep the vagina distended against the mesh. Antibiotic irrigation may also be used to irrigate the mesh.

FIGURE 17.34 Exposing posterior vagina.

FIGURE 17.35 Mesh secured to anterior vagina.

Robotic Burch Retropubic Urethropexy

There are currently no studies looking specifically at the use of robotic retropubic urethropexy, although three patients undergoing the procedure are mentioned in reports by Partin and Daneshgari. This surgical procedure is primarily utilized in conjunction with RSCP for the treatment of overt or occult stress incontinence especially with urethrovesical junction hypermobility or urethrocele. The major obstacle to overcome is the lack of tactile sensation for placing the periurethral sutures. The advantages of laparoscopic retropubic urethropexy (LRPU) and robotic Burch retropubic urethropexy are improved hemostasis, visualization, and accurate, symmetric suture placement and tensioning. Paravaginal repair for additional lateral midvaginal support may also be placed.

Surgical Technique

The technique is initially the same as performing an LRPU (Marshall-Marchetti-Krantz procedure or Burch procedure). With a Foley catheter in the bladder, the peritoneum is incised in an inverted U incision over the bladder dome following the pelvic arch from the intersection of the pubic ramus and obliterated umbilical vessels to the same spot on the contralateral side. The pubic bone is exposed,

P.302

and the avascular retropubic space of Retzius is entered to mobilize the bladder and open the space widely, taking care to avoid the obturator neurovascular structures laterally and identify the bladder neck, obturator internus muscle, arcus tendineus fasciae pelvis, and pearly white fibromuscular anterior vaginal wall (pubocervical fascia). One of the table-side assistants places a large cervical dilator in the vagina adjacent to the urethra and bladder neck in the same way one would place fingers for an open or laparoscopic dissection while the second table-side assistant retracts the fatty tissue and bladder medially. Venous bleeders are coagulated with the fenestrated bipolar, and monopolar shears are used for the dissection. A double purchase of 0-Dacron suture on a CT-2 needle is placed 2 cm lateral to the mid- to proximal urethra over the elevated vaginal dilator and is secured to the cartilaginous periosteum of the pubic bone median raphe (Marshall-Marchetti-Krantz stitch). This is repeated on the opposite side, and the next suture is placed cephalad and lateral to the MMK stitch 2 cm lateral to the urethra-vesicle junction with double purchase and secured to Cooper ligament (Burch stitch). The knots for these sutures are tied using a sliding knot for tensioning to leave a 2- to 3-cm suture bridge (Fig. 17.38). Due to the lack of tactile sense, it is easy to fracture the sutures if not tensioned carefully using visual clues. Reperitonealization is optional. IV indigo carmine dye is administered, and cystoscopy is performed with a 70- or 110-degree telescope to confirm that no sutures were placed in the bladder and for assessment of ureteral patency.

FIGURE 17.36 Mesh secured to posterior vagina.

FIGURE 17.37 Mesh secured to sacral promontory.

FIGURE 17.38 Placement of Burch and MMK stitches for urethropexy.

Robotic Myomectomy

As with sacrocolpopexy and lymph node dissection, myomectomy is another procedure traditionally performed by laparotomy. Although successfully performed laparoscopically, it is technically challenging with a steep learning curve. The robotic platform has been adapted for this operation.

Table 17.5 lists the five retrospective, observational studies that have evaluated RM compared to open abdominal myomectomy (AM) or laparoscopic myomectomy (LM). Advincula and Nash each compared RM to AM. Both studies found that RM group took considerably longer, especially as the volume of the myomas increased. The RMs resulted in shorter hospital length of stay, but hospital charges were significantly higher, although AM had higher nursing costs. The weight of myomas removed was similar in the study by Advincula, but was lower for RM versus AM in the Nash study. Bedient and Nezhat compared RM to LM. Uterine size, myoma size, and number of myomas in the LM group were greater compared to the RM in the Bedient study but not in the Nezhat study. Barakat and colleagues evaluated RM, LM, and AM. They identified larger myoma weights in the RM group compared to LM, but they detected slightly smaller weights than those removed in the AM group. Overall, these studies seem to indicate that at least in the early stages of RM, operating times are longer with less blood loss and shorter length of stay. Complications and conversion to laparotomy do not appear to be increased. There are no long-term pregnancy data, and cost for RM is higher.

Surgical Technique

The initial technical aspects are similar to preparation for hysterectomy as described previously. Either a straight or side dock technique is utilized. Depending on uterine volume and size, the 8-mm port sites should be placed higher and more lateral if possible for larger myomatous uteri. The surgical principles are the same as for open AM and LM. As described by Frick and Falcone, an intrauterine catheter may be placed to instill indigo carmine dye to detect if there is entry into the endometrial cavity during dissection. Vasopressin is injected either directly through the abdominal wall or via an accessory port into the myometrium for

initial vasoconstriction and hemostasis. A monopolar hook or shears are used to make the incision. It is preferable to utilize one uterine incision for multiple myomas if possible. The tableside assistant provides countertraction on the myoma with a grasper or a single-tooth tenaculum. For this operation, the third robotic operating arm is useful for providing countertraction, stabilization, and retraction during the dissection. Bipolar or Gyrus PK may be required to seal larger vessels. If multiple myomas are removed, they should be counted to ensure they are not lost into the upper abdomen. Once the myomas are enucleated, the myometrium is closed in the usual way with layered reapproximation using either interrupted or running delayed absorbable suture (Vicryl, PDS, or V-Loc barbed suture) to close dead space and minimize hematoma formation. Usually, myomas are reduced and removed by a commercial morcellator.

Additional Robotic Procedures in Gynecology

Magrina and colleagues reported on 85 patients undergoing robotic adnexectomy compared to 91 patients undergoing the same procedure laparoscopically. Blood loss, operating time, length of stay, and complications were similar in both groups with no clear advantage to the robotic approach. Additional gynecologic procedures performed robotically and reported by Magrina, Ramirez, Burnett, and Sundaram include radical trachelectomy, staging for early ovarian cancer, and vesicovaginal fistula repair. Nam and colleagues reported the use of robotic technology applied to single-incision laparoscopic surgery. Without question, the robotic platform will be applied to an increasing number of gynecologic procedures.

COST ANALYSIS

While robotic surgery may reduce blood loss and length of stay, shorten recovery time compared to laparotomy, and show comparable results to laparoscopic surgery, cost remains the most significant drawback. [Table 17.6](#) lists results of studies by Holz, Barnett, Bell, Landeen, Jonsdottir, and Sarlos comparing costs among robotic hysterectomy, conventional abdominal hysterectomy, laparoscopic hysterectomy, and vaginal hysterectomy. Three of the studies make comparisons between procedures performed for benign reasons, while the remaining three studies address cost comparisons in the treatment of endometrial cancer. Cost analyses are difficult to interpret on the basis of a high number of variables and variation in how hospital systems attribute expenses and depreciate equipment. Most studies are retrospective and do not collect real-time expenses, which should vary over time. In addition to hospital expenses, estimates of societal expenses such as recovery time and time off work vary greatly. Bell and colleagues compared actual costs and estimated societal costs of

robotic hysterectomy, laparoscopic hysterectomy, abdominal hysterectomy, and staging lymphadenectomy in endometrial cancer patients. Robotic surgery costs were significantly less than abdominal hysterectomy and comparable to laparoscopic surgery. When comparing actual costs for robotic surgery to laparoscopic surgery for endometrial cancer, Holz and colleagues found hospital costs to be significantly higher for robotic surgery. The higher costs are mostly attributable to the price of disposable instruments. Societal costs were not included in the calculations.

In a well-publicized review of the billing data of almost 10,000 hysterectomies done at many different hospitals in the United States, Wright et al. reported that the median total cost for robotic hysterectomy was \$2,200 more than the cost of a laparoscopic hysterectomy. This study showed that cost did not decrease significantly with increasing surgeon experience. The median total cost (not charges) for a laparoscopic hysterectomy in the United States in 2010 was \$6,679, while the cost for a robotic hysterectomy was \$8,868. These costs were direct costs for the operative procedure and did not reflect capital costs to purchase the instrumentation or societal costs of patient loss of functionality during recovery.

Using decision modeling to compare costs among robotic, laparoscopic, and open procedures for treatment of endometrial cancer, Barnett and colleagues included societal costs as a component of the calculations. They found laparoscopic surgery to be the least expensive, with robotic surgery less costly than abdominal hysterectomy. The differences in cost would be minimized if disposable equipment costs decreased. When comparing abdominal, laparoscopic, vaginal, and robotic hysterectomy for benign conditions, Jonsdottir and colleagues found vaginal hysterectomy to have the lowest operative cost and robotic surgery to have the highest operative cost. However, when total hospital cost for all four procedures was compared, little difference was noted. As a general summary of cost-effectiveness, the initial purchase and maintenance of robotic equipment cannot be understated. If an increasing number of procedures that previously would have been performed by laparotomy are performed by the minimally invasive robotic approach, shorter hospital stays, fewer complications, and a shorter recovery times would benefit the patient and society. That said, there

P.305

is currently little proof to support this assumption. Ideally, a large randomized trial comparing surgery performed by laparotomy, laparoscopy, or robotics would give a more precise conclusion. Given the current level of surgeon and patient bias, it is unlikely that being randomized to laparotomy would be acceptable.

TABLE 17.6 Robotic Cost Comparison

	SOURCE OF COSTS	ROBOTIC SURGERY	LAPAROSCOPIC SURGERY	STANDARD LAPAROTOMY	VAGINAL
		HOSPITAL COST	HOSPITAL COST	HOSPITAL COST	HOSPITAL COST
Holz et al. (2010)	Actual costs	5,084 (median)	3,615 (median)		
Barnett et al. (2010)	Decision modeling

IMPLEMENTING A ROBOTIC SURGERY PROGRAM

The decision to start a program in robotic surgery is complex and costly. In some circumstances, the decision is forced, as in the case of communities unable to recruit urologists out of training due to lack of availability of a robot for radical prostatectomy. In other cases, the decision is elective and designed to enhance an existing surgical program. At times, the robotic program is for marketing purposes to attract more patient referrals for the hospital and surgeons: the “build it, and they will come” theory. Regardless of the original reason to start a robotic surgical program, commitment is the essential requirement. Commitment must

come from four unified sectors: the hospital or clinic making the financial outlay, a dedicated group of surgeons, the anesthesia department, and the nursing department. Weak or missing commitment from any of the above members will almost guarantee failure. From an institutional standpoint, commitment to the initial purchase, ongoing maintenance, designation of a sufficiently large OR, and willingness to assign designated, competent staff is required. Anesthesiologists and anesthesiologists are faced with caring for a patient in 30 degrees of Trendelenburg position, without access to patient extremities, and minimal access to a fully padded face. Ventilatory requirements become more challenging as patient size increases and more complex cases are scheduled. Dedicated bedside assistants and circulating nurses are a critical component to assembling an outstanding robotic surgical team because they are committed to perform a sufficient number and variety of robotic cases to acquire skills needed to become increasingly more efficient. Finally, the surgeons must commit to a protracted learning curve, selecting appropriate patients, and to constantly making fine adjustments to enhance the program. The ultimate goal is shifting complex laparotomy cases to minimally invasive robotic cases with improved outcomes, lower complication rates, shorter recovery times, and improved quality of life for the patients.

BEST SURGICAL PRACTICES

- The surgeon considering adding robotic techniques to his or her practice should be committed to a sufficient number and frequency of cases to maintain the newly acquired skills.
- For surgeons unaccustomed to utilizing different energy sources during open or laparoscopic procedures, the robotic platform will be more challenging and potentially associated with a greater risk of injury until adequate experience is acquired.
- Sharp dissection and attention to normal tissue planes rather than blunt dissection will result in better visibility and reduced bleeding and trauma.
- Patient selection, optimal positioning of the patient on the operating table, and correct positioning of the uterine manipulator will minimize surgeon frustration.
- Vaginal cuff dehiscence can be minimized by extending the bladder dissection off the anterior vagina, avoiding excessive thermal damage to the vaginal incision, placing sutures well back from the vaginal incision, minimizing tension on the vaginal cuff closure, and stressing to the patient the importance of avoiding sexual intercourse for at least 6 weeks following surgery.
- Set the expectations for early dismissal and rapid return to normal activity when robotic surgery is proposed.
- Insist on developing an efficient, competent, and committed surgical team.

Chapter 18

Operative Hysteroscopy

Mindy S. Christianson

Kyle J. Tobler

Howard A. Zacur

DEFINITIONS

Hysteroscopy—Direct visual inspection of the cervical canal and uterine cavity through a rigid or flexible hysteroscope.

Index of refraction—The bending of light caused by the ratio of its velocity in room air to its velocity within an optical fiber.

Resectoscope—A specialized electrosurgical endoscope that consists of an inner and outer sheath equipped with a 30-degree telescope. The inner sheath has a common channel for the telescope fluid medium and electrode.

Uterine synechiae—Adhesions that form between the anterior and posterior walls of the uterus as a result of trauma or infection in a milieu of estrogen deprivation.

INTRODUCTION

Hysteroscopy is a term derived from the Greek words *hystera*, which means uterus, and *skopeo*, which means “to view.” In 1869, Pantaleoni successfully performed this procedure in a living human subject. He used a tube with an external light source to detect “vegetations within the uterine cavity.” No attempt was made at this time to distend the uterine cavity. During the past 145 years, developments in optics, fiber optics, instruments, and distending media have resulted in new equipment and techniques that allow the gynecologic surgeon to diagnose and treat many intrauterine cavity disorders. Hysteroscopy is a standard part of the gynecologic surgeon's armamentarium and the preferred minimally invasive choice for treatment of intrauterine pathology.

Abnormal vaginal bleeding may occur as the result of many different intrauterine cavity disorders. Dilating the endocervical canal and then blindly probing or curetting the uterine cavity to diagnose and treat these disorders would seem far less effective than performing a diagnostic and/or operative hysteroscopy. Critics have cautioned, however, about the risk of disseminating endometrial cells into the peritoneal cavity from the pressure of either gaseous or liquid distending medium during hysteroscopy. In 2000, reports by Zerbe and colleagues and Obermair and colleagues demonstrated that endometrial cancer cells could be found in peritoneal fluid following hysteroscopy with saline as distending medium in women with endometrial cancer. Whether to use hysteroscopy in evaluating abnormal bleeding in women at risk for endometrial cancer was questioned by the authors of these reports. A retrospective cohort analysis by Soucie and associates in 2012 linked a registry of women diagnosed with endometrial cancer with performance of hysteroscopy, staging of endometrial cancer, and death rates. This study concluded that hysteroscopy in women with endometrial cancer was not associated with causing a higher stage of disease. The authors concluded that hysteroscopy should continue to be used as a safe diagnostic tool for abnormal uterine bleeding.

With the emergence of minimally invasive gynecology surgery as a recognized advantage to patients, operative hysteroscopy has earned a special niche in this area. The advantages

of hysteroscopy as an accurate diagnostic technique are that it not only allows direct visual observation and accurate localization of pathology but also provides a means to sample the site most likely to yield positive results. Hysteroscopy generally is a low-risk technique that uses the endocervical canal, the natural passageway of the body, to gain entry into the intrauterine environment. Commonly performed procedures utilizing hysteroscopy include diagnostic hysteroscopy, tubal sterilization, polypectomy, myomectomy, and excision of uterine septa. Nonhysteroscopic techniques to treat intrauterine septa and adhesions are obsolete. Ablation or resection of the endometrium is considered an acceptable alternative to hysterectomy for the management of abnormal uterine bleeding. Submucous myomas no longer require hysterectomy because they can be satisfactorily managed conservatively by operative hysteroscopy. Cornual obstruction and interstitial tubal obstruction also are now managed hysteroscopically. Teaching operative hysteroscopy techniques is a key aspect of residency training curriculums and postgraduate seminars. However, as operative hysteroscopy case numbers have increased, the number of complications has also risen. Most of these complications are caused by operator error and inexperience.

FIGURE 18.1 **A:** Computerized simulation permits the gynecologist to interact by manipulating a hysteroscopic morcellator and resecting a virtual submucosal myoma or polyp. **B:** The simulator uses equipment that is balanced similar to actual hysteroscopes. **C:** Two common 4-mm telescopes are shown here. *Top* is a 12-degree, and the *bottom* is a 30-degree telescope. **D:** Telescopes must couple to a 5-mm sheath to be practically functional. The distention liquid or gaseous medium gains access to the uterine cavity via the inner sheath, and fluid exits the uterus via the outer sheath.

Learning how to perform an adequate hysteroscopy and then becoming competent to do hysteroscopic surgery are practice, skill-related techniques. Older methods of acquiring endoscopic skills focused on course attendance, preceptorship, and practice. During the late 1990s and continuing to the present, simulators have been developed to facilitate hand-eye coordination exercises. Several of the computer-based models with advanced interactive graphics provide sophisticated models for the student to shave myomas, ablate endometrium, and pass cannulas into tubal ostia (**Fig. 18.1A, B**).

P.309

However, the most basic skill levels a hysteroscopist must attain are the ability to insert the scope safely into the uterine cavity followed by satisfactory distension of the cavity to obtain clear visualization of that cavity. The preceding is not taught by simulation and must be learned *in vivo*. Without this skill set, hysteroscopy cannot be successfully performed.

FIGURE 18.1 (Continued) E: Telescopes are available with either straight-on (0 degrees) or foreoblique (30 degrees) viewing objective lenses. **F:** A telescope can be conveniently subdivided into three parts: eyepiece, barrel, and objective lens. (Parts A and E reprinted from Baggish MS, Valle RF, Guedj H. *Hysteroscopy: visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams &

INSTRUMENTATION

Hysteroscopes may be classified as rigid or flexible and possessing fixed or variable focus and be designated for either diagnostic or operative use. Scope diameter, lens offset, sheath diameter, ability to be used with a variety of distending media,

P.310

and ability to use either bipolar or monopolar cautery are key characteristics of the instrumentation.

FIGURE 18.2 Contemporary operative hysteroscopy is performed with a digital camera attached to the eyepiece of the telescope. The operator and assistants all view the field by way of a high-resolution video monitor.

Viewing through the hysteroscopic telescope may still be done by using the naked eye, but is now almost always done by using a camera and video screen. As might be expected, the images obtained by the hysteroscope may vary depending upon the type of camera and video screen used with highdefinition systems providing the sharpest images (**Fig. 18.2**).

Telescopes

The telescope has three parts: the eyepiece, the barrel, and the objective lens (**Fig. 18.1F**). The 4-mm telescope (lens) gives the sharpest, clearest image in addition to a small outside diameter (**Fig. 18.1C**). The most desirable optics provide a large field that subtends an angle of approximately 105 degrees. However, 3-mm diameter telescopes, which have greatly improved optics, provide comparable views. These contemporary 3-mm diameter telescopes coupled to endoscopic video systems with zoom lenses are highly satisfactory for office hysteroscopy as well as for operative hysteroscopy. Telescopes are available in a variety of viewing angles with the 0-degree straight-on or a 30-degree fore-oblique view being the most common (**Fig. 18.1E**). Other viewing angles available include 12 degrees, 15 degrees, and 70 degrees. The major advantage of the 0-degree lens is that it allows the operator to see operative devices as a relatively distant panorama, whereas this view is lost when 30-degree lens is used. Surrounding the optics are numerous small-diameter incoherent fiberoptic bundles that provide intense cold illumination to the operative field.

Light Generators

The quality and power of light delivered to the telescope depend on the wattage and characteristics of the remote light generator and the type and structural integrity of the connecting fiberoptic light cable. Three general types of light generators are available: tungsten, metal halide, and xenon. The xenon white light is a powerful generator that provides high-quality color and intensity and is the most commonly used today.

Fiberoptic light cables must be intact to convey the optimal light from the generator to the telescope. Broken fibers can be easily identified by viewing the stretched-out cable against a dark background and looking for light emitting through the sides of the cable. The liquid cable conducts light effectively and provides superior light when combined with a xenon generator.

Diagnostic and Operative Sheaths

A diagnostic sheath is required to deliver the distending medium into the uterine cavity. The telescope fits into the sheath and is secured by means of a watertight seal that locks into place. The sheath is 4 to 5 mm in diameter, depending on the outer diameter of the telescope, with a 1-mm clearance between the inner wall and the telescope, through which either carbon dioxide (CO₂) or liquid distending medium is transmitted (**Fig. 18.1D**).

Medium instillation into the sheath is controlled by means of an external stopcock. Even the 5-mm instrument allows easy access through the narrow endocervical canal past the point of maximal constriction, the internal os. Therefore, diagnostic hysteroscopy usually can be performed without cervical canal dilatation. If the hysteroscope is inserted into the canal under direct vision, and if the axis of the cervical and uterine canal is carefully followed until the corpus is reached, there should be no risk of creating a false passage or perforation. Imprecise or loose coupling between the telescope and sheath will result in leakage of the medium at that interface.

Operative sheaths have a larger diameter than do diagnostic sheaths, ranging in size from 7 to 10 mm and average 8 mm in diameter (**Fig. 18.3**). The operative sheath allows space for instillation of the medium, for the 3- to 4-mm telescope, and for the insertion of operating devices. The operating channel is sealed with a rubber nipple or gasket to prevent leakage of the distending medium (**Fig. 18.3C**). The standard operating sheath consists of a single common cavity shared by the medium, telescope, and operating tools. Disadvantages of this type of sheath are inability to flush the uterine cavity with the distending medium and difficulty manipulating the operative tools within the cavity. Hysteroscopes with isolated channels overcome the problems inherent to the common cavity sheath (**Fig. 18.4**). The dual operating channels permit flushing of the cavity and precise placement of operating accessories. A popular model today is the isolated-channel sheath consisting of a double-flushing sheath (**Fig. 18.4D, E**) that permits media instillation by way of the inner sheath and media return by way of the perforated outer sheath. The constant flow of the fluid medium in and out of the cavity creates a very clear operative field. The single isolated operating channel has a diameter sufficiently large (3 mm) to permit an entirely new generation of larger, sturdier operating tools to be used (**Fig. 18.4**). The new sheath combines the advantages of the resectoscope with the facility of the operating hysteroscope.

A

B

C

FIGURE 18.3 A: Instrumentation for hysteroscopic procedures. From top down: outer sheath of the diagnostic scope; the inner sheath of the diagnostic scope (not coupled together); operative sheath that includes inflow, outflow, and an instrument port; 4-mm telescope capable of insertion into either the operative sheath or diagnostic sheath. **B:** The terminal bridge reflects the cannula to angulate and facilitate its entry into the tubal ostium. (Reprinted from Baggish MS, Valle RF, Guedj H. *Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission. Copyright © 2007, Lippincott Williams.) **C:** An operating sheath with input and output channels as well as flushing capability. The operating channel is sealed with a rubber nipple and has a 7-F instrument inserted.

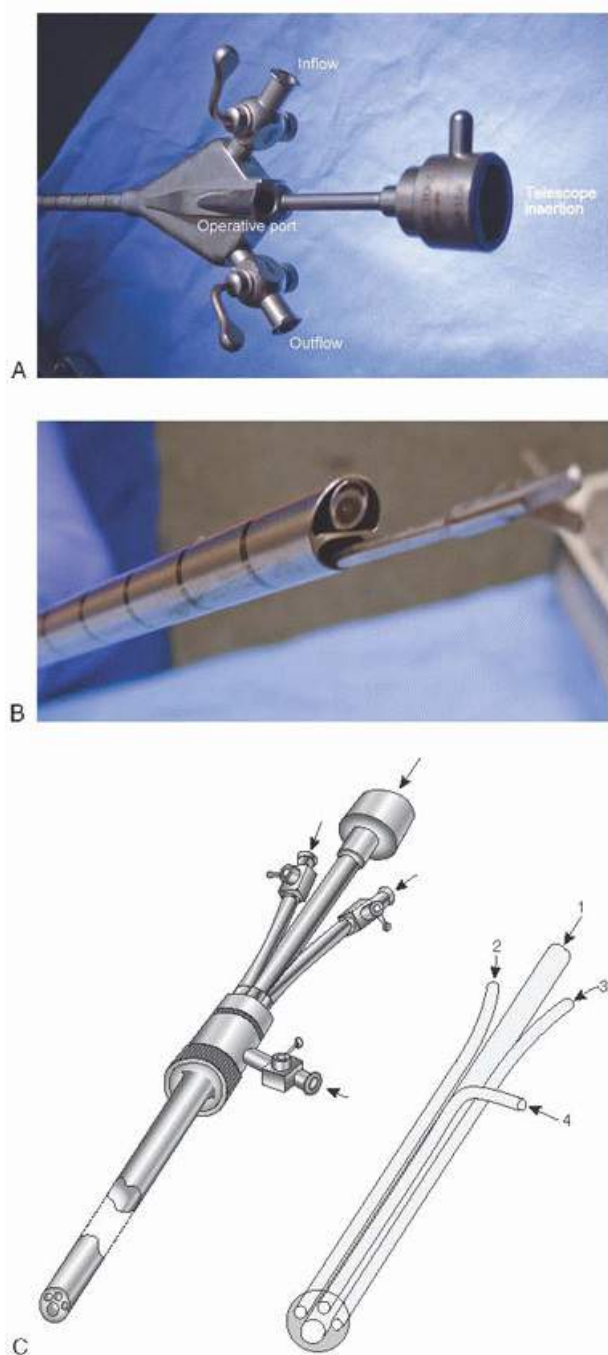

FIGURE 18.4 A: A single-channel operating sheath consists of a single cavity that the telescope, distending medium, and operating instruments share. **B:** Terminal portion of the operative sheath with scissors extended through. The top channel allows placement of the telescope, inflow, and outflow. The lower port allows passage of the operative instrument. **C:** A dual-channel operating sheath is constructed with (1) isolated channels for a telescope, (2 and 3) two operating devices, and (4) distending medium.

FIGURE 18.4 (Continued) D: The terminal portion of the second-generation isolated-channel hysteroscope shows the channel for the 4-mm optic (**top**) and a 3-mm operating channel for a variety of large accessory instruments (**bottom**). The two channels at either side are the fluid intake channels. **E:** The double sheath mechanism of the isolated-channel hysteroscope. The perforations in the outer sheath are for fluid return. The uterus is continuously flushed.

The resectoscope is a specialized electrosurgical (monopolar or bipolar) endoscope that consists of an inner sheath and outer sheath (**Fig. 18.5A**). The outer sheath is for fluid return as described above. The inner sheath has a common channel for the telescope, fluid medium, and electrode (**Fig. 18.5B**). The double-armed electrode is fitted to a trigger device that pushes the electrode out beyond the sheath and then pulls it back within the sheath (**Fig. 18.5C**). The operating tools consist of four basic electrodes: a cutting loop, ball, button, and angulated needle (**Fig. 18.5D-G**). Most resectoscopes are equipped with a 30-degree telescope. The lens is angled toward the electrode to permit a clear view of the near operative field. Vision of the electrode is lost when the electrode is fully extended outward. Most operating sheaths measure 8 mm or more in outer diameter, so dilatation is usually required for insertion. Contemporary small-diameter resectoscopes use a 3-mm telescope and a 7- to 7.5-mm sheath.

A

B

C

FIGURE 18.5 A: The resectoscope shown here is equipped with fluid entry and exit ports. A flushing sheath as the trigger mechanism is pulled back the electrode extends out from the terminal portion of the sheath. **B:** The terminal portion of the sheath shows the output external sheath. Fluid enters through the inner sheath (terminus white). **C:** A 30-degree telescope couples to the sheath. The electric cord carries current, which is transmitted to the electrode.

FIGURE 18.5 (Continued) **D:** The cutting loop electrode is the instrument for shaving submucous myomas. **E:** The ball or barrel electrode is the instrument most utilized for endometrial ablation. **F:** The button electrode is specifically employed to point coagulation. **G:** The angulated needle electrode is favored for fine cutting, for example, adhesions or pedunculated myomas.

CAMERA

In most cases today, hysteroscopy employs the endoscopic microchip camera coupled directly to the telescope, with digital cameras and digital recorders. Endoscopic video camera lenses range in focal length from 25 to 38 mm. A 28- to 30-mm lens provides satisfactory magnification. The view with the coupled camera provides magnification comparable to that obtained during microsurgery. If a video recorder is available, a permanent record of the procedure can be recorded. A xenon light generator provides the best illumination for video techniques, although less expensive light sources may be satisfactory when coupled to newer cameras, which are highly light sensitive.

ACCESSORY INSTRUMENTS

The standard accessories are the 7-F (i.e., 2.3-mm) alligator grasping forceps, biopsy forceps, and scissors. The small size of these semirigid instruments makes them particularly fragile, as excessive torque at the junction of the shaft and handle frequently leads to breakage. Flexible devices are less likely to fracture and are equally as facile compared with the semirigid variety. Development of the large isolated channel sheath has made the use of totally flexible 3-mm operating instruments feasible. The scissors and graspers are substantially heavier and much less prone to breakage (**Fig. 18.6A-D**).

A variety of monopolar and bipolar electrodes are also now available for operative hysteroscopy. Monopolar balls, needles, shaving loops (3 mm), and ridged (vaporizing) loops can be inserted through the large operating channel. Bipolar needles for myolysis, as well as bipolar ball and cutting loop electrodes, have been manufactured (**Fig. 18.7**), together with bipolar scissors and needles. The hysteroscopic sheath has an advantage over the resectoscopic sheath, allowing insertion of an aspirating cannula (2.3 or 3 mm), which permits the operator to selectively clear the field of bubbles and debris that cannot be removed by the way of the return second sheath. Nevertheless, the resectoscope is generally easier to use for the average gynecologist.

