A bimanual pelvic examination is performed on the anesthetized patient. The cervix is then exposed, and a uterine cannula is attached to the cervix. In addition to permitting intraoperative chromopertubation, the cannula enables manipulation of the uterus and enhances laparoscopic visualization.

Once the laparoscope is inserted, the entire peritoneal cavity is inspected. Inspection commences in the upper abdomen and includes the liver and the undersurface of the diaphragm, which are inspected in a clockwise fashion. Particular attention is then focused on the lower abdomen and pelvis. To improve access to the pelvis, the patient is placed in the Trendelenburg position. The bowel is displaced upward, initially by manipulating the uterus and thereafter by using a probe or other appropriate instrument inserted through a second puncture,

usually placed suprapubically in the midline, or in one of the lower quadrants.

A general panoramic inspection of the pelvis is performed with the laparoscope at some distance from the pelvic organs. This permits a general impression to be formed. Subsequently, a systematic survey is performed. The laparoscope is advanced; appropriate manipulation of the uterus, with the cervical cannula, and of the suprapubic probe enhances visibility of specific organs. The uterus is assessed, along with its anterior surface, the vesicouterine pouch, and the dome of the bladder.

The uterus is then moved into anteversion. The fundus and the posterior surface of the uterus, the uterosacral ligaments, and the pouch of Douglas are thoroughly inspected. If fluid is present in the pouch, its nature is noted. It may be necessary to aspirate the fluid to inspect the underlying peritoneal surfaces. To aspirate the fluid, the probe is replaced by a suction cannula, which can also be used as a manipulating probe. The aspirated fluid can be sent for microbiologic or biochemical studies as deemed necessary. The cul-de-sac and the lateral peritoneal surfaces are inspected for any scarring or evidence of endometriosis. In addition, the peritoneum over the pararectal spaces and over the sacrum should be evaluated.

The extent and type of pelvic and periadnexal adhesions are noted (**Fig. 21.9**). Each tube and ovary and the respective pelvic sidewalls are thoroughly scrutinized. Once the anterior surface of the ovary is inspected, the ovary is elevated and flipped upward with the probe, exposing its posterior surface, the fossa ovarica, and the pelvic sidewall down to the level of the uterosacral ligament, which are assessed. The tube is inspected from the proximal to the distal end. Attention is paid for any evidence of fusiform swelling at the uterotubal junction (which is usually caused by salpingitis isthmica nodosa or endometriosis); the distal end of the tube is scrutinized for the presence of fimbrial phimosis or frank distal tubal occlusion (hydrosalpinx) (**Fig. 21.10**). The ovarian fimbrial relation is assessed, and the fimbriae are viewed en face. Once the other adnexa are similarly assessed, chromopertubation is performed by injection of dilute indigo carmine or methylene blue solution through the uterine cannula. The passage of the dye solution is followed through the tube, and the nature of the spill is examined by viewing the fimbriae to determine the presence of prefimbrial phimosis or fine fimbrial adhesions that may impede ovum pickup.

P.371

FIGURE 21.9 Laparoscopy. Periadnexal adhesions cover and fix the distal half of the fallopian tube.

Abdominal, pelvic, and periadnexal adhesions may impede laparoscopic access to the pelvis and the adnexa; this may necessitate preliminary adhesiolysis.

Hydroculdoscopy (Fertiloscopy)

Hydroculdoscopy was introduced to visualize the fallopian tubes, ovaries, and the cul-de-sac of Douglas. The technique is a modification of the traditional “culdoscopy,” which has been largely abandoned. It was introduced as a diagnostic technique to replace laparoscopy in the investigation of infertile women, hence the name “fertiloscopy.”

With the patient properly positioned, a bimanual examination is carried to examine the pelvic organs and confirm that the pouch of Douglas is free. The posterior fornix of the vagina is exposed, and the pouch of Douglas is entered using a Veress-type needle. Once the needle is appropriately placed, 200 to 250 mL of saline solution is introduced into the pouch of Douglas through the Veress needle. A trocar/cannula that permits the introduction of a small-caliber endoscope or a “fertiloscope” is then inserted.

The procedure permits the visualization of the pouch of Douglas, the posterior surface of the uterus, the fallopian tubes, and ovaries. Tubal patency can be ascertained by the introduction of a dilute methylene blue solution into the uterine cavity, through an appropriate cannula. If tubal damage is suspected, a salpingoscopy may be performed during the same procedure.

FIGURE 21.10 Laparoscopy. Thin-walled dilated hydrosalpinx with extensive pelvic and periadnexal adhesions.

FIGURE 21.11 Fertiloscopy: views of ovarian drilling via hydroculdoscopy using a bipolar electrode.

Initially introduced as a diagnostic tool, the technique has also provided surgical access for certain therapeutic

procedures including minor adhesiolysis and ablation of minor endometriotic lesions; it also permits performance of ovarian drilling.

The first ovarian drilling by hydrocuidoscopy was performed in France in 1999 at the Antoine Beclère Hospital by Hervé Fernandez, introducing a bipolar Versapoint probe into the pouch of Douglas through a site lateral to that of the endoscope. The patient was markedly obese and was found to have polycystic ovaries as reported by Fernandez in 2001 ([Fig. 21.11](#)). Ovarian drilling using this access has since been performed in many centers; the reported results appear similar to those performed by laparoscopy.

It is evident that the procedure cannot be undertaken if the cul-de-sac of Douglas is occluded. The view obtained with hydrocuidoscopy is localized and very different from the panoramic view obtained by laparoscopy; furthermore, it does not offer the wide surgical applications that laparoscopic surgical access offers. However, it does have a role in replacing a laparoscopy in appropriately selected patients.

TREATMENT OF TUBAL INFERTILITY

Until the mid to late 1980s, reproductive surgery was the main option of treatment for the infertile woman with damaged fallopian tubes to achieve a pregnancy. This changed dramatically due to significant progress realized in IVF in the decade of the 1990s. The Society for Assisted Reproductive Technology reports rates in the United States progressed from 12.3% of births per initiated cycle in 1990 to 25.4% in 1999, 2004. The 1990s also witnessed the introduction and acceptance of intracytoplasmic sperm injection (ICSI), which proved to be a panacea in the treatment of male infertility.

There are now two realistic treatment options for the treatment of tubal and peritoneal factor infertility: reconstructive surgery and assisted reproduction techniques (ART). Surgery also experienced significant progress and development in the last three decades. Furthermore, presence of a credible alternative with IVF permits the reproductive surgeon to operate on cases with a better prognosis, which was not the case before the end of the 1980s. We have known for a long time that one of the important factors influencing surgical outcome is the degree of tubal damage. Operating on patients with better prognosis translates in superior outcomes as has been

P.372

well demonstrated. Surgery and IVF must not be regarded as competitive but rather as complementary treatments necessary to achieve the desired goal. The choice of treatment is ideally dependent on multiple considerations, both technical and nontechnical.

Technical considerations refer to proper assessment of the clinical findings of the couple. It is evident that IVF is the only treatment option for women with inoperable fallopian tubes and tubal disease coincident with another important fertility factor, such as male factor infertility. Not infrequently, a woman will require reconstructive surgery to make IVF possible or more frequently to increase the success rate with IVF. Some patients are better served with surgery.

The provision of accurate information regarding both IVF and tubal surgery is essential in the decision-making process of the couple. The couple must be given the live birth rate per cycle of IVF, the cumulative birth rate after multiple cycles of treatment, and the potential complication rates, including multiple pregnancy, abortion, and ectopic pregnancy. In addition, the effect of frozen embryo replacement on the cumulative pregnancy rate must be considered in the analysis. Similar information must also be provided regarding reconstructive tubal surgery. It is imperative that such figures reflect the experience of the center in which treatment will be performed and not those reported in international journals.

Nontechnical considerations include age, cost, and the wishes of the couple. Female fecundity is adversely affected by age. Fecundity begins to decline at approximately 31 years of age. This trend has been observed

both in “normal” couples and in those with unexplained infertility. This decline becomes even more evident after 35 years of age. In women of advanced reproductive age, the marked decline of fecundity rate per cycle of IVF must be weighed against the fact that reconstructive surgery offers multiple cycles during which conception can occur. Therefore, although the younger woman may consider surgery for a given condition, those in more advanced reproductive age, 37 and over, may be advised to consider IVF first.

Health insurance coverage and the cost of the procedure, depending on the jurisdiction, and the resources of the couple play important roles in the decision-making process. Another, often underestimated potential factor is the economic impact of a multiple pregnancy, which occurs much more frequently with IVF.

The perceptions and wishes of the couple regarding treatment options depend on many influences, including their own values and ethical views. There may be disagreement between partners. The physician should provide detailed information for the couple as clearly and accurately as possible and should abstain from interfering with their decision making except to clarify misunderstandings and misinterpretations. The physician must advise against active treatment when the prognosis is poor because treatment with essentially no chance of success cannot be justified.

The significant improvement in the outcomes of ART was largely due to the simplification of techniques, both clinical and laboratory, progress made in cryopreservation, and the replacement of multiple embryos. Another important factor was the commercialization of these services, which proved lucrative. The number of IVF programs in the United States increased from 267 in 1994 to 461 in 2004, and the number of cycles performed quadrupled during the intervening 20 years from approximately 32,000 to 128,000, which represented a \$1.25 billion business. During the same period, there has been a significant decline in the use and teaching of reconstructive infertility surgery. In vitro fertilization started increasingly to be offered, as primary treatment option, in most cases of tubal factor infertility. These changes have occurred despite the acceptance of laparoscopic access to perform many of the reconstructive tubal operations and the use of minilaparotomy incision for more complex anastomotic procedures, both of which have become day care procedures. Concerned with this trend, as early as 1992, we emphasized that both therapeutic options had a place, that treatment should be individualized based on the clinical findings and circumstances of the couple, and that these two options were not competitive but rather complementary. We are of the same opinion today.

Assisted reproduction has revolutionized reproductive medicine; we are in full recognition of this fact. We also believe that reproductive surgery has an important place in the treatment of tubal infertility and in assisting to improve ART outcomes in those who need preliminary surgery. We are gratified to find in ASRM's “Committee Opinion: Role of Tubal Surgery in the Era of Assisted Reproductive Technology” published in March 2012 support for many opinions we have held about the role of reproductive surgery since early 1990s, when ART results started to show significant progress. We strongly recommend the reader to obtain a copy of this document.

In Vitro Fertilization and Embryo Transfer

Reconstructive tubal surgery was the only treatment option for infertile women with damaged fallopian tubes, until the recent past. This is no longer the case due to significant improvement in outcomes and much wider availability of IVF and ART that provide such couples with a realistic therapeutic alternative.

Data collected prospectively for ART treatments during the year 2009, the last year for which there was a detailed analysis available at the time of writing, from 441 clinics in the United States provided the following outcome data, which were tabulated by the Centers for Disease Control and Prevention (CDC) in 2011. There were 146,244 cycles of ART in 2009. Of these 102,478 (70.1%) were fresh nondonor and 26,069 (17.8%) were frozen nondonor cycles; 11,038 (7.5%) were fresh donor and 6,659 (4.6%) were frozen donor cycles. The majority of the women treated (61.1%) were 35 years of age and more, and only 38.9% were under 35. The

overall live birth rate per cycle started in the fresh nondonor group was 30% and in the frozen nondonor group was also 30%. The birth rate was the same in 2010. In cycles that resulted in a clinical pregnancy, 81.3% resulted in live births. Of live births, 69.5% were singleton births and 28.9% were twins and 1.6% triplets or greater multiples.

Of note, a 2013 report from the CDC indicates the number of ART cycles performed in the United States has more than doubled from 64,036 cycles in 1996 to 147,260 in 2010. More important is the improvement in the overall live birth rate per cycle started from 12.3% in 1990 to 30% in 2010.

Intracytoplasmic sperm injection represents a very important progress in ART; it has proven to be a panacea in the treatment of male infertility. As early as 2003, it was demonstrated that in male factor infertility, the use of ICSI is associated with a success rate that almost equals that of standard IVF in the absence of male factor (**Table 21.2**). Furthermore, since the same time there has been an increasing use of ICSI for fertilization of oocytes even in couples without a male factor. In the United States in 2010, ICSI was used in 66% of IVF cases.

The outcome of both standard IVF and ICSI is adversely affected by the age of the female partner. There is a linear decline after age 35 in both the overall live birth rates and the implantation rate of embryos as clearly evident in **Table 21.3** that summarizes the US IVF results for the year 2010.

P.373

TABLE 21.2 CDC 2003 Assisted Reproductive Technology Report

LIVE BIRTHS PER OOCYTE RETRIEVAL IN ART CYCLES 2003

	AGE (YEARS)				
	<35	35-37	38-40	41-42	>42
Male factor infertility					
IVF	42.6%	35.9%	26.2%	16.1%	6.0%
IVF with ICSI	41.8%	35.0%	24.1%	13.5%	4.2%
No male factor infertility					
IVF	42.6%	35.9%	26.2%	16.1%	6.0%
IVF with ICSI	37.8%	32.2%	21.8%	11.0%	4.2%

ART, assisted reproductive technology; IVF, in vitro fertilization; ICSI, intracytoplasmic sperm injection.

There has been an increase in the use of frozen nondonor embryos and improvement in outcomes. Frozen nondonor embryos were used in approximately 18% of all ART cycles performed in 2009, compared to 14% in 2003. The rate of thawed embryos resulting in live births is 30.3%, similar to the overall rate with fresh nondonor cycles, which is quite impressive. Although replacement of frozen thawed embryos improves the cumulative

success rate for a couple, the overall net effect remains limited because not all of the cycles provide spare embryos and not all of the frozen embryos withstand the thawing process.

In vitro fertilization and embryo transfer is not risk free, especially in stimulated cycles. Although uncommon, ovarian hyperstimulation, bleeding, and infection can occur. Pregnancies resulting from IVF have an abortion rate of approximately 17%. The overall tubal pregnancy rate is approximately 1% to 2% of ART cycles. A 1991 study from our center by Zouves et al. demonstrated a tubal pregnancy rate of 2.6% (of clinical pregnancies) among IVF patients without tubal factor infertility. However, this rate was 12% in patients with prior tubal disease and tubal surgery.

Assisted reproductive technology procedures are associated with a significant increase in the rate of multiple pregnancies (relative risk [RR] >20). The Centers for Disease Control (CDC) Assisted Reproductive Technology report for 2009 indicated that of the resulting live births, only 69.5% were singletons, 28.9% twins, and 1.6% triplets or higher order. These results show a modest improvement compared to those of 2003, which were 65.8%, 31.0%, and 3.2%, respectively. The high rate of multiple pregnancies is due to the number of embryos transferred. Since transfer of more embryos improves the overall pregnancy rate, there is a temptation to do so. In Europe, where in many jurisdictions the number of embryos to be transferred is limited, both the live birth outcomes and the multiple pregnancy rates are lower ([Table 21.4](#)).

The high rate of multiple births has a tremendous personal and social impact. Perinatal morbidity and mortality are markedly increased in pregnancies complicated by multiple gestations. The cost, both emotionally and financially, of caring for premature or abnormal children is great. It was demonstrated that monofetal pregnancies also are associated with elevated risk as compared with non-ART singleton pregnancies; more than 10% of monofetal births are preterm, and the perinatal mortality rate (approximately 19 per 1,000) is higher than non-ART singleton pregnancies. This has not changed; the 2009 US outcomes for fresh nondonor ART cycles indicate preterm birth rates of 11.6% for singletons from single-fetus pregnancy, 19.0% for singletons from multiple-fetus pregnancy, 60% for twins, and 97.5% for triplets or more. The percentages of low-birth-weight infants for the same group were 8.7%, 16.7%, 56.1%, and 92.1%, respectively.

A 1994 study by Rufat et al. from France that analyzed a total of 1,637 IVF pregnancies resulting in 1,263 deliveries and 1,669 live born or stillborn children demonstrated a preterm birth rate of 22.7% of all deliveries and 12.2% of singleton deliveries compared with 5.6% among all deliveries in France, and 34.7% of babies weighed less than 2,500 g compared with 5.2% among all deliveries in France. The rates of perinatal, neonatal, and infant mortality were higher than the national

P.374

average. Another important study by Bergh et al. from Sweden compared the obstetric outcomes of babies conceived with IVF ($n = 5,856$) to all babies born in the general population during a span of 13 years (1982-1995) demonstrated that children resulting from IVF conception had increased rates of low birth weight (RR = 5), major malformations (RR = 1.4), cerebral palsy (RR = 4), and death (RR = 2). Such elevated personal and societal costs must be considered when embarking on any ART procedure.

REPRODUCTIVE SURGERY

Reproductive surgery encompasses much more than procedures designed to improve fertility, as understood by some. In fact, in addition to fertility-promoting procedures, such as reconstruction of fallopian tubes and salpingo-ovariolysis, it includes all surgical procedures performed on the pelvic organs of female children, adolescents, and childbearing age women, and not only when performed in those who present with infertility. It must be noted that *“female infertility is frequently caused by misdiagnosis or delayed diagnosis and treatment of acute conditions in young and/or reproductive age women, such as PID, ectopic pregnancy, appendicitis, etc. It is also caused by surgical procedures that are unnecessary, unnecessarily extensive and/or traumatic, resulting in damage to or loss of normal reproductive organs and development of post-operative adhesions.”* These observations clearly demonstrate the need to stress the importance of reproductive surgery, and to avail surgeons and especially gynecologists with training opportunities in this field.

Surgery was the only available therapeutic option for infertility caused by tubal and peritoneal factors until the mid-1980s. Traditional surgical techniques often yielded poor outcomes frequently as a result of extensive postoperative adhesions. In my textbook *“Microsurgery in Female Infertility”* published in January 1983, I wrote “I have vivid recollections of the frustration and disappointment I felt, when assisting as a resident at second-look laparotomies for removal of prosthetic devices such as Mulligan hoods, at finding extensive adhesions in the

peritoneal cavity; with bowel, omentum, and the internal genitalia adherent to one another. Extensive adhesiolysis and separation of structures were often necessary in order to visualize the oviducts and remove the prosthetic devices left in situ during the prior reconstructive operation.”

We have had important developments in the field of reproductive surgery in the past four decades. Gynecologic microsurgery was introduced in the early 1970s; simultaneously, laparoscopic surgical access was used for tubal reconstruction, especially in distal tubal disease. Used initially by open access, microsurgical tenets were also applied in procedures performed by laparoscopic access. The use of magnification and especially microsurgical principles yielded significantly improved outcomes, particularly in tubal anastomosis.

The use of laparoscopy for surgical access provided the advantages that are now well recognized: less postoperative discomfort and analgesic requirement, shorter hospital stay and postoperative recovery period, improved cosmetics, and frequently reduced costs. Many laparoscopic interventions became ambulatory procedures, the patient being able to return home the same day. It also did not take long to realize that this mode of surgical access yielded results that were not dissimilar to those obtained via laparotomy, provided of course the technique used was the same. Experience with laparoscopy permitted modification of open interventions for more complex cases, such as tubocornual anastomosis, where a small minilaparotomy incision replaced a formal laparotomy, permitting such procedures also to be performed on ambulatory basis.

The overall risks of reconstructive tubal surgery are small and include the recognized complications of anesthesia and surgery. Surgery, if successful, offers multiple cycles in which to achieve conception and the opportunity to have more than one pregnancy. The abortion rate subsequent to reconstructive tubal surgery is not increased over that of the normal population. The live birth and ectopic pregnancy rates depend on the specific nature of the tubal disease and the extent of tubal damage.

MICROSURGERY

Principles

Microsurgery has been defined as “surgery under magnification.” In fact, magnification is only a single facet of microsurgery, which embraces a broad concept of tissue care designed to minimize tissue damage and the use of measures that prevent and/or decrease an acute inflammatory reaction in the peritoneal cavity. These are measures applicable to both open and laparoscopic access; they include the following:

- Use of a delicate, atraumatic technique designed to minimize tissue injury, which in addition includes judicious use of electrical or laser energy and frequent intraoperative irrigation with heparinized lactated Ringer solution to keep serosal surfaces moistened to prevent desiccation
- Prevention of foreign body contamination of the peritoneal cavity
- Obtaining meticulous pinpoint hemostasis, using a microelectrode, minimizing adjacent tissue damage.
- Complete excision of abnormal tissues
- Identifying proper cleavage planes and precisely align and approximate tissue planes with fine nonreactive sutures
- Performing a thorough pelvic lavage using heparinized lactated Ringer solution at the close of the procedure to remove from the peritoneal cavity any blood clots, foreign body, or debris that may be present.

Additional measures help to decrease acute inflammatory reaction. Specifically before the close of the procedure, we leave 300 to 500 mL of lactated Ringer solution with 500 mg

of hydrocortisone succinate in the peritoneal cavity. General measures assist in this regard: use of preoperative

and postoperative antiinflammatory medications, for example, Voltaren suppository, infiltration of a local anesthetic before placing the incision, and the administration of a single dose of prednisone postsurgery.

Magnification, with an operating microscope or with an endoscope, provides many advantages; it permits prompt identification of abnormal morphologic changes, recognition and avoidance of surgical injury, and application of the preceding principles with the use of fine instruments and suture materials. Microsurgery is a surgical attitude as much as a technique.

In the late 1960s, Swolin used magnification with loops—electrosurgery with a fine electrode for the reconstruction of distal tubal occlusion. In addition, he strived to reduce peritoneal trauma by keeping the operative site moistened by frequent irrigation. In Vancouver, we expanded the microsurgical techniques; using an operating microscope, we applied them in the correction of pathologic cornual and midtubal occlusions (tubocornual anastomosis and tubotubal anastomosis) and in reversal of sterilization. This approach permitted us to perform tubocornual anastomosis as opposed to a tubouterine implantation—which was the standard procedure at the time—in cases of pathologic cornual occlusion. An anastomosis in such cases preserves tubal integrity and thus is a more physiologic approach of tubal reconstruction.