A complete bipolar system marketed under the trade name of Versapoint (Gynecare, Ethicon, Somerville, NJ) permits cutting and ablation via operative hysteroscopes or via a dedicated bipolar resectoscope. The mechanism for the bipolar current flow through the electrode is illustrated in **Figure 18.8A**. The electrodes measure 5-F diameter (i.e., 2 mm) and therefore can be accommodated by standard and isolated hysteroscopic channels (**Fig. 18.8B**). The biggest advantage of this bipolar technology is that saline may be used as the distending medium for the operative hysteroscopy. This obviates the risk of hyponatremia (see sections on media and complications). Hysteroscopic morcellators have also been developed as an alternative to the resectoscope in removing uterine submucosal myomas. Two such systems are TRUCLEAR hysteroscopic morcellator (Smith & Nephew, Andover, MA) and the MyoSure tissue removal system (Hologic, Bedford, MA) (**Fig. 18.9A, B**). Both systems use suction-based, mechanical energy, rotating tubular cutter systems rather than the high-frequency electrical energy used by resectoscopes. The benefits of these systems include the ability to use isotonic distension media such as normal saline and an improved visual field as resected “fibroid chips” are removed.

The Flexible Hysteroscope

The 4.8-mm-diameter fiberoptic hysteroscope consists of three sections: a soft flexible front section, a rigid rotating middle section, and a semirigid rear section. In 1990, Lin

P.314

and colleagues reported their experiences with this instrument in 153 procedures, including transcervical tubocornual recanalization, chorionic villus sampling, and retrieval of lost intrauterine devices (IUDs). The flexible hysteroscope has particular advantage in its ease of aligning the catheter for tubal canalization. Several manufacturers now produce fiberoptic (flexible hysteroscopes) (**Fig. 18.10**). Contemporary fiberoptic hysteroscopes are available with single-use, sterile sheaths that eliminate need to sterilize equipment between cases.

FIGURE 18.6 **A:** Direct vision intrauterine biopsies may be performed utilizing the biopsy forceps. **B:** Crocodile-jawed forceps are ideal for grabbing and retaining devices or tissue within the uterine cavity. **C:** Scissors have a variety of intrauterine applications, including cutting adhesions and uterine septa. **D:** Tenaculum allows a puncturing grasp that is more secure than that of the crocodile-jawed forceps.

A

FIGURE 18.8 A: The mechanism of action for the Versapoint bipolar electrode is illustrated. The coiled bottom portion is the active electrode, and the upper (separately illustrated) metal portion serves as the return electrode. The saline medium facilitates the conduction of current between the two poles. **B:** Several bipolar electrodes are shown. The major advantage of bipolar devices is the ability to use normal saline as the distending fluid medium.

P.316

FIGURE 18.9 A: Hysteroscopic morcellator setup by Hologic. Note the angled telescopic portion, which allows the camera to be attached. Disposable device is inserted down an operative channel. **B:** Hysteroscopic morcellator setup by MyoSure. From top down is the angled telescope with an operative channel and media inflow port. The outer sheath includes an articulated obturator that allows for a blind entry if preferred by the surgeon. The motor attaches to suction and the below disposable morcellating piece. **C:** The working/cutting end of the morcellator. Note the blunt end with a protected rotating blade located inside the curvature, which oscillates cutting tissue and pulling cut portions inside the lumen of the instrument for removal. Cutting can only occur along the lateral open edge.

DISTENDING MEDIA

Under normal circumstances, the uterine cavity is a potential space, with the anterior and posterior walls in close apposition. To achieve a panoramic view within the uterus, the walls must be separated. The thick muscle of the uterine wall requires a minimum pressure of 40 mm Hg to distend the cavity sufficiently to see with a hysteroscope. Because the endometrium is richly endowed with blood vessels, touching it with the sheath of the hysteroscope often produces bleeding. Although a variety of distending media can be used to attain the desired degree of distention, it usually requires pressures approximating 70 mm Hg, which at the same time propels the medium through the oviducts into the peritoneal cavity. Overdilatation of the cervix with a loosely applied hysteroscopic sheath results in leakage of the medium, suboptimal pressure, and poor expansion of the uterine cavity. In contrast, a tight application of the sheath maintains the medium within the cavity, keeps intrauterine pressure above mean arterial pressure, and maintains a clear operative field.

FIGURE 18.10 Flexible fiberoptic hysteroscopes can be manipulated to turn at virtually any angle.

Media can be conveniently divided into gaseous or liquid. The latter may be further subdivided into high-viscosity and low-viscosity fluids.

GASEOUS MEDIA

Carbon Dioxide

CO₂ is a colorless gas that is highly soluble when mixed with blood. It can be used to safely distend the uterus when instilled with a proper insufflation apparatus. CO₂ is ideal for diagnostic hysteroscopy. The hysteroscopic insufflator (**Fig. 18.11**) delivers CO₂ into the uterus at a flow rate measured in cubic centimeters per minute, in contrast to the laparoscopic insufflator, which allows CO₂ to flow in at a rate of liters per minute. The laparoscopic insufflator is both unsuitable and unsafe for hysteroscopic insufflation. The rate of flow of CO₂ into the uterus should never exceed 100 mL per minute, and pressure should be adjusted below 150 mm Hg. Before CO₂ is infused, the hysteroscopic tubing and the hysteroscope must be purged of air. Additionally, the Trendelenburg position should be avoided.

When CO₂ flow is excessive, bubbles appear and obscure the field. CO₂ tends to flatten the endometrium, and this artifact can obscure pathology. When CO₂ is improperly instilled, emboli form and can produce severe derangements in cardiovascular physiology. Advantages of CO₂ as a distention medium include its neatness. It does not foul instruments, it does not mess up the office or operating room, and it allows entry evaluation of the endocervical canal. CO₂ is therefore an excellent diagnostic medium. The disadvantage of CO₂ is that it cannot be used for operative hysteroscopy due to risk of CO₂ embolism.

FIGURE 18.11 CO₂ is infused using a specific hysteroscopic insufflator that measures the flow rate (100 mL per minute) and uterine pressure (not to exceed 150 mm Hg). Laparoscopic CO₂ insufflation devices cannot be used for hysteroscopy due to a much higher flow rate designed to expand the abdominal cavity.

LIQUID MEDIA

High Viscosity

Hyskon (32% dextran 70 in dextrose) is a colorless, viscid solution that is rarely used today for diagnostic and operative hysteroscopy. An advantage of Hyskon is its immiscibility with blood, which permits excellent visualization, even during active bleeding. A disadvantage of Hyskon is that dried residue tends to harden and clog hysteroscopic sheath channels. Two types of severe patient reactions unique to Hyskon have been reported: a syncratic anaphylactoid reaction and a bleeding diathesis. The hematologic reaction is caused by excessive vascular uptake of dextran, which allows a more general manifestation of its physiologic actions, including fibrinoplastic action, stearic exclusion, alteration of platelet adhesiveness, and interference with von Willebrand factor (factor VIII_R). Hyskon also places a patient at risk for fluid overload. The osmotic activity of dextran is such that for each gram of Hyskon instilled into the vascular space, 20 mL of interstitial water will be pulled into the circulation; 100 mL of Hyskon (32% dextran) will expand the plasma volume by $32 \text{ g} \times 20 \text{ mL}$, or a total of 640 mL. As the volume of intravascular Hyskon increases, a critical level is reached, and pulmonary edema occurs. Finally, dextran 70 (Hyskon) is a mixture of macromolecules ranging from 25 to 125 kd. Although the lower-weight molecules are rapidly excreted, the larger molecules can interfere with glomerular filtration and will remain in the bloodstream for 4 to 6 weeks.

Low Viscosity

Low-viscosity fluids must be continuously flushed through the uterine cavity if a clear view is to be obtained. Delivered fluid must be continuously circulated out of the cavity and clean fluid constantly added to make up for the deficit and maintain uterine distension. A standard diagnostic sheath does *not* allow for flushing. Therefore, if a low-viscosity fluid is used for distension, the view may be suboptimal because blood can mix with the distending fluid, creating a colored fluid through which the operator will see the field. The safest distending medium will be isoosmolar—that is, the electrolyte content will amount to 300 mOsm. Additionally, the sodium content of the fluid should approximate 140 mEq/L. The ideal lowviscosity fluid medium is 0.9% sodium chloride.

Regardless of the type of medium infused, the surgeon is responsible for monitoring the infused volume and reconciling that volume with the collected volume. Positive infusion differences require that the procedure be stopped when deficits range from 500 mL (for hypoosmolar fluids) to 1,000 mL (isoosmolar fluids). The surgeon and anesthesiologist must communicate, because fluid overload scenarios will usually necessitate the anesthesiologist helping to manage the ensuing pathophysiology. Additionally, intravenous fluids infused by the

anesthesia team will add to the increased circulatory volume. Finally, any fluid including physiologic salt solutions can produce pulmonary edema when excessive volumes are administered via the hysteroscope, because the pressure gradient to maintain uterine distension is 60 to 70 mm Hg and subendometrial venous pressure is 4 mm Hg. Inevitably, fluids will diffuse into the venous circulation.

Low-viscosity distention media may be delivered by hanging a 2- to 3-L bag or bottle of fluid 6 to 8 feet above the operating table, permitting the fluid to infuse by gravity feed (**Fig. 18.12A**). An alternative is instilling low-viscosity fluid by rotary pump (**Fig. 18.12B**). The newest pumps weigh the fluid in real time and give the surgeon a constant readout of flow rate and total volume of fluid infused (**Fig. 18.12C, D**). Use of an automated fluid pump and monitoring system is advocated by both the American Congress of Obstetricians and Gynecologists and the American Association of Gynecologic Laparoscopists to most accurately monitor inflow and outflow and prevent complications associated with fluid overload.

Normal Saline, Ringer Lactate

Normal (physiologic) saline (0.9% sodium chloride) is perhaps the safest of any hysteroscopic media. Complications of excessive vascular absorption include fluid overload and pulmonary edema, which are managed by diuresis and support. The medium is readily available in 3-L sterile bags that can be mounted on an intravenous pole or given via an infusion pump. Garry and colleagues (1992) reported excellent safety results and precise maintenance of uterine pressure by using a pump delivery system, which was combined with one of the operating channels of the dual-channel operating sheath to provide an outflow tract and thus a constant flow rate through the uterine cavity.

Unfortunately, because saline is an efficient conductor of electrons, it does not permit a current density that is high enough for tissue action when using a monopolar system. Saline is therefore not suitable for monopolar electrosurgery, although it is effective when the Nd:YAG laser, the KTP/532 laser, bipolar electrode, and mechanical devices such as scissors are the hysteroscopic accessories of choice.

The optimal drape for the operating room is the urologic pouch (tucked under the buttocks) with a plastic reservoir pocket into which the outflow fluid may be collected and quantified to determine the fluid deficit (the difference between instilled fluid and returned fluid). The surgeon should be given a running account by a nurse or surgical assistant of the volume of fluid instilled, which is calculated as the liters of fluid hung minus volume of return fluid. Whenever any significant fluid deficit is calculated, usually considered 2.5 L for isotonic saline, the procedure should be discontinued and scheduled for completion at a later date.

Glycine 1.5% and Sorbitol 3%

Glycine (1.5%) and sorbitol (3%) solutions were first used in urologic surgery, principally for male patients. They were adopted later by gynecologists for use with monopolar electrosurgical devices such as the resectoscope. Both glycine and sorbitol are used for hysteroscopic distension, but both have disadvantages inherent to their composition. Since these solutions are hypoosmolar (sorbitol, 178 mOsm/L; glycine, 200 mOsm/L), the principal hazard relates to their vascular absorption and the creation of an acute hyponatremic, hypoosmolar state. A fluid deficit equal to or greater than 750 mL should alert the surgeon to a likelihood of hyponatremia and hypoosmolality. Two reports have presented data concerning significant complications secondary to hyponatremia. In one series of four women, two died (50% mortality); in the other, one of four women died (25% mortality). Absorption of hypoosmolar solutions produces a gradient between the circulating blood and the brain cells. The brain cells respond by pumping cation out to diminish the positive infusion of water into the brain. Unfortunately, the cation pumping mechanism of the brain is deficient in women, secondary probably to the actions of progesterone, and women are at significantly greater risk for the development of life-threatening cerebral edema when a hypoosmolar state exists. At a minimum, intraoperative and 4-hour postoperative serum sodium levels should be requested on a stat basis if concern for a fluid deficit using a hypoosmolar medium

exists. A unique disadvantage of glycine is that it can be metabolized to ammonia and cause neurologic damage.

P.318

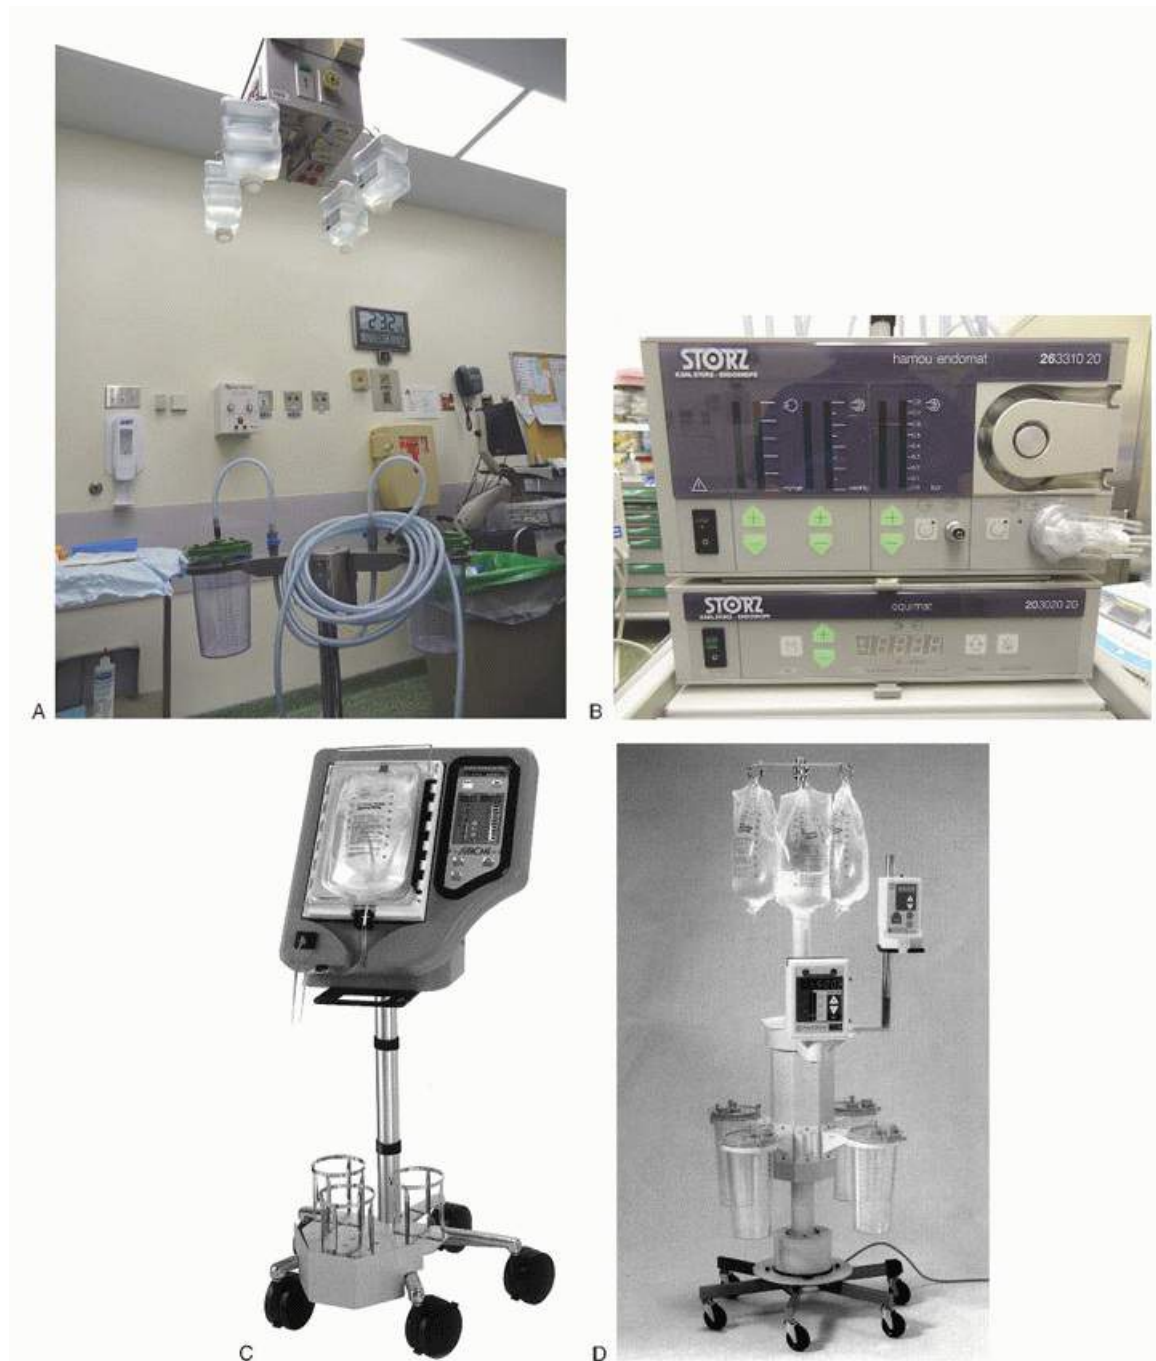

FIGURE 18.12 **A:** This fluid instillation system is suspended from the ceiling and is equipped to handle four 3-L bottles or bags. The height is easily adjusted to provide a head of pressure to infuse into the uterus. **B:** The advantage of this pump relates to its ability to provide a constant flow of low-viscosity fluid and to maintain sufficient pressure to keep the uterine walls distended. **C:** This pump delivery system not only delivers fluid but also weighs each bag and continuously calculates fluid volume infused and volume collected. **D:** This apparatus is very similar to the technology shown in part (C), but permits the usage of multiple bags of fluid.

P.319

5% Mannitol and 2.2% Glycine

Mannitol (5%) and glycine (2.2%) may be used with electrosurgical devices and are approximately isoosmolar. Mannitol has an osmolality of 285 mOsm and is an osmotic diuretic. Its optical characteristics are equivalent to glycine and sorbitol; however, it is a safer medium. In a study of 181 hysteroscopic examinations using isotonic

2.2% glycine, although there was a mean decrease in sodium of 9 mmol/L in patients absorbing 1,000 mL, the serum osmolality remained normal with no significant adverse sequelae.

DIAGNOSTIC HYSTEROSCOPY TECHNIQUES

Diagnostic hysteroscopy can be performed in an office setting under local anesthesia. The injection of lidocaine 1%, 10 to 15 mL, directly into the cervix produces adequate anesthesia. Discomfort for the patient can be further diminished by ibuprofen (Motrin), 600 to 800 mg, administered 30 minutes before the procedure. Patients who require cardiac prophylaxis (e.g., artificial heart valves) should be covered by appropriate antibiotics. Informed consent clearly reviewing the risks, benefits, and alternatives should be obtained.

FIGURE 18.13 A: The Sims retractor is excellent for retracting the posterior vaginal wall and is easily removed following placement of the hysteroscope. **B:** Bivalve speculum can be used with similar results as the Sims retractor and is ideal for use in the absence of an assistant. The speculum or Sims retractor should be removed once the hysteroscope is positioned in the external cervical os to allow full mobility with a direct entry technique.

Accurate knowledge of the position of the uterus is critical to safely facilitate the procedure. The optimal view of the uterus is obtained during the proliferative phase of the menstrual cycle. After placing the patient in the dorsal lithotomy position, the perineum and vagina are gently swabbed with Betadine or another suitable antiseptic solution. A Sims retractor or breakaway speculum is inserted to allow visualization of the cervix (**Fig. 18.13**). The edge of the cervix at the 12 o'clock position is grasped with a single-toothed tenaculum. A suitable

P.320

telescope is selected and checked by the operator for clarity of the eyepiece and objective lens. If necessary, the lens is cleansed with a soft saline-soaked or water-soaked sponge. The light generator is switched on, and the fiberoptic cable is attached to the telescope. The telescope is inserted into the diagnostic sheath, and the selected medium is flushed through the sheath to expel any air within the sheath (**Fig. 18.14A, B**).

FIGURE 18.14 A: The diagnostic lens (telescope) and its 5-mm inner diagnostic sheath are excellent instruments for office or surgicenter outpatient hysteroscopy. **B:** Close-up showing 4-mm telescope engaging into both the inner and outer diagnostic sheaths (note: the locking pins are still in the open position).

If CO₂ is the selected medium, the flow rate is adjusted to deliver 30 mL per minute. The hysteroscope is engaged into the external cervical os. As the endoscope is advanced, the gas separates the walls of the endocervix, allowing an excellent view of the endocervical folds and crypts. The internal os is seen above as the endoscope is manipulated along the axis of the canal and through the os under direct vision (**Fig. 18.15A, B**). Flow is adjusted to a rate 60 mL per minute when the isthmus is entered.

Routine dilatation of the cervix should be avoided, because even gentle insertion of cervical dilators can traumatize the endocervix and endometrium. Typically, the endocervical canal shows longitudinal folds, papillae, and clefts. The internal os appears as a narrow constriction at the top of the endocervical canal. The isthmus is a cylindrical extension above the os. The corpus is a capacious cavity above the isthmus. The central point of müllerian duct fusion is seen projecting down from the fundus. The cornua occupy either side of this fused area. The tubal ostia are visible at the upper extremities of the fundal cornua and show great variation in their appearance and angle of entry into the uterine cavity. The uterine endometrium is smooth and pink-white in color during the proliferative phase. The gland openings appear as white-ringed elevations surrounded with netlike vessels. During the secretory phase of the cycle, the endometrium is lush and velvety; it protrudes into the cavity irregularly and can be easily mistaken for small polyps. The hue of secretory endometrium is magenta. When CO₂ is the distending medium, the endometrium is artificially flattened. Although the cornua are easily recognized, the tubal ostia may not be seen during the latter phase of the menstrual cycle.

FIGURE 18.15 A: Hysteroscopic image using CO₂ to distend the intrauterine cavity. The hysteroscope's objective lens is just above the internal os allowing a panoramic view of the cavity. The recesses to the right and left are the cornu. **B:** This view is taken within the distended cervix looking upward into the dark corpus. Note a

paracervical polyp along the lateral edge.

OPERATIVE HYSTEROSCOPY TECHNIQUES

To begin, the telescope is inserted into the operative or resectoscope sheath. If the operative sheath is used, a proper nipple is selected and attached to the opening of the operating channel (**Fig. 18.16A, B**). The sheath is flushed with the distending medium, and the light cable is attached. Careful dilatation with Pratt dilators should be performed until the operative sheath negotiates a tight passage through the cervix. With the medium flowing, the hysteroscope can be inserted into

P.321

the uterine cavity under visualization. The uterine cavity is scanned, and the operator mentally notes landmarks (e.g., the tubal ostia, depth of the cornua, the location and attachments of the lesion, the proximity of the internal cervical os). The flow of the debris with the liquid medium will also help the operator locate the tubal ostia. If there is difficulty viewing the cavity clearly, the hysteroscope has probably been inserted too deeply, and the telescope has come in contact with the uterine wall. When the view is blocked, the most prudent first maneuver is to pull the instrument back with the medium flowing into the uterus.

FIGURE 18.16 A: The telescope is secured by means of a watertight pin and screw mechanism. **B:** Close-up of operating sheath. A pink-colored nipple cover is attached to the operating channel, which allows passage of the instrument without backflow of distention media. The two stopcocks are for infusion of the distending medium and return and jettison of circulating fluid. Note all stopcocks are opened.

After a clear view is obtained, the operating device (e.g., electrode or scissors) is inserted into the cavity and advanced to make contact with the endometrium for relative calibration and spatial orientation within the cavity. The cavity can also be further distended with a constant flow sheath by closing off the return valve stopcock. The valve is then opened, and the cavity is flushed clear.

In certain cases, it is advantageous to perform a simultaneous laparoscopy to permit an assistant to view the serosal surface of the uterus to provide some additional insurance against inadvertent perforation. Clinical scenarios in which simultaneous laparoscopy may be beneficial include excision of a septum, lysis of uterine adhesions, and excisions of large submucous myomas.

ELECTROSURGICAL DEVICES AND LASERS

Electrosurgical devices and lasers both exert their tissue actions in a similar fashion. Light energy from lasers is transformed to thermal energy by electron flow. Lasers and electrosurgical devices both produce coagulation at 60 to 70°C and vaporization at 100°C (**Table 18.1**), and both require sufficient power density to exert the desired action. Similar tissue actions can be produced by raising the power density or by keeping the power constant and increasing the tissue exposure time. A 1-mm laser fiber delivering 30 watts (W) of power to tissue will create a power density of 3,000 W/cm². A 3-mm ball electrode will need to generate 300 W of power to create a similar power density. The Nd:YAG laser, which works by thermal energy, is the preferred laser for hysteroscopic surgery. The Nd:YAG laser beam can be transmitted equally well with any distending medium, whereas

monopolar electrosurgical devices operate most effectively in an electrolyte-free medium.

The surgeon must be familiar with the physics governing the actions of electrosurgical tools and lasers and with the tissue actions exerted by these energized devices. A knowledgeable surgeon would not use a ball device to cut or a loop electrode to coagulate tissue. Proper selection of wattage depends on disease pathology and location. High power applied for a long period of time is risky and puts the patient at risk for tissue injury.

Regardless of whether a resectoscope, handheld electrode, or laser is used, depth of tissue action is extremely important. Transmural injury is possible at high-power densities or with prolonged exposure. One must keep in mind that the thickness of the distended uterine wall (0.5 to 1 cm) is considerably less than that of the nondistended uterine wall (1.5 to 2 cm) (**Fig. 18.17A, B**). Uterine perforation by either a laser fiber or an electrode is much more serious than perforation by scissors or another mechanical device, because the thermal energy can inflict great damage to surrounding structures (e.g., bowel or bladder). The injury may not attain its maximum damage until 2 or 3 days after surgery. Therefore, either laparoscopy or laparotomy is indicated in such cases to determine the extent of injury.

TABLE 18.1 Gross Effects of Thermal Injury as Caused by Both Laser and Electrosurgery Apparatus

APPROXIMATE DEGREE OF HEAT	THERMAL DAMAGE CAUSED
<40°C	No significant cell damage.
>40°C	Reversible cell damage, depending on the duration of exposure. ^a
>49°C	Irreversible cell damage (denaturation). ^a
>70°C	Coagulation (Latin: coagulation 5 clotting). Collagens are converted to glucose.
>100°C	Phase transition from liquid to vapor of the intracellular and extracellular water. Tissue rapidly dries out (desiccation) (Latin: ex siccō 5 dehydration). Glucose has an adhesive effect after dehydration.
>200°C	Carbonization (Latin: <i>carbo</i> 5 coal). Medical pathologic burns of the fourth degree.

^aAccording to Bender and Schramm (1968).

FIGURE 18.17 A: A uterus that is removed at hysterectomy shows the thick walls of the myometrium. These walls average approximately 1.5 cm in thickness, with the exception of the cornu, where the myometrium is thinner. **B:** The uterus is distended with the liquid medium. The walls of the uterus are now much thinner, averaging 0.5 to 1 cm in thickness.

SPECIFIC PROCEDURES IN HYSTEROSCOPIC SURGERY

Septate Uterus

Modern hysteroscopy has rendered the correction of the septate uterus relatively simple and straightforward by the transcervical route. Uterine septae are a treatable factor contributing to pregnancy wastage usually secondary to spontaneous abortion. The diagnosis of a uterine septum is usually made after a hysterosalpingogram or during a diagnostic hysteroscopy. Unfortunately, neither of the studies mentioned above differentiates between septate and bicornuate uteri. Historically, a diagnostic laparoscopy has been most helpful for an accurate differential diagnosis. A laparoscopic view of a septate uterus will reveal a wide but otherwise normal fundus, whereas the bicornuate uterus typically appears heart shaped. More recently, **MRI** of the pelvic has emerged as an imaging modality that in most cases can differentiate between a septate and bicornuate uterus. A bicornuate uterus, if pregnancy wastage is demonstrated, should be treated by a Jones or Strassman procedure. A septate uterus should be treated hysteroscopically. The standard technique, first reported in 1978 by March and colleagues, is to cut the septum with scissors under direct hysteroscopic view.

Cararach and colleagues compared hysteroscopic incision of septate uteri during a 5-year period (81 women) using a scissors or resectoscope approach and found only marginal benefit in favor of the former. Choe and Baggish used the Nd:YAG laser fiber to transect septa in 14 women. Of 13 patients who conceived, 10 delivered a live-born, term infant (87%), compared with a preoperative term pregnancy rate of 11%. Laser, resectoscope, or needle electrodes are more appropriate for the broad and usually vascular septum. Four recent studies by Litta et al., Pabuccu and Gomel, Saygili-Yilmaz, and Patton and Novy evaluated reproductive outcomes following hysteroscopic metroplasty. The percentage of pregnancies reaching term following metroplasty ranged from 50% to 83%.

Uterine rupture during pregnancy and more specifically in labor has been reported after hysteroscopic metroplasty with or without uterine perforation. It would therefore be prudent to inform the patient who will undergo metroplasty of the subsequent risk, so that she is knowledgeable and can inform her obstetrician should she become pregnant.