Microsurgery, in fact, finds its ultimate application in tubal anastomosis. The use of magnification, microsurgical instruments, and sutures enables the recognition of subtle abnormalities—even in the presence of tubal patency, excision of abnormal tissues, and correct alignment of the tubal segments and precise apposition of each layer. Indeed, the application of microsurgery has significantly improved the outcome of such procedures. However, in the treatment of distal tubal occlusion, any improvement attributable to the use of microsurgical techniques has been relatively modest, despite the reduction in postoperative adhesions and improved tubal patency rates.

The introduction of microsurgery into gynecology has yielded benefits much greater than simple improvement in the outcome of certain fertility operations. It created a great awareness of the effects of peritoneal trauma and the resulting postoperative adhesions. It also promoted the use of conservative approaches that are now considered standard of care for women undergoing surgical treatment for benign gynecologic disease. These are additional and important reasons to continue to teach reconstructive infertility surgery. Thus, microsurgery is a surgical philosophy, a delicate surgical approach designed to minimize peritoneal trauma and tissue disruption and prevent postoperative adhesions while increasing the accuracy of the procedure and improving the outcome.

Microsurgical techniques are equally applicable to both open and laparoscopic access. We demonstrated the applicability of microsurgical techniques by laparoscopy for adhesiolysis, salpingo-ovariolysis, fimbrioplasty, and salpingostomy as early as the mid-1970s. Microsurgical techniques must be used in all reproductive operations, irrespective of the mode of access. This is especially important today because most such procedures are performed by laparoscopy and minilaparotomy.

The laparoscope also provides a degree of magnification. Bringing the distal end of the laparoscope close to the area of interest, one achieves excellent visibility and illumination. There are microsurgical advantages inherent to laparoscopic access. Operating within a closed peritoneal cavity eliminates the need to use packs and prevents the introduction of foreign materials such as lint and talcum powder. The pressure effect of the pneumoperitoneum diminishes venous oozing and permits spontaneous coagulation of minor vessels. It is possible to perform intraoperative irrigation to expose any bleeding vessels and keep tissues moistened. Fine electrodes can also be used to achieve precise electrosurgical hemostasis. Like microsurgery, laparoscopic procedures are performed with few instruments. The instrument manufacturers have at last recognized the need for proper microsurgical instruments for laparoscopy; they are now readily available.

We must stress, however, that the large volume of gas insufflation necessary in operative laparoscopy causes desiccation of the mesothelial cells that line the peritoneum; furthermore, it has been recognized that CO₂ is toxic to mesothelial cells. This phenomenon may enhance the development of postoperative adhesions. Hypoxia

causes retraction of the mesothelial cells exposing the extracellular matrix. This causes substances and cellular elements that enhance adhesion formation or decrease repair to enter the peritoneal cavity. Both animal and more recently human work demonstrated that the noxious effects of CO₂ pneumoperitoneum may largely be avoided by modifying the gas mixture by adding small percentages of O₂ and N₂O, keeping the gas mixture fully humidified and at a temperature of 31°C.

Major Equipment and Surgical Instruments

The major equipment includes an electrosurgical generator suitable for both general and microsurgical work and, depending on the access mode used, either an operating microscope or appropriate laparoscopic equipment. Most of the good modern electrosurgical generators can be used for both general work and microsurgical work. Such generators are now standard equipment in most operating rooms.

When access to the pelvis is achieved by laparotomy or minilaparotomy, magnification is obtained by the use of an operating microscope or loops. Loops provide low levels of fixed magnification. It is difficult to work with loops that provide a magnification greater than four times. They are suitable for use only in simple short procedures and are quite helpful when used to divide adhesions or excise endometriotic lesions located deep in the pelvis. Magnification is best obtained with an operating microscope that provides magnification ranges from 2 to 40 times; coaxial illumination of a constant visual field enables precise focusing and change of levels of magnification. In gynecologic microsurgery, an objective lens with a focal distance of 250 to 300 mm allows for a suitable working distance under the lens. The microscope can be mounted on the floor or ceiling. Focusing, varying the level of magnification, and other functions of the microscope can be manual or motorized. The latter version is preferable because changes can be readily accomplished through controls on a foot pedal while the surgeon's hands remain in the operative field. Most modern operating microscopes are equipped with beam splitters, which permit the fitting of two pairs of binoculars so that both the surgeon and the assistant can simultaneously view the operative field. A miniature television camera can also be fitted to the same beam splitter, which enables the operating room personnel to follow the surgery on the monitor and allows video recordings of the procedure to be made.

When laparoscopic access is used, a good laparoscope equipped with a high-resolution mini TV camera and a high-resolution monitor is required. The laparoscope does not offer the stereoscopic vision and the excellent depth of field that the operating microscope provides. Nonetheless, first generations

P.376

of three-dimensional laparoscopic equipment and magnification devices have been produced. Progress is under way.

FIGURE 21.12 The working tips of the principal microsurgical instruments: plain forceps, scissors, and needle holder.

Good microsurgical instruments for open access have been present since the 1970s. Microsurgical instrument for laparoscopic access became available in the last two decades. Although their shapes are obviously different, their functions are similar. The basic microsurgical instruments are few and include plain and toothed platform microforceps, microscissors, microneedle holder, and straight scissors and/or a microblade to transect the tube (**Fig. 21.12**). The forceps have rounded tips with a shaft designed so that they, like the scissors and needle holder, have good ergonomics and can be used comfortably. Teflon-coated probes with variable rounded tips are used for retraction.

Electromicrosurgery requires the use of a true insulated microelectrode of 100 or 150 μm in diameter with a free pointed conical tip. The microelectrode is connected to the handle of the electrosurgical unit with an adaptor. A rocker switch mounted on the handle allows delivery of current in cutting, coagulating, or blend modes. Irrigation can be performed with an appropriate laparoscopic irrigator. For open procedures, a device with a fingertip control (Gomel irrigator) (**Fig. 21.13**) is commercially available and enables accurate irrigation.

FIGURE 21.13 The Gomel microvascular irrigator. An intravenous cannula has been attached to the tip of the irrigator. Fingertip control of the sliding valve permits one to initiate or stop irrigation.

Immediate Preoperative Preparation

Before the induction of anesthesia, the surgeon must ensure that all necessary equipment and instruments are present and in working order. After the induction of anesthesia, the patient's bladder is catheterized with a Foley catheter, which is connected to continuous drainage. If intraoperative chromopertubation is required, either a pediatric Foley catheter or an appropriate uterine cannula is introduced through the cervix and fixed in place. The catheter or cannula is connected either directly or by means of an extension tube to a syringe filled with dilute dye solution.

When open surgical access is used, anteversion and elevation of the uterus can be achieved either by selecting a suitable uterine cannula or by packing the vagina. With the latter option, a pediatric Foley catheter should first be placed in the uterine cavity if intraoperative chromopertubation is desired.

Surgical Access

As indicated earlier in the text, many reconstructive tubal operations can be performed by laparotomy, minilaparotomy, or laparoscopic access. The selection of the specific access route depends on the nature of the lesion, the type of procedure required, and the skill of the surgeon. The aim is to select the access route that will

yield the best outcome for the patient.

Many reconstructive operations, especially those for distal tubal disease, can be efficiently performed by laparoscopic access. Because of the advantages inherent in undertaking such a procedure at the time of the initial diagnostic laparoscopy, it is preferable that a surgeon trained in this type of surgery perform the initial laparoscopy.

Access by Laparoscopy

Once a proper pneumoperitoneum is obtained, the principal trocar and cannula are inserted (usually intraumbilically), the trocar is removed, and the laparoscope is introduced through the cannula. The details of performing a laparoscopy will not be described in this chapter. A thorough laparoscopic survey is performed as described earlier in this text, and the nature and extent of the tubal and pelvic lesions is assessed. The information yielded by the prior complemented by the laparoscopic findings and the status of the other fertility parameters, permits the surgeon to select the therapeutic approach that is best for the patient.

The laparoscopic survey requires the establishment of a secondary portal for the introduction of a probe or other appropriate instrument. This ancillary portal is placed suprapubically in the midline or in one of the lower abdominal quadrants. The undertaking of reconstructive surgery will necessitate the establishment of additional portals of entry. These are placed, depending on the clinical findings and the procedure to be performed, at sites that permit easy access to the operative field.

Open Access: Minilaparotomy

In reconstructive tubal surgery, a transverse suprapubic incision is the type used most often. Since 1985, we have used a small, minilaparotomy, suprapubic transverse or vertical (if a midline or paramedian scar is present) incision to gain access to the pelvis. The length of this minilaparotomy incision is usually 4.5 to 6 cm. The prior pelvic findings and especially the depth of the patient's subcutaneous adipose layer determine the length of the incision. The site of the proposed incision is infiltrated with a long-acting anesthetic agent, such as

P.377

0.25% bupivacaine (Marcaine) solution. A transverse suprapubic incision is made and extended down to the fascia. The subcutaneous fat is dissected over the fascia, in the midline upward and downward. The fascia is then incised vertically in the midline. The recti muscles are separated in the midline, and the peritoneum is incised vertically, with the incision curved laterally at the lower end to avoid the bladder. The subcutaneous tissues are reinfused with the same solution before closure of the skin incision. Thereafter, a bilateral ilioinguinal nerve block is established. The small size of the incision; the lack of bowel manipulation, along with gentle handling of tissues during the procedure; and the use of local anesthesia reduce postoperative discomfort and analgesia requirements. This approach permits prompt mobilization of the patient and discharge from the hospital or surgical center usually on the same day. These patients return to normal activity almost as rapidly as those who have had their procedures performed laparoscopically.

It is essential that the surgical personnel thoroughly wash their gloves after they have been put on and again before making the peritoneal incision. Once the peritoneal cavity is entered, retraction is obtained with a disposable device that provides both wound protection and circumferential retraction with maximal exposure for the incision size. Varying sizes of such devices are available from many manufacturers and are preferable to standard retractors. Pads soaked in heparinized (5,000 U/L) lactated Ringer solution can be introduced into the pouch of Douglas to further elevate the uterus and isolate the bowel already displaced by a mild (10- to 15-degree) Trendelenburg tilt.

Once the surgical site is well exposed, the operating microscope is positioned. Although the operating microscope can be draped, we have not found this to be necessary, particularly if foot pedals control the

microscope. Intraoperative irrigation is performed with heparinized lactated Ringer solution in an intravenous bag that is elevated and connected with intravenous tubing to a Gomel microsurgical irrigator (**Fig. 21.12**). This enables periodic irrigation of the exposed peritoneal surfaces and ovaries to prevent desiccation and to visualize individual bleeders.

Pelvic Lavage

At the close of a reconstructive procedure, irrespective of the type and the mode of access, the operative site is inspected to ensure that complete hemostasis has been achieved. Any bleeding vessels are electrodesiccated. A thorough pelvic lavage is then performed with the irrigation solution until the fluid remains clear. Pelvic lavage serves to remove from the peritoneal cavity any blood clots or other debris that may be present.

When laparoscopic access is used for the procedure, underwater examination of the operative site may be performed. When the irrigation fluid remains clear, the pneumoperitoneum pressure is reduced and the region inspected with the distal end of the laparoscope under the surface of the fluid. This permits prompt recognition of any small bleeding vessels, which can be desiccated with the use of a microelectrode or microbipolar forceps.

Once the irrigation fluid is completely suctioned out of the pelvis, some investigators leave varying amounts of physiologic solution in the peritoneal cavity to reduce postoperative adhesions. We use 300 to 500 mL of lactated Ringer solution to which 500 mg of hydrocortisone succinate is added. There are promising new products designed to prevent adhesion formation that are easy to apply by both open and laparoscopic access; these are currently undergoing clinical trials. The topic of ancillary measures for adhesion prevention is outside the purview of this chapter and will not be discussed further.

SURGICAL TECHNIQUE

In this chapter, the following procedures are discussed: salpingo-ovariolysis, fimbrioplasty, salpingostomy, tubotubal anastomosis to repair midtubal disease or to reverse a prior sterilization, tubocornual anastomosis to treat proximal tubal disease, and other procedures performed rarely in unusual circumstances. The techniques used for these procedures are essentially the same irrespective of the access route.

Whereas procedures for distal tubal disease are very amenable to laparoscopic access, anastomotic procedures are technically more difficult to accomplish by this route. Isthmic-isthmic and isthmic-ampullary anastomosis (usually used for sterilization reversal) have been performed with varying degrees of accuracy via laparoscopic access, but accomplishing other types of anastomoses (especially tubocornual) through this access route is much more challenging.

With microsurgical procedures, our aim has always been to keep the techniques as simple as possible for the outcomes to be reproducible, not only by surgical virtuosi but also by all physicians who practice in this field. Our more recent technical modifications, including access through a minilaparotomy incision and the use of a protractor, were the result of the same thought process. Although we remain enthusiastic proponents of laparoscopic access, we do not let this enthusiasm blind us to the possibility that some procedures may still be performed better by modifications and improvements in traditional methods.

Salpingo-Ovariolysis

Pelvic and periaxonal adhesions usually are the sequel of PID. These adhesions may be broad or shallow; they are usually not too vascular and extend from one structure to another. In so doing, they tend to leave a space or potential space between the involved structures, an aspect that facilitates adhesiolysis (**Fig. 21.14**). Dense cohesive adhesions often result from prior surgery. In this case, adjacent structures are intimately conglutinated. The adherent surface is devoid of the superficial mesothelial layer of the peritoneum. In other words, the underlying stromal layers of the two structures coalesce. The lysis of such an adhesive process is technically

difficult and is associated with a very high percentage of recurrence.

Periadnexal adhesions usually coexist with other types of tubal damage. Thus, salpingo-ovariolysis is often an integral part of other reconstructive procedures. However, periadnexal adhesive disease may be the sole apparent lesion, in which case

P.378

fertility depends on the severity and nature of the adhesions. Even in the presence of a patent tube, extensive adhesions may encapsulate the tube (especially the fimbriated end, the ovary, or both) and prevent ovum pickup (**Fig. 21.9**). By fixing the fimbriated end of the patent tube away from the ovary, adhesions may distort their spatial relationship and, hence, the functional proximity that exists between these two organs. For example, the fimbriated end of a patent tube may be adherent to the anterior abdominal wall or the uterine fundus, whereas the ovary is fixed in the pouch of Douglas. Periovarian adhesions may also affect follicular development, as has been demonstrated in both animal and human studies. Human studies were usually performed on patients undergoing IVF treatment.

FIGURE 21.14 Salpingolysis. The space between the two involved structures facilitates division.

When salpingo-ovariolysis is performed by open access, adhesiolysis is usually commenced by defining the distal margins of the adhesions. The division of adhesions at their distal attachment frees the adnexa, making it possible to elevate and bring them closer to the abdominal wall. This move facilitates the remainder of the procedure. Elevation of the adnexa is achieved by the use of inert pads soaked in the irrigation fluid. Adhesiolysis is then completed by systematically excising the adhesions from the tubal serosa or ovarian surface (**Fig. 21.14**). With laparoscopic access, it is usually preferable to reverse this order and commence the adhesiolysis at the level of the adnexa.

Adhesions are put on tension with a toothed forceps, and the site of incision is exposed. Division is effected electrosurgically or with appropriate microsurgical scissors. It is imperative to divide adhesions one layer at a time, slightly lateral to their attachments to the organ to avoid damaging the adjacent peritoneum. Adhesions are often composed of two layers, even though they may initially appear as a single layer. They tend to attach to an organ at two different levels. It is essential to enter between the two layers first; this permits exposure of the demarcation line between the adhesion and the mesothelium of the adjacent structure. Each layer of adhesion is then put on a stretch with toothed forceps, the demarcation line is identified, and the adhesion is transected. With open access, placement of a Teflon rod under the incision line enhances exposure. Damage to the peritoneum or ovarian surface is avoided by keeping the transection line 1 mm away from these surfaces. Prominent vessels along the transection line are individually electrodesiccated.

When a microelectrode is used for this purpose, the electrosurgical unit is put on the blend or cut setting. Pure coagulating current (coag mode) may be used to obtain hemostasis of individual bleeders, which are exposed under a jet of irrigation fluid. With open access, an elongating adaptor may be attached to the handle of the electrosurgical unit to facilitate adhesiolysis in the deeper parts of the pelvis.

All of the broad adhesions are excised and removed from the pelvis. Shallow adhesions are simply divided. In this case, a small opening is made on the adhesion, through which a fine instrument or Teflon rod is introduced. This permits separation of the adjacent structures and better visualization of the adhesion, which is incised without damaging these structures. The procedure is completed with a thorough pelvic lavage with the irrigation solution mentioned earlier in the text.

The technical principles are identical when laparoscopic access is used for the procedure. In this case, however, because there is no need to lift the adnexa close to the abdominal wall, the salpingo-ovariolysis is commenced with the tube and ovary. Once again, the performance of effective and safe salpingo-ovariolysis requires clear identification of each adhesive layer, which is grasped and retracted, permitting clear identification of the attachments to the organ of interest. The adhesions are incised parallel to the organ of interest and approximately 1 mm away to prevent damaging its mesothelial envelope (**Figs. 21.15** and **21.16**). Division is accomplished electrosurgically with a microelectrode or mechanically with fine scissors. We use scissors for laparoscopic salpingo-ovariolysis and electrodesiccation to secure obvious vessels or bleeders encountered along the incision line. As described earlier, shallow adhesions are simply divided, whereas broad adhesions are excised (by dissecting them free at all points of attachment) and removed through one of the ancillary portals (**Fig. 21.16**).

FIGURE 21.15 Salpingo-ovariolysis by laparoscopic access (same patient as in **Fig. 21.9**). Division of adhesions parallel to the tube.

Cohesive adhesions require identification of the dissection plane. This is achieved by making a small incision and developing a tissue plane either by spreading the jaws of the scissors, by blunt dissection, or by hydrodissection (injecting irrigation solution into the site under pressure). It is important to abstain from using thermal energy in such cases because of the inherent danger.

It should not be necessary to use open access, excepting rare circumstances, for the purpose of salpingo-ovariolysis. Our primary approach in such cases has always been by laparoscopic access and whenever possible at the time of the diagnostic survey.

Results of Salpingo-Ovariolysis

The reported intrauterine pregnancy rates resulting from open microsurgical salpingo-ovariolysis range from 41% to 57%. The rates for live births are 37% to 57%, and the rates for ectopic pregnancies are 5% to 8% of operated patients. In one of these studies, 33 of 63 (52.4%) patients who underwent open microsurgical salpingo-ovariolysis achieved intrauterine pregnancies; in addition, 3 (4.8%) had ectopic pregnancies at 2-year followup. These 63 patients reported by Tulandi had been randomized to two cutting modalities: electrosurgery ($n = 33$) and CO₂ laser ($n = 30$). The results were identical in both subgroups. Indeed, there has been no demonstrable improvement in the outcome of such procedures with the use of lasers in both clinical and experimental studies.

The preexisting tubal patency and the uncontrolled nature of the salpingo-ovariolysis series reported in the literature may cast doubt on the value of this procedure. The Canadian Infertility Evaluation Study Group addressed this issue by studying treatment-dependent and treatment-independent pregnancies in patients with periadnexal disease whose fallopian tubes were not completely occluded. This was a multicenter, controlled, randomized study. The cumulative pregnancy rates reported by Tulandi and colleagues in 1989 were 59% among 69 patients in the group who underwent microsurgical salpingo-ovariolysis and only 16% among the

P.379

78 control patients who were not treated. This study confirms that pregnancies may occur in a small proportion of women with periadnexal adhesions and patent tubes and also proves the therapeutic value of salpingo-ovariolysis in such cases.