Hysteroscopic Technique

The uterine septum is viewed from the level of the internal cervical os. The endoscope is moved into each chamber of the divided uterine cavity, and the locations of the tubal ostia are noted. The hysteroscope is again

withdrawn to a level just above the internal os. The appropriate operating instrument is inserted through the sheath, and the septum is divided in its midportion (**Figs. 18.18** and **18.19**). There is usually no need to remove tissue, as the septal tissue retracts after it is incised. In many cases, it is beneficial to perform simultaneous laparoscopy. As the fundus is approached, the operator depends on a signal from the assistant performing the laparoscopy to indicate when the quality of the hysteroscope light demonstrates transmission through the intact uterine wall. A dialog between the hysteroscopist and laparoscopist prevents perforation. A newer technique permits the operator to scan the uterus ultrasonographically to

P.323

determine whether the myometrium has been entered and to monitor the amount of space existing between the operating device and the serosal surface of the uterus. The surgeon should be aware of the common tendency of the cutting instrument to drift posteriorly and should clip the septum squarely in the middle. When the drift goes unnoticed, the operating instrument can cut into the myometrium and cause pulsatile bleeding. Similarly, correcting the septum too perfectly at the level of the fundus will result in deep penetration into the myometrium and subsequent hemorrhage. If a multichannel hysteroscope is used, a 3-mm ball electrode may be used to coagulate the bleeding vessel. The double-needle bipolar electrode is a safe alternative method for electrocoagulation.

FIGURE 18.18 *Upper left:* Hysteroscopic view of a septate uterus immediately before cutting the septum. *Center:* The septum is cut approximately at midpoint, taking care not to drift too far posteriorly. Thicker septa are cut from periphery inward to the center. *Upper right:* The septum has been completely incised. Note the avascular and fibrous appearance of the septum, just lateral to the resection both cornea are congruent with the resection. (Photographs courtesy of Dr. Lauren Schwartz.)

If bleeding does ensue, a Foley catheter with a 10-mL balloon can be inserted into the endometrial cavity at the end of the procedure and inflated to 5 to 6 mL. The pressure exerted by the bag on the uterine walls is sufficient to control the bleeding promptly. The bag is deflated 6 to 12 hours postoperatively and is removed if no further bleeding ensues. Patients are usually advised to take conjugated estrogen daily following surgery. Antibiotics are not routinely administered.

Uterine Synechiae

Adhesions form between the anterior and posterior walls of the uterus as a result of trauma or infection in a milieu of estrogen deprivation. This condition is often referred to as Asherman syndrome. Classically, this problem follows an abortion or postpartum hemorrhage, for which a vigorous curettage has been performed to

control the bleeding. Friedler and associates reported the incidence of adhesions after one abortion to be 16.3%. This figure rose to 32% after three or more abortions. The severity of adhesions also typically rises as the number of abortions increases. In most cases, the patient does not resume menstruation; however, a minority of patients continues to menstruate normally. Because the patient is subsequently infertile or amenorrheic, a hystrogram is performed. The radiograph reveals filling defects that vary from minimal to severe (i.e., virtually obliterating the endometrial cavity). Previous treatment of uterine synechiae consisted of blind curettage, and the results were predictably poor. With the advent of operative panoramic hysteroscopy, treatment progressed to identification of adhesions and sharp incision of the adhesions with scissors (**Fig. 18.20**).

Adhesiolysis surgery is probably the most difficult of hysteroscopic operations. Because numerous vascular channels are opened, the risk of intravascular absorption of the medium is high. Rock and colleagues reported a technique of laparoscopically injecting the uterus with leucomethylene blue dye to help identify the junction at which the anterior and posterior walls were adhered. Capella-Allouc and associates reported 31 cases of severe adhesions that underwent hysteroscopic lysis ranging over one to four operations. The number of subsequent pregnancies after treatment was 43%, and the live birth rate was 32%. A 2004 report from Belgium of 46 women with Asherman syndrome, of whom one third had severe adhesions, described live births as greater than 40%.

Hysteroscopic Technique

A thorough diagnostic hysteroscopy is performed to assess the degree of adhesion formation and deformity of the cavity. Small openings in the curtain of adhesions in which there are flow patterns of tiny blood fragments and tissue debris are helpful and should be sought out, as are any normal anatomic landmarks. Photographs, videotapes, and detailed drawings are helpful reminders in planning the strategy for cutting these adhesions.

Simultaneous laparoscopy is often prudent to prevent and immediately recognize perforation of the uterus. Flexible or semirigid scissors, the resectoscope, Versapoint, or the Nd:YAG laser are the operating instruments of choice, although some operators use the monopolar needle electrode at 40 to 50 W of cutting power, BLEND 1 or 2. The laser is initially set to deliver 30 to 50 W of power. The medium is instilled into the cavity by way of an operating sheath. Filmy and central adhesions should be cut first, always following the fluid flow. Marginal and dense adhesions should be tackled last, always cutting from below and moving upward. A second key to success is to maintain the hysteroscope in midchannel relative to the uterine walls. The cavity can usually be restored to reasonably normal architecture. Bleeding is not uncommon during this operation, particularly when cutting marginal adhesions, because the border between adhesion and myometrium is blurred.

The patient should be placed on conjugated estrogens during postoperative recovery. Placement of an IUD or uterine stent (Cook OB/GYN) (**Fig. 18.21**) within the cavity to keep the walls from adhering is a standard postoperative measure.

Cannulation of Fallopian Tube

Novy and associates described a technique for passing a special catheter into the tubal ostium and through the obstructed interstitial portion of the tube. The procedure was successful in 92% of the cases. Dumesic and Dhillon reported a tubal cannulation procedure in which they used a flexible guiding insert to facilitate passage of the cornual cannulation catheter. These techniques are useful for treating interstitial obstruction secondary to cellular debris and tubal spasm. The obvious advantage of this cannulation technique is its usefulness in treating cases that might otherwise require tubocornual anastomosis. Pregnancy rates range from 25% to 54% in 6 months.

Hysteroscopic Technique

A 5.5-F Teflon cannula with a metal obturator (Cook OB/GYN) is introduced through the operating channel of the hysteroscopic sheath. The obturator is removed. A 3-F catheter with a guide cannula wire is introduced into the

way of a Y-adapter on the end of the cannula, engaged into the tubal ostium, and gently advanced into the tube. When the cornual portion of the tube is negotiated or when resistance is encountered, the guide wire is withdrawn and indigo carmine dye injected through the 3-F catheter. Simultaneous laparoscopy allows one to see the dye exit the fimbriated end of the tube and confirm patency. Alternatively, one can place a radiologic plate beneath the patient and inject opaque dye ([Fig. 18.22](#)).

FIGURE 18.20 A: A thin transverse adhesion spanning the intrauterine cavity between the lateral and anterior-posterior walls. **B:** Hysteroscopic Mayo scissors used to incise the adhesion. Note: due to high risk for uterine perforation, no electrocautery is used.

FIGURE 18.20 (Continued) **C:** Incision moving laterally. **D:** Opening into the upper/superior portion of the uterine cavity now visualized. **E:** Complete visualization of the newly opened intrauterine cavity.

FIGURE 18.21 This specially designed balloon may be placed within the uterine cavity. Uninflated, it can be used to prevent formation of adhesions following hysteroscopic lysis of adhesions. When inflated, it can be used to tamponade bleeding from the uterine wall. The intrauterine pressure will usually control bleeding. A 10-mL

FIGURE 18.22 An inner guide wire is inserted via direct hysteroscopic view into the tubal ostium and advanced. An outer cannula is then advanced over the guide wire. Indigo carmine may be injected to demonstrate tube patency to an assistant viewing from above via laparoscopy. (Reprinted from Baggish MS, Valle RF, Guedj H. *Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.) Copyright © 2007, Lippincott Williams & Wilkins.)

Uterine Polyps

Functional and nonfunctional polyps are a common cause of abnormal uterine bleeding. Functional polyps tend to be smaller than nonfunctional polyps. If a hysteroqram is performed, a focal filling defect will be seen. Diagnosis is directly and readily made by hysteroscopy. Polyps protrude into the endometrial cavity. A functioning polyp has a lining identical to the surrounding endometrium. The nonfunctioning polyp presents as a white protuberance covered with branching surface vessels. Thick-walled vessels are usually seen within the depths of the polyps. Polyps are relatively easy to diagnose and treat. Gebauer and colleagues compared blind removal of uterine polyps (curettage and polyp forceps) with hysteroscopy. Polyps were diagnosed in 43% of cases by curettage. Out of 45 cases in which polyp forceps removed the polyp, remnants of or complete polyps remained in 31 cases. The authors concluded that hysteroscopically controlled polyp extraction was superior to blind techniques.

Endometrial polyps secondary to tamoxifen therapy in women undergoing treatment for breast cancer is a problem for which hysteroscopy may prove to be indispensable. Taponeco and colleagues reported on 414 breast cancer patients who underwent hysteroscopy (334 treated with tamoxifen and 80 controls). Significant

differences were found in malignant (7.8%) and atypical (9%) hyperplastic polyps between the treated group versus controls (0 cases). The authors recommended that hysteroscopy and biopsy should be performed on any woman receiving tamoxifen who reports uterine bleeding. Garuti and colleagues compared the accuracy of blind sampling of the endometrium versus hysteroscopically directed biopsies in postmenopausal women receiving tamoxifen for breast cancer. The authors reported a sensitivity and negative predictive value of 100% with each technique. However, the specificity (80% versus 68%) and positive predictive value (69% versus 43%) were better for hysteroscopic versus blind sampling.

Hysteroscopic Technique

A multichannel operating hysteroscope is inserted into the uterine cavity, and a retractable electric snare loop is inserted through the 3-mm channel of the operating sheath. The polyp is encircled by the loop such that the loop encompasses the polyp base as it is tightened. The polyp is cut off at the base with 30 to 40 W of power for cutting current. The snare is then removed, and an alligator jaw forceps is inserted. The polyp is grabbed by the forceps. The hysteroscope is withdrawn, removing with it the freed polyp, which is sent to the pathology laboratory for histologic evaluation. The site of removal is inspected again and the procedure terminated. If any bleeding is observed, a 3-mm ball electrode is applied to the site for coagulation (40 to 50 W). Alternatively, a polyp may be cut at its base with a needle electrode or laser fiber. The polyp may also be shaved by means of the resectoscope (**Fig. 18.23**).

Myoma Uteri

Submucous myomas characteristically appear as white spherical masses covered with a network of fragile thin-walled vessels when viewed by hysteroscopy. Myomas typically are sessile or pedunculated. A hysteroogram shows a filling defect that is not dissimilar to that produced by a polyp. Unfortunately, blind dilation and curettage is a grossly inaccurate method of diagnosing this disorder. Although subserous and intramural myomas rarely produce alarming symptoms, even when they attain

P.327

relatively large size, smaller lesions in the submucous location invariably cause considerable bleeding.

FIGURE 18.23 A functioning polyp on the right corpal wall of the uterus is resected by means of a resectoscopic

loop electrode. Note that the technique is the same as the one employed for shaving a submucous myoma. (Reprinted with permission from Baggish MS, Valle RF, Guedj H. *Hysteroscopy: visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

In the past, a diagnosis of submucous myoma was usually followed by a recommendation for hysterectomy. Today, hysteroscopic surgery offers a therapeutic alternative to that radical approach. Gonadotropin-releasing hormone (GnRH) analogues such as leuprolide acetate (Lupron) or goserelin acetate (Zoladex) have been recommended as supplementary preoperative medical therapy. The general plan is to treat symptomatic patients for 2 to 3 months preoperatively to reduce the size and vascularity of the lesion during surgery. All patients should be given detailed information concerning the need for typing and holding of blood and the possibility of hysterectomy if intractable bleeding occurs.

Valle in 1990 reported data on 59 cases of abnormal bleeding, dysmenorrhea, and infertility that were diagnosed as submucous myomas. Hysteroscopy eliminated or markedly decreased bleeding in 52 of these cases. In 1989, Baggish and Sze treated 71 patients with symptomatic myomas and four patients with incidental submucous myomas. The treatment methods used with the multichannel hysteroscope were Nd:YAG laser ($n = 41$), monopolar loop ($n = 6$), monopolar needle ($n = 6$), bipolar needles ($n = 10$), and electrosurgery or scissors and laser ($n = 12$). As with Valle's series, results were excellent; 65 of 75 (87%) returned to normal menses postoperatively.

Emanuel and colleagues reported 285 women who underwent hysteroscopic resection of submucous myomas. The median follow-up was approximately 4 years (1 to 104 months), and 85.5% of the operated patients required no further surgery. Clark and associates treated 37 women using the bipolar Versapoint electrode via ablation or excision. Improvement of bleeding symptoms was reported in 78% of the patients, and 92% were satisfied with the treatment. No significant complications were reported.

Hysteroscopic Technique

Several variations of hysteroscopic procedures are now available to manage submucous myomas. Resectoscopic instrumentation has vastly improved in recent years compared with earlier instruments. Self-flushing sheaths, straight and offset cutting loops, and diminished-diameter, low-profile scopes are among these recent improvements. In addition, electrosurgical generators have been modernized and are safer devices than instruments from the 1970s and 1980s. Under video control, the resectoscopic technique consists of progressive shaving of the myoma and harvesting pieces of tissue for subsequent histologic evaluation. For fundal myomas, the straight electrode is the most effective device, whereas the angulated electrode is preferred for lesions located on the anterior or posterior walls (**Fig. 18.24A**). The electrode should be activated only while returning toward the hysteroscope, never while advancing outward away from the lens. The greatest disadvantage to this technique centers on the need to repeatedly remove the shaved nuggets of tissue (**Fig. 18.24**).

Other electrosurgical techniques may be employed in conjunction with the large isolated-channel, flushing hysteroscope. Three-mm needles, shaving loops, and bipolar electrodes may be used to perform all of the optional operations described above for the resectoscope (**Fig. 18.25**). The fine-needle electrode can be substituted for laser fiber to excise pedunculated or section sessile myomas. The 3-mm retractable cutting loop can perform shaving procedures in a fashion similar to that of the resectoscope loop. The bipolar needles can be plunged many times into the substance of the submucous myoma of any size to coagulate the interior of the myoma (myolysis).

If postoperative bleeding occurs, a 10-mL Foley balloon is placed in the cavity and blown up to 5 mL for 6 to 12 hours. If the cavity is large, a 30-mL balloon inflated with 10 to 15 mL of water can be used. Some gynecologic

a simultaneous laparoscopy when large myomas (3 to 5 cm) are resected and extracted. Regardless of myoma size, a simultaneous laparoscopy should be performed whenever concern for perforation exists. The central fundal myoma is associated with the greatest risk of uterine perforation.

FIGURE 18.24 A: The shaving technique for the elimination of a submucous myoma is shown using an angulated loop electrode via the resectoscope. (Reprinted from Baggish MS, Barbot J, Valle RF. *Diagnostic and operative hysteroscopy*, 2nd ed. St. Louis, MO: Mosby-Year Book, 1999, with permission. Lippincott Williams & Wilkins, 2007.) **B:** A chunk of tissue has been cut out of this myoma. The resectoscopic loop is seen above (left). The picture to the right shows the loop extended farther into the cavity (arrow).

FIGURE 18.25 A-C: Several techniques and instruments may be used to deal with submucous myomas. **A:** shows a laser fiber within an irrigation cannula cutting a myoma at its base. **B:** shows an electrode shaving a myoma. **C:** shows an electrosurgical needle cleaving a piece of a submucous myoma. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

Reports caution that uterine rupture can occur during pregnancy after hysteroscopic myomectomy. This is particularly the case when the operator attempts to resect the intramural portion of the submucous myoma. As such, patients should inform their obstetricians of a history of a hysteroscopic myomectomy in the event they become pregnant. Regarding risk of malignancy from submucosal fibroids, the risk of leiomyosarcoma is less than 1%. Nevertheless, any myoma or part of a myoma that is excised should be sent to the pathology laboratory for evaluation. This, of course, includes resectoscopic fragments.

Sterilization

Surgical methods of performing female sterilization from tubal ligation to total salpingectomy are discussed in other chapters of this book. These methods are well established and in widespread use with low failure rates. Attempts to perform female sterilization hysteroscopically using plugs or causing proximal obstruction by electrical or chemical means have been attempted in the past. High complication and failure rates resulted in cessation of their use. In November 2002, the Food and Drug administration (FDA) approved the use of the Essure microinsert, which is inserted hysteroscopically. Essure is widely used today. A detailed description of the Essure microinserts and the technique for placing them via hysteroscopy can be found in [Chapter 27](#) of this text.

Endometrial Ablation

Since the first practical method of hysteroscopic ablation was described in 1981, several thousand cases have been performed by a variety of techniques, including the Nd:YAG laser, the resectoscopic roller ball or loop, and, most recently, the long hysteroscopic ball electrodes. Garry and associates in 1995 reported 600 endometrial laser ablations performed on 524 women. No major operative morbidity was reported. The success rate (mean age, 43 years) was 83.4%. Baggish and Sze have performed 568 ablations; 401 of these were performed with the Nd:YAG laser and 167 by electrosurgery. Excellent results were obtained in 89% of the women treated, and amenorrhea was achieved in 58%. Again, no major operative complications were observed. Magos and coworkers reported 250 cases of endometrial resection with a 92% improvement in abnormal bleeding. However, data obtained from the Royal College of Obstetricians and Gynaecologists' MISTLETOE (Minimally Invasive Surgical Technique—Laser, Endothermal, or Endoresection) Study in 1997 revealed a 6.4% rate of significant complications associated with endometrial resection alone and a rate of 11.4/1,000 with emergency hysterectomy. This compares with complication rates of 2.7% and 2.1% for laser and rollerball, respectively. The latter two techniques had emergency hysterectomy rates of 1.3/1,000 (i.e., 11 times less than endometrial resection). Nonhysteroscopic minimally invasive techniques for endometrial ablation have emerged in recent years and replaced hysteroscopic endometrial ablation in most settings. These techniques, which include thermal balloon ablation, microwave endometrial ablation, and radiofrequency electromagnetic energy, are reviewed in detail in [Chapter 26](#).

Hysteroscopic Technique

Operative Hysteroscopy

- Patient in lithotomy position.
- Bimanual examination: uterus anteverted or retroverted.
- Position fluid collection bag under the buttocks.
- Prior to starting, verify the following: hysteroscope assembly and outflow inflow tubes correctly connected, light cord and camera attached to telescope, and white balance.
- Verify correct distention media.
- Verify pressure, flow, and fluid deficit alarm settings on automated pump delivery system.
- Cervix visualized with bivalve speculum or Sims retractor.
- Tenaculum applied to the anterior lip of the cervix.
- Dilation of cervix, if required (dilation not required for diagnostic scope); do not overdilate.
- Place hysteroscope in external os, with distention media flowing; insert under direct visualization; countertraction applied using tenaculum (verify that inflow valve is open and outflow valve is closed).
- Once inside uterine cavity, remove speculum or Sims retractor with the hysteroscope in place; verify/orient position by identifying the tubal ostia.
- Insert operative instruments (must have rubber stopper over port prior to opening instrument port valve); maintain the distal end of the hysteroscope in constant visualization while inserting the instrument.
- Operative portion: If visualization is cloudy, open outflow valve to clear, then reclose; may leave slightly open for fluid circulation if necessary.
- Attempt to only touch intrauterine walls when necessary to avoid bleeding, which will cloud the field.
- Check fluid deficit: Approximately every 5 minutes, halt procedure at a deficit of 1000-1500 mL (hypoosmolar) or 2,500 mL (isoosmolar) depending on distention media used.
- Termination of procedure: fluid deficit calculated and recorded in operative notes/dictation.

FIGURE 18.26 A: The ball electrode is dragged from side to side via moving the entire hysteroscope, thereby ablating the uterine fundus. **B:** The anterior and posterior walls are ablated by dragging the energized ball electrode from above downward. This creates 2- to 3-mm furrows in the endometrium. Conduction heat damage

can extend another 1 to 2 mm. (Reprinted from Baggish MS, Valle RF, Guedj H. *Hysteroscopy: visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

All patients who might be candidates for endometrial ablation should have been managed first by hormonal treatment in an attempt to control the abnormal uterine bleeding. If this strategy fails, and if the woman does not desire to bear children, then she is a candidate for endometrial ablation. A preoperative diagnostic hysteroscopy, endometrial sampling, or both should be performed to exclude endometrial carcinoma or atypical hyperplasia, and all pertinent hematologic studies and consultations should be performed. All patients are pretreated to atrophy the endometrium with medication such as a GnRH agonist.

A simultaneous laparoscopy is not performed during endometrial ablation unless a perforation or other transmural injury is suspected. Depending on the technique selected, either 5% mannitol or 0.9% saline is used as the distending medium. The operating hysteroscope or resectoscope is inserted into the uterine cavity. One method to treat the fundus is by dragging the laser fiber or the ball electrode from side to side (cornu to cornu) (**Fig. 18.26A**). The anterior and lateral walls are ablated next, before the posterior wall. Ablation should not be extended below the internal os into the cervix (**Fig. 18.26B**). Power settings for the electrosurgical generator range from 50 to 150 W, depending on the size of the ball, barrel, or loop electrode (**Figs. 18.27** and **18.28**). Laser power is set at 40 to 60 W. The goal of the ablation operation is to destroy the visible endometrium, including the cornual endometrium, to a depth of 1 to 2 mm. The conduction heat will actually spread deeper, usually to 3 to 5 mm, depending on how long the device remains on the tissue. This penetration translates into extensive superficial myometrial destruction and coagulation of the radial branches of the uterine cavity

P.330

(**Fig. 18.29**). When the endometrium sloughs, regeneration is prevented because basal and spiral arterioles do not survive the 100°C heat exposure. Over a period of 6 to 8 weeks, the uterine walls scar and shrink. Subsequent sampling or hysteroscopy is possible after endometrial ablation (**Fig. 18.30**). The mean duration of the operation is about 30 minutes. Patients usually are sent home on the day of surgery. The operation is usually completed with little or no blood loss.

FIGURE 18.27 The resectoscope with ball electrode attached is inserted into the uterine cavity. Initially, the cornu and fundus are carefully ablated, taking care to keep dwell time low to reduce the risk of deep heat conduction injury. Next, the anterior wall is ablated, followed by the posterior wall. (Reprinted from Baggish MS, Valle RF, Guedj H. *Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

Miscellaneous Procedures

Intrauterine Device Removal

The gynecologist is occasionally called to search for and remove an IUD with an indicator string that is not seen in the cervix. In such circumstances, the operating hysteroscope is a vital tool with which to locate the device and remove it under direct visualization. The hysteroscope is inserted, and the device is viewed. If a string is seen, an alligator jaw forceps is inserted, and the string is grasped. The hysteroscope is withdrawn, pulling the device through the uterine cavity and the cervix to the exterior. If the IUD is embedded, then a rigid grasping forceps is required. The IUD is located, and the large jaws of the rigid instrument grab the extruded portion of the IUD itself. Strong pressure is exerted on the jaws as the sheath of the hysteroscope is slowly withdrawn from the uterus, into the cervix, and out of the vagina.

FIGURE 18.28 Endometrial resection is performed in a manner similar to ablation; however, instead of a ball electrode, a cutting loop is substituted. This is clearly a riskier procedure compared with ablation by either laser or ball electrode, particularly relative to deep myometrial resection with the accompanying risks of hemorrhage and/or perforation. (Reprinted from Baggish MS, Valle RF, Guedj H. *Hysteroscopy: visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

Biopsy of Intrauterine Lesions

When a tumor is suspected, the operative hysteroscope is inserted into the cavity, a 9-F biopsy forceps is directed to the tumor site, and multiple biopsy specimens are obtained in a fashion analogous to that used with

colposcopic biopsies. A 9-F plastic cannula is inserted by way of the operating channel, and strong suction is applied to the mouth of the cannula

P.331

by means of a 30-mL syringe. The cannula is removed, and the contents are flushed out with saline into a bottle of fixative. Similarly, a 9-F curette can be inserted under direct vision. Alternatively, a diagnostic hysteroscope can be inserted into the uterus. The site of pathology is noted. The endoscope is withdrawn, a Novak curette is inserted into the cavity, and biopsy specimens are taken at the previously located site. Finally, the hysteroscope is pulled back to the level of the internal cervical os, a small Novak curette is inserted alongside the hysteroscope, and a directed biopsy specimen is obtained.

FIGURE 18.29 The uterus was removed 5 days after an Nd:YAG laser ablation. Note the extensive laser injury involving about half the thickness of the myometrium. Laser penetration depends not only on power but also on the length of time the laser beam remains in contact with the tissue.

FIGURE 18.30 **A:** Complete destruction of the endometrium has been afflicted by means of Nd:YAG laser ablation. The fiber is seen at the 11 o'clock position. **B:** Close-up view of ablated endometrium shown in part A. Note the laser fiber to the left. **C:** Endometrial resection is performed via a shaving technique utilizing the resectoscope.

COMPLICATIONS

Unfortunately, accurate data concerning complications are hard to obtain. As greater numbers of gynecologists have begun to perform operative hysteroscopy, the rate of complications has increased. Complications include bleeding, uterine perforation, creation of false passages, and excess fluid absorption and subsequent pathologic responses. Propst and colleagues reviewed data on 925 women who had hysteroscopies. Operative complications occurred in 2.7% of patients.

P.332

Excessive fluid absorption was the most common complication. Myomectomy and resection of uterine septum had greatest odds for complication (odds ratio [OR] 7.4).

Intraoperative and Postoperative Bleeding

The most common complications inherent to hysteroscopic surgical procedures are intraoperative and postoperative bleeding. Intraoperative bleeding can be managed by aspirating the blood and by increasing the pressure of the distending medium so that it exceeds arterial pressure and compresses the walls of the uterus sufficiently to stop bleeding. The bleeding vessel may then be coagulated with a 3-mm ball electrode

and the use of forced coagulation at 30 to 40 W of power or by multiple jabs with bipolar needles at 20 to 30 W of power with the generator set for automatic bipolar. If the counterpressure of the medium is relaxed (at the termination of the procedure) and bleeding continues, then control is best obtained by inserting an intrauterine balloon initially inflated to 2 to 5 mL. If this pressure does not promptly stop the bleeding, then a larger balloon can be distended to 10 mL until the bleeding has stopped (**Fig. 18.21**). More distension may be required for larger uteri. Care must be taken because overinflation of an intrauterine balloon can itself rupture the uterus. The balloon remains in place for 6 to 8 hours, is partially deflated for 6 hours, and, finally, is totally deflated before removal. When the bleeding is pulsatile, the source is arterial rather than venous. If this type of bleeding is not immediately controlled by balloon compression, then emergent hysterectomy or uterine artery embolization will usually be required. Delayed postoperative bleeding is most commonly associated with endometrial slough (after ablation), chronic endometritis, or spontaneous extrusion and expulsion of the intramyometrial portion of a previously resected submucous myoma. Bleeding-clotting studies should be obtained in cases of late postoperative bleeding, particularly if these studies were not performed preoperatively in women with a diagnosis of abnormal uterine bleeding (preoperative endometrial ablation or myomectomy).

A French group in 2003 prospectively studied a decade of operative hysteroscopies (2,116 cases). Thirteen cases of major bleeding were reported, with six requiring intrauterine catheter placements. The highest-risk procedure for associated hemorrhage was hysteroscopic adhesiolysis.

Uterine Perforation

Uterine perforation can occur during any operative hysteroscopy procedure but is most common during septum resection, myomectomy, and lysis of adhesions. The best insurance against this complication is simultaneous laparoscopy. Among novice operators, perforation can occur even during insertion of the hysteroscope. With appropriate care, this sort of perforation should not happen, because the cervix and internal os should be negotiated under direct visualization, and the cavity should likewise be entered under direct visualization. Examination under anesthesia is also simple and lets the operator know the direction of the uterine axis.

As we noted above, the most dangerous perforations are those associated with lasers and electrosurgical devices. The risk of this type of injury can be reduced by not activating the energy device during a thrusting or forward movement. The foot pedal is activated only during the return phase of the laser fiber or electrosurgical electrode. If a perforation does happen with an energy device, then laparotomy or laparoscopy is required to ensure that no injury has been inflicted on the intestine, bladder, or ureter (**Fig. 18.31**).

A risk of perforation is associated with the septum transection in its final phase at the level of the uterine fundus because the operator may have some difficulty determining

P.333

where the septum ends and the myometrium begins. This risk is constant regardless of the cutting instrument used. The operator rapidly becomes aware that uterine perforation has occurred because distention becomes difficult to maintain and the flow of the distending medium exits at the perforation site (**Fig. 18.32**). An alert assistant viewing by laparoscope should warn the hysteroscopist of impending perforation the moment an increasing intensity of light transmission through the thinning uterine wall is observed. If perforation is unnoticed and if simultaneous laparoscopy is not performed, a serious complication is even possible with a nonenergy instrument, but this is far less common than those occurring with lasers or electrodes. Nevertheless, if a perforation is suspected, that patient should be carefully observed in the hospital. Injuries to the iliac vessels can occur as the result of uterine perforation. An unexplained falling blood pressure, together with medium leakage, should alert the surgeon to this possibility. Perforation of the uterus during hysteroscopy can place a woman at an increased risk for uterine

rupture during a future pregnancy.

FIGURE 18.31 A: The operator should never apply power to an energy device while advancing the electrode. The power can safely be applied as the electrode returns toward the sheath. (Reprinted from Baggish MS, Valle RF, Guedj H. *Hysteroscopy: Visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.) **B:** Laparoscopic image of a uterine perforation that occurred while using the hysteroscopic resection loop.