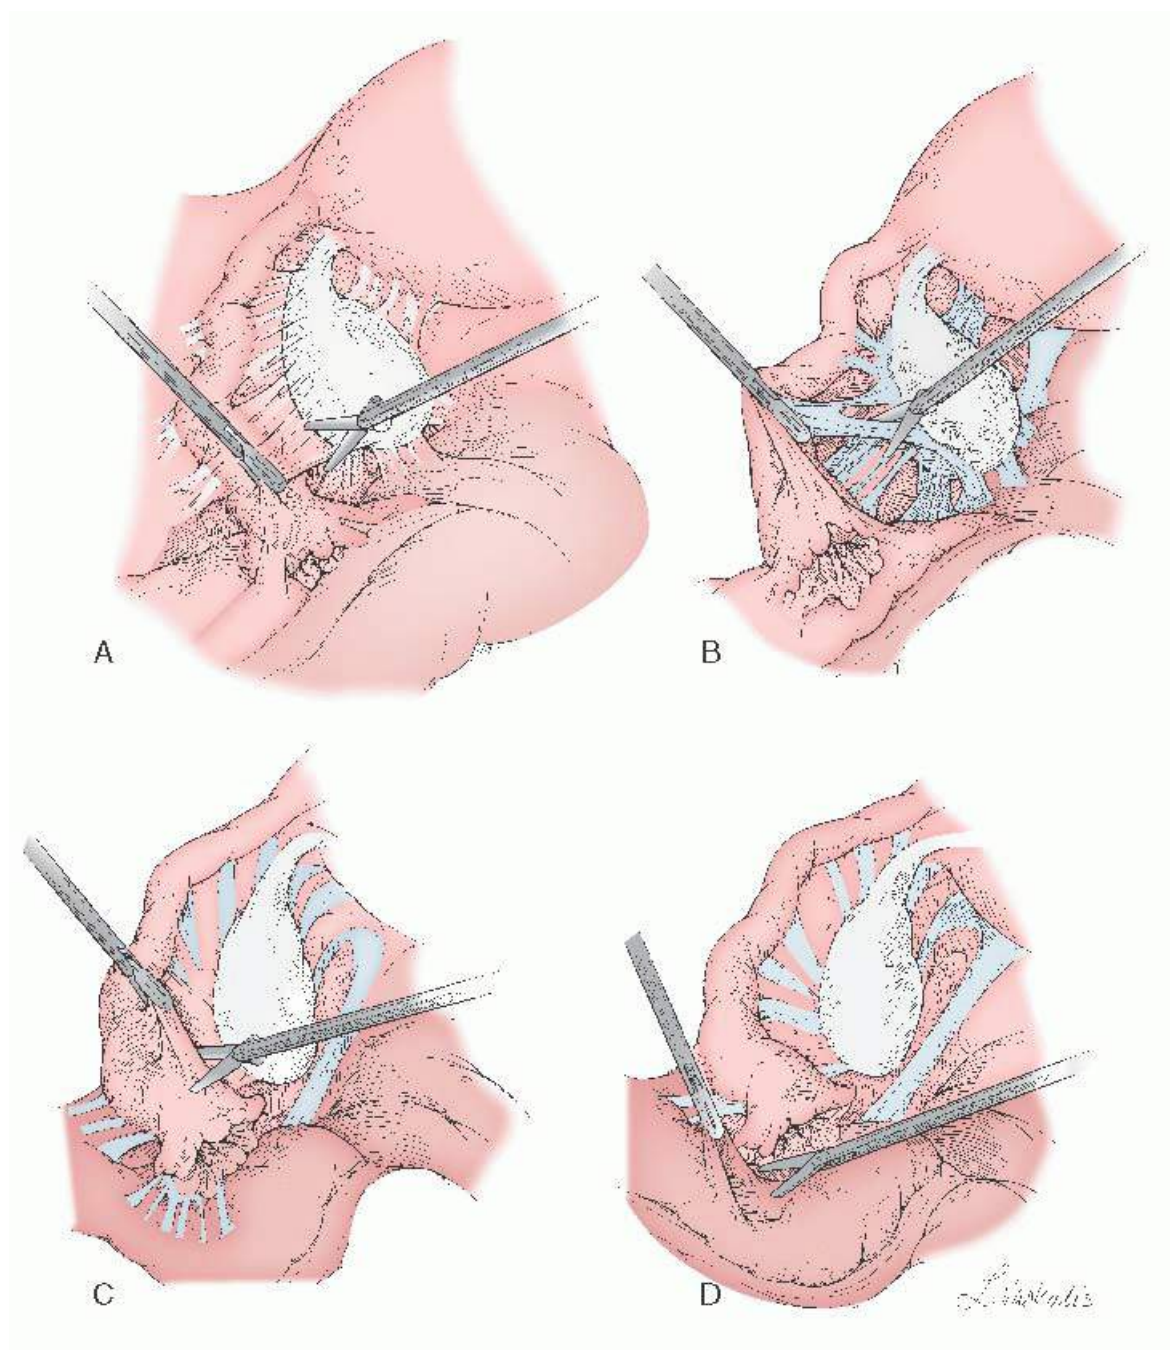

FIGURE 21.16 Salpingo-ovariolysis. **A:** Division of adhesions commences in a wellexposed area. **B:** Adhesions are stretched and are divided one layer at a time parallel to the organ of interest. **C:** Broad adhesions are freed at all points and removed from the peritoneal cavity. **D:** Salpingo-ovariolysis being completed. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St Louis, MO: Mosby, 1995:171, with permission.)

In the early stages of development of operative laparoscopy, we demonstrated that laparoscopic salpingo-ovariolysis yields results similar to those obtained by open access. We also stressed the importance of adhering to microsurgical principles in the performance of such procedures by both open and laparoscopic access. In 1983, we reported a series of 92 patients who underwent salpingo-ovariolysis by laparoscopy. The duration of involuntary infertility was longer than 20 months for all patients. Periadnexal adhesions were severe in 79 patients and moderate in 13. Moreover, the series included only those patients in whom ovum pickup by the tube on the side with lesser disease was deemed impossible or greatly hampered. At the time of the survey, the patients had been monitored postoperatively for a period of 9 months or longer. Of the 92 patients, 57 (62%) achieved at least one intrauterine pregnancy, 54 (59%) had one or more live births, and 5 (5.4%) had ectopic pregnancies. Ten of the patients who did not get pregnant had a second-look laparoscopy that demonstrated no

significant residual adhesive process.

Similar results were corroborated by Bruhat et al. and Donnez et al. at other centers in Europe and by Favez in North America. This demonstrates that the results of laparoscopic salpingo-ovariolysis, as expected, depend on the severity of the adhesions. The reported intrauterine pregnancy rates after laparoscopic salpingo-ovariolysis range from 51% to 62%, and ectopic pregnancy rates range from 5% to 8% of operated cases. Although no prospective, randomized trials exist, these results appear similar to those yielded by laparotomy.

Fimbrioplasty

Fimbrioplasty is the reconstruction of the fimbriae or infundibulum in a tube that exhibits fimbrial agglutination or prefimbrial phimosis and results in partial distal occlusion. Often, the tube and ovary are involved in adhesions, in which case salpingo-ovariolysis must precede the fimbrioplasty. The technique of fimbrioplasty, which will be described further, is the same irrespective of the access route used. Our approach is invariably by laparoscopic access.

Fimbrial phimosis results from the agglutination of the fimbriae. A small opening is usually present at the distal end of the tube unless this opening is covered by fibrous tissue. The latter usually becomes evident when the tube is distended by transcervical chromopertubation. When the opening is covered by fibrous tissue, this tissue must be incised or excised

P.380

to gain access to the fimbriae (**Fig. 21.17**). Agglutination of the fimbriae can be corrected simply by introducing a fine forceps, a 2-mm alligator forceps with jaws closed through the phimotic fimbrial opening. The jaws of the forceps are opened within the tubal lumen, and the forceps are gently withdrawn with the jaws open. Deagglutination is achieved by repeating this movement a few times, varying the direction in which the jaws of the forceps are opened (**Fig. 21.18**). When sufficient gentleness is used during this manipulation, bleeding is usually negligible and stops spontaneously.

FIGURE 21.17 Fimbrioplasty: to free agglutinated fimbriae. **A:** The 3-mm alligator-jawed forceps is introduced through the stenosed opening. **B:** The jaws of the forceps are opened within the tube. **C:** The forceps is gently withdrawn while the jaws are kept open. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St Louis, MO: Mosby, 1995:173, with permission.)

When the stenosis is located at the level of the true abdominal tubal ostium, which is located at the apex of the infundibulum, the fimbriae may have a normal appearance. However, when chromopertubation is performed, the ampullary portion of the tube distends before any exit of dye solution. In this instance, it is necessary to place an incision on the antimesosalpingeal border of the tube, which commences at the infundibulum and continues past the stenotic area into the distal ampulla. The tube is stabilized by introducing a thin Teflon probe through the stenotic opening into the distal ampulla; the incision is made electrosurgically by using a microelectrode. This is the approach we generally use. Alternatively, the area can be injected with 1 mL of dilute vasopressin solution (1 IU in 30 mL of normal saline) and the incision made mechanically with microsurgical scissors. Bleeders are desiccated electrosurgically. The edges of the two flaps thus created are folded back either by securing them to the adjacent ampullary serosa with no. 7-0 or 8-0 polyglactin 910 (Vicryl) sutures or by electrosurgery (or a defocused CO₂ laser beam), which desiccates the serosal aspect of the flaps, causing them to fold backward (Fig. 21.19).

Results of Fimbrioplasty

Very few investigators have classified fimbrioplasty as an independent procedure. Most include such patients in their salpingostomy series. French and Belgian centers include fimbrioplasty (correction of partial distal tubal occlusion) as stage 1 in their salpingostomy series.

Patton et al., in a series of microsurgical fimbrioplasty procedures in 40 patients, reported total intrauterine and ectopic pregnancy rates of 63% (25 patients) and 5% (2 patients), respectively, after 24 months of follow-up. The outcome of the intrauterine pregnancies and the live birth rates were not provided.

In 1983, we reported 40 such patients, all treated by laparoscopic access. Live births occurred in 19 (48%), and two patients (5%) had tubal gestations. In 1979, Mettler et al. reported a crude pregnancy rate of 31% among 51 women. The anatomic location and outcome of these pregnancies were not recorded. In 1990, Dubuisson et al. reported 31 such patients. After 18 months of follow-up, eight patients (25.8%) had intrauterine pregnancies, and four (12.9%) had ectopic pregnancies. In 1986 in a series of 100 patients, Donnez et al. reported a total pregnancy rate of 61%. The location and outcome of these pregnancies were not provided. A 1991 report by Canis et al. included 32 such patients with their salpingostomy patients; 16 (50%) of these achieved intrauterine pregnancies, but the outcome was not reported. Surprisingly, there were no tubal pregnancies.

FIGURE 21.19 Bilateral hydrosalpinx with periadnexal and pelvic adhesions.

Salpingostomy (Salpingoneostomy)

Salpingostomy, or salpingoneostomy, is the creation of a new stoma in a tube with a completely occluded distal end (hydrosalpinx). Salpingostomy can be terminal, ampullary, or isthmic, depending on the anatomic location at which the new stoma is fashioned.

Isthmic and ampullary salpingostomy are of historic interest, except for the reversal of prior fimbriectomy (Kroener sterilization), in which ampullary salpingostomy may have a place. We demonstrated that success with ampullary salpingostomy in such cases is dependent on ampullary length and suggested that reconstructive surgery should only be undertaken when more than one half of the ampulla is present. In 1980, we reported a small series of 14 patients submitted to ampullary salpingostomy for reversal of sterilization. They all met the requirement of having more than one half of the ampullary segment preserved, at least on one side. Six of these women had one or more intrauterine pregnancies (42.9%); of whom five had live births (35.7%); the other had a midtrimester abortion. There were no ectopic pregnancies. Subsequently, experiments by Halbert et al. performed on rabbits corroborated the necessity of having one half or more of the ampulla preserved. This recommendation is corroborated by a 2001 study, by Tourgeman et al. reporting on 41 women who had fimbriectomy reversal.

Distal tubal occlusion is usually associated with varying degrees of pelvic and periadnexal adhesions that must first be lysed. Thereafter, the distal end of the tube is examined to ensure that it is not adherent to the ovary or other structures. If the distal tube is adherent, it must be dissected free until the tubo-ovarian ligament is exposed. Only by freeing the tube can the surgeon ensure that the neostomy is being performed at the appropriate site.

Once the salpingo-ovariolysis is completed and the tube is totally freed, it is distended by transcervical chromopertubation. The occluded terminal end of the tube is examined under magnification, which permits recognition of the relatively avascular zones that radiate from a central punctum. The tube is entered at this central point with use of the microelectrode or microsurgical scissors, and the incision is extended toward the ovary over an avascular line (**Figs. 21.20A, B, and 21.21A**). This incision fashions a new fimbria ovarica that maintains the tuboovarian relation. At this point in the procedure, it becomes

possible to view the tube from within when placing additional incisions along its circumference to complete the creation of a new stoma. These additional incisions are made between endothelial folds over avascular areas. In

so doing, one avoids cutting through vascular mucosal folds, which will be shaped as fimbriae, and bleeding is minimized as a result (**Figs. 21.20C, D and 21.21B, C**). Any bleeding points that occur are exposed under a jet of irrigation fluid and desiccated individually with a microelectrode or microbipolar forceps. Once a satisfactory stoma is achieved, the flaps created in the process are everted either by securing them without tension to the ampullary seromuscularis with interrupted no. 7-0 or 8-0 Vicryl sutures (**Fig. 21.20E**)—this is the approach we prefer—or by desiccating their serosal surface, which causes them to fold backward. Desiccation is achieved either electrosurgically with a small ballshaped electrode and a low power density or with CO₂ laser using a defocused beam. The procedure is concluded with a thorough pelvic lavage, as described earlier in this chapter (**Fig. 21.21D**).

FIGURE 21.20 Salpingostomy. **A:** The occluded distal end of the tube usually has a centrally placed avascular area, from which avascular scarred lines extend in a cartwheel manner. **B:** The first incision is made along an avascular line toward the ovary. **C:** Avascular lines are incised by viewing from within the tube along the circumference of the initial opening. **D:** Cutting along the avascular lines is continued until a satisfactory stoma is fashioned. **E:** The flaps can be everted by placing two or three no. 6-0 absorbable synthetic sutures. (From Gomel V, Taylor PJ. *Diagnostic and operative gynecologic laparoscopy*. St Louis, MO: Mosby, 1995:174, with permission.)

FIGURE 21.21 Microsurgical salpingostomy by open access. **A:** The terminal end of the tube is entered at an avascular central point, and the incision is extended toward the ovary. **B and C:** The tube is then viewed from within, and small incisions are placed along the circumference of the tube. **D:** Completed salpingostomy; the infundibular portion of the tube has well-preserved epithelium and folds.

Considering the results of salpingostomy obtained by laparoscopy approach and those obtained by open access, and considering further the significant improvement in IVF results, an open salpingostomy should rarely be indicated.

If during the initial diagnostic laparoscopy, the surgeon decides to perform the salpingostomy, or for that matter any other reconstructive tubal procedure, by open access, and if pelvic and/or periadnexal adhesions exist, these adhesions can be lysed laparoscopically at their distal margins, thus mobilizing the adnexa. Such an undertaking permits the subsequent salpingostomy or other procedure to be readily performed through a minilaparotomy incision.

Results of Salpingostomy

In the major published series, the live birth rate after microsurgical salpingostomy ranges from 20% to 37%, and the ectopic pregnancy rate ranges from 5% to 18% (**Table 21.4**). Work performed in the past 40 years has made it evident that the major determinants of the outcome of salpingostomy are the degree of preexisting tubal damage, the extent and nature of periadnexal adhesions (**Figs. 21.21** and **21.22**), and the surgical technique (**Fig. 21.23**). The following factors were quantified in a numerical scoring system to predict the prognosis of the surgical outcome: ampullary diameter, tubal wall thickness, nature of the tubal endothelium, extent of adhesions, and type of adhesions. This scoring system was approved by the American Fertility Society (current ASRM) and published in 1988. In cases deemed favorable (mild), the reported live birth rates after microsurgical salpingostomy range from 40% to 60%. This rate drops to less than 20% in cases considered unfavorable (severe).

In 1990, we reported a series of 90 patients who underwent microsurgical salpingostomy with a minilaparotomy incision. Nineteen (21.1%) were lost to follow-up and were considered failures. Twenty-seven (30%) patients achieved one or more intrauterine pregnancies, and eight (8.9%) had tubal pregnancies. Ectopic gestations occurred in two additional patients

P.383

who also had intrauterine pregnancies. Twenty-three (25.6%) women were successful in having one or more live births. These 90 patients were assessed with the classification approved by the American Fertility Society. On the basis of this classification, 73 patients had extensive (severe) damage, and 17 had limited (mild) damage. In the group of 73 patients, 15 (20.5%) had one or more intrauterine pregnancies, and 13 (17.8%) had one or more live births. In the “mild” group of 17 patients, 12 (70.6%) had one or more intrauterine pregnancies, and 10 (58.8%) had one or more live births ($P < 0.05$) (**Table 21.5**). These observations emphasize the importance of a thorough preoperative investigation and proper patient selection.

FIGURE 21.22 Microsurgical salpingostomy by open access. The tube is markedly dilated and exhibits a flat epithelium with poorly preserved folds.

On the surface, the results yielded by laparoscopic salpingostomy appear to be somewhat inferior to those obtained by open access. However, laparoscopic salpingostomy offers distinct advantages: it can be performed during the initial diagnostic laparoscopy, avoiding a second intervention and resulting in cost savings.

FIGURE 21.23 Second-look laparoscopy following salpingostomy demonstrating a patent tube and a paucity of adhesions (the same patient as [Fig. 21.10](#)).

The ASRM's committee opinion, in regard to fimbrioplasty and salpingotomy, is as follows: "Although IVF is preferred over salpingostomy for mild hydrosalpinges in older women and for those with male factor or other infertility factors, salpingostomy before IVF may improve the subsequent likelihood of success of IVF while still giving the patient the option to attempt spontaneous conception.... The evidence is fair to recommend laparoscopic fimbrioplasty and neo-salpingostomy for the treatment of mild hydrosalpinges in young women with no other significant infertility factors."

Hydrosalpinx and IVF

Since the work of Strandell et al. in 1994, 1999, and 2001, many more reports confirmed the deleterious effect of hydrosalpinx on the outcome of IVF treatment and corroboration on the benefit of salpingectomy before IVF, which significantly increases the rate of success. A Cochrane meta-analysis by Johnson et al. in 2004 confirms the earlier work of Strandell et al. in demonstrating that the odds of ongoing pregnancy and live birth (OR 2.13, 95% CI 1.24 to 3.65) were increased after laparoscopic salpingectomy for unilateral or bilateral hydrosalpinges, visible by ultrasonography, before IVF.

Surprisingly, there have been few reports on the effect of a salpingostomy, as opposed to a salpingectomy, on pregnancy outcomes with subsequent IVF.

Several hypotheses have been put forward to explain the detrimental effect of a hydrosalpinx on fertility and specifically IVF outcome. A "washout effect" owing to the passage of the collected tubal fluid to the uterine cavity at the time when embryos are transferred is one such—and more likely—hypothesis. This washout may also occur sometime after transfer. As evidence indicates, many embryos ascend to the tube after transfer and eventually return to the uterus when the tube assumes a prouterine transport. It is at this time that the fluid contained in the hydrosalpinx, by passing to the uterus, may wash the embryos out. Other hypotheses related to the hydrosalpinx fluid include an embryotoxic effect, bioactive factors in the fluid adversely affecting endometrial receptivity, and an inadequate glucose supply in this fluid. These latter hypotheses have not been confirmed scientifically; the washout effect remains the most likely mechanism.

The assumption that the deleterious effect of large hydrosalpinges may be owing to a washout of the transferred embryos is supported by a study of Van Voorhis et al. in 1998. They compared women with hydrosalpinges ($n = 34$) with women who had tubal disease but no hydrosalpinges ($n = 124$) undergoing IVF treatment. Women with hydrosalpinges were found to have a reduced clinical pregnancy rate (18% vs. 37%, $P = 0.053$), a reduced ongoing pregnancy rate (15% vs. 34%, $P = 0.051$), and a reduced implantation rate (7% vs. 18%, $P = 0.003$) after IVF procedures. Among women who had hydrosalpinges, 16 had their hydrosalpinges aspirated at the time of oocyte retrieval and 18 did not. Aspiration of hydrosalpinges was associated with a higher clinical pregnancy rate (31% vs. 5%, $P = 0.07$), a higher ongoing pregnancy rate (31% vs. 0%, $P = 0.015$), and a higher implantation rate (14 vs. 1%, $P = 0.015$) as reported by Van Voorhis et al. However, others have indicated that aspiration of hydrosalpinx fluid is of little value before oocyte retrieval or embryo transfer.

In a study performed in our department reported by McComb and Taylor, in 2001, 23 infertile women, with a duration of infertility of 19 to 146 months (mean 53.6 months) and who had a unilateral hydrosalpinx and a patent contralateral patent tube, were submitted to a laparoscopic salpingostomy of their terminally occluded fallopian tube. The subsequent intrauterine and ectopic pregnancy rates were

P.384

43.5% and 4%, respectively. The average time to conception was 13.4 months (range 0 to 71 months). If a single patient whose surgery-pregnancy time interval was 71 months is excluded, the average surgery-pregnancy time interval of the others becomes 7 months. Both the high intrauterine pregnancy and low ectopic pregnancy rates and the short surgery-pregnancy time frame strongly suggest these conceptions occurred through the previously patent (lesser damaged) oviduct. It also suggests that salpingostomy alleviated the deleterious effect of the unilateral hydrosalpinx on embryo implantation.

^aFollow-up period more than 8 years.

^bFollow-up period more than 1 year.

^cFollow-up period more than 4 years.

^dTwenty-three of these were iterative procedures; only three of these patients (13%) had live births.

^eThirty-seven of these procedures were performed with the carbon dioxide laser.

^fThe total number of salpingostomies was not given; 153 is the number of patients who responded to the questionnaire.

^gEight of the nine patients had prior salpingostomy by conventional techniques that resulted in reocclusion.

^hPerformed with the carbon dioxide laser.

NS, not stated.

The beneficial effect of salpingostomy in IVF was demonstrated in 1998 by Murray and colleagues in a small number of cases. Obviously salpingostomy, in addition, offers the woman the potential of achieving a pregnancy naturally. This and other evidence suggest that there may well be a place for laparoscopic salpingostomy, instead of salpingectomy, in selected cases.

We in Vancouver have preferred to perform a salpingostomy instead of a salpingectomy preceding IVF treatment in the absence of factors contraindicating this approach. The ASRM's committee opinion, in this regard, is as follows: "Although IVF is preferred over salpingostomy for mild hydrosalpinges in older women and for those with male factor or other infertility factors salpingostomy before IVF may improve the subsequent likelihood of success of IVF while still giving the patient the option to attempt spontaneous conception.... Patients with poor-prognosis hydrosalpinges are better served by salpingectomy followed by IVF." And further on the text: "Intuitively, it makes sense that laparoscopic neo-salpingostomy before IVF should improve the pregnancy rate, but there are still no confirmatory studies."

Tubotubal Anastomosis

The term *tubotubal anastomosis* refers to an anastomosis performed anywhere along the tube either to treat occlusions resulting from disease processes or to reverse a prior sterilization. The procedure used to repair proximal or cornual tubal disease is usually referred to as *tubocornual anastomosis*.

Microsurgery finds its ultimate application in tubotubal anastomosis. The precision afforded by this technique allows total excision of occluded or diseased portions, proper alignment, and excellent apposition of each layer of the proximal and distal tubal segments.

Depending on the tubal segments that are approximated, tubotubal anastomosis can be intramural-isthmic, intramuralampullary, isthmic-isthmic, isthmic-ampullary, ampullaryampullary, or ampullary-infundibular. This section first describes the fundamentals of tubotubal anastomosis and then the technical variations necessary to deal with each specific type of anastomosis.

Basic Principles of Tubotubal Anastomosis

When periadnexal adhesions are present, salpingo-ovariolysis is first completed. When access is achieved through minilaparotomy, the side to be worked on is elevated with the use of pads soaked in the irrigation solution. The contralateral adnexa are left in their natural position to prevent desiccation. When access occurs by way of laparoscopy, the mesosalpinx under the site of anastomosis may be injected with 1 to 2 mL of dilute vasopressin solution to reduce oozing and facilitate hemostasis.