As uterine perforation often occurs during the dilation prior to actually placing the hysteroscope, there has been much interest in optimizing the dilatation process to avoid perforation and other complications such as creating a false passage and cervical laceration. Use of misoprostol, a synthetic prostaglandin E₁, has been studied extensively as a cervical dilator prior to hysteroscopy to prevent complications associated with dilatation. A 2011 systemic review by Selk and Kroft did not rule out a beneficial effect of misoprostol on cervical dilation or surgical complications in operative hysteroscopy, but the authors were unable to conclude that evidence currently supports the routine use of misoprostol prior to hysteroscopy.

Management of Fluid Overload

Fluid overload associated with hysteroscopy is rare, with 1 study of 21,676 patients reporting the complication in 0.02% of cases. However, the pathophysiologic ramifications for the patient can be severe and life-threatening. Therefore, the gynecologic surgeon must be vigilant in preventing this important complication. The risk of complications varies with the distention medium.

FIGURE 18.32 Perforation should be immediately suspected when the endometrial cavity depressurizes and collapses around the hysteroscope, creating a compromised view of the cavity. (Baggish MS, Valle RF, Guedj H. *Hysteroscopy: visual perspectives of uterine anatomy, physiology and pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

Methods to prevent fluid overload include the following: (a) Use isotonic fluids such as normal saline whenever possible, (b) monitor the fluid deficit closely, (c) maintain intrauterine fluid pressure at 70 to 80 mm Hg, and (d) limit surgical operating time to 1 hour or less. Serious complications due to hyponatremia have been reported from use of hypoosmolar fluids such as sorbitol and glycine. For instance, absorption of 1,000 mL of glycine distension medium during hysteroscopy is associated with a reduction in serum sodium of approximately 10 mEq/L. The American Congress of Obstetricians and Gynecologists' Committee on Gynecologic Practice recommends termination of a case with a deficit of 750 mL with hypoosmolar fluids when patient is elderly or has comorbid conditions. The case should be terminated for a deficit of 1,000 to 1,500 mL for all other patients. When an isotonic distension medium is used, the case should be terminated when the deficit reaches 2,500 mL. With this finding, in addition to terminating the case, a stat sodium level should be sent and patient should be administered a loop diuretic such as furosemide. Severe hyponatremia should be managed in cooperation with an intensive care specialist; the patient should be very closely monitored and may require hypertonic saline.

Poor Visibility in the Operative Field

Inability to see the operative field is a common problem. The usual cause of this problem is deep insertion of the hysteroscope so that the telescope lies directly in contact with the endometrium. The surgeon will see nothing but a red blur. The natural tendency is to push the hysteroscope deeper in. This strategic mistake invariably leads to perforation. Another cause of visibility problems is blood within the uterine cavity secondary to dilatation. The fastest way to deal with a bloody cavity is rapid flushing with the hysteroscopic medium combined with aspiration using a cannula placed into the cavity via the operating channel.

Overdilatation of the cervix is an equally common mistake that results in excessive leakage of distending medium and an inability to maintain distension, with the resultant inability to perform the operative hysteroscopy. Blood and debris can cloud the field to such a degree that accurate operative endoscopy is

impossible. If the operator cannot clearly see the field, it is better to discontinue the procedure rather than press on

P.334

and risk a catastrophic error. It is easy to become disoriented in the uterine cavity if normal anatomic landmarks cannot be recognized.

Gas Embolus

Gas embolism is a well-documented complication of operative hysteroscopy using CO₂ as the distending medium, with a 0.51% incidence of subclinical events and a 0.03% incidence of symptomatic events in a review of 3,932 cases by Brandner et al. As previously mentioned, a fatal CO₂ gas embolism is especially likely to occur if a laparoscopic CO₂ insufflator is connected to the diagnostic hysteroscope.

Air embolism may also occur commonly during operative hysteroscopy when fluid distending media are used, with an incidence from 10% to 50% having been reported. Differences in incidence rates are most likely due to differences in methods used to detect embolization. Methods include noticing a decrease in end-tidal CO₂, which is not very specific, and detecting a millwheel murmur. Transesophageal echocardiography appears to be the most sensitive and specific monitoring method. Introduction of ambient air into the uterine cavity by repeated passes of the hysteroscope or by creation of vapors by use of electrosurgery is thought to be responsible for causing air emboli. Air then passes into venous sinuses of the uterus either passively or actively from the pressure of the liquid media. If a gas embolism is suspected, the procedure should be stopped immediately. Avoiding the Trendelenburg position during operative hysteroscopy has been suggested to decrease the risk of gas embolism.

Infection

Infection is an unlikely complication associated with hysteroscopy. Hysteroscopy should be avoided in the presence of gross cervical infection, uterine infection, or salpingitis. Infection is otherwise uncommon after even extensive intrauterine surgery (e.g., adhesiotomy or myomectomy). Prophylactic antibiotics should be administered only when indications exist such as a history of rheumatic carditis, congenital heart defect, or prolapsed mitral valve or in cases of suspected chronic endometritis (submucous myoma or imbedded IUD). Baggish and colleagues in 1999 observed only 13 infections out of 5,000 cases that could be casually related to the hysteroscopic operation. Salat-Baroux and associates reported 7 mild infections out of 4,000 hysteroscopic examinations. On the other hand, McCausland and coworkers reported three cases of tuboovarian abscess after operative hysteroscopy. Agostini and colleagues reported 30 infections associated with 2,116 operative hysteroscopies. Eighteen of these infections were cases of endometritis.

Operator Technique

The most serious complications happen because of operator error. Most often, these are the result of inexperience and are avoidable. Difficult cases beyond the capabilities of the primary care gynecologist should be referred to the expert hysteroscopist. Skill in one area of endoscopy (e.g., operative laparoscopy) does not confer similar expertise in operative hysteroscopy. Indeed, the opposite may be truer.

During the postoperative period, operative complications should be the initial exclusion diagnosis for any patient who is not recovering according to the usual pattern. Worsening postoperative pain, fever, nausea, distension, and free intraperitoneal air are the signals of bowel injury. Diminished urinary output, fever, and distension suggest bladder or ureteral trauma. Falling blood pressure and rapid thready pulse, with or without distension, should raise concerns of a vascular problem and third-space hemorrhage.

Most negligence cases adjudicated in favor of the plaintiff have involved delayed initiation of appropriate treatment for an operative complication. Cases involving injury recognized at the time of surgery and correctly managed in a timely fashion do not usually become medicolegal problems.

Equipment Failure

As previously reviewed in this chapter, diagnostic and operative hysteroscopic procedures utilize complex equipment requiring attention for correct instrument assembly, connection to electrical or laser energy sources as well as connections to video cameras and monitors for proper administration of distending media. In a recent prospective observation study by Courdier, equipment failures were divided into four categories: imaging, transmission of fluids and light, the electric circuit, and surgical instruments. During 51 operative hysteroscopies, 37.3% (19) were complicated by equipment failures. Most common problems included nonavailable or damaged hysteroscopic connections and fittings, faulty connections, or an incorrect setting of the suction system. Surgeon error and staff error contributed to many of the documented errors. Surgeons performing diagnostic and operative hysteroscopy should be able to assemble and disassemble the hysteroscopic instruments, be able to connect and activate the video monitoring systems, and be capable of operating the hysteroscopic fluid monitoring systems. Creation of checklists for surgeons and assistants to review prior to performing the hysteroscopic procedure may be of value.

BEST SURGICAL PRACTICES

- Abnormal uterine bleeding is most comprehensively evaluated by hysteroscopy and sampling as opposed to blind curettage.
- A gynecologist or gynecologist-in-training can best learn hysteroscopy by performing 25 to 50 diagnostic hysteroscopies before initiating operative procedures.
- Infusion of liquid, low-viscosity media during operative hysteroscopy must be accurately measured and recorded, especially hypoosmolar media such as glycine or sorbitol.
- Perforation during operative hysteroscopy with an energy device requires laparotomy to inspect intraabdominal structures for thermal injury.
- A clear, unobstructed view of the intrauterine milieu is necessary before the initiation of any endouterine surgery.

Chapter 19

Control of Pelvic Hemorrhage

Lindsay M. Kuroki

David G. Mutch

DEFINITIONS

Argon beam—Ionizing energy transmitted through argon gas stream that achieves hemostasis by creating eschar, tissue destruction, and formation of necrotic tissue with less depth of penetration than conventional electrocoagulation.

Autologous blood transfusion—Transfusion performed with the patient's own blood. This may benefit patients with a rare blood type and antibodies and may even be an acceptable alternative to Jehovah's Witness patients. However, these are the exceptions, and in general, autologous blood donation is not routinely recommended due to evidence that shows that autologous blood donors are more likely to undergo any transfusion (autologous and/or allogeneic blood) due to lower baseline preoperative hematocrit and a more liberal transfusion policy when using autologous blood.

Bogota bag—Sterile plastic bag used for temporary abdominal closure in setting of damage control protocol, suspected intra-abdominal compartment syndrome, or as a temporizing abdominal closure in the face of severe hemorrhage requiring packing and future evaluation with delayed closure.

P.337

Hemostatic clips—Small V-shaped clips of stainless steel, titanium, or plastic that can be applied on small vessels or tissue for hemostasis.

Homologous blood transfusion—Transfusion of blood or blood products from another human being.

Parachute pack—Sometimes called an umbrella pack. A towel or large sheet is inserted through the vagina into the pelvis, and it is then filled from below with gauze packing. The edges are twisted together, and the pack is pulled down against the pelvic floor to control deep pelvic bleeding after pelvic surgery, most commonly exenteration.

Peanut dissector—A long clamp with a small cotton bud placed in the tip of the jaws. It is a useful tool for blunt pressure dissection of small spaces.

Total blood volume—About 8% of total body weight or between 4.5 and 5.0 L in the average woman. Acute blood loss of 25% of total blood volume (about 1,500 mL) produces symptoms of tachycardia, hypotension, and decreased urine output. Transfusion should be considered when operative blood loss exceeds 15% of total blood volume. This can be roughly calculated by multiplying the patient's weight in kilograms by 10 (750 mL for a 75-kg woman).

The prevention and control of bleeding are fundamental to the success of any operation. Preoperative, intraoperative, and postoperative hemorrhage are potential complications in every patient undergoing gynecologic surgery. Preoperative hemorrhage is encountered in a variety of circumstances, such as intraperitoneal bleeding from a ruptured ectopic pregnancy or in patients on anticoagulation who have intraperitoneal hemorrhage associated with ovulation. Intraoperative hemorrhage can result from vascular injury, and postoperative bleeding is often due to unrecognized bleeding at the time of surgery that was obscured by reflex vasoconstriction or hypotension.

Surgical techniques and operations are designed to control bleeding and avoid hemorrhage, but inevitably,

every surgeon will be confronted with uncontrolled bleeding. The surgeon who anticipates the next procedural step has the fund of knowledge to troubleshoot and the surgical skill set to act quickly will exhibit the leadership necessary to direct the operative team so that control of bleeding can be accomplished promptly and effectively.

Many benign gynecologic conditions are associated with abnormal uterine bleeding (AUB). Daily dietary intake of iron usually is sufficient to replace the iron lost with normal menstruation but may be inadequate to compensate for acute blood loss anemia. Outpatient preoperative evaluation of such patients should include a pregnancy test; complete blood count (CBC), including mean corpuscle volume (MCV); measurement of thyroid-stimulating hormone (TSH); and a Pap smear. Based on the history elicited, testing for *Chlamydia trachomatis* should be considered in patients who are at high risk for infection; coagulation studies in those who have a strong personal or family history of bleeding disorders; and an endometrial biopsy in patients suspected of hyperplasia or malignancy. Transfusion before elective gynecologic surgery may be indicated; however, other alternatives such as hormonal therapy and iron supplementation may also help optimize the patient's hemoglobin and iron stores. The preoperative use of epoetin alfa (recombinant erythropoietin) for correction of preoperative anemia has been used successfully in orthopedics. However, its application in gynecologic surgery remains unclear and is probably most applicable in gynecologic patients with chronic renal failure, nonmyeloid (hematopoietic) leukemia, or human immunodeficiency virus (HIV). Occasionally, a patient's personal or religious beliefs (e.g., Jehovah's Witnesses) may not be compatible with receiving blood products and therefore require more extensive preoperative counseling and/or treatment planning before elective surgery. Some of these patients may also benefit from recombinant erythropoietin.

FUNDAMENTAL CONCEPTS OF NORMAL COAGULATION

Every surgeon should understand the basic mechanisms of normal hemostasis that can be applied when surgical injury to tissue is inflicted. Bleeding during gynecologic surgery usually results from cutting or injuring a vessel, but occasionally, it may result from a preexisting condition or defect in the clotting mechanism. The surgeon should be able to quickly recognize when normal hemostasis is interdicted and operate efficiently to correct vascular injuries and coagulopathies and minimize blood loss.

The following is a discussion of the principles and concepts of normal hemostasis, abnormal hemostasis (congenital and acquired), and management techniques. Coagulation is the working interrelation of five aspects of a complex biochemical and vascular system that causes the formation and dissolution of the fibrin platelet plug. These five components are (a) vasculature, (b) platelets, (c) plasma clotting proteins, (d) fibrinolysis and clot inhibition, and (e) the hypercoagulable response. How these five components interrelate in the normal setting must be understood before one can appreciate how they relate to bleeding or abnormal clotting in disease states. For the purposes of this chapter, we will focus on the first three factors.

Vasculature

The vasculature presents an endothelial-lined flexible conduit through which red cells, white cells, platelets, and all of the plasma proteins flow. At the interface between the flowing blood and vessel wall are several inhibitory biochemical systems that prevent the generation of the platelet-thrombin clot. The antiplatelet substance prostacyclin, produced in the vessel wall, inhibits platelet adhesion to the site of injury. The surface antithrombin III-heparin sulfate complex inhibits deposition of thrombin and fibrin.

A tear in the vessel wall removes the endothelial cell layer, exposing the basement membrane, smooth muscle, collagen, and supporting adventitia. These substances are biochemical activators of platelets and have their own thromboplastic activity. This activity initiates fibrin generation and deposition. A disease or medication that

interferes with or intensifies this process can cause bleeding or inappropriate clotting, respectively. The vessel wall is diagrammed in [Figure 19.1](#).

Congenital diseases associated with inadequate connective tissue and vascular dysfunction associated with bleeding are rare. The more frequently seen conditions are hereditary hemorrhagic telangiectasia, Ehlers-Danlos syndrome, and Marfan syndrome, which are characterized by defects in collagen, leading to poor clot formation and platelet activation at the injured site.

Acquired diseases associated with bleeding include deficiencies in vitamin C; Cushing syndrome; acute and chronic inflammatory diseases, such as infectious vasculitis and immune vasculitis; pyrogenic purpura; embolic purpura; and anaphylactoid reactions from drugs. Myeloproliferative disorders, such as multiple myeloma and Waldenström macroglobulinemia,

P.338

produce abnormal proteins that interfere with vascular function and therefore permit bleeding.

FIGURE 19.1 Vessel cross-section.

Platelet Function

Platelets are disk-shaped fragments of the large multinucleated megakaryocytes released from the bone marrow on a daily basis (normal count is $150 \times 10^3/\text{mL}$ to $400 \times 10^3/\text{mL}$), with a lifespan between 8 and 10 days ([Fig. 19.2](#)). The surface activation of the receptor sites on the platelet results in a biochemical chain reaction, generating thromboxane A_2 , which in turn causes contraction of the protein thrombosthenin. This triggers platelet release of dense granules with nonmetabolic adenosine diphosphate (ADP). ADP is a potent platelet-aggregating agent that stimulates more platelets and eventually generates a platelet plug.

The congenital diseases associated with poor platelet function are divided into four types of dysfunction: (a) adhesion to collagen, (b) adhesion to subendothelium, (c) release reaction defects, and (d) ADP aggregation defects. Von Willebrand disease (vWD) ([Table 19.1](#)) is the most common hereditary coagulation abnormality, although acquired forms have been described. Excessive bleeding results from the absence, decreased production, or abnormal function of von Willebrand factor, a large multimeric protein synthesized by megakaryocytes and vascular endothelium. This protein is responsible for the proper binding of platelets to the exposed collagen surface at the site of vascular injury. Its absence, therefore, prevents formation of the platelet plug necessary for hemostasis. Clinical manifestations of vWD vary in severity and often go unrecognized until

to aspirin or other antiplatelet medications, increasing their tendency to bleed more at the time of surgery.

FIGURE 19.2 Platelet cross-section.

TABLE 19.1 More Commonly Seen Rare Congenital Clotting Disorders

NAME	INCIDENCE (PER MILLION)	TREATMENT
Factor VIII (classic hemophilia A, sex-linked)	60-80	FVIII concentrate
Factor IX (classic hemophilia B, sex-linked)	15-20	FIX concentrate
von Willebrand disease (dominant, autosomal)	5-10	Cryoprecipitate (DDAVP), factor VIII concentrate with von Willebrand factor

DDAVP, deamino-D-arginine vasopressin. The remainder of the known congenital clotting factors are very rare and occur with such low frequency that their discussion, diagnosis, and management can be found elsewhere (see Harker LA. *Hemostasis manual*, 2nd ed. Philadelphia, PA: FA Davis, 1974; Corriveau DM, Fritsma GA. *Hemostasis and thrombosis*. Philadelphia, PA: JB Lippincott Co., 1988; Triplett DA, ed. *Laboratory evaluation of coagulation*. Chicago, IL: ASCP Press, 1982).

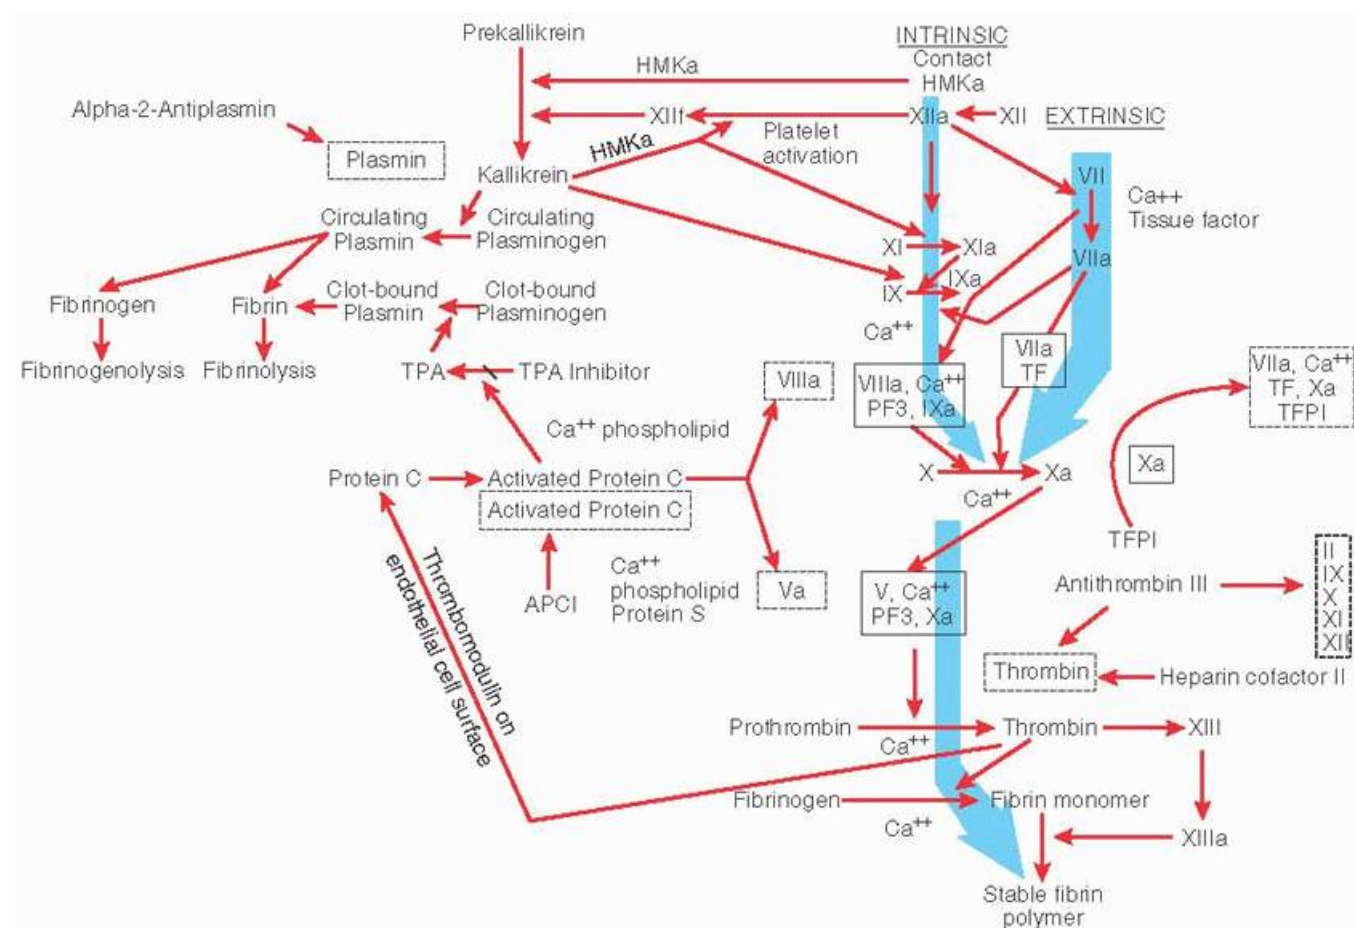

FIGURE 19.3 Coagulation system. *Dashed boxes* indicate destruction of factors. (APC1, activated protein C1; HMKa, high molecular weight kininogen; PF3, platelet factor 3; TPA, tissue plasminogen activator; TF, tissue factor; TFPI, tissue factor pathway inhibitor.)

Acquired defects in platelet function are much more common and can be classified into two groups: (a) those due to an underlying condition, such as renal failure, myeloproliferative disorders (polycythemia vera, chronic myelogenous leukemia), and increased fibrin split products in consumptive coagulopathies, and (b) those that are iatrogenic, such as defects caused by medications (aspirin, nonsteroidal anti-inflammatory drugs, antibiotics, antihistamines, tricyclic antidepressants, dextran) and cardiopulmonary bypass surgery.

The laboratory assessment of platelet function has been extrapolated from the research laboratory and is now more readily available. The routine analysis of platelet function should begin with a platelet count and platelet function analyzer (PFA-100). However, in special cases, evaluation of platelet adhesion and aggregation and/or biochemical markers for measuring platelet turnover (e.g., platelet factor 4 and β -thromboglobulin assays) may be useful, although not predictive of surgical bleeding.

Plasma Clotting Proteins

Plasma clotting proteins are a group of serine proteases and cofactors that interact in a synergistic system to generate fibrin. The activation of the clotting system can be initiated in two ways: either by contact activation with factor XII or through thromboplastin activation of factor VII. The clotting cascade is diagrammed in [Figure 19.3](#). The most common congenital factor deficiencies associated with bleeding are hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency). Both are seen in males and rarely in female disorders with sexlinked inheritance patterns. The majority of other congenital bleeding disorders have an autosomal recessive inheritance pattern or a dominant pattern with variable penetrance, making them extremely rare and less pertinent to this discussion.

However, acquired factor deficiencies are common. For example, critically ill patients on antibiotics that kill vitamin K-producing bacteria in the intestine and those who are diet restricted to nothing by mouth are at high risk for a coagulopathy due to loss of vitamin K-dependent factors II, VII, IX, and X. Other commonly acquired multifactor deficiencies are seen in acute and chronic liver disease such as viral hepatitis and alcoholic cirrhosis; consumptive coagulopathies, as in sepsis and placenta abruption; washout coagulopathies, seen in patients who require multiple transfusions after severe blood loss anemia; and major trauma.

The laboratory assessment of the plasma clotting factors has traditionally begun with prothrombin time (PT; factors V, VII, and X, prothrombin, and fibrinogen) and activated partial thromboplastin time (APTT; factors VIII, IX, XI, and XII). Specific factor assays also can identify the exact deficiencies. One must remember that a factor deficiency as low as 30% can generate a normal PT and APTT. This relation is important in investigating minimal prolongations of the PT or APTT that appear insignificant but nonetheless could be obscuring a deficiency. The tissue factor pathway inhibitor modulates activated factors X and VIII but is not apparently clinically significant.

PREOPERATIVE COAGULATION ASSESSMENT FOR SURGICAL PATIENTS

Preoperative evaluation of any patient may be divided into two general categories: elective versus emergency surgery.

Elective Surgery

The elective gynecologic surgical patient must be evaluated by general medical history and specific nature of the surgery. **Table 19.2** highlights the most important positive and negative findings. Preoperative coagulation screening (**Table 19.3**) should supplement the history and physical and be individualized according to risk factors elicited (e.g., a prior emergency surgical procedure; positive personal or family history of spontaneous bleeding or easy bruising; use of medications that can affect coagulation, such as antiplatelet medication; acquired vitamin K deficiency; and fibrinolytic therapy).

The risks of blood-borne infections and adverse reactions are always present, but the documented need for blood transfusion(s) as a lifesaving measure will validate the decision so long as it is congruent with the patient's

religious and personal beliefs. Standard preoperative orders for blood require knowledge of the specific needs of the patient and the indicated surgery. For the routine gynecologic procedure, such as simple hysterectomy in an otherwise healthy woman, a type and screen is appropriate. If an unexpected antibody is identified, the blood bank should notify the ordering physician and set aside 2 units of antigen-negative, crossmatched, compatible blood. In an emergency, the blood bank can always release universal donor type O-negative blood immediately.

In more complex procedures such as pelvic exenteration for cancer, where there usually is significant blood loss, a type and crossmatch for the average number of units used are appropriate and encouraged. With extremely difficult procedures or other complicating medical conditions, additional blood, fresh frozen plasma, and platelets may be required during the procedure and should be requested preoperatively.

Emergency Surgery

As an emergency procedure proceeds, decisions regarding blood replacement must be made. A direct approach to blood replacement therapy and the complications of such therapy depends on a clear understanding of the following concepts.

1. Transfusion with packed red cells may help compensate for the volume of the estimated blood loss but iatrogenically may cause a bleeding disorder (e.g., thrombocytopenic hemophilia). Therefore, platelets and fresh frozen plasma may also be indicated.
2. The patient's bleeding potential is dynamic and will change rapidly and frequently with the loss of blood and replacement therapy.
3. Direct monitoring before, during, and after surgery offers the best chance to diagnose and manage bleeding problems. It also allows formulation of plans and adjustment of the replacement therapy.

COMPONENT THERAPY FOR REPLACEMENT BEFORE SURGERY

With surgery planned, the preoperative data can be evaluated. Assuming the patient does not have hemophilia, vWD, severe liver disease, or liver failure, a prolonged PT and APTT may suggest a less common acquired or congenital bleeding disorder. Assistance from a clinical pathologist or hematologist should be requested if an intrinsic bleeding disorder is suspected.

TABLE 19.3 Tests to Indicate Coagulation Status

TEST	REFERENCE RANGE ^a	LEVEL OF ALARM	SIGNIFICANCE
Hematocrit (%)	37-47	25	Tissue anoxia
White cell count (mL)	4×10^3 to 12×10^3	3×10^3 to 25×10^3	Susceptibility to infection, leukemia
Platelet count (mL)	140×10^3 to 400×10^3	100×10^3 to 700×10^3	Bleeding, myeloproliferative disorder
Fibrinogen (mg/dL)	150-400	100	Bleeding, liver disease, intravascular consumption

Prothrombin time (s)	10-13	14	Bleeding factor deficiency
Activated partial thromboplastin time (s)	28-38	40	Bleeding factor deficiency, inhibitor
PFA-100	Collagen-epinephrine	Prolonged closure time	Screen for medication effect
Bleeding time (will not predict surgical bleeding)			
^a Reference ranges may vary in each laboratory, reflecting method, instrumentation, and reagents.			

P.341

COMPONENT THERAPY FOR REPLACEMENT DURING SURGERY

According to Schiffman and Steinbronn, when intraoperative blood loss exceeds 15% of the patient's estimated blood volume, the surgeon should consider red blood cell transfusion to replace the acute blood loss. As a general rule, 15% of an adult's blood volume (in milliliters) equals the patient's weight (in kilograms) times 10. For example, for a 75-kg woman (165 pounds), 15% of blood volume is (75×10) 750 mL. When considering the risks and benefits of transfusing blood, the following should be considered: the patient's estimated blood volume and hemoglobin/hematocrit prior to surgery, the estimated intraoperative blood loss, the anticipated additional blood loss, and the risk of hypoxic and metabolic complications.

When massive blood replacement therapy is under way, intraoperative monitoring of coagulation at 2-hour intervals or after every 10 units of blood transfused is usually sufficient. It is important to remember that a patient bleeding during a surgical procedure has a higher demand for clotting factors and platelets than does a patient at bed rest. The use of blood and blood components in the management of massive bleeding that is due to a major vessel rupture has the following objectives:

1. To maintain sufficient blood volume and circulating red cells to carry enough oxygen to sustain life.
2. To replace blood sufficiently to achieve adequate coagulation and hemostasis, assuming there was extensive loss of plasma clotting factors and platelets.
3. To avoid falling so far behind in replacement that consumptive coagulopathy leads to exacerbated bleeding at the microvascular level due to insufficient clotting factors and platelets.

These objectives require repeated assessment of the patient throughout the surgical procedure and clear communication with anesthesia and the operating room staff.

The following guidelines are recommended for component therapy in clinical situations requiring massive blood replacement to maintain normal hemostasis.

Correction of the deficit in blood volume with crystalloid volume expanders will generally maintain hemodynamic stability, while transfusion of packed red blood cells is used to improve and maintain tissue oxygenation. Each unit of packed cells contains approximately 250 mL of red cells and, in an adult, will raise the hematocrit by roughly 3% unless there is continued bleeding (**Table 19.4**). Development of massive transfusion protocols has resulted in improved outcomes and decreased mortality. Most protocols focus on delivering a minimum ratio of 2 units (500 mL) of fresh frozen plasma for every 3 units of packed red blood cells and 1 unit of platelets (300 mL)

for every 5 units of packed red blood cells. The size and age of the patient affect blood replacement. Posttransfusion labs should include CBC, PT, and APTT.

Platelets should be given when the platelet count falls below 100,000/mL in massive hemorrhage (measurement error of a platelet count can be as high as 62,000/mL in a bleeding patient). When a long surgical procedure is anticipated, or when more than 6 units of blood are given, 6 units of platelets in a volume of 300 mL should be given toward

P.342

the end of the surgical procedure or when surgical hemostasis is achieved. This amount should be administered once to provide a maximum bolus effect. Because platelets are often difficult to obtain, their use should be reserved until near the end of the procedure. Pooling and transporting the platelets can take up to an hour, so the blood bank should be given sufficient notice to have them readily available in surgery when needed. In assessing the patient's coagulation status, it should be remembered that clotting factors are constantly changing.

TABLE 19.4 Blood Products

BLOOD PRODUCT	VOLUME (ML)	ADDITIONAL FACTORS	EXPECTED RESPONSE	COMMON INDICATIONS
PRBC 1 unit	200-250	Fibrinogen: 10-75 mg	Increase: 1 mg/dL Hgb 3% Hct	ABLA MTP Surgical blood loss
Platelets SDA	300-500	Fibrinogen: 2-4 mg/mL (360-900 mg)	Increase: 30-60 K/mm ³	Plt count <10 K MTP
RDP ^a	50 per unit	Clotting factors: Equivalent of 200-250 mL of plasma "6 pack" of pooled RDP similar to SDP		Bleeding with known qualitative plt defect
FFP ^b 1 unit	180-300	Fibrinogen: 400 mg Clotting factors: 1 mL contains 1 active unit of each factor	Decrease: PT/INR PTT	Coagulopathy Warfarin overdose DIC
Cryo 10 pack		Fibrinogen: 1,200-1,500 Clotting factors: VIII, vWF, XII	Decrease: PT/INR PTT Increase: Fibrinogen	vWD DIC Hemophilia A

^a4-10 RDP units are pooled prior to transfusion.

^bDuration of FFP effect is approximately 6 h.

When the PT and APTT are prolonged (more than 14 and 40 seconds, respectively) after replacement therapy, intrinsic disease must be considered initially, if only to be ruled out later. A borderline hemophiliac or patient with liver disease may manifest excessive bleeding after stress, trauma, or blood replacement because of the increased coagulation needs. Therefore, administration of fresh frozen plasma in 2 units (500-mL) doses should begin to correct the deficiencies caused by massive red blood cell replacement. If oozing continues despite the rapid transfusion of 6 units of fresh frozen plasma, a clotting problem or other ongoing bleeding disorders should be suspected and additional support sought.

When the fibrinogen level falls below 100 mg/dL, transfusion of 20 units of cryoprecipitate will provide about 150 mg/dL fibrinogen in a 70-kg person. A low fibrinogen level is rare because fibrinogen is stable and present in fresh frozen plasma. Liver disease or intravascular consumption must be suspected if the fibrinogen level is initially less than 100 mg/dL and remains low throughout surgery and recovery. Twenty units of cryoprecipitate will achieve therapeutic levels quickly and permit monitoring over several hours.

The goals of intraoperative monitoring are as follows:

- To assess changes in the coagulation mechanism resulting from blood loss and replacement therapy.
- To identify the coagulation components affected and determine the correct components to initiate therapy and achieve the following values: PT less than 14 seconds, APTT less than 40 seconds, fibrinogen more than 100 mg/dL, and platelets more than $80 \times 10^3/\text{mL}$. Posttransfusion laboratory monitoring should be drawn after 1 to 2 hours to determine the success of replacement.
- To assess the efficacy of replacement component therapy in an extensive operative procedure.

COMPONENT THERAPY FOR POSTOPERATIVE REPLACEMENT

The presurgical and intraoperative threshold levels for hematocrit, platelet count, PT, APTT, fibrinogen, and clot retraction also apply postoperatively, and a comparison of these values provides an accurate assessment of the bleeding patient. When laboratory values are abnormal, however, further surgery can be delayed until an attempt at aggressive specific component therapy is made. When abnormal coagulation studies exist, the following causes predominate, in order of frequency (most frequent first):

1. Low platelet count owing to transfusion of only packed red cells or fresh frozen plasma.
2. Prolonged PT and APTT due to transfusion of packed red cells without fresh frozen plasma. Careful monitoring of venous and arterial pressure, as well as cardiac output, should be considered in blood component therapy. Often, a slower rate of administration can achieve hemostasis without cardiovascular overload. If nearly normal coagulation values are achieved, but bleeding continues, surgical causes for bleeding should be considered.
3. Low fibrinogen level owing to dilution with plasma expanders or concurrent development of a disseminated intravascular coagulation (DIC).

The goals of postoperative monitoring are as follows:

- To assess for a coagulopathy and determine possible etiologies, including blood replacement.
- To determine the effectiveness of specific component therapy and identify the need for additional components.
- To enable the surgeon to distinguish surgical from nonsurgical bleeding.

Close postoperative monitoring, whether the patient is bleeding or not, will achieve these objectives with the ultimate goal of recognizing and resolving bleeding disorders in a timely manner.

RISKS OF BLOOD TRANSFUSION

Transfusions of whole blood were given sporadically before 1900, usually to treat specific diseases rather than to replace lost blood volume. It was not until the work of Cannon and Bayliss in 1919, and of Blalock in 1930, that it was proven that the important factors in shock were the loss of circulating blood volume and the decreased return of venous blood to the right heart. Eventually, banking and storage of donated blood became possible with refrigeration and the addition of sugar and later sodium citrate as an anticoagulant.

Homologous blood must be collected from carefully selected volunteer donors and properly matched to the potential recipient. The risks of red blood cell transfusion were reviewed by a National Institutes of Health and Food and Drug Administration Consensus Development Conference on Perioperative Red Cell Transfusion and published in 1988. The following excerpt is taken directly from their report.

In deciding whether to use red blood cell transfusion in the perioperative period, the need for possibly improved oxygenation must be weighed against the risks of adverse consequences, both short term and long term. The disadvantages are of two general types (**Table 19.5**): transmission of infection and adverse effects attributable to immune mechanisms. In addition, massive transfusion, defined as the replacement by transfusion of more than 50% of a patient's blood volume in 12 to 24 hours, may be associated with a number of hemostatic and metabolic complications (e.g., ionized calcium, potassium, and acid-base disturbances).

In modern blood banking practice, bacterial contamination of red blood cell units is rare. For practical purposes, the transmissible agents of greatest concern are viruses.

- Cytomegalovirus infection occurs with moderate frequency among those recipients without prior infection. Most of these infections are asymptomatic, except among immunocompromised people. The use of the newer leukocyte reduction filters ($<5 \times 10^6$) is under extensive clinical study and application as an alternative to cytomegalovirus-negative blood.
- Human T-cell lymphotropic viruses occur with low but not negligible frequency among donor populations in the United States. It is not known whether transfusion-transmitted infection with these viruses results in T-cell leukemia/lymphoma and/or neurologic disease several to many years later.
- On rare occasions, other microbial agents—including parvoviruses, malaria, *Toxoplasma*, Epstein-Barr virus, and *Babesia*—cause infection and disease.

P.343

TABLE 19.5 Blood Transfusion Risks

DISEASE OR SITUATION	RISK
Viral infection	
HIV	1:1.9 million
HTLV	1:250,000-1:2.0 million

Hepatitis B

1:180,000

Hepatitis C

1:1.6 million

Bacterial contamination

Platelet packs (stored at room temperature)

1:12,000

Packed or whole red blood cells

1:5 million

Fatal red cell hemolytic reaction

1:250,000-1:1.1 million

Delayed red cell hemolytic reaction

1:1,000-1:1,500

TRALI

1:5,000

Febrile red cell nonhemolytic reaction

1:100

Allergic (urticarial reaction)

1:100

Anaphylactic reaction

1:150,000

HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; TRALI, transfusion-related acute lung injury.

From Zoon KC. Ten years after: what has been achieved by Consent Decrees: the FDA view. *Paper presented at: Fifth Annual FDA and the Changing Paradigm for Blood Regulation*; January 16-18, 2002; New Orleans, LA, 2002; Schreiber GB, Busch MP, Kleinman SH, et al. The risk of transfusion-transmitted viral infections: the retrovirus epidemiology donor study. *N Engl J Med* 1996;334:1685; Dziechowski JS, Anderson KC. Transfusion biology and therapy. In: Fauci AS, Martin JB, Braunwald E, et al., eds. *Harrison's principles of internal medicine*. 14th ed. New York, NY: McGraw-Hill, 1998:718; Goodnough LT, Brecher ME, Kanter MH, et al. Transfusion medicine: first of two parts—blood transfusion. *N Engl J Med* 1999;340:438.

It is known that the incidence of hepatitis transmission increases with the number of donor exposures. This relationship is probably true for other transfusion-transmitted infections. HIV presently poses only a remote hazard because of strict donor selection and laboratory screening procedures. The consequences of HIV infection are rarely seen until 2 or many more years have elapsed, but ultimately, morbidity and mortality are extremely high.

Immunologic consequences also complicate homologous red blood cell transfusion. Hemolytic and nonhemolytic reactions are largely caused by alloimmunization to red blood cell and leukocyte antigens. Compatibility testing virtually has eliminated immediate hemolytic transfusion reactions; however, if they occur, they are largely due to human error. Nonhemolytic febrile reactions occur in 1% to 2% of recipients due to sensitization to leukocyte antigens but may be reduced by the use of leukocyte reduction filters ($<5 \times 10^6$).

It is important for gynecologic surgeons to discuss with their patients the possible need for transfusion of blood products and review the risks, benefits, and alternatives of such treatment. The most common transfusion-

related viral infection, however, is non-A, non-B hepatitis, which accounts for 90% to 95% of cases of previous transfusion-acquired hepatitis and possibly as many as 3,000 deaths per year in the United States. When mortality or significant morbidity occurs with blood transfusion, the gynecologic surgeon must be able to show that the transfusion was indicated.

There are alternatives to blood and blood component transfusion that may be considered in critically ill patients such as those with sepsis and DIC. The drug-activated protein C, drotrecogin alfa (Xigris), is recombinant human-activated protein C (drotrecogin alfa, activated). It is used in replacement therapy in sepsis and holds a great promise in the management and survival in sepsis. By replacing this essential naturally occurring anticoagulant, there is reversal of the bleeding and thrombosis seen with sepsis. Its specific application in septic gynecologic surgical patients has not been reported in any large study.

Recombinant-activated factor VII (FVII) (NovoSeven) has been clinically demonstrated to successfully manage patients with FVIII and FIX inhibitors. It has also been used in the management of bleeding in cardiovascular surgery, liver failure, Coumadin overdose, and DIC. It has significantly reduced the use of blood components in these disorders, and although expensive, it has the potential to greatly improve patient outcomes.

By reducing the need for blood and blood components with the use of activated protein C (drotrecogin alfa), and recombinant-activated FVII, one can reduce the infectious disease exposure of blood as well as the generation of allogeneic antibodies.

AUTOLOGOUS BLOOD TRANSFUSION

Blood collected from a patient for retransfusion at a later time into the same patient is called autologous blood. Autologous blood transfusions account for over 5% of blood donated in the United States, with the majority obtained by preoperative donation, and have been endorsed by the Council on Scientific Affairs of the American Medical Association and by the Committee on Hospital Transfusion Practice of the American Association of Blood Banks.

The American Association of Blood Banks' standards for elective preoperative autologous blood donation include the following guidelines:

- A hemoglobin of no less than 11 g/dL or a packed cell volume of no less than 34%.
- Phlebotomy no more frequently than every 3 days and not within 72 hours of surgery.

Preoperative autologous donation is generally discouraged in patients over the age of 80 and absolutely contraindicated in patients with an active infection, and any of the following conditions would also preclude a patient from undergoing preoperative autologous donation: unstable angina or angina at rest, a myocardial infarction within the last 3 months, heart failure, aortic stenosis, ventricular arrhythmias, transient ischemic attacks, or marked hypertension.

If established screening and administration guidelines are followed, autologous blood has potential to be the safest type of blood for transfusion. It minimizes the risks of immunologically mediated hemolytic, febrile, or allergic reactions as well as viral transmissions such as hepatitis, malaria, cytomegalovirus, and HIV. In patients with rare blood types who

P.344

have antibodies to common blood antigens, it may be the only blood available for transfusion. Autologous blood transfusion may be acceptable to Jehovah's Witnesses and should be offered preoperatively if a patient meets criteria for donation and based on the indicated procedure.

Despite these benefits, several aspects of the provision of preoperative blood donation remain controversial, including extent of testing, release of infectious units, participation of known infectious donors, transfusion of

autologous blood to other recipients, the use of erythropoietin, and cost-effectiveness. Furthermore, improper handling, storage, or labeling of saved units has potential to cause several complications including hemolysis, bacterial infection/sepsis, and pulmonary edema due to volume overload, respectively. A meta-analysis by Forgie et al. found that patients who underwent preoperative autologous donations were more likely to undergo any transfusion with autologous and/or allogeneic blood (odds ratio 3.0) due to both a lower preoperative hematocrit (average of 3.5 units lower in patients who donated autologous blood compared to controls) and a more liberal transfusion policy when using autologous blood. Another drawback of autologous blood donation is the high cost that accounts for the extra time, enhanced clerical requirements, storage, and early delivery to the hospital. This expense is only exacerbated by the fact that approximately 50% of donated blood is generally wasted, rather than transfused to other patients. Depending on the age of the patient and likelihood of transfusion, the cost-effectiveness of autologous transfusion ranges from \$235,000 to \$23 million per quality adjusted year of life saved. Given these disadvantages, and considering that only about 2% of patients undergoing elective hysterectomy require blood transfusion(s), routine preoperative autologous donation cannot be recommended.

Intraoperative Autologous Transfusion

The frequency of intraoperative autologous transfusion has increased appreciably in the past decade, especially for cardiovascular operations. Keeling and colleagues reported on the use of the Haemonetics Cell Saver for autologous intraoperative transfusion in 725 consecutive general hospital patients. Seventy-five percent were cardiovascular patients, but a variety of other patients, including gynecology and obstetric patients, were represented. At least until additional data are available to the contrary, intraoperative autologous transfusion is contraindicated in patients with malignant disease and in patients with bacterial contamination of blood in the operative field. A series of 25 myomectomy operations by Shapiro and Toledo demonstrated that intraoperative autologous transfusion is convenient to use and does not interfere with the performance of the procedure.

The Haemonetics Cell Saver operates by retrieving blood from the operative site by suctioning it into a double-lumen catheter, in which it is immediately anticoagulated with heparin. It is then collected in a cardiomy reservoir, where a filter removes gross debris. The blood is then pumped to a spinning centrifuge bowl, where the red blood cells are separated, washed with normal saline solution, and then concentrated to a hematocrit of about 50%. The supernatant waste that is subsequently collected contains saline, anticoagulant, activated coagulation factors, platelets, leukocytes, free hemoglobin, and other small debris. The washed, packed red blood cells are pumped into a reinfusion bag. The blood is then directly transfused to the patient through a filter. It takes approximately 8 to 10 minutes to process about 250 mL of packed cells. The machine is maintained and operated by a trained technician.

BASIC SURGICAL PRINCIPLES TO AVOID EXCESSIVE BLEEDING IN PELVIC SURGERY

Knowledge of basic anatomy and precise surgical technique are the basis for avoiding hemorrhage. Good exposure, appropriate instruments and correct placement of clamps, skillful dissection technique, and careful suture placement may help minimize blood loss. The surgeon who knows the patient, the disease entity being treated, the technical details of the planned surgical procedure, and his or her own technical abilities can confidently make judgments that minimize risks and complications, allowing for the best possible surgical outcome.

Among the many contributions to surgery made by William S. Halsted, first chief of surgery at Johns Hopkins Hospital, was a surgical technique that emphasized meticulous dissection, gentleness in the handling of tissues, accuracy in hemostasis, precision in wound approximation, and asepsis. It is impossible to place too much emphasis on the need for optimal exposure to limit blood loss. During vaginal operations, a contracted pelvic outlet will limit access and visibility, and often, a leiomyomatous uterus may require morcellation to allow

sufficient exposure for safe vaginal removal. A Schuchardt incision may be required to improve exposure during vaginal operations. If exposure is inadequate, bleeding from vessels in the upper broad ligament may not be controllable from below, and an abdominal incision may be necessary to achieve final hemostasis. When hemorrhage is a problem during vaginal or laparoscopic surgery, the question always arises, "When should the operation be converted to an open abdominal procedure so that improved exposure and better access can be used to control the bleeding?" The answer to this question will vary depending on a variety of circumstances, but good exposure will go a long way. Once the decision is made to convert to an exploratory laparotomy, the exposure achieved will depend on the choice of incision, the method of retracting, the placement and intensity of the lights, and presence of assistants. Suction should be available and is preferred over sponges for two reasons. First, sponges can cause damage to delicate serosal surfaces. Second, a determination of the amount of blood lost can be more accurate if the largest percentage has actually been suctioned into a calibrated bottle and measured. One can then add to this exact amount an estimate of the amount of blood lost on the drapes, sponges, and lap packs. Good lighting of the surgical field is important. In addition to the standard surgical room lights, a headlight worn by the surgeon and/or the assistants is very useful in providing focused lighting deep in the pelvis. There are also lighted retractors and disposable, fiberoptic, and lighted suction irrigators, which may be helpful in vaginal surgery.

For pelvic laparotomy, the patient usually is placed in Trendelenburg position and the bowel is packed with moist laparotomy sponges to allow better exposure into the pelvis. Depending on the incision type, a Bookwalter or Balfour retractor with a C-arm may be useful.

It usually is possible and always desirable to keep the number of clamps in the operative field to an absolute minimum so as not to obscure the source of bleeding. The length of the instruments may vary depending on the thickness of the abdominal wall and depth of the pelvis. The handles of the instruments should come all the way out and above the level of the incision so as not to interfere with the operator's view of the pelvis. The surgeon must stand high enough to see down into the pelvis, and the patient's abdominal wall should be at about the level of the operator's umbilicus.

Cushing, a neurosurgeon, introduced the hemostatic silver metal clip in 1911, to occlude cranial vessels inaccessible to ligation. More recently, clips have been made of stainless

P.345

steel, tantalum, and the new synthetic absorbable nonopaque polydioxanone polymer. The latter has the advantage of not causing the streaked artifact of metal clips when subsequent computed tomography (CT) of the pelvis is performed. Clips cause little tissue reaction, are available in different sizes, are easily applied, and provide secure control of bleeding vessels in relatively inaccessible places in the pelvis where ligation would be more difficult. A small vessel can be quickly occluded with a clip even before the vessel is cut, thus keeping the field dry. Clips are especially useful in retroperitoneal dissections. Disposable applicators loaded with multiple clips are available, obviating the need for reloading and facilitating rapid use. If appropriately used, clips can reduce blood loss, facilitate dissection, and reduce operating time.

Working with Bovie, Cushing also pioneered the use of electrosurgery for hemostasis. Modern electrosurgical units are radiofrequency generators that supply 500,000 to 2 million Hz of alternating current to the tip of the electrode. An electrosurgical instrument can be used to coagulate small vessels or to cut through fat or muscle. If a "blend" cut is used, small vessels will be coagulated as the instrument divides the tissue.

The needlepoint electrode can be used for precise incisions with minimal tissue injury from collateral thermal effect. Superficial coagulation of small vessels can be achieved by holding the electrode close to the tissue, pressing the "coagulation" button, and allowing the sparks to jump to the tissue surface. It is important to not let blood pool, as dry surfaces are much more effectively coagulated with the electrosurgical instrument. If bleeding is brisk, the vessel is grasped with a fine-pointed clamp or forceps, and hemostasis can be achieved by touching

the metal clamp with the tip of the electrosurgical instrument and applying current. Bipolar electrodes built into tissue forceps are also very effective for coagulating smaller vessels during tedious dissections. Experience in the use of electrosurgery will result in maximum efficiency with minimum tissue damage.

Argon beam coagulation is another technique to achieve hemostasis that uses a unipolar current of inert argon gas. Since its introduction in the late 1980s, the argon beam coagulator has found wide utility in gynecology but is most commonly utilized in complete cytoreduction of advanced ovarian carcinoma, especially if the liver and diaphragm are involved. It provides a more homogenous, adherent eschar with less depth of necrosis compared with standard electrosurgical coagulation. The flow of argon gas clears and controls the bleeding, and the ionizing energy is transmitted through the argon gas stream. The maximum temperature reached is 110°C, compared with the 205°C of traditional electrosurgical generators, thereby minimizing tissue destruction, charring, and formation of necrosis. With a thorough knowledge of pelvic anatomy, the surgeon should emphasize the development of pelvic planes and spaces. This will avoid unnecessary bleeding and allow more accurate placement of clamps on vessels. Certain parts of the dissection can be delayed until later, especially if blood loss is likely to be increased. For example, during an abdominal hysterectomy, dissection of the bladder away from the cervix and vagina may be associated with blood loss and should not be performed at the beginning of the case. Furthermore, exposure of the anterior lower uterine segment and cervix is not required until the uterine vessels and broad ligament need to be clamped.

In the early days of abdominal pelvic surgery, postoperative hemorrhage was common because an effective technique of hemostasis was not known. The usual method of performing abdominal hysterectomy involved use of a ligature en masse around the lower uterus. It was not until 1889 that Stimson published a technique for secure individual ligation of the uterine and ovarian vessels that significantly reduced the incidence of postoperative hemorrhage. Kelly published a similar technique with illustrations in 1891. In abdominal operations today, all major vascular pedicles should be individually ligated, twice if technically feasible. Delayed-absorbable sutures should be used and square knots firmly tied. Vascular pedicles should be small and the vessels skeletonized as much as possible so that a secure ligature with little extraneous tissue can be accomplished. A vascular pedicle where the tip of the clamp is free, such as the infundibulopelvic ligament, should always be ligated first with a free tie to occlude the vessels. The pedicle is then secured with a transfixion suture ligature placed between the previous free tie and the clamp. This technique avoids hematoma formation and the rare occurrence of a traumatic arteriovenous fistula. If a suture ligature is to be held long for traction or later identification, there is a danger that it will become loosened or be pulled off, with a resulting hematoma or bleeding. Sutures used to ligate vessels should usually be cut and rarely held for traction for that reason. Specifically during a vaginal hysterectomy, the upper broad ligament containing the utero-ovarian ligament and the fallopian tube should be doubly clamped. The lateral-most clamp is replaced by a free tie completely around the pedicle. Tied tightly, this ligature compresses the vessels in the pedicle so that the most medial clamp (the one closest to the uterus) can then be replaced with a suture ligature placed through the pedicle, passed around the tip of the clamp both ways, and tied tightly around the pedicle. This second transfixion ligature is one vascular ligature that is usually held long for identification purposes.

The newer delayed-absorbable sutures and smaller-gauge sutures are strong enough to ligate vessels. However, it is dangerous to use fine suture to ligate large pedicles. The suture may break or cut through the tissue if there is too much tension on the pedicle. Fine needles with small sutures are useful for controlling localized venous or arterial bleeding, but larger suture with bigger bites is less likely to pull through infected or malignant tissue. Proper suture selection for the specific technique is an important part of obtaining hemostasis.

INTRAOPERATIVE MEASURES TO CONTROL PELVIC HEMORRHAGE

Despite adequate technical skills and careful dissection, serious hemorrhage can suddenly complicate any

operative procedure. Excessive bleeding in an area of dissection stains tissues, obscures visibility, restricts technical freedom, and gradually adds up to a significant amount of blood loss that may require replacement. The outcome of such situations is dependent on the surgeon's quick reaction time, knowledge base, technical ability, and leadership to produce a good outcome. The first task is to control the hemorrhage. A finger should immediately be placed on the bleeding point for prompt, atraumatic control. When the blood has been suctioned out and the fingertip exposed, it may be gently rolled off the bleeding point while a fine-tipped clamp or forceps is poised to compress the bleeding vessel and suction is ready to provide exposure. Depending on the location of the bleed and adjacent structures, the Bovie may be used safely by touching the metal clamp with the tip of the electrosurgical instrument and applying current. In most instances, this will adequately control the hemorrhage, although it is often necessary to place another clamp, clip, or suture adjacent to the first in order to control the other side of the lacerated vessel or other nearby bleeders. It is most important to avoid placing too many clamps in the area because this will obscure the bleeding site and cause additional trauma to the vessels. Multiple sutures and/or clips may also cause more

P.346

bleeding and can injure adjacent structures, such as the ureter, bladder, pelvic vessels, and nerves. Electrocautery should not be used to attempt to control significant bleeding. It will only cause increased bleeding and more tissue injury.

If an immediate attempt to control the hemorrhage by simple means is unsuccessful, the bleeding should be controlled again with pressure, with a fingertip, with a sponge forceps, or occasionally by packing. The surgeon should step back, take a deep breath, and carefully consider the situation. The anesthesiologist should be made aware of the hemorrhage and consulted about the patient's stability, blood loss up to this point, availability of blood for transfusion, and intravenous access. The anesthesiologist will play an important role in fluid and blood replacement, monitoring coagulation factors and ensuring perfusion of vital organs. Therefore, it is important that he or she be fully aware of the situation and an active participant in such decisions as how long to safely proceed with surgery. The anticipated difficulty in controlling the hemorrhage must be continually reassessed and clearly communicated among the surgical team. The surgeon should request appropriate help to alleviate the situation, which may include additional suction, specific instruments, more scrub and/or circulating nurses, and even more experienced assistants or intraoperative consults (e.g., gynecologic oncologist, urologist, colorectal surgeon, general surgeon, vascular surgeon). It is prudent to anticipate these things and account for the time it will take for help to arrive. If the patient is stable and any necessary equipment has been readied, it is reasonable to reconsider the anatomy, obtain good exposure, and have another try at controlling the bleeding. Often, the 10 minutes or so that the hemorrhage has been controlled by pressure will result in a substantial reduction in the bleeding. Perhaps the vessel or bleeding site can be more clearly seen and controlled with a clamp, stitch, or clip. Arterial bleeding in the pelvis is usually readily identified due to blood spurting and easier to control because the vessels have thick walls and are not as easily torn further. If the artery can be clamped, it usually can be ligated, a clip can be applied, or both. If an artery has mostly retracted from view with only one small edge still visible, that edge may be grasped with a clamp and gently twisted, thus decreasing the amount of bleeding sufficiently to allow clipping or ligation. Venous hemorrhage in the pelvis may be a much more difficult problem. Such bleeding can vary in magnitude from a trivial ooze to life-threatening hemorrhage. Pelvic veins can be fragile, tortuous, hidden from view, and distended. Blood returning through the lacerated vein can come from multiple deeper sources that are unavailable for ligation. Placing clamps and sutures blindly is dangerous, can inadvertently injure surrounding structures, and can even cause more bleeding. Avoid electrocoagulation of a laceration in a large vein as it will inevitably create a larger hole, making it even more difficult to secure.

Sometimes, the best procedure is to hold a finger or a pack against the bleeding site for a minimum of 5 minutes, after which the bleeding may stop or decrease so that the bleeding vessel can be identified and controlled with a clip or a suture. Digital pressure to control venous bleeding takes advantage of the fact that the pressure in

pelvic veins is very low, and atraumatic compression is less likely to cause further tearing injury to the vein. Sometimes, careful dissection is required to free the vessel above and below the source of bleeding to allow more precise ligation or clipping. If the vessel can be sufficiently liberated, another instrument is gently slipped beneath the first one so that its point is free. Then, a fine ligature is placed around the clamp. If necessary, clips can also be placed on each side of the tie.

If the bleeding has still not been controlled at this point or if bleeding cannot be controlled by pressure on the bleeding site, consultation should be requested for additional help and expertise. By this time, the surgeon may feel frustrated, and it is important to maintain control of the operation and the surgical team. Blood and clotting factors should be replaced as discussed earlier in this chapter, the patient kept warm, and the whole situation reevaluated with input from all members of the team. One should appreciate the importance of avoiding acidosis and hypothermia, as both have potential to interfere with normal functioning of the coagulation system (e.g., assembly of coagulation factor complexes involving calcium and negatively charged phospholipids and enzymatic activity of plasma coagulation proteins, respectively). The surgeon must maintain focus and exert good judgment and leadership. This includes using the skills and ideas of each member of the surgical team and knowing which ideas to use, when to use them, and when to ask for help.

Special Techniques

Diffuse venous oozing, which may be associated with malignancy, inflammation, or extensive lysis of adhesions, can usually be controlled by electrocautery or packing for 5 to 15 minutes. When these techniques are not effective, various hemostatic agents may be considered. However, it is important to remember that the patient must have normal clotting factors for these products to be most effective. Most of these agents have been studied in animal models, with very little literature comparing these agents head to head in human subjects.

Older agents such as oxidized, regenerated cellulose (ORC) come in a thin, pliable, woven sheet (Surgicel NuKnit, Johnson & Johnson, USA) or a soft, multiple-layered, fuzzy pad that can be separated into thin sheets or used as a pliable pad (Surgicel Fibrillar, Johnson & Johnson, USA). Additionally, it has bactericidal activity against gram-positive and gram-negative organisms and takes approximately 14 days to be fully absorbed. Absorbable, gelatin foam pads (Gelfoam, Pharmacia and Upjohn, USA) are also available in several sizes and can be cut to fit. These stiff sponges are about 4 mm thick and can be applied dry or moistened with saline to make them pliable. Both of these sheets or pads can be applied to an oozing surface and covered with a pressure pack for 5 minutes or so, during which time clot formation will form on the cellulose or gelatin matrix.