The principles of tubotubal anastomosis are the same, irrespective of the mode of access used. The proximal tubal segment is distended by transcervical chromopertubation. This helps in the identification of the site of occlusion. The tube is transected, with appropriate scissors, adjacent to the site of the occlusion or, in the case of a previous tubal sterilization, near the occluded end. The occluded end or the occluded segment of the tube is grasped with a strong-toothed forceps to expose the site and facilitate the transection (**Fig. 21.24A, B**), which is effected with straight scissors or a sharp microblade. It is essential to halt the incision at the mesosalpinx, in the immediate periphery of the tubal muscularis, to avoid damaging the adjacent vascular arcade. Dye solution can now escape from the transected tubal lumen (**Fig. 21.24C**).

The occluded tubal segment is excised from the mesosalpinx electrosurgically or with scissors, the line of incision kept close to the tube to avoid damaging the vessels mentioned earlier (**Fig. 21.24D, E**). The cut surface is examined under high magnification to ensure that the tube is normal. Healthy tube is devoid of scarring and exhibits normal muscular and vascular architecture together with intact mucosal folds (**Fig. 21.24F**). Hemostasis is obtained by precise electrodesiccation of the more significant bleeders, which are located between the serosa and muscularis. Each is exposed by irrigation and desiccated with an insulated microelectrode. If open access is used, gentle compression of the tube between thumb and forefinger facilitates this process. Desiccation of minor bleeders is unnecessary because they stop spontaneously. Desiccation of the tubal epithelium must be avoided to prevent damaging it and adversely affecting future tubal function. Major tubal vessels (such as those composing the vascular arcade) may be divided inadvertently or by necessity. These can be electrodesiccated with monopolar or bipolar current. Overzealous electrodesiccation must be avoided to prevent devitalizing the anastomosis site.

When there is no significant luminal disparity between the two segments, the distal portion is prepared in a similar manner. Before transection, the distal segment is distended by

P.386

descending hydropertubation, which consists of injecting a few milliliters of irrigation fluid or dilute dye solution through the fimbriated end to identify the distal limit of the occluded portion or, in the case of a prior sterilization, to identify the real extremity of the stump. The tubal segments are approximated in two layers. The first of these joins the epithelium and muscularis, and the second joins the serosa. We generally use no. 8-0 Vicryl sutures swaged on a 130-micron shaft, 4- or 5-mm-long, taper-cut needle for tubal anastomosis. The first suture of the inner musculoepithelial layer is always placed at the mesosalpingeal border (6 o'clock position) to ensure proper alignment of the two segments of the tube (**Fig. 21.24G**). All of the sutures are placed in a way that positions the knots peripherally.

FIGURE 21.24 Microsurgical tubotubal anastomosis for reversal of Fallope-ring sterilization. **A:** Prior tubal sterilization with Fallope ring. **B:** The occluded end of the isthmus is grasped, and the tube is transected with scissors. **C:** Dye solution escapes from the lumen. **D:** The occluded tubal segment is excised from the mesosalpinx electrosurgically by the use of a microelectrode.

FIGURE 21.24 (Continued) **E:** The excised Fallopian ring with the attached loop of the tube. **F:** The cut surface of the patent tube is assessed under high magnification. **G:** The first suture is placed at the 6 o'clock position. **H:** Once the 6 o'clock suture has been tied, subsequent sutures are placed with the use of a single strand of suture as a continuous series of loops. **I:** Each suture is tied individually after the division of the loop between successive sutures. **J:** The apposition of the inner musculoepithelial layer is complete. **K:** The anastomosis is completed with approximation of the serosa.

P.387

In exceptional circumstances when the distance between the two segments is great, the mesosalpinx adjacent to the cut ends of the two tubal segments can be approximated first, using a single interrupted no. 7-0 or 8-0 suture. This step brings the tubal segments into close proximity; thus, it facilitates placement of the sutures of the inner layer and reduces the tension that would have existed when tying these sutures.

Once the 6 o'clock suture is tied, the placement of three or more additional sutures (depending on the type of anastomosis) is required to appose the inner layer. These additional sutures can be placed by using a single strand of suture as a continuous series of loops, including the muscularis and the epithelium of the two segments

(Figs. 21.24H and 21.25). The sutures are tied individually, after the division of the loop between each successive suture (Fig. 21.24I). This approach facilitates and speeds up suture placement. We advise against the use of a splint in the lumen of the tube because this does not facilitate the procedure and may traumatize the endothelium. Instead, if necessary, the cut surface may be stained with methylene blue or indigo carmine solution to accentuate the visibility of the individual layers.

After approximation of the inner layer (Fig. 21.24J), chromopertubation should demonstrate tubal patency and a watertight anastomotic site. The serosa is joined either with interrupted sutures or with two continuous sutures, one that runs anteriorly and the other posteriorly, starting at the antimesosalpingeal border (12 o'clock). Finally, the defect in the mesosalpinx is repaired (Fig. 21.24K).

Tubotubal Anastomosis to Repair Midtubal Disease

The most common reason to perform a tubotubal anastomosis is reversal of sterilization. Midtubal occlusions resulting from disease processes are rare. Such lesions usually affect the intramural or proximal isthmic segments and require a tubocornual-type anastomosis.

The causes of midtubal occlusion include endometriosis and tubal pregnancy, usually undiagnosed or treated by observation and rarely medically. A tubal pregnancy treated medically with methotrexate administration or surgically by linear salpingotomy may result in tubal occlusion at the gestational site (Fig. 21.26A-C). As described by Urma et al., treatment of tubal pregnancy by segmental excision will leave the tube in two segments, as with a tubal sterilization. Rare causes of occlusion include congenital absence of a midtubal segment and tuberculosis. In the latter instance, reconstruction is contraindicated.

In an intact tube, the site of occlusion may be apparent on inspection; palpation of the tube may identify an indurated segment that is the likely site of occlusion. As mentioned earlier, transcervical chromopertubation distends the proximal segment up to the site of occlusion and helps the surgeon define its proximal limit. The tube is transected either immediately proximal to the occluded segment or in the occluded zone itself. Successive transection of the tube at 1- to 2-mm intervals helps identify the normal segments proximal and distal to the occlusion site.

Irrespective of the type of anastomosis, the basic steps of the procedure are the same. The luminal diameter of the tube is not uniform and is significantly greater in the ampullary segment. The technical variations required largely depend on the disparity of the luminal calibers of the two segments to be joined.

Intramural-Isthmic Anastomosis

Anastomosis between the intramural and isthmic segments is the type of anastomosis most often required to treat cornual disease. In most cases of reversal of sterilization, a short segment of isthmus is usually present. This short segment is frequently adherent to the side of the uterus as a result of retraction of the adjacent mesosalpinx, thus giving the appearance of total absence of the proximal tube. The presence of

P.388

a portion of isthmus would have been evident from HSG. Transcervical chromopertubation distends this small segment of isthmus, facilitating identification of its distal margin and its dissection from the uterus. The dissection must be effected carefully to avoid damaging the tube itself and the vessels supplying it. The conservation and appropriate preparation of this segment, even when very small, converts the anastomosis to an isthmic-isthmic type and facilitates the procedure.

FIGURE 21.25 Microsurgical tubotubal anastomosis: after the 6 o'clock suture has been tied, placement of subsequent sutures using a single strand of suture as a continuous series of loops.

FIGURE 21.26 A: Midtubal occlusion due to prior ectopic pregnancy. **B:** The occluded portion of the tube has been excised and **(C)** two layer anastomosis performed between the two normal-appearing tubal segments.

In the absence of any isthmus (as may be the case subsequent to either a tubal sterilization or excision of an isthmic pregnancy), maintenance of uterine distention by chromopertubation will indicate the site where the intramural segment should be sought, between the uterine insertion points of the round and ovarian ligaments. Excision of the serosa and underlying scar tissue over the distended area may permit the dye solution to stream out of the intramural segment. In some instances, to access normal tube, it is also necessary to dissect the muscularis of this segment from the surrounding uterine muscle for 1 or 2 mm with microscissors or a

microelectrode. After this, the tube is transected with microscissors. This process may have to be repeated until the patent and normal tube is reached, at which point dye solution should stream out of the lumen.

Because of extensive vascularity, dissection in the cornu usually causes significant oozing that hinders visibility. When more than superficial dissection of this region is anticipated, initial infiltration with dilute vasopressin solution (1 U of vasopressin in 30 mL of normal saline) significantly decreases capillary oozing and facilitates the procedure. With the use of a 30-gauge needle on a 3-mL syringe, the cornual region of the uterus is injected with 2 mL of this solution in a circular fashion under the serosa 1 cm medial to the uterotubal junction. The resulting vasoconstriction is recognized by serosal blanching.

In this type of anastomosis, there is no significant luminal disparity between the two segments of the tube. Hence, the isthmus is simply transected near the occluded end and prepared, as described earlier. A two-layer anastomosis is then performed. Once the inner layer has been joined, the serosa and superficial muscle of the cornual region are approximated to the serosa of the isthmus. The defect under the tube is repaired by suturing the mesosalpinx to the serosa of the lateral edge of the uterus.

Intramural-Ampullary Anastomosis

The salient feature of intramural-ampullary anastomosis is the considerable luminal disparity that exists between the intramural and ampullary segments. The key technical issue lies in the preparation of the occluded proximal end of the ampulla, where an opening into the ampullary lumen, which is not much larger than that of the intramural segment, must be fashioned.

The intramural segment is first prepared as described under intramural-isthmic anastomosis. To identify the occluded end of the ampulla, which may be buried between the leaves of the mesosalpinx, the tube is distended with a few milliliters of dye or irrigation solution introduced through the fimbriated end. Alternatively, a malleable blunt probe can be introduced through the infundibulum and gently threaded toward the occluded end. With the use of microscissors, the serosa over the tip of the ampullary stump is incised in a circular manner. The serosa and any scar tissue under it are then excised to expose the muscularis of the occluded end. The center point of the exposed muscularis is grasped with toothed microforceps, and a small incision is made into the ampullary lumen with the microscissors. This opening is enlarged to correspond in size

P.389

to the lumen of the proximal tubal segment by excising a tiny circular portion of muscularis and epithelium (Figs. 21.27A, B and 21.28). The resulting opening is slightly larger than the intramural lumen, and because of absence of significant disparity, anastomosis of the two segments can be performed as described for isthmic-isthmic anastomosis (Fig. 21.29).

FIGURE 21.27 Preparation of the ampullary stump in intramural-ampullary or isthmic-ampullary anastomosis. **A:**

The serosa over the tip of the ampullary stump is incised in a circular manner and excised. **B:** The center point of the exposed muscularis is grasped, and a small opening is made into the lumen.

Isthmic-Isthmic Anastomosis

Isthmic-isthmus anastomosis is the simplest type of anastomosis to perform. The lumina are comparable in size. The technique is the same as that described earlier under the basic principles of tubotubal anastomosis.

Isthmic-Ampullary Anastomosis

The salient feature of this type of anastomosis is also the considerable luminal disparity that usually exists between the lumina of the isthmus and ampullary segments. The isthmus stump is prepared as described under "basic principles of tubotubal anastomosis." In most instances, the occluded end of the ampullary stump will be free, enabling a lumen of appropriate diameter (comparable in size to that of the isthmus segment) to be fashioned, as described under intramural-ampullary anastomosis (**Figs. 21.27A, B and 21.28**). A two-layer anastomosis is then performed as described under the basic principles of tubotubal anastomosis (**Fig. 21.25**). Although the muscularis of the ampulla is considerably thinner than that of the isthmus, this poses no problem in approximating the epithelium and muscularis of the two segments.