Microfibrillar collagen “flour” (Avitene, Davol, USA or InStat, Johnson & Johnson, USA) is a soft, granular material that can be placed on a semidry surface or into a small crevice for hemostasis. This bovine collagen material acts as a fibrin nidus to accelerate thrombus formation on the surface of the vessel. It will only control bleeding from a small arteriole or venule. Caution must be exercised when using this material because it can produce secondary fibrosis in the pelvis and even a persistent palpable mass. There have been reports of retroperitoneal fibrosis and ureteral obstruction secondary to the use of this hemostatic agent.

Other attempts to control severe bleeding from deep pelvic veins include a combination preparation such as Floseal (thrombin/gelatin) or a combined approach with Gelfoam and Avitene, stacked one on top of the other. If coagulation factors have been depleted because of multiple transfusions, the Gelfoam can be soaked in thrombin. When the material is applied, the field should be as dry as possible. Constant pressure can be applied by placing sutures that can be tied on top of the sandwiches. There is a new commercial product made of absorbable collagen sponge coated with human coagulation factor and thrombin that sounds very good, but it is not yet U.S. Food and Drug Administration (FDA) approved for use in the United States (TachoSil, Nycomed, Denmark).

Malviya and Deppe have reported the successful use of fibrin glue, a biodegradable tissue adhesive sealant and topical hemostatic agent, to control life-threatening hemorrhage in one obstetric and two gynecologic patients. The fibrin glue (Tisseal, Baxter Pharma, USA or Crosseal, Ethicon, USA) is prepared from equal amounts of cryoprecipitate (highly concentrated human fibrinogen) and bovine thrombin. It imitates the last stages of physiologic coagulation at the local site. It is available as a spray applicator or in a dual syringe set. This technique has been used successfully in microvascular, cardiovascular, and thoracic surgical procedures and has recently been reported in controlling hemorrhage in liver transplantation. Schwartz and colleagues compared spray-on fibrin sealant to standard techniques for hemostasis in 121 patients undergoing liver resection. Time to achieve hemostasis and postoperative complications was significantly less in the patients randomized to fibrin sealant. This technique should be helpful in extensive pelvic dissections for gynecologic cancer, especially to control low-pressure pelvic vein bleeding that is not controllable by other standard measures.

Gynecologic surgeons usually do not have the luxury of using tourniquets to control bleeding. There are, however, two special procedures in which tourniquets may be useful—myomectomy and uterine unification operations. The tourniquet is fashioned in the manner used by vascular, thoracic, and trauma surgeons to occlude major vessels. A vessiloop or a small Silastic pediatric catheter can be used for this purpose. A tourniquet loop can be placed around the uterine isthmus through a small hole made in the broad ligament just lateral to the uterine vessels. Loops also can be placed around both infundibulopelvic ligaments through the same hole in the broad ligament. When these are snugged down tightly and held with a Kelly clamp, the entire circulation to the uterus can be occluded. This technique can reduce blood loss to a minimum in these two procedures. Similarly, vessel loops or vascular clips can be used above and below the defect when repairing a sizable hole in the wall of a large vein or artery that cannot be sacrificed.

FIGURE 19.4 Ligation of the right hypogastric artery. The clamp is passed laterally to medial, and the ligature is placed around the anterior division of the hypogastric artery. Note the ureter is attached to the peritoneum, which

is reflected medially.

For completeness of discussion, hypotensive anesthesia has been used for radical pelvic surgery in the past, but it is rarely used and not recommended for routine gynecologic surgery. Reducing the circulation to the operative field by deliberate induction of hypotension has the potential to be a safe and effective anesthetic technique in carefully selected patients.

Hypogastric Artery Ligation

One of the methods of controlling severe pelvic hemorrhage is ligation of both hypogastric arteries. In 1893, at the Johns Hopkins Hospital, Howard Kelly performed bilateral hypogastric artery ligation to control hemorrhage during a hysterectomy for uterine cancer. Hypogastric artery ligation was later reintroduced by Mengert and colleagues and then extensively investigated by Burchell, who demonstrated that the arterial pulse pressure just distal to the point of ligation was decreased significantly (77%) on the same side. If both hypogastric arteries are ligated, the pulse pressure is decreased by 85%, presumably allowing blood clots to form at the site of bleeding from damaged vessels. Blood flow in vessels distal to the point of ligation is decreased by only 48%.

Because it is important to preserve some of the collateral circulation to the pelvis—including the lumbar, iliolumbar, middle sacral, lateral sacral, superior and middle hemorrhoidal, and gluteal arteries—it is important to ligate the anterior division of the hypogastric artery distal to the origin of the posterior parietal branch, as demonstrated in **Figure 19.4**. In ligating the hypogastric artery, the peritoneum is opened over the external iliac artery from the round ligament to the infundibulopelvic ligament, and the hypogastric artery is identified and

P.348

gently skeletonized. The ureter is left attached to the medial peritoneal reflection to avoid disturbing its blood supply. The hypogastric vein is also identified on the pelvic sidewall, if possible; but as long as the artery is well visualized and dissected from the sidewall, it is not necessary to risk more bleeding by isolating the hypogastric vein. The posterior branch of the hypogastric artery must be clearly identified before double ligation of the anterior division is performed. Nonabsorbable suture is passed around the artery with a right-angle clamp and tied. A second free-tie suture is placed distal to the initial ligature to avoid recanalization. Transfixion or division of the vessel is not recommended in this procedure. The hypogastric arteries should be ligated bilaterally, if possible, to obtain the best results. In addition, we believe that the arterial branch closest to the bleeding point should be ligated if this can be done without increasing bleeding or risk to other pelvic structures. For example, because the uterine artery is the first visceral branch of the hypogastric artery, it may be feasible to identify this artery and ligate it separately if the bleeding is from the uterus. This may be a somewhat more difficult than ligating the entire anterior division of the hypogastric artery and should not be attempted in the face of massive pelvic bleeding, distorted pelvic anatomy, or shock.

When massive bleeding is present but there is no indication to remove the uterus (e.g., certain obstetric operations), it is important to ligate both ovarian arteries in addition to bilateral hypogastric artery ligation. This procedure is easily accomplished by extending the lateral peritoneal incision up and parallel to the infundibulopelvic ligaments. It is imperative to first identify the ureter. The ovarian artery should be ligated with a single, permanent ligature, but the artery should not be cut. This avoids the need for multiple ligatures and the risk of retraction and retroperitoneal bleeding of the vessel. A single hemoclip also can be placed on each ovarian artery as a quicker and easier method of occlusion. Care should be taken to avoid injury to the ovarian vein. If there is difficulty in distinguishing the artery from the ovarian vein, ligation of both the ovarian artery and vein within the infundibulopelvic ligament is acceptable. Even though ligating both the arterial and venous circulation to the ovary leads to a high incidence of postoperative cystic enlargement of the ovary, this complication is preferable to the risk of recurrent pelvic bleeding when the ovarian arteries are not ligated. Pregnancy after hypogastric artery ligation has been studied, and many reports of full-term deliveries after

bilateral hypogastric artery ligation with and without bilateral ovarian artery ligation have been described. Such testimony provides compelling evidence of the abundant collateral blood supply to the uterus that can develop over time. According to Burchell, the blood flow to the pelvis is reduced by as much as 50%; however, ischemic necrosis of pelvic tissues does not occur unless additional collateral pathways are destroyed.

FIGURE 19.5 In addition to ligation of the anterior division of the hypogastric artery, the blood flow to the uterus through the ovarian artery can be ligated in the medial mesosalpinx without interfering with the blood flow to the tube and ovary.

Ovarian Artery and Uterine Artery Ligation

As an alternative to ligating the ovarian artery in the infundibulopelvic ligament, Cruikshank and Stoelk have described a technique of ligating this artery at the point of its anastomosis with the uterine artery in the medial mesosalpinx. This point of ligation allows maintenance of the blood flow to the tube and ovary but occludes the ovarian artery blood flow to the uterus (**Fig. 19.5**). Because this technique allows uninterrupted blood supply to the ovaries, it is probably preferable.

For post-cesarean delivery hemorrhage, Fehrman has recommended bilateral ligation of the uterine arteries as primary treatment. First, the uterus should be elevated upward and angled away from the targeted uterine artery. The artery should be identified by palpation, and a 0 absorbable suture is passed into and through the myometrium about 2 cm medial to and below the uterine vessels. The needle is brought out through an avascular area in the broad ligament, cephalad and lateral to the uterine vessels. The suture is tied and the procedure is repeated on the other side. When this method was used in 66 patients, only 6 required hysterectomy to achieve hemostasis. If bilateral uterine ligation is not effective in controlling the uterine bleeding, supplementary ligation of the round and the ovarian ligaments at their junction with the uterine corpus is recommended.

The vaginal artery can originate as a separate branch from the hypogastric artery. Uncontrollable bleeding from the vagina may not be stopped by hysterectomy or by ligation of the uterine arteries and therefore requires hypogastric artery ligation.

The collateral circulation of the female pelvis is extensive and provides a variety of intercommunicating sources of arterial blood from various sites. These collateral vessels anastomose with the hypogastric artery and the blood supply to the uterus through a number of circuitous arterial pathways in the pelvis. During a difficult hysterectomy, the collateral circulation can create problems in achieving adequate hemostasis. Therefore, it is important to have a clear understanding of the various extrapelvic arteries that communicate with the pelvic circulation. If bleeding occurs postoperatively, one can consider embolization utilizing interventional radiology.

Surgical Control of Pelvic Hemorrhage

Hypogastric Artery Ligation

- Open the peritoneum over the external iliac artery from the round ligament to the infundibulopelvic ligament.
- Identify hypogastric artery at its origin from the common iliac artery or at the medial margin of the psoas muscle, and follow it up to the common iliac artery bifurcation.
- Leave the ureter attached to the medial peritoneal reflection.
- Identify the hypogastric vein more laterally on the pelvic sidewall.
- If possible, identify the anterior and posterior branches of the hypogastric artery.
- About 2 cm distal to the origin of the hypogastric artery, using a right-angle clamp, pass a nonabsorbable suture around the artery.
- Place a second free-tie suture distal to the initial ligature to avoid recanalization.
- Transfixion or division of the vessel is not recommended.

Ovarian Vessel Ligation

- Extend the lateral peritoneal incision up and parallel to the infundibulopelvic ligaments.
- Identify the ureter.
- Ligate the ovarian vessel with a single, permanent ligature, avoiding the ovarian vein.
- A single clip also can be placed on each ovarian artery as a quicker and easier method of occlusion.

Uterine Artery Ligation

- The uterus should be elevated upward and angled away from the targeted uterine artery.
- Identify the uterine artery by visualization or palpation.
- A 0 absorbable suture is passed into and through the myometrium about 2 cm medial to and below the uterine vessels. The needle is brought out through an avascular area in the broad ligament, cephalad and lateral to the uterine vessels. The suture is securely tied.

Packing Techniques

In rare cases, standard techniques of pressure, clipping, ligation, or application of hemostatic agents is unsuccessful for controlling bleeding. Several techniques may be considered in these cases. Trauma surgeons will occasionally pack persistent venous bleeding and close the abdomen when the procedure has been prolonged and/or the patient is unstable. The patient is then reoperated on in 24 to 48 hours when coagulation factors and blood volume have been repleted. In some cases, the packing can be brought out through a large, hollow, soft rubber drain placed in a separate incision in the abdominal walls. The packing can then be removed through the drain in 48 hours under a light general anesthesia without opening the abdomen. If bleeding persists, it can sometimes be controlled by vascular embolization by interventional radiology.

Some surgeons have found the parachute pack, or umbrella pack, to be useful as a last resort to control persistent venous bleeding from the pelvic floor muscles after pelvic exenteration. This area is very deep in the pelvis, and exposure may be unsatisfactory from either above or below. This technique involves the formation of

a large pack of loose gauze within an outstretched, opened piece of gauze or plastic sheet. The center of the sheet is inserted through the vagina and positioned in the pelvic cavity from above. The pack is then stuffed from below with multiple gauze packing rolls (**Fig. 19.6A**). When an adequate volume has been obtained, the corners of the sheet are twisted together, and the stuffed packing is pulled down against the pelvic floor, compressing the vessels of the pelvic floor muscles and paravaginal tissues (**Fig. 19.6B**). Downward traction is maintained by clamping the twisted sheet at the vaginal introitus with several sturdy clamps. These are padded with gauze or foam rubber as they rest tightly against the perineum. The handles should be taped shut but may be reclamped from time to time to maintain pressure on the towel as it stretches. Place a Jackson-Pratt or Blake drain(s) in the pelvis to monitor for continued bleeding and an indwelling urinary catheter (if the bladder is still present) to avoid outflow obstruction and monitor urine output. The pack can be left in place with perineal traction for 24 to 48 hours until the bleeding has diminished and coagulation factors and other parameters have normalized. The pack is removed vaginally by first withdrawing the internal gauze and then the outside bags, sheet, or towel.

Temporary abdominal closure techniques are commonly practiced due to concern for abdominal compartment syndrome but should also be part of the surgeon's repertoire when enforcing damage control due to excessive pelvic hemorrhage. Because a second operative procedure is required for definitive repair, the abdomen is intentionally left open to facilitate reexploration, and the patient is closely monitored in an intensive care unit to correct for hypovolemic shock, hypothermia, metabolic abnormalities, and any coagulopathy. Several techniques for temporary abdominal closure include the Bogota bag, absorbable mesh, negative pressure systems (towel- and sponge-based), pack dressings, and the Wittmann patch or Velcro burr. Regardless of the technique used, they are characterized by a tension-free closure.

The Bogota bag, first described in 1984 by Oswaldo Borr  ez in Bogot  , Colombia, is a sterile plastic bag (typically a 3-L urinary irrigation bag), which is placed over the abdominal defect and sutured to the skin or fascia of the anterior abdominal wall. It serves as a hermetic barrier to minimize fluid loss, avoid evisceration, and prevent musculoaponeurotic necrosis and has the additional benefit of allowing direct visualization of abdominal contents should ischemic bowel be a concern.

Different types of mesh closures using porous material have been used. For example, an Esmarch rubberized dressing can be sutured to the skin or fascia. Alternatively, a fenestrated plastic dressing can be used to drape over the abdominal contents and securely tucked into the paracolic gutters. Jackson-Pratt drains are placed superiorly and inferiorly, and a sterile operating room pack is positioned over the drape. Then, an loban dressing is used to effectively close the wound.

Velcro dressings are another useful addition to abdominal closures that are sutured to the fascia and then advanced every 4 to 6 hours, bringing the fascia closer together. This technique has a lower risk of abdominal compartment syndrome since the Velcro will unfasten as the intra-abdominal pressure increases. It also has the advantage of easy access/reentry into the abdomen, by simply unfastening the Velcro at the midline.

In addition to abdominal packing, other potential etiologies of abdominal compartment syndrome that are pertinent to gynecologic patient include blunt or penetrating abdominal trauma, intra-abdominal or retroperitoneal bleeding, patients with massive ascites, bowel wall edema, and those postsurgical patients who may be third spacing due to shock. It is imperative to have a high level of suspicion and recognize an early triad of abdominal compartment syndrome—oliguria, elevated peak airway pressures, and elevated intra-abdominal pressure.

P.350

One of the first opportunities to assess for elevated intraabdominal pressure is in the operating room, during abdominal closure. If the peak inspiratory pressure on the ventilator rises by 15 to 20 mm Hg, it is likely that the abdominal viscera are compressing the diaphragms. If the retroperitoneal pressure exceeds that within the inferior vena cava (IVC), venous return is compromised, leading to diminished cardiac output hypotension. Measurement of intravesical pressure (>25 mm Hg) is the standard method to screen intra-abdominal

hypertension and abdominal compartment syndrome.

FIGURE 19.6 A and B: The parachute pack can be used to control bleeding from the deep pelvic veins after pelvic exenteration. A plastic sheet or towel is packed with gauze rolls through the vaginal or perineal opening. The ball of gauze packing is then pulled down to exert pressure against the vessels of the pelvic floor.

Potentially Troublesome Anatomic Locations

Iliac Vessels

One of the most dangerous places in the pelvis to dissect is in the region of the bifurcation of the common iliac artery and vein. This landmark is the superior border for pelvic lymphadenectomy in many gynecologic oncology staging procedures. The hypogastric vein and its branches are at risk of injury when dissecting between the distal common iliac artery and the psoas muscle, as well as deeper in the area of lumbosacral nerve trunks. When the surgeon places gentle traction on surrounding areolar tissue, a relatively loose and thin-walled vein may inadvertently be torn or pulled into the dissecting scissors. One should proceed cautiously, being cognizant of important adjacent structures, especially since the vein wall may not be distinct. Severe hemorrhage threatening exsanguination can result from laceration of either the external iliac vein or the hypogastric vein where they join together, or from laceration of their major branches. On the medial side of these veins, the lateral sacral veins disappear into the sacral foramina. Fatal hemorrhage can result from laceration of these vessels as well, especially if they are torn where they enter the foramina, preventing adequate exposure of the cut end and inability to clamp, ligate, or clip the vessel. Instead, they are kept open by their attachment to the walls of the foramina, and extreme measures may be required to control such bleeding. One can try to pack the foramen with bone wax, but this usually is not successful. Alternatively, multiple layers (sandwiches) of absorbable gelatin

sponge (Gelfoam) and microfibrillar collagen (Avitene) can be held in place with a strong pressure pack for 20 minutes and, perhaps, ultimately the packing can be fixed with sutures. This area deserves its reputation as the “corona mortis” of the pelvis.

Obturator Fossa

Numerous variations in the branches of the hypogastric artery and vein are encountered in dissecting the obturator fossa, especially in the floor of the fossa. The “web” of paracervical tissue separating the paravesical and pararectal spaces contains branches of the hypogastric artery and vein. These vessels must be carefully ligated with clips or sutures during a radical hysterectomy. The dissection can be carried down between the paravesical and pararectal space by carefully ligating or clipping each vessel encountered, thus uniting those two spaces.

P.351

The obturator artery and vein are usually found just below the obturator nerve. If injured, they may be ligated or clipped. Should these vessels retract through the obturator foramen into the upper thigh without being ligated, bleeding into the thigh may be a significant problem.

Pararectal Space

Development of the pararectal space between the ureter and the hypogastric artery must be done carefully because of the danger of injuring the internal iliac veins against the pelvic sidewall. The dissection is directed posteriorly at first, but soon changes to a more caudal direction. Failure to make this directional change can result in laceration and bleeding from veins in the bottom of the space. If development of the pararectal space is difficult, such as after pelvic radiation therapy, the paravesical space should be opened first, allowing the cardinal ligament to be identified and taken down in a serial fashion starting with the uterine vessels at their origin. The pararectal space should gradually be opened inferiorly, with the ureter identified medially and the iliac veins visualized laterally. The pararectal space can be expanded with sharp dissection or with pressure from a peanut dissector, and with care to avoid excessive force.

Aortic Area

The removal of lymph nodes around the aorta and vena cava can result in serious hemorrhage from either vessel if not done carefully and with adequate exposure. An abdominal incision that provides sufficient exposure for a routine pelvic operation is not ordinarily sufficient for dissection around the aorta and vena cava unless the incision is extended. Although the vena cava usually can be ligated without serious problems, a laceration in the vena cava should be repaired. Bleeding is controlled by placing a finger over the site of injury and gaining the necessary exposure by retraction and suctioning. A running stitch using 5-0 Prolene suture on a small vascular needle is used to close the laceration from side to side as the finger is slowly withdrawn. The same technique can be used to repair lacerations in other large veins, such as the common and external iliac veins. Often, there are no untoward results, but repair of the laceration is often preferable. A patch graft of Gore-Tex or other materials can be sewn over the hole. Since veins are of low pressure, this is often successful and maintains the function of the vein. In contrast, lacerations of the common and external iliac arteries must always be repaired. These vessels cannot be ligated without serious consequences, and if the injury is not repairable, the artery should be replaced.

Presacral Space

In the presacral region, bleeding usually can be avoided by choosing a plane of dissection that is superficial to the anterior sacral artery and vein. The retrorectal space can easily be entered using blunt dissection staying in the correct plane superficial to the presacral fascia and the vessels that overlie the periosteum of the sacrum. If done properly, this plane can be developed inferiorly to the tip and lateral margins of the sacrum without

appreciable bleeding. Timmons and colleagues and Khan and associates have recommended using metal thumbtacks to control presacral hemorrhage when the usual methods fail. Sterilized metal thumbtacks are placed directly over the bleeding point in the presacral fascia and pushed all the way into the sacrum with the thumb. Others have used a combination of bone wax, thumbtacks, packs, and hemostatic agents with success. Careful attention should be taken when using clips, ligatures, or cautery, as bleeding from the veins can be aggravated by imprecise use of these techniques.

POSTOPERATIVE BLEEDING

With normal hemostasis and proper surgical technique, postoperative hemorrhage is a rare occurrence. Every patient, however, should be carefully monitored postoperatively for signs of occult bleeding. The intensity and duration of the monitoring will depend on the type of surgery, any complications, and the medical condition of the patient. In addition to measuring vital signs and strict urine output, the abdominal incision and/or the perineum, and any intraperitoneal/subcutaneous drains, should be inspected for bleeding. Any sign of restlessness in the patient may be an indication of blood loss. Maintain a low threshold to check a CBC if there is a suspicion of postoperative bleeding or acute blood loss anemia. Because the risk of postoperative hemorrhage is low in routine, uncomplicated gynecologic surgery, many experts do not recommend routinely checking the hematocrit or hemoglobin postoperative. But in more extensive or complex surgery, a follow-up hematocrit or hemoglobin 4 to 12 hours after surgery may be helpful to guide postoperative management.

Occult intraperitoneal bleeding is one of the most serious postoperative complications after abdominal or vaginal surgery. Early warning signs may be insidious and not recognized until 12 to 18 hours after surgery was completed. However, the patient may suddenly develop severe hypotension, tachycardia, tachypnea, restlessness, and abdominal distention, prompting expedited intervention(s). In most cases, a small vessel has been slowly bleeding. Only after a significant blood loss has occurred do changes in the vital signs or symptoms of abdominal distention alert the clinician to a problem. In retrospect, subtle signs of hypovolemia, including tachycardia and decreased urine output, usually have been present.

Nonetheless, diagnosis of intraperitoneal bleeding in the postoperative patient can be difficult. Peritoneal signs are subtle and can be masked by incisional pain and analgesic medications. Unfortunately, the initial examination of the abdomen may be quite benign, as the peritoneal cavity has a large capacity for occult blood loss without appreciable abdominal distention. As much as 3,000 mL of blood (about 65% of the total blood volume of a 70-kg person) can be hidden in the peritoneal cavity, with only a 1-cm increase in the radius of the abdomen. Abdominal ultrasound is a rapid, noninvasive, readily available method of confirming the diagnosis of intraperitoneal bleeding. Alternatively, if a patient has experienced an unexpected drop in hematocrit postoperatively but is stable, an abdominal and pelvic CT scan is another good way to identify (or rule out) intra-abdominal hemorrhage or a hematoma ([Fig. 19.7](#)).

FIGURE 19.7 Axial CT image of the pelvis in a 52-year-old woman who is 5 hours post-op from a vaginal hysterectomy. Note the extravasation of contrast from an arterial injection into the right internal iliac artery.

P.352

Sometimes, it is difficult for the surgeon who performed the original operation to convince himself or herself that bleeding is persistent and intervention is urgently needed. Consultation with a colleague is often helpful in these situations. A routine coagulation profile, ordered at the first suspicion, or even simple observation of clot formation in a tube of blood at the bedside is helpful. However, the experienced surgeon knows that the most common reason for intraperitoneal blood and postoperative shock is loss of surgical hemostasis—a vessel has become disligated. The question now becomes: Should the patient be immediately taken back to the operating room to identify and control the bleeding or taken to the radiology suite in an attempt to control the bleeding by embolization? Both techniques are highly effective, and most often, the decision is dictated by the stability of the patient as well as the suspected source of bleeding. For instance, if the patient is unstable with a rapid pulse, falling blood pressure, and/or low urine output, or if the interval since surgery is short, suggesting fairly rapid hemorrhage, it is recommended to quickly return to the operating room where a team of anesthesiologists and direct one-to-one monitoring of the patient can allow prompt replacement of blood products and treatment of hemorrhagic shock. On the other hand, if the patient is reasonably stable and bleeding does not appear to be brisk, then it is reasonable to try to identify the bleeding artery and embolize it by transcatheter interventional radiologic techniques. A CT angiogram is useful in distinguishing if there is bleeding that can be embolized.

Whichever plan is selected, one or more large-bore intravenous lines should be started, and fluid replacement should begin with packed red blood cells ordered and started as indicated and available. A Foley catheter should be in place to allow close monitoring of urine output, and broad-spectrum antibiotics should be started. If the patient is not in the recovery room, she should be transferred there or to a monitored bed with easy access to the operating room. Preprocedure labs should be obtained, including coagulation studies, and the operating room and anesthesia service should be notified, as well as the interventional radiology team if appropriate.

Arterial Embolization

In 1969, Nusbaum and colleagues described arterial embolization to control bleeding from esophageal varices by selectively cannulating the superior mesenteric artery and infusing small doses of vasopressin into terminal vessels. The subsequent use of particulate matter to achieve hemostasis within bleeding viscera developed rapidly. Selective angiographic arterial embolization has been used to control hemorrhage after abdominal and vaginal hysterectomy and other gynecologic operations, hemorrhage from cervical cancer and gestational trophoblastic disease, postpartum hemorrhage, hemorrhage from abdominal pregnancy, and retroperitoneal hemorrhage. Experience has shown that selective pelvic artery embolization is a comparatively simple and safe procedure. Dramatic results can be seen. Clinical success rates of more than 90% are routinely reported when embolization is used for postsurgical and posttraumatic hemorrhage. Therefore, embolization rather than surgical ligation is appropriately selected as the primary procedure to control bleeding in patients who are stable or who cannot tolerate another operation.

Intravascular embolization requires the expertise of a skilled interventional radiologist. Percutaneous catheterization of the femoral artery under local anesthesia provides direct access in a retrograde manner to the hypogastric artery (**Fig. 19.8**). The brachial artery can also be used for access to the vascular system. If prior hypogastric artery ligation has obstructed this pathway, arteriography of the pelvic vasculature through one of the collateral arteries usually localizes the specific bleeding vessel or vessels, although with greater difficulty. The site of bleeding can be accurately identified with angiography and fluoroscopy if the rate of bleeding is 2 to 3 mL per minute or more. The hypogastric artery or the specific collateral vessel is cannulated for injection (**Fig. 19.9A-C**). A variety of materials can be used for embolization, including small pieces of Gelfoam, metal coils,

small Silastic spheres, autologous clot, subcutaneous tissue, and other hemostatic materials. Gelfoam is one of the most practical and easily injected materials. It is sterile and nonantigenic, remains in the vessel for 20 to 50 days, and forms a fibrin mesh framework on which blood clots can develop. Its immediate effect is to obstruct the distal artery or arteriole and reduce pulse pressure in the bleeding vessel, thereby permitting clot formation and cessation of bleeding. Material is injected under angiographic observation. When it becomes evident by repeat angiography that the bleeding vessel has been occluded, the catheter is removed and the patient is carefully monitored for evidence of further bleeding.

FIGURE 19.8 The femoral artery can be catheterized under local anesthesia to provide access to the hypogastric artery and its branches.

After embolization, patients usually have no complications or evidence of the effects of local ischemia. Those who have not had a hysterectomy will resume normal menstruation. Some patients will exhibit evidence of a mild postembolization syndrome, including pain, fever, leukocytosis resulting from vascular thrombosis, and tissue necrosis. A few isolated cases of more serious problems have been reported, including bladder necrosis, vesicovaginal fistula, neuropathies, and renal toxicity from the contrast medium. The overall complication rate is estimated to be less than 10%.

FIGURE 19.9 Selective angiogram with the catheter tip positioned in the right internal iliac artery (same patient as shown in [Fig. 19.8](#)). **A:** The tortuous right uterine artery is filled and some wispy extravasation is seen (**arrow**). **B:** A delayed image shows more extensive extravasation. **C:** After five microcoils have been injected, the bleeding has been controlled. No extravasation is seen with an injection of contrast in the common iliac artery. (Courtesy of Dr. Leann Stokes, Vanderbilt University.)

Reoperation

If reoperation is selected, the patient should be as stable as possible, with blood actively being transfused or at least available in the room. Two suctions should be ready and an adequate staff with sufficient number of assistants involved. If the patient has previously had an abdominal operation, the incision should be reopened. A preoperative ultrasound or CT scan should have identified the bleeding as intraperitoneal or retroperitoneal. The previous procedure should be mentally reviewed to identify any possible ligatures that were tentative or any troublesome bleeding sites that may have continued to bleed. When the abdomen is opened, the clots should be evacuated and a search instituted for the bleeding sites, starting with the most likely locations. Care should be taken when removing clots from the pelvic area.

Bleeding sites should be carefully ligated, sutured, or clipped. It is not unusual to reopen the abdomen and find no active bleeding sites. This is somewhat disconcerting because of the concern that the problem will repeat itself after the abdomen is again closed. Every attempt should be made to identify the source of bleeding, including irrigation with warm, sterile water to allow better visualization.

During reoperation, patients are at increased risk of ureteral injury. In addition to exercising care in clamping and ligating bloodstained tissue with distorted anatomy, it may be wise to prove ureteral integrity at the end of the operation. This can be done by injecting 5 mL of indigo carmine dye

P.354

intravenously and observing efflux of dye from each ureteral orifice through the cystoscope or by direct visualization if the bladder dome is already opened. After reoperation, patients are also at increased risk of developing postoperative complications such as pulmonary atelectasis, ileus, postoperative infection, incisional complications, and coagulation disorders from multiple transfusions. The anticipation of these complications allows the adoption of measures to prevent or manage them correctly should they occur.

Postoperative hemorrhage from the vaginal vault usually comes from the vaginal artery in the lateral vaginal fornix or from one of its branches. Most often, the lateral vaginal angle, including the vaginal artery, is not properly secured or slips off the pedicle. To prevent such bleeding, this stitch should be anchored to more lateral tissue so that the angle cannot slip out of the ligature. This stitch should not be held because traction will loosen it. Excessive vaginal bleeding may be noted in the recovery room or after the patient has returned to her room. Every attempt should be made to establish an objective measurement of the amount of blood lost and to follow vital signs and serial hematocrit values. One must realize that the vagina is a distensible organ. If a clot occludes the vaginal introitus, a large amount of blood—sometimes several hundred milliliters—can distend the vagina behind it and not be evident on a perineal pad. When significant vaginal bleeding is present, the patient should be examined in dorsal lithotomy position. This may be possible in the recovery room with analgesia, but a return to the operating room for an examination under anesthesia should be used if necessary. The vaginal apex should be inspected. If the source of bleeding is visualized, it should be clamped and ligated from below. Figure-of-eight using 0 delayed-absorbable transfixion sutures should be placed to include the vaginal mucosa and underlying paravaginal tissue. Care must be taken to avoid the inadvertent placement of a suture into the musculature of the bladder wall, the ureter, or the underlying rectum. If bleeding is not controlled by this technique, it is unwise to continue to add suture on top of suture in a frantic effort to control the vaginal bleeding. In such cases, it is probable that the bleeding vessels have retracted well above the vaginal apex and cannot be reached by this approach.

If surgical hemostasis cannot be achieved transvaginally, laparotomy may be necessary. A vaginal pack will not control significant bleeding from the vaginal vault that has already required a return to the operating room, although a temporary pack may slow the blood loss while the patient is prepared for laparotomy. A Foley catheter should already be in place. In some patients, the hemorrhage will be delayed until 10 to 14 days after surgery, when the sutures lose their tensile strength. Furthermore, posthysterectomy disruption of the vaginal vault with hemorrhage also can result from coitus.

Bleeding from anterior and posterior colporrhaphy usually is from veins that have not been secured. In this situation, a fairly tight vaginal pack effectively compresses these vessels and controls the bleeding. It seldom is necessary to reexplore an anterior or posterior colporrhaphy to locate and ligate a specific bleeding vessel. Again, a Foley catheter is necessary while the pack is in place to bypass urethral obstruction.

A postoperative pelvic hematoma can cause serious morbidity, especially if it is large and becomes infected. Hematomas can develop above the vaginal vault, along the pelvic sidewall, in the retroperitoneum extending up to the kidneys, in the paravesical space, in the abdominal wall, and in the ischiorectal fossa and vulva. A

hematoma in the ischiorectal fossa and on the vulva may be obvious on examination when the patient reports discomfort in the area. If it is below the puborectalis muscle attachment to the vagina, it will not dissect into the pelvis but rather be limited to the perineum and buttocks. A pelvic hematoma may be recognized in a patient whose postoperative discomfort and anemia exceed what is normally expected, whose temperature is progressively increasing, and whose postoperative abdominal distention is slow to resolve. A definitive diagnosis can be made by ultrasound or CT scan, which is helpful in delineating its exact size and location. An extended, postoperative course may be alleviated if a large hematoma can be evacuated and drained via a small closed suction drain placed by interventional radiology. However, in specific cases, drain placement may be difficult to perform or even contraindicated, in which case it may be preferable to allow the hematoma to gradually resolve over a few months. Unfortunately, sometimes a hematoma will not resolve completely, and residual fibrosis will persist and continue to be symptomatic. Hemorrhage after uterine curettage is extremely rare, even when complicated by perforation. Under most circumstances, the curettage should be stopped and the patient's vital signs checked for several hours. Most patients have an uncomplicated postoperative recovery and are stable to be discharged home the same day. However, if the perforation was caused by a wide, blunt instrument (such as a curette or a suction device), if the uterus is pregnant or contains cancer, or if fatty tissue appears in the curettage specimen, then overnight observation should be considered and the patient closely observed for intraperitoneal bleeding or a broad ligament hematoma. Diagnostic laparoscopy should be performed immediately after perforation if significant injury is suspected to assess for damage to surrounding organs, especially bowel, and determine if a hematoma or active bleeding is present. Alternatively, if the perforation is midline and no trauma is suspected, careful observation is a reasonable option. A misdirected curette can lacerate the uterine artery and vein, with subsequent intraperitoneal bleeding or broad ligament hematoma formation. In such cases, laparotomy may be necessary to fully evaluate and control the bleeding. As a last resort, hysterectomy may not be indicated if there is severe damage to the uterus or to control bleeding.

Hemorrhage from cervical conization can occur in the first 24 hours or 7 to 14 days later when cervical sutures lose their tensile strength. Patients may also bleed heavily after a loop electrosurgical procedure (LEEP) due to inadequate electrocautery, possible vaginal laceration, or delayed relaxation of small vessels that were initially vasoconstricted at the completion of the procedure. If the patient is bleeding heavily at any time after conization or LEEP, a speculum exam should be performed and the cervix and vaginal walls should be thoroughly inspected. Measures to control the bleeding include resuturing, electrocautery, and Monsel solution. If bleeding is not profuse, Monsel solution, Gelfoam, and/or a small vaginal pack can be tried. In taking the conization specimen, one must be certain that the apex of the cone intersects the endocervical canal. If the cervical incision is misdirected to one side or the other, the uterine vessels are in danger of laceration and cause serious hemorrhage or broad ligament hematoma. To prevent this problem, the cervix should first be sounded to ascertain the direction of the endocervical canal and the incision planned accordingly.

SUMMARY

Careful preoperative evaluation of the patient and thoughtful preoperative planning on the part of the surgeon and surgical team will help prevent or minimize significant operative blood loss. However, intraoperative or postoperative hemorrhage does occur from time to time and represents a significant

P.355

challenge to the technical skill and the emotional control of the surgeon. He or she must take charge of the situation, organize a plan to control the bleeding, clearly communicate with other members of the surgical team, and, finally, execute the technical steps necessary to obtain hemostasis. Each part of this approach is important. We hope that the ideas and techniques discussed in this chapter will make the reader more prepared to meet this challenge.

BEST SURGICAL PRACTICES

- Preparation to prevent and control operative bleeding starts before the surgical procedure. The patient should be thoroughly evaluated for risk factors that may increase the possibility of hemorrhage. Congenital and acquired coagulation disorders need to be diagnosed by a careful and thorough history and appropriate lab tests. The surgical approach should be individualized to the patient's condition, goals of treatment, and the abilities of the surgical team. Preoperative consultations with other specialists should be sought if indicated. All medical conditions of the patient should be optimized prior to elective surgery.
- The possibility and risks of blood transfusion should always be discussed with the patient as part of informed consent before surgery. The risk of a febrile reaction to transfusion is approximately 1%. Transmission of hepatitis B via transfusion occurs about 1 in every 180,000 transfusions, whereas the risk of HIV transmission with modern blood banking procedures is approximately 1 in 1.9 million.
- During the operative procedure, good exposure, keen awareness of the anatomy, and careful dissection, clamping, and suturing are all important technical skills that will reduce the risk of uncontrolled hemorrhage. Ultimately, excellent surgical judgment and leadership must be used to achieve the best possible outcome for the patient.
- When life-threatening intraoperative hemorrhage occurs, the surgeon should identify the source of the bleeding, apply pressure, and orchestrate the operative team to help achieve hemostasis. This is one of the most challenging of all emergencies and requires leadership; sound judgment; knowledge; precise, efficient technical skills; and clear communication lines.
- When intraoperative blood loss exceeds 15% of the patient's blood volume (about 500 to 1,000 mL), transfusion should be considered. The patient's medical history, vital signs, the probability of additional blood loss, and anticipated course of management should dictate how urgent to initiate transfusion of specific blood products (e.g., packed red blood cells, platelets, cryoprecipitate).
- Hematocrit and coagulation factors—as well as serum calcium, electrolytes, and glucose—should be followed at least every 120 minutes or after 10 units of transfusion. Although it is best to use actual serum levels of coagulation factors, as a rough guide, after every 6 to 8 units of packed red cells, 2 units of fresh frozen plasma should be given. If fibrinogen levels fall below 100 mg/dL, 20 units of cryoprecipitate should be given. A bolus of 6 units of platelets should be given if the platelet count falls below 100,000 and the patient is actively bleeding.
- The gynecologic surgeon should be able to use special techniques such as packing, thrombotic agents, and hypogastric artery ligation and know their indications for the control of pelvic hemorrhage.
- Postoperative bleeding may be difficult to diagnose, but a high level of suspicion due to intraoperative complications and attention to clinical detail (vital signs, strict ins and outs especially output from the Foley catheter and any pelvic drains, incisional or vaginal bleeding, etc.) will facilitate prompt recognition and appropriate management. Abdominal and pelvic ultrasound and CT imaging are also very helpful in making the diagnosis of postoperative bleeding and localizing the site of bleeding.
- Embolization of arterial bleeders by interventional radiology and reoperation are both effective techniques to manage postoperative hemorrhage. When the patient is relatively stable and an experienced interventional radiology team is available, embolization is generally preferred because it is associated with less morbidity.

Chapter 20

The Impact of Assisted Reproductive Technology on Gynecologic Surgery

Hey-Joo Kang

Zev Rosenwaks

DEFINITIONS

Controlled ovarian hyperstimulation—Administration of exogenous gonadotropins to induce growth of multiple ovarian follicles within a single menstrual cycle.

Developmental states—*Morula*—The stage between 72 and 96 hours after insemination, from the 16-cell stage to formation of the blastocyst. *Blastocyst*—The stage consisting of an inner cell mass from which the fetus develops and a trophectoderm from which the placenta develops. It is distinguished from the morula by the presence of a fluid-filled cavity.

Embryo transfer—The delivery of viable embryos to the uterine fundus for implantation. This is traditionally done transcervically or less commonly by laparoscopic cannulation of the fallopian tubes.

Intracytoplasmic sperm injection (ICSI)—Procedure by which a single sperm is injected directly into a mature oocyte assisted fertilization.

Mature oocyte—An oocyte at metaphase II of meiosis. Fertilization may occur at this stage of development.

Noncommunicating hydrosalpinx—Accumulation of distal tubal fluid that is unable to pass into the peritoneal cavity.

Oocyte—The immature female gamete.

Oocyte retrieval—The removal of oocytes after controlled ovarian hyperstimulation by ultrasound-guided needle aspiration. In rare instances, laparoscopic retrieval may be necessary.

Ovarian hyperstimulation syndrome (OHSS)—A complication of assisted reproductive technology that occurs almost exclusively with the use of gonadotropin stimulation. It is a condition of vascular hyperpermeability secondary to the release of vasoactive substances (vascular endothelial growth factor, tumor necrosis factor- α , interleukins) from the overstimulated ovaries. The transudation of protein-rich fluid from the intravascular to the extravascular compartment can lead to ascites, hemoconcentration, electrolyte imbalance, or hepatic and renal dysfunction. Severe OHSS can lead to vascular collapse, acute respiratory distress syndrome (ARDS) and even death.

Prezygote—The stage of pronuclear formation after penetration of the mature (MII) oocyte by spermatozoon. At this stage, male and female pronuclei are evident as well as the second polar body. This is the stage immediately preceding syngamy, the fusion of two nuclei to form a single nucleus of the zygote.

Zona pellucida—The glycoprotein membrane surrounding the plasma membrane of an oocyte.

Zygote—Single cell stage after pronuclear breakdown (syngamy) but before first cleavage.

ASSISTED REPRODUCTIVE TECHNOLOGY

Assisted reproductive technology (ART) is inclusive of any procedure involving fertilization of the oocyte outside the body. The first live birth from ART was reported in 1978 by Patrick Steptoe and Robert Edwards following laparoscopic retrieval of a single oocyte from a naturally stimulated ovary. The most frequently practiced ART

procedure is in vitro fertilization (IVF). It involves a sequence of events beginning with controlled ovarian hyperstimulation, harvesting of oocytes, fertilization with spermatozoa, culturing of embryos, and replacement into the uterine cavity. Also under the umbrella of ART are laparoscopic tubal transfer of gametes (gamete intrafallopian transfer; GIFT), zygotes (zygote intrafallopian transfer; ZIFT), and embryos (tubal embryo transfer; TET). These techniques have largely been supplanted by IVF in light of their requirement for laparoscopy and considerable technical advances in both IVF and embryo culture conditions.

Assisted Reproductive Technology and the Expectations of Pregnancy

Consideration should first be made to the success rates of ART without surgical intervention. If this is deemed reasonable, it may be prudent to forgo surgery—and the inherent risks therein—and proceed directly to IVF. The decision to proceed with surgical intervention also requires detailed knowledge of its impact on subsequent pregnancy rates and should only be entertained if pregnancy rates could be significantly improved or the need for ART eliminated altogether.

Data on ART outcomes are collected every year to provide information to prospective patients as well as clinicians. The 2010 data from the Society for Assisted Reproductive Technology (SART) report pregnancy rates for fresh and frozen nondonor oocytes per cycle of IVF ([Table 20.1](#)). Success rates are clinic specific, and this information is available through <http://sart.org>.

Female age is the single most important predictor of IVF success rate due to the direct relationship between advancing female age and genetic instability of the oocyte. Over 90% of maternally derived aneuploidy stems from meiosis I chromosomal segregation errors. Two main mechanisms for oocyte aneuploidy have been described by Fragouli and colleagues. The first occurs exclusively during meiosis I with premature division of a chromosome into its two sister chromatids, followed by their random segregation. The second error is nondisjunction of entire chromosomes during meiosis I and meiosis II leading to hyperhaploid ($n = 24$) and hypohaploid ($n = 22$) gametes. As a result, advancing age of the female partner is inextricably

P.360

coupled with a decline in pregnancy and live birth rates. Coincidental with age, ovarian reserve also plays a major role in a woman’s reproductive potential. Thus, any discussion of prognosis should be made in the context of ovarian reserve assessment.

TABLE 20.1 2010 Success Rates of IVF Cycles^a Using Fresh Embryos from Nondonor Oocytes

	AGE RANGES				
	<35	35-37	38-40	41-42	>42
Number of cycles	39,473	20,250	20,706	9,650	5,546
Percentage of cycles resulting in pregnancies	47.7	38.8	29.9	20.1	8.9
Percentage of cycles resulting in live births	41.7	31.9	22.1	12.5	4.1
Reliability range	(41.2-42.1)	(31.3-32.6)	(21.5-22.7)	(11.8-13.1)	(3.6-4.7)

Percentage of retrievals resulting in live births	44.6	35.5	25.4	14.9	5.3
Percentage of transfers resulting in live births	47.8	38.4	28.1	16.8	6.3
Percentage of cycles with elective single embryo transfer	9.6	5.3	1.7	0.6	0.5
Percentage of cancellations	6.6	10.0	12.9	16.5	22.0
Implantation rate	36.9	27.0	17.7	9.6	3.7
Average number of embryos transferred	2.0	2.2	2.6	3.0	3.1
Percentage of live births with twins	32.4	27.2	22.1	16.9	9.6
Percentage of live births with triplets or more	1.5	1.5	1.1	1.1	0.9

ASSISTED REPRODUCTIVE TECHNOLOGY AND ENDOMETRIOSIS

Endometriosis is endometrial tissue found outside the uterus. This ectopic tissue responds to the hormonal changes of a menstrual cycle and can be a significant cause of morbidity. The precise pathophysiology of endometriosis and its impact on fertility depend upon the degree of endometriosis present in the ovaries and pelvis. Proposed mechanisms include distortion of pelvic anatomy and abnormal peritoneal environment characterized by increased inflammatory cytokines and oxidative stress, which may interfere with follicular development, ovum pickup, fertilization, and embryo development.

For patients who are infertile and have no other cause for infertility, it can be tempting to explore the pelvis via laparoscopy to diagnose and ultimately ablate lesions from endometriosis. There are two randomized prospective trials evaluating the efficacy of laparoscopic ablation of mild-to-moderate endometriosis and postoperative natural fecundity. The Canadian Collaborative Group on Endometriosis (ENDOCAN) randomized 341 patients with unexplained infertility for 2 years or more to diagnostic laparoscopy versus ablation and followed patients for 36 months. They found a modest increase in fecundity rates in those whose endometriosis was ablated, from 2.4% to 4.7%. Ultimately, eight women required surgery to achieve one additional pregnancy. The second, an Italian study led by Parazzini, randomized 96 women to diagnostic laparoscopy versus ablation followed for 1 year and found no increase in spontaneous conception rates. However, when adjuvant GnRH agonist was used postoperatively over a brief time interval, spontaneous conception was increased from 18% to 39%.

In the context of ART, pregnancy rates in patients with mild-to-moderate endometriosis who forgo surgery are comparable to patients with unexplained infertility. The conception rates after ART are significantly higher compared to those who are managed expectantly for up to 24 months following ablative surgery. In a study by Suzuki et al., even patients with more advanced endometriosis experienced monthly fecundity rates of 22% to 25%, questioning the need for laparoscopic intervention prior to ART. Thus, surgery can marginally improve spontaneous conception rates in individuals with infertility and stage I—II endometriosis but does not approach success rates achieved with ART.

There are several considerations to be made in women with asymptomatic severe endometriosis and fertility. If there is significant anatomic distortion, surgery vis-à-vis fimbrioplasty or lysis of adhesion, in instances where adnexa are adherent to surrounding structures, can improve fertility. Reports on postoperative natural pregnancy rates are sparse and in the range of 7% to 15% over 12 months.

Garcia-velasco and Arici demonstrated that with respect to ovarian endometriomas, laparoscopic cystectomy prior to IVF does not appear to improve pregnancy rates. Since endometriosis can be destructive to the ovarian reserve of young women, surgical intervention may be appropriate for this patient group. Rapidly growing endometriomas may indicate an underlying malignancy or borderline tumor. Therefore, any adnexal structure with a documented increase in size over a short time interval should be investigated for pathologic diagnosis. Depending on its size and location within the ovary, endometriomas may

P.361

present structural impedance at oocyte retrieval. Each scenario provides a legitimate reason to favor removal prior to IVF.

ASSISTED REPRODUCTIVE TECHNOLOGY AND TUBAL INFERTILITY

Tubal factor infertility accounts for 30% of cases of female infertility and 9% of diagnoses among couples who underwent ART treatments in the United States in 2010. Tubal health is evaluated by hysterosalpingogram (HSG). In this procedure, contrast is placed into the uterine cavity and the fallopian tubes are visualized using fluoroscopy. The luminal diameter should be less than 1 mm at the isthmic portion of the fallopian tube and typically increases to 2 to 3 mm at the ampullary end. Free spill of contrast should be visualized to confirm tubal patency. Assisted reproductive technology was originally devised as a method to overcome tubal factor infertility. Statistically, current success rates after IVF exceed that of surgical repair. However, IVF can be financially and emotionally burdensome, and there are some instances when surgical correction can restore normal reproductive anatomy and should be considered before proceeding to IVF.

The optimal candidate for tubal reconstruction is young (<30) with a history of voluntary surgical sterilization without coexistent infertility factors. She should be counseled regarding postrepair conception rates, which range from 18% to 45% over a 12-month period, as well as ectopic pregnancy rates of 7% to 25%, as reported by Collins. Postoperative fecundity rates are subject to patient selection, technical skill of the surgeon, as well as the final length of the repaired fallopian tube.

Proximal Obstruction

The final diagnosis of proximal tubal disease by HSG should be reserved until confirmed with further testing. Tubal spasm or failure to produce adequate antegrade pressure of dye can be misinterpreted as proximal occlusion. Procedural options permitting simultaneous diagnosis and correction of proximal obstruction are fluoroscopic cannulation, laparoscopic chromotubation, and hysteroscopic catheterization. Each of these is sufficient to assign a final diagnosis of proximal tubal obstruction. If proximal obstruction is confirmed and efforts to establish patency are unsuccessful, IVF is the treatment of choice for these patients.

Hysteroscopic Catheterization—This procedure begins with appropriate distention media. A hypoosmotic media

like glycine is ideal because it is immiscible with blood, ensuring clear visualization of the tubal ostia. First, standard chromopertubation of the fallopian tubes is done to confirm the diagnosis of proximal obstruction. The hysteroscope is then introduced through the cervical os, and tubal ostia are visualized. A soft flexible catheter with a metal introducer is directed through the obstructed side to a depth of 1 to 2 cm, and the inner metal introducer is removed while the outer sheath is advanced further into the isthmic portion of the fallopian tube. Indigo carmine is introduced through the operator's end of the catheter. A concurrent laparoscopy confirms spill of dye through the fimbriated end, and the catheter is removed. Laparoscopy also ensures prompt recognition of bleeding or tubal perforation.

Distal Obstruction/Hydrosalpinges

Surgical correction of mild tubal disease may be appropriate for young women. Correction may involve lysis of peritubal adhesions or fimbrioplasty. In fimbrioplasty, every effort should be made to use a laparoscopic approach to reduce the risk of adhesion formation. If tubal caliber is normal and the fimbriated end agglutinated, the closed tip of a pair of fine forceps is introduced through the distal end and gently separated. The procedure should be repeated to reduce the rate of reocclusion. Care should be taken to avoid bleeding, as this increases the risk of scarring the delicate fimbria. Peritubal adhesions should be filmy and clear and separated without the use of cautery. Patton reported fecundity rates of parous women after this procedure in the range of 63% over 24 months, with a 5% ectopic pregnancy rate. However, women with severe distal disease and those over 37, who have diminished ovarian reserve and increased aneuploidy rates, should forego surgery and proceed directly to IVF.

The study of ART outcomes has altered our management of hydrosalpinx. Patients with dilated, fluid-filled fallopian tubes may experience decreased pregnancy rates with IVF. The theories behind such observations include embryo toxicity and alterations in endometrial receptivity markers from exposure to tubal fluid. An interruption in embryo-endometrial cross talk could result from retrograde flow of tubal fluid. In fact, a recent survey of reproductive endocrinologists conducted by Omurtag and colleagues reported increased consideration of salpingectomy for hydrosalpinx without evidence of spill into the peritoneal cavity by HSG, presuming a greater degree of retrograde flow. In general, when the decision has been made to intervene surgically prior to ART, proximal tubal occlusion with bipolar cautery or surgical clips has comparable benefit to salpingectomy in patients with challenging access to adnexa.

Most studies support removal of ultrasound-visible hydrosalpinges prior to IVF; however, individual consideration should be made in women who are poor surgical candidates secondary to adhesive disease. Some of these patients may benefit from hysteroscopic placement of coiled tubes passed antegrade into the tubal ostia. In this procedure, flexible inserts containing polyethylene terephthalate fibers are guided by the hysteroscope and passed directly into the fallopian tubes. The inserts induce a fibrotic reaction that will permanently occlude the tube and thereby prevent retrograde flow of fluid into the uterine cavity. A follow-up HSG 3 months after insertion will confirm complete occlusion.

Because the current success rate of IVF in women with tubal disease exceeds that of surgical repair, it remains the treatment of choice. However, American Society for Reproductive Medicine (ASRM) practice guidelines state that tubal reconstructive surgery is a reasonable treatment option for young women with mild tubal disease and for those with ethical, religious, or financial restrictions that preclude IVF.

ASSISTED REPRODUCTIVE TECHNOLOGY AND SURGICAL MANAGEMENT OF UTERINE MYOMAS

Advising the infertile female on the management of an asymptomatic fibroid is a frequent clinical dilemma. It is unclear whether the presence of fibroids without cavity involvement can be considered the sole cause for infertility. Theories behind adverse sequelae of myomas include mechanical obstruction of tubal ostia, chronic

intracavitary inflammation, and increased uterine contractility.

There exist very few randomized trials to guide the gynecologic surgeon on the reproductive benefit of surgery in this situation. Metwally and colleagues identified that only three randomized clinical trials exist evaluating the effect of surgical intervention on subfertility, and a vast number of retrospective and observational studies make up the remaining body of literature. Two of the RCTs compare laparoscopic versus abdominal myomectomy and find they appear to have similar outcomes in miscarriage, pregnancy, and live birth rates.

P.362

Only one RCT evaluates surgical intervention versus no intervention and subsequent fertility. Casini et al. randomized 181 young women with myomas less than 4 cm and unexplained infertility to surgical intervention or expectant management for 1 year. Women with submucous myomas benefited from intervention with an increase in pregnancy rate of 27% in the expectantly managed group to 43% in the operative group ($P < 0.05$). Improvement after surgery in women with intramural myomas without cavitory involvement ($n = 76$) did not reach significance but trended higher in the operative group.

It is generally accepted that subserous myomas do not adversely affect pregnancy or live birth rates, thus removal is rarely warranted. Pritts' review showed agreement among studies on the topic: submucous myomas decrease pregnancy rates and increase the incidence of miscarriage. For the majority of patients with submucous myomas, surgical resection restores pregnancy rates to match those with a normal uterine cavity.

The management of intramural myomas not distorting the uterine cavity has become the focus of much debate in the ART world. Large intramural myomas appear to diminish pregnancy and live birth rates in infertile women; however, there is no conclusive evidence that surgical removal restores these rates. Therefore, the decision must weigh risks versus potential benefit of myomectomy. Risks for morbidity include bleeding necessitating hysterectomy or transfusion; postoperative adhesions, especially involving the fallopian tubes; and infection. When the potential obstetric complication of uterine rupture and an increased likelihood of cesarean section are considered, it is clear that there is reason for caution about recommending myomectomy for unproven benefit.

ASSISTED REPRODUCTIVE TECHNOLOGY AND THE INDICATION FOR HYSTERECTOMY

Prior to ART, it was standard practice to remove the uterus and bilateral adnexa in cases of pelvic pain from endometriosis or adnexal mass. The uterus was considered a vestigial organ without the accompanying adnexa and a source for carcinoma of the cervix or endometrium later in life. Now, patients with these conditions achieve pregnancies through the use of donor oocytes. The uterus should also be conserved for premenopausal women who have the opportunity and desire to cryopreserve oocytes/embryos prior to surgery.

ASSISTED REPRODUCTIVE TECHNOLOGY AND THE PRESERVATION OF FERTILITY AFTER SURGICAL MENOPAUSE

Improved survival rates for women with cancer have led to the pursuit of fertility preservation. As such, recent years have witnessed the development of methods for gamete, embryo, and ovarian tissue cryopreservation from the prepubertal girl to the adult woman. Although it is beyond the scope of this chapter to describe the technical aspects of cryopreservation, the fundamental principles of cryopreservation and success rates upon thaw will be reviewed. The purpose of this section is to provide the gynecologic surgeon with appropriate options that should be offered to the patient about to undergo bilateral oophorectomy or gonadotoxic therapy.

Ovarian Tissue Cryopreservation

This method offers the ability to cryopreserve thousands of primordial follicles without a delay in cancer treatment. In the majority of diagnosed cancers, chemotherapy is initiated soon after diagnosis. Because gonadotropin stimulation and oocyte retrieval usually require 2 to 3 weeks, it may be timeprohibitive to freeze

embryos for potential future use. Breast cancer patients may have a brief window between surgery and chemotherapy, but supraphysiologic estrogen levels seen with IVF—especially in those with ER/PR+ tumors—risk stimulation of the primary tumor.

Strips of ovarian cortical tissue are surgically removed by laparoscopy or laparotomy and immediately frozen through slow cooling or vitrification. The tissue can later be thawed and the primordial follicles matured in vitro or can be autotransplanted back into the patient. Returning the tissue at or near the original location is referred to as orthotopic transplantation, while placing the tissue in a separate site such as the forearm or abdominal wall is heterotopic transplantation. With a forearm graft, the ovarian tissue is grafted into the subcutaneous space located above the brachioradialis fascia. The patients then must undergo gonadotropin stimulation, harvest, and uterine embryo transfer to conceive.

There have been approximately 20 reports of human live births using ovarian cortical tissue cryopreservation with autotransplantation, the first one reported in 2004. Thus, this technique should be considered experimental. Of note, this is the only treatment option for prepubertal girls. The potential drawbacks to be discussed are potential reseeding of tumor cells, especially in systemic cancers such as in leukemia, and in cases of high tumor potential as in BRCA gene carriers.

Oocyte Cryopreservation

Candidates for oocyte cryopreservation include premenopausal women scheduled for prophylactic oophorectomy for BRCA gene mutation, severe pelvic pain for endometriosis, or oncologic patients requiring gonadotoxic therapy. Oocyte cryopreservation necessitates a minimum delay in treatment for the primary disease of 2 to 3 weeks, and toleration of a transient rise in estrogen levels up to 4,000 pg/mL. In breast cancer patients with ER/PR+ tumors, some medical oncologists allow for one cycle of oocyte cryopreservation in the brief window between surgery and chemotherapy. It is prudent in these patients to use an aromatase inhibitor in conjunction with gonadotropin stimulation to maintain a low estradiol level.

Since the first pregnancy from frozen oocytes was described by Chen in 1986, there has been intense interest in the potential of oocyte cryopreservation. Since embryo cryopreservation using the slow-cooling method was an established technique with reasonable thaw survival and pregnancy rates, the application of slow cooling was extended to oocyte freezing. However, the oocyte has much higher water content compared to the embryo, and initial success was hampered by formation of ice crystals during cooling, causing a disruption in the meiotic spindle. In mature oocytes, metaphase chromosomes are lined up along the equatorial plate by the meiotic spindle, and this delicate spindle is easily damaged by ice crystal formation. Ultimately, changes to the sucrose and sodium concentrations were able to improve outcomes with the slow-freeze technique.

Vitrification is the solidification of a solution without formation of ice crystals. Oocytes are exposed to high concentrations of cryoprotectant followed by immersion into liquid nitrogen, creating a glass-like state. Its advantage over slow freeze is the avoidance of ice crystal formation and thus any consequent damage to the meiotic spindle. Hardening of the zona pellucida after thaw can create a challenge to successful fertilization, but is overcome by the use of intracytoplasmic sperm injection (ICSI). The majority of studies on thaw survival rates and pregnancy rates favor vitrification over the slow-freeze technique.

The ASRM reports number of live births following oocyte cryopreservation remains small but is rapidly rising. Thaw survival rates are approaching 98%, and pregnancy rate per

P.363

thawed oocyte is 4.2%. Although pregnancy rates are slowly improving with more experience, some published data touting success rates approaching that of fresh embryo transfers should be interpreted with caution given these data are derived from donor oocytes from young women without a history of infertility. Both chromosomal and congenital aneuploidy rates in thawed oocytes and live births are comparable to rates following natural

conception.

Oocyte freezing can be offered to any patient from adolescence to adulthood about to undergo bilateral oophorectomy or gonadotoxic therapy if the diagnosis will allow for the required time and hormonal stimulation necessary for oocyte harvest. Success rates as well as potential risks (OHSS, postoperative intraabdominal bleeding, and infection following oocyte retrieval) can now be reasonably quantified to allow for informed decision making.

Embryo Cryopreservation

If the patient has a stable partner at the time of diagnosis, embryo cryopreservation is the treatment of choice. This is a routine procedure in ART laboratories with reliable success rates performed through aforementioned techniques of slow freeze or vitrification. Embryos can be cryopreserved at any developmental stage, from prezygote, zygote, preembryo, morula, or blastocyst stage ([Fig. 20.1](#)). Decisions on the optimal

P.364

stage to freeze depend upon the experience of individual clinics. Although success rates vary by many factors—clinic experience, female age at the time of cryopreservation, and number and quality of embryos banked—a pregnancy rate of up to 60% can be reasonably achieved.

FIGURE 20.1 Embryos can be cryopreserved at any developmental stage (A-L).

CONCLUSION

The natural inclination of a gynecologic surgeon is to intervene in the setting of visible pathology. With regard to endometriosis, the benefit of surgical intervention varies based on degree of disease and intended fertility treatment. In cases of tubal occlusion, access to ART dictates whether surgical intervention is necessary. Each case is unique and must be considered individually. Therefore, the true challenge in treating the infertile couple in the age of ART is to understand whether surgical intervention is beneficial or an unnecessary delay to achieving pregnancy.

BEST SURGICAL PRACTICES

- The success rates of ART without surgical intervention should be considered before a recommendation for surgery is made.

- Success rates of ART are largely dependent on female age.
- Oocyte aneuploidy rates rise with advancing female age.
- For mild-to-moderate endometriosis, surgery can marginally improve spontaneous conception rates but does not approach success rates with ART.
- Patients with severe endometriosis may benefit from surgery prior to ART if lysis of adhesions is performed to restore female anatomy, thus reducing potential complications of oocyte retrieval.
- Pathologic diagnosis should be made for any rapidly expanding ovarian cyst to exclude malignancy prior to ART.
- Evidence does not support prophylactic removal of an asymptomatic endometrioma prior to ART with a goal of increasing pregnancy rates. However, removal should be considered in patients where size and location may obstruct oocyte harvest.
- Only young women (<35) with reasonable remaining tubal length and no coexistent risk factor for infertility should be considered for tubal reanastomosis. In the majority of patients with bilateral tubal disease or history of voluntary sterilization, ART should be recommended.
- Surgery for severe tubal disease should be reserved for young women who have ethical, religious, or financial restrictions that preclude IVF.
- Hydrosalpinges visible on transvaginal ultrasound should be removed prior to ART.
- Women with noncommunicating hydrosalpinges not visible on ultrasound could benefit from salpingectomy prior to ART. It is also reasonable to proceed directly to ART and reconsider salpingectomy if an initial attempt is unsuccessful.
- Subserous myomas do not adversely affect pregnancy or live birth rates, thus removal is rarely warranted.
- Submucous myomas decrease pregnancy rates and increase risk of miscarriage. Removal of submucous myomas should be advocated.
- Intramural myomas that do not distort the cavity may still reduce pregnancy rates and increase miscarriage rates. It is unclear if removal restores pregnancy rates to match rates achieved by women with unexplained infertility without myomas. Decisions made should be specific to the size, location, and coexistent conditions of the patient.
- Ovarian tissue cryopreservation can be performed without significant delay, does not require ovarian stimulation, and is the only fertility preservation option for prepubertal girls. It is currently considered experimental with a limited number of live births to date.
- Oocyte cryopreservation can be offered to adolescent and single adult women where controlled ovarian hyperstimulation and a delay in gonadotoxic treatment would not adversely affect the patient's outcome.
- Embryo cryopreservation remains the treatment of choice in fertility preservation for adult women with stable partners.

Chapter 21

Reconstructive Tubal Surgery

Victor Gomel

DEFINITIONS

Fallopscopy—A transvaginal endoscopic procedure to examine the fallopian tubes, especially the intramural and isthmic segments.

Fimbrial phimosis—Agglutination of the fimbriae.

Fimbrioplasty—The reconstruction of the fimbriae or tubal infundibulum.

Hydrosalpinx—A distally occluded tube, usually secondary to infection, which distends with accumulation of serous fluid.

Hysterosalpingography (HSG)—An x-ray-based contrast test to assess the uterine cavity and the fallopian tubes.

Pelvic inflammatory disease (PID)—An inflammatory disorder of the uterus, fallopian tubes, and adjacent pelvic structures usually secondary to a sexually transmitted infection.

Salpingo-ovariolysis—The division and/or excision of periadnexal adhesions with the aim of restoring normal anatomy.

Salpingoscopy—An endoscopic examination of the ampullary portion of the tubal lumen.

Salpingostomy—The creation of a new stoma in a tube with a completely occluded distal end.

Tubal cannulation—The passage of a flexible guide wire and narrow-gauge cannula through the proximal tubal ostia along the length of the tube.

Tubotubal anastomosis—The surgical approximation of tubal segments after tubal sterilization or excision of an occluded or diseased portion of tube.

The fallopian tube is a very important organ for the survival of our species. Human life normally originates in the proximal ampulla of the fallopian tube where the oocyte and sperm meet and where fertilization takes place. The physiologic functions of the human oviduct include pro-ovarian sperm transport to the site of fertilization, ovum pickup and prouterine transport of the ovum, ampullary retention of the fertilized oocyte (approximately 72 hours), provision of a suitable environment for fertilization to occur and for the zygote to survive, and, eventually, transport of the zygote from the ampulla to the uterine cavity. Alterations in any of these functions (caused by either damage to the ciliated epithelium or tubal distortion or occlusion) can result in tubal implantation (owing to the lack of transport of the zygote to the uterus) or infertility (owing to the prevention of sperm meeting the oocyte).

In vitro fertilization (IVF) techniques, which have experienced significant improvement in the past three decades, in effect replicate most of the functions of the fallopian tube, except for transport of the preembryo into the uterine cavity. This last step (embryo replacement) is performed using a cannula into which the embryo(s) is aspirated; the cannula then is introduced into the uterus through the cervical canal, and the embryo(s) is deposited in the uterine cavity.

TUBAL FACTOR INFERTILITY

Much of the increase in the incidence of both infertility and tubal pregnancy in the past four decades has been

the result of tubal damage after sexually transmitted pelvic infections. The commonly isolated organisms are *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Mycoplasma hominis*, of which *Chlamydia* is the most common. These organisms appear to account for most primary invasions; however, in 15% to 60% of cases of acute pelvic inflammatory disease (PID), aerobic or anaerobic bacteria, or both, can also be identified. The clinical picture can vary from an almost asymptomatic condition to a life-threatening event. As demonstrated by Westrom and colleagues, and by Paavonen and Egert-Kruuse, patients with a more severe clinical appearance often have both aerobic and anaerobic infections.

The classic clinical picture of PID, which includes pain, fever, and lower genital tract infection, occurs in less than 50% of affected patients. Gomel reported that more than half of the patients who were investigated for infertility and were found to have a hydrosalpinx gave no previous history of acute PID. This observation has since been confirmed. Indeed, the wide variation in the clinical presentation makes the diagnosis problematic.

It has been estimated that acute PID occurs at a rate of 10 cases per 1,000 women per year in the age group 15 to 39 years and at a rate of 20 cases per 1,000 women per year in the age group 15 to 24 years. Just as there is difficulty in diagnosing PID, there is difficulty in ascertaining the trend in its incidence. Westrom and colleagues reported that in PID cases, the rate of isolating *Chlamydia* per population of 100,000 has increased annually since 1984.

Data from Westrom and colleagues, and from Paavonen and Egert-Kruuse, indicate the infertility rate after a single episode of PID correlates with the degree of residue of tubal damage. Tubal infertility also increases with recurrent episodes of PID. Infertility occurred in 8% of patients with one episode, 20% with two episodes, and 40% in those with three or more episodes of PID. Further, up to two thirds of cases of tubal factor infertility and one third of cases of ectopic pregnancy may be attributable to *C. trachomatis* infection.

INVESTIGATION

The investigation of the infertile couple should be concluded rapidly, accurately, and inexpensively, with as little invasion as possible. In addition, the emotional needs of the couple must be recognized and addressed.

Investigation must commence with a thorough clinical assessment of the couple. A detailed history followed by a thorough physical examination permits the selection of the necessary tests to undertake. A positive history of PID or the finding of *Chlamydia* antibodies has a predictive value for tubal pathology of odds ratio (OR) 3.7 (1.7 to 8.4) and that of ruptured appendicitis of OR 4.4 (2.5 to 7.6). This chapter discusses only investigations specific to tubal and peritoneal factors of infertility.

Tubal Insufflation

Tubal insufflation is a tubal patency test, first described by Rubin, which is now rarely performed. The procedure uses an endocervical cannula connected, by rubber tubing, to a mercury manometer and a source of carbon dioxide (CO₂). The rate of gas flow through the system is gradually increased to approximately 30 to 60 mL per minute. Tubal patency is determined by one or more of the following: a written record of the rise and rapid fall of the gas pressure, auscultation of the lower abdomen for the gas passing through the tubes into the peritoneal cavity, or direct visualization of the pressure changes on a mercury manometer.

This historic tubal patency test has been replaced by hysterosalpingography (HSG) and/or salpingosonography. Both of these tests should be performed before ovulation, about the

P.366

tenth day of the cycle. Administration of one of the nonsteroidal anti-inflammatory medications is helpful to the patient as it reduces her discomfort due to uterine cramping and thus diminishes diagnostic errors.

Hysterosalpingography

Hysterosalpingography is a contrast study of the uterine cavity and fallopian tubes. It is a simple, inexpensive, safe, and rapid diagnostic procedure that, when performed properly, provides valuable information about the uterine cavity and tubal patency and architecture.

Contraindications to HSG include pregnancy, uterine bleeding, lower genital tract infection, PID, and allergy to the contrast material. In women with a history of recurrent PID, or with any suggestion of a recent exacerbation, there is a significant risk of reactivation of quiescent PID. This occurs in approximately 3% of such patients. To combat this risk, some centers prophylactically administer antibiotics. During the preliminary history and physical examination, the physician must search for possible contraindications and screen for and treat any lower genital tract infections, before performing an HSG. Prophylactic antibiotics prior to HSG are indicated in selected cases, particularly if hydrosalpinx is suspected.

Technique

Hysterosalpingography must be timed to occur between the complete cessation of menstruation and ovulation. This will avoid the risk of disturbing a luteal phase pregnancy. Such timing also avoids radiation exposure to the oocyte that will resume meiosis after the luteinizing hormone surge. Administration of a nonsteroidal anti-inflammatory medication before the procedure reduces the patient's discomfort and diminishes errors associated with HSG. The latter is especially applicable to errors regarding cornual occlusion. This has been clearly demonstrated in a study by Lang and Dunaway.

An oil-soluble or water-soluble contrast medium can be used. A recent Cochrane meta-analysis by Luttjeboer et al. concluded that use of an oil-soluble media increases subsequent pregnancy rates when compared with *no* intervention (OR 3.30; 95% confidence interval [CI] 2.00 to 5.43); however, there was no significant difference in the odds of pregnancy with oil-soluble versus water-soluble media (OR 1.49; 95% CI 0.95 to 1.54). Water-soluble media are most widely used; they are better tolerated by the patient; further, water-soluble media coat the surfaces without sticking to them, producing sharp and finely shaded images and greater visual detail of the lesions. These characteristics enable better assessment of the intraluminal architecture (**Fig. 21.1**). The contrast material is eliminated within 30 minutes.

FIGURE 21.1 Hysterosalpingogram. Early film demonstrates a normal uterus and a left hydrosalpinx. On the right, there is an ampullary defect (*arrow*) at the site of a previous tubal pregnancy, which was treated with parenteral methotrexate administration.

After the patient has emptied her bladder, she is placed on the radiographic table. A bivalve speculum is inserted into the vagina, and the cervix and upper vagina are washed with an antiseptic solution. The appropriate cannula, which is filled with contrast material and emptied of any air, is attached to the cervix in such a way as to ensure a tight seal. The speculum is removed before the injection of contrast material. Removal of the speculum is important (especially if the metal variety is used), not only to decrease the patient's discomfort but also to avoid obscuring the cervical canal and vaginal fornices on the x-ray films.

Hysterosalpingography must be performed under fluoroscopic control with the use of an image intensifier. With the syringe attached to the cannula, the contrast material is injected very slowly to avoid discomfort, contraction of the uterus, spasm of the uterotubal junction, and obscuring of the lesions with a large quantity of contrast material. Films are taken to record salient features as they appear on the monitor. An average of three to five films are taken. Preliminary films are of limited value; they can be used to identify misplaced intrauterine contraceptive devices or areas of pelvic calcification. Such information can also be gained by examining the first film.

As the contrast material is injected slowly and intermittently, the endocervical canal, isthmus, and uterine cavity are visualized. To straighten the uterus, firm traction is maintained on the cervix. A film is taken at this point. It is essential to obtain films early during the procedure to record any intrauterine lesions and details of the intratubal architecture. Such details are obscured by larger amounts of contrast material in the uterus, tubes, and peritoneal cavity. Another film is taken when the contrast material starts to escape into the peritoneal cavity (**Fig. 21.1**). Injection of medium is continued slowly until tubal patency is unquestionably established. Manipulation of the uterus with the cannula may be necessary to display specific tubal segments. A film is obtained when abnormal findings are encountered. In certain cases, a true lateral film may provide useful information. When taking this exposure, the traction on the cervix is temporarily released to obtain information regarding the position of the uterus, the location of intrauterine lesions, and the course and configuration of the tubes.

The last phase of the procedure includes a delayed fluoroscopic examination and a film taken 10 to 20 minutes (when water-soluble contrast material is used) after removal of the cannula. This examination and film may yield information about the external contour of the internal genitalia, the shape of the ovarian fossa, and the presence of periadnexal adhesions.

With adherence to proper technique, complications are rare. Major complications include PID, uterine perforation, bleeding from the tenaculum site, and intolerance to iodine, especially if intravasation of contrast occurs. Oil-soluble media may cause granulomas in the pelvis and serious complications if intravasation occurs; a case of cerebral embolization has been reported by Dan et al.

Hysterosalpingography performed using water-soluble media provides precise information about the uterus and oviducts that can assist in patient management. Abnormal uterine findings include fusion anomalies, T-shaped uterus, submucous fibroids and endometrial polyps, intrauterine synechiae (**Fig. 21.2**), and other less commonly identified lesions, such as adenomyosis. Tubal abnormalities that can be observed are listed in **Table 21.1** and shown in figures from Gomel and colleagues (**Figs. 21.3, 21.4, 21.5** and **21.6**).

It must be noted that HSG has limitations: (a) it often does not indicate the exact nature of intrauterine lesions; (b) it is associated with false-positive results with regard to cornual occlusion, which may necessitate a selective salpingography and/or tubal cannulation; and (c) it has a low positive

P.367

predictive value in the diagnosis of periadnexal adhesions and endometriosis. For these reasons, laparoscopy and, when necessary, hysteroscopy are undertaken to elucidate the diagnosis. Indeed, HSG and laparoscopy are complementary, not competitive, procedures in the investigation of infertility associated with tubal and peritoneal factors.

FIGURE 21.2 Hysterosalpingogram in a patient with Asherman syndrome. Contrast material outlines the cervical canal and a part of the lower uterine cavity, the remainder of which is obliterated by synechiae. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St Louis, MO: Mosby, 1995:106, with permission.)

In many instances, HSG demonstrates the presence of severe tubal damage or conditions deemed inoperable. Severe intratubal adhesions, and distal tubal occlusion in association with cornual lesions, such as salpingitis isthmica nodosa, are examples of contraindications of reconstructive surgery. In such instances, the couple may be advised of the significance of the findings, and IVF may be recommended as primary treatment, without recourse to laparoscopy.

We have been viewing and continue to view a well-performed HSG as a good, inexpensive, initial test to assess the uterine cavity and the fallopian tubes and are pleased to note concurrence in the American Society for Reproductive Medicine's (ASRM's) committee opinion in this regard: *"There is good evidence to support HSG as the standard first line test to assess tubal patency, but it is limited by false positive diagnoses of proximal tubal blockage."* It further states: *"The evidence is fair to recommend tubal cannulation for proximal tubal obstruction in young women with no other significant infertility factors."*

TABLE 21.1 Abnormalities of the Oviduct

ABNORMALITIES OF THE OVIDUCT		
ABNORMALITY	SIGNS	COMMENTS
TUBOCORNUAL REGION		
Failure of contrast to enter tube	Simple obstruction	May be owing to tubal spasm; may be unilateral or bilateral
Salpingitis isthmica nodosa (SIN)	Appears as a simple obstruction or as spicules of contrast radiating from tubal	May be unilateral or bilateral

lumen

Endometriosis	Similar to SIN, usually with more pronounced punctate pattern	May be unilateral or bilateral
Polyps	Small globular or elongated vacuoles surrounded by contrast medium	

ISTHMUS

Occlusion	Contrast outlines portion of the isthmic segment.	Most commonly owing to prior surgical sterilization or tubal pregnancy, less commonly to SIN, and uncommonly to tuberculosis and endometriosis
-----------	---	--

AMPULLA

Intraluminal adhesions	Patchy filling defects	Caused by endosalpingeal infection
Tubal pregnancy	Obstruction, stenosis, round defect, occasionally calcification	

INFUNDIBULUM

Hydrosalpinx	Obstruction usually bilateral	Most common type of occlusion
Phimosi of distal tubal ostium	Intraluminal retention of contrast medium and slow intraperitoneal spill from stenosed tube	Both conditions are usually sequelae of PID

INTRAPERITONEAL SPREAD

Adhesions	Localized pooling and loculation of contrast medium around distal end of oviducts	
-----------	---	--

FIGURE 21.3 Hysterosalpingogram showing bilateral proximal isthmic lesions typical of salpingitis isthmica nodosa. The right tube is occluded, whereas the left is still patent. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St Louis, MO: Mosby, 1995, with permission.)

Selective Salpingography and Tubal Cannulation

Selective salpingography is the injection of a contrast medium directly into the uterine tubal ostium with the use of a special radiopaque cannula inserted through the cervix. The increased pressure generated by the direct injection helps to overcome obstructions associated with mucous plugs or minor synechiae. Data from Thurmond, Novy et al, and Papaioannou et al. indicate selective salpingography is technically possible in approximately 90% of available tubes.

Cannulation of the tube requires the use of a special flexible guide wire and narrow-gauge cannula. This cannulation system is introduced through the larger cannula, which is used for selective salpingography.

If HSG demonstrates a cornual or proximal tubal obstruction ([Fig. 21.7](#)), selective salpingography with or without tubal cannulation ([Fig. 21.8](#)) should be the next step; this is ideally performed in the same setting. These techniques are useful in differentiating true from false cornual occlusion. The benefits of this approach have been shown for apparent cornual spasm, obstructions caused by amorphous material (tubal plugs), and tubal synechiae. Indeed, half of the tubes that were proximally blocked at selective salpingography were found to be normal after tubal catheterization in the largest series reported to date. It is doubtful that these techniques have a real therapeutic effect on pathologic occlusions that are due to obliterative fibrosis, chronic follicular salpingitis, salpingitis isthmica nodosa, or endometriosis.

FIGURE 21.4 Hysterosalpingogram. Both tubes exhibit extensive intratubal adhesions. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St Louis, MO: Mosby, 1995:106, with permission.)

FIGURE 21.5 Hysterosalpingogram showing bilateral hydrosalpinx. The longitudinal epithelial folds are preserved in the left tube. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St Louis, MO: Mosby, 1995:106, with permission.)

Salpingosonography

Salpingosonography is a sonographic technique to assess the uterine cavity and tubal patency. After the insertion of a Foley catheter into the cervix, transvaginal sonography is carried out to assess the pelvic structures. Then, a 20-mL syringe is filled with 10 mL of saline solution followed by 10 mL of air. Air is injected first slowly, and passage is followed through the tube; saline is then injected to cause the air bubbles to flow more visibly through the tube. Air-filled albumin microspheres have also been used for this purpose. Several authors (Chenia et al., Inki et al., Strandell et al.) found salpingosonography to have a concordance with laparoscopy of

P.369

approximately 80% and with HSG between 72% and 90%. Although the concordance with HSG with regard to passage of contrast into the peritoneal cavity appears high, it is important to remember that salpingosonography does not provide any information about the intratubal architecture. Yet, the pain scores associated with both of these techniques were comparable, as demonstrated in a prospective study by Cheong and Li in 2005.

FIGURE 21.6 Hysterosalpingogram. The tubes exhibit findings typical of a prior tuberculous salpingitis. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St Louis, MO: Mosby, 1995:108, with permission.)

FIGURE 21.7 Hysterosalpingogram showing bilateral cornual occlusion. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St. Louis, MO: Mosby, 1995:109, with permission.)

Salpingoscopy

Salpingoscopy is the endoscopic examination of the ampullary portion of the tubal lumen. This can be accomplished with a small-gauge rigid or flexible endoscope during either laparoscopy or laparotomy. If the distal tube is totally occluded (hydrosalpinx), it is necessary to make a small opening at the fimbriated end to permit the introduction of the scope. The tubal lumen is visualized while distended with physiologic solution injected through the outer sheath of the rigid endoscope or the channel of the flexible scope. The distal end of the tube must be appropriately manipulated to bring it into the axis of the scope. Salpingoscopy permits direct assessment of the tubal epithelium. The findings have been classified into five grades. Grade 1 refers to normal mucosal architecture. Grade 2 refers to tubes that demonstrate variable degrees of flattening of both major and minor mucosal folds, which are largely preserved. Grade 3 refers to tubes that demonstrate focal adhesions between mucosal folds. Grade 4 refers to tubes with extensive intraluminal adhesions or disseminated flattened epithelial areas. Grade 5 refers to tubes that are rigid and hollow with a complete loss of epithelial folds. Findings at salpingoscopy appear to be predictive and prognostic of pregnancy outcome.

FIGURE 21.8 Tubal cannulation (same patient as in [Fig. 21.7](#)). The occlusion has been relieved, and the tube has opacified. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St. Louis, MO: Mosby, 1995:109, with permission.)

Microsalpingoscopy has been used to examine the integrity of the tubal mucosa more closely.

Microsalpingoscopy uses an endoscope that has magnification capability enabling visualization of individual cells of the tubal epithelium. The epithelium is stained with concentrated methylene blue solution injected through the cervical cannula. It is then assessed under magnification. The level of staining of the nuclei of the tubal cells is inversely proportional to functional integrity of the mucosa. This technique is at present investigational; thus, its value remains to be determined.

Fallopосcopy

Fallopосcopy is a transvaginal microendoscopic technique aimed at exploring the entire length of the tube, especially the intramural and isthmic segments. A linear eversion catheter system has been used to perform fallopосcopy without the need for preliminary hysteroscopy and anesthesia. The patient requires premedication to decrease the discomfort associated with the procedure.

The system includes a linear eversion catheter with an outer plastic polymer body 2.8 mm in diameter and a sliding stainless steel inner body 0.8 mm in diameter, containing a 0.48-mm fiberoptic endoscope. The tip of the outer catheter is angulated so it can be directed toward the uterotubal junction. Once the tubal ostium is identified, the tip of the catheter is held against the ostium. The pressure within the eversion catheter is increased, and the membrane of the eversion catheter is introduced into the fallopian tube for a short distance. The endoscope is pushed down the lumen to the tip of the introduced catheter. The image obtained is displayed on a high-resolution color monitor. The eversion catheter and the endoscope it houses are advanced in the described manner, slowly and gradually, with the endoscope always maintained within the inverting membrane to prevent the tip of the endoscope from piercing the tubal wall.

Fallopосcopy may be used as a means of tubal catheterization and has the added benefit of permitting assessment of the lumen of the tube, especially its intramural and isthmic segments. Kerin et al. proposed a classification based on a scoring system that takes into account the degree of tubal patency, tubal dilatation, epithelial and vascular changes, intratubal adhesions, and other abnormal findings.

This technique, which requires expensive disposable equipment, did not gain clinical acceptance.

Tests Designed to Assess Tubal Function

Salpingography, salpingoscopy, and fallopосcopy are designed to assess tubal patency and morphology. Many procedures designed to assess tubal function have been proposed but did not attain clinical acceptance.

Early attempts at using radioactive microspheres as oocyte surrogates to evaluate egg transport did not appear to be clinically valuable. Uher et al. have introduced biodegradable microspheres into the pouch of Douglas by either cul-de-sac puncture or laparoscopy. These microspheres, which

P.370

were recognizable by fluorescence, were collected in a cervical cup 24 hours later. Microspheres were present in the cup in 66% of 69 patients with unexplained infertility and in 100% of 20 patients with male factor infertility.

Radionuclide Hysterosalpingography

Radionuclide HSG is a scintigraphic procedure designed by Brundin and colleagues to evaluate the spontaneous pro-ovarian transport of microspheres in the genital tract. A solution containing ^{99m}Tc -labeled albumin microspheres is squirted toward the external cervical os of the cervix and upper vagina. The subsequent

transport of the microspheres through the cervix, uterus, and tubes is monitored by a gamma camera equipped with a pinhole collimator. The pro-ovarian transport of microspheres depends on both the anatomic patency and the functional integrity of the uterus and oviducts. This test is designed to assess primarily the sperm transport function of the uterus and tubes. This technique is still experimental, but preliminary work reported by Lundberg et al. indicates it is not predictive of fertility potential.

Laparoscopy

Laparoscopy permits direct visualization of the peritoneal cavity, pelvis, and internal reproductive organs. It can also test tubal patency with the use of concomitant chromopertubation. It is the most accurate way to identify periadnexal adhesive disease and endometriosis. Laparoscopy also provides the necessary surgical access to perform surgical procedures. Hysteroscopy and salpingoscopy, when indicated, may be performed during the same setting. Laparoscopy is an invasive procedure that usually requires a general anesthetic. It is important to be reminded that most of the major vascular and bowel injuries occur with the initiation of laparoscopy, during the introduction of the Veress needle, principal trocar, and ancillary trocars.

There are those who argue in favor of an immediate laparoscopy bypassing HSG. An analysis of 18 published series demonstrates good congruence between laparoscopic and HSG findings. These collected data indicate that the sensitivity and specificity of HSG are approximately 76% and 83%, respectively. These studies represent a selected population of patients in whom the prevalence of tubal occlusion was 38%. This prevalence figure falls to 10% in studies of large numbers of unselected patients, which reflects more accurately the general population. If the sensitivity and specificity figures reported above are applied to a hypothetical group of patients with a 10% rate of tubal occlusion, only 3% of those with a normal HSG will have an abnormal laparoscopy. Thus, the laparoscopy will be normal in approximately 97% of patients. These data support delaying endoscopy for 4 to 6 months in those with an apparently normal HSG, except in women of older reproductive age.

Based on the preceding information, a well-performed HSG should be the preliminary investigation for tubal factor infertility. This approach permits the identification of (a) uterine anomalies and lesions; (b) cornual occlusion or lesions, even in the presence of cornual patency; (c) distal tubal occlusion; and (d) assessment of intratubal architecture. This information is of paramount importance to the surgeon at the time of laparoscopy, especially if the condition is amenable to laparoscopic surgery, which should be performed in the same setting. Indeed, with the advanced imaging techniques and newer therapeutic modalities available today, laparoscopy, solely for the purpose of diagnosis, should be rarely required.

Laparoscopic Survey

A thorough laparoscopic survey will identify any adhesions, along with their extent and nature; reveal the presence of endometriosis, its extent, and other abdominal and pelvic lesions; and permit assessment of the uterus, ovaries, and tubes. The information yielded by the prior HSG and this survey enable the surgeon to undertake reconstructive laparoscopic surgery and to recommend surgery by open access or the use of assisted reproductive technologies. These will be discussed later.