FIGURE 21.28 Preparation of the ampullary stump in intramuralampullary or isthmus-ampullary anastomosis.

Occasionally, circumstances will not permit the use of the technique described earlier in the preparation of the occluded ampullary end. The ampullary stump may be occluded by a permanent suture or clip, and removal of this suture or clip may lead to the creation of an opening that is much larger than the isthmus lumen and through which lush epithelial folds will prolapse. If the opening into the ampullary lumen is significantly larger than that of the isthmus segment (either inadvertently or by necessity), it will be necessary to either enlarge the isthmus lumen or narrow the ampullary lumen. To enlarge the lumen of the isthmus segment, a 2- to 3-mm slit is made with scissors at its antimesosalpingeal border. Partial excision of the corners thus created results in an enlarged oval opening (**Fig. 21.30A**). To approximate the inner musculoepithelial layer, the 6 o'clock suture is placed first and tied. Five additional sutures are usually required, and these are placed as described earlier. The 12 o'clock suture must incorporate the muscularis and epithelium of the ampulla and the same tissues at the apex of the isthmus slit (**Fig. 21.30B**). Approximation of the serosa and closure of the defect in the mesosalpinx complete the anastomosis. An alternative approach is to reduce the size of the large ampullary opening. This is achieved by plicating the muscular layer

surrounding the opening with interrupted sutures, after which the prolapsing epithelium is invaginated.

FIGURE 21.29 Tubocornual anastomosis (intramural-ampullary) completed. The anastomosis site is patent, as evident from the distention and blue discoloration of the tube as a result of chromopertubation. There is no leakage from the anastomotic site.

FIGURE 21.30 Isthmio-ampullary anastomosis in the presence of significant luminal disparity. **A:** Enlargement of the isthmio lumen. **B:** Placement of the 12 o'clock suture.

Ampullary-Ampullary Anastomosis

The proximal ampullary segment is transected near the occluded end, which is then excised from the mesosalpinx as previously described. An opening that corresponds in size to the lumen of the proximal segment is made in the occluded end of the distal ampullary segment, as described under isthmicoampullary anastomosis.

In this type of anastomosis, the major difficulty to be overcome is the propensity of the ampullary epithelium to prolapse through the lumen. Although investigators such as Winston have advocated excision of these epithelial fronds, we advise against this approach because it may lead to development of intratubal adhesion formation at this site. The epithelial fronds can be replaced with pressure from the irrigating solution or with the tip of the plain microforceps while the successive sutures of the inner layer are tied. One must be careful not to include these epithelial fronds within a suture or knot or between the segments that are being approximated. Because of the larger circumference of the ampulla, approximation of the two ampullary segments will require a greater number of interrupted sutures than in an isthmico-isthmico anastomosis.

Ampullary-Infundibular Anastomosis

An ampullary-infundibular anastomosis may be necessary when a distal ampullary portion of the tube has been ablated or excised either during a prior sterilization or during removal of a tubal gestation, leaving distally the infundibular segment only. The occluded ampulla is prepared as described previously. To make anastomosis of the two segments possible, it is necessary to fashion an opening in the infundibular portion. To do so, a Teflon probe with a conical tip is introduced into the infundibulum from the fimbriated end, and a circular opening is fashioned with microscissors, from the medial side, corresponding in size to the lumen of the ampullary segment. A two-layer anastomosis is then performed.

Results of Tubotubal Anastomosis for Reversal of Sterilization

The major published series report live birth rates between 40% and 80% after microsurgical tubotubal anastomosis for reversal of sterilization ([Table 21.6](#)). The ectopic gestation rates are usually low.

The factors that affect the outcome of such procedures are multiple and include the following: the type of prior sterilization, the site of anastomosis, and the length of the reconstructed tube or tubes, which are interrelated factors; the presence of single versus double reconstructed oviducts; the status of the tubes (presence or absence of disease); the extent and nature of adhesions and the presence of other pelvic disease; the status of other fertility parameters, especially that of the male partner; and significantly the age of the woman and the surgical technique used. Therefore, the outcome depends on the degree of rigor in selection criteria and the quality of the surgical technique. This is corroborated by the results of two relatively recent reports on sterilization reversal, which include two large series from Korea by Kim and colleagues in 1997 ([Table 21.6](#)). In our experience, in the absence of a male factor, the three most important parameters that predict outcome are the age of the female partner, the length of the reconstructed tube, and the surgical technique. A reconstructed tubal length of less than 4 cm adversely affects outcome; this likely reflects the loss of ampullary length and consequent loss of oviductal oocyte retention.

It is possible to perform tubotubal anastomosis by laparoscopic access to reconstruct a previous tubal sterilization. The outcomes reported in the literature are very variable, and most report results inferior to those obtained by open access. This is largely due to modification of the recognized microsurgical technique to make the laparoscopic procedure simpler to perform.

The first report on laparoscopic tubotubal anastomosis was a case report by Sedbon et al. in 1989; instead of microsurgical suturing for the apposition of the tubal segments, they used biologic glue over a stent. Pregnancy outcome was not reported. Early reports on tubotubal anastomosis were small case series, performed with simplified techniques, and despite the majority of the cases in these series were reversal of simpler types of

sterilization reversal, the results were relatively poor.

Most surgeons who attempted tubotubal anastomosis by laparoscopic access using the microsurgical technique, described earlier in this text, found that operating times are prolonged. Many attempted to simplify the technique by using glue as described above or using only two sutures for the apposition of the prepared tubal segments, as first reported by Dubuisson and Swolin in 1995. In this technique, the first suture (4-0 Vicryl) approximates the mesosalpinx immediately beneath the two segments of the tube and the second (6-0 Vicryl) the tube at 12 o'clock position. The second suture incorporates the serosa and muscularis of the two segments of the tube. There are several recent reports in the literature on this type of modified technique.

^aResurvey of 1980 series; follow-up period more than 18 months.

^bFollow-up period more than 18 months.

^cFollow-up period more than 4 years.

^dFollow-up period more than 1 year.

^eFollow-up period more than 3.5 years.

^fFollow-up period more than 2 years. There were eight ongoing pregnancies in addition to the live births.

^gFollow-up period more than 5 years. There were 31 ongoing pregnancies in addition to the live births.

^hExcluded 89 patients lost to follow-up and 8 patients who did not attempt a pregnancy from their series of 172 women, limiting the evaluation to the remaining 164.

ⁱThey only reviewed 886 of the 961 patients. The 71.1% birth rate is the result of 630 births from the 886 cases included in the analysis.

^jTubal anastomosis performed with single-suture technique.

^kTubal anastomosis performed by using two-layer microsurgical technique.

^lThere were 31 ongoing pregnancies in addition to the live births.

^mA screening laparoscopy was performed, and only those having a distal tubal segment of 4 cm and a

proximal segment of 3 cm were included.

ⁿComparative study with cases performed with open access. Laparoscopic anastomosis performed without sutures; the technique is described in the text.

^oExcluded 7 patients lost to follow-up, analyzing 127 of the 134 cases. The text does not give birth rates; it indicates that 51 of 120 women with bilateral anastomosis and 4 of 7 women with unilateral anastomosis had ongoing pregnancies. Therefore, 55 of the 127 women (43%) had ongoing pregnancies.

^pThey excluded 14 of the 160 cases for various reasons together with 49 lost to follow-up, and analyzed the remaining 97 patients. NS, not stated.

P.392

There are also publications reporting on the laparoscopic use of a truly microsurgical, two-layer anastomosis technique. The largest of these series is from 1999 by Yoon et al. from Korea, which includes 202 cases. Fifteen of these were lost to followup, and one had no partner. The remaining 186 were monitored for a minimum of 12 months. One hundred fifty-four achieved intrauterine pregnancies, a rate of 77% if we consider, as most series do, 15 cases lost to follow-up as failures. Ninety-eight delivered healthy infants, 25 pregnancies ended in abortion, and 31 patients had ongoing pregnancies at the time of the survey. If we assume all 31 ongoing pregnancies resulted in a live birth, the live birth rate in this series would have been 64%. There were five cases of ectopic pregnancy. These results are not too dissimilar to those achieved by open access, which supports the premise of the importance of the technique used and not the mode of access. In 2001, Cha et al., also from Korea, further supported this assumption. In their study, they compare the fertility outcome in 81 women who had microsurgical reversal of sterilization, 37 by laparoscopic and 44 by open access. The outcomes include only intrauterine and tubal pregnancy rates, which were similar in both groups: 75.7% and 70.5%, respectively; there was one tubal pregnancy in each group ([Table 21.6](#)).

Attempts to develop simple techniques that would yield equivalent results by laparoscopic access continue to be made. A 2005 study by Wiegerinck et al. reports the use of the following laparoscopic technique for tubal anastomosis: *“Once the tubal ends to be anastomosed were prepared, a splint was inserted into the proximal tube through a guiding catheter inserted vaginally.”* The splint was then introduced into the distal portion of the tube. The distal portion was aligned with the proximal segment over the splint. The seromuscularis of the two segments was fixed at the 3 and 9 o’clock positions using microclips of 3-mm size. Subsequently, fibrin glue was applied on the anastomotic surface. The splint was taped externally to the Foley catheter and removed 4 hours after the end of the procedure. Although they report similar results for both the laparoscopic group and a control group (selected from patients whose procedure was performed through a Pfannenstiel incision), it is surprising that the cumulative rate of ongoing pregnancy at 3 years in the control group was only 52% and in the laparoscopic group only 45%. This, despite the fact that in the latter group more than 90% of the sterilizations had been performed by clips or Silastic rings, and their average age was only 34.9 years. Schepens et al. from

the same group more recently reported on 134 patients; due to the fact that the patient population includes cases from 1997 to 2008, they must have included the 41 reported earlier ([Table 21.6](#)).

Several groups have explored robotically assisted tubal anastomosis. Initial reports in 2000 of small series by Falcone and Degueldre, both of whom were proficient in microsurgery, used a technique similar to that described earlier in this text. They reported the use of the robot-facilitated suturing but increased the length of the procedure. A recent large series that included Degueldre reported a birth rate of 60% following robotic-assisted reversal of sterilization. They stressed the fact that the use of the robot was associated with prolonged operating times and increased costs. Tubotubal anastomosis is a relatively simple operation for a physician skilled in microsurgery. It is difficult at this stage to justify the use of a robot for such cases, while its use would better serve more complex surgical procedures.

Using metaanalysis, Watson et al. examined the role of microsurgery versus macrosurgery in the reversal of sterilization. The available studies were limited by the lack of randomized controlled trials and the use of historical control groups. However, as expected, the use of magnification and microsurgical approach for sterilization reversal and for adhesiolysis and salpingostomy led to higher intrauterine pregnancy and lower ectopic rates.

Microsurgical tubotubal anastomosis for reversal of sterilization produces excellent results that are principally dependent on the status and the length of the reconstructed tube. Live birth rates of 60% to 80% can be achieved, provided that the reconstructed tube is longer than 4 cm and the ampullary portion greater than 2 cm. The second most important factor is the woman's age. The tubal pregnancy rates are usually low.

The advantages of laparoscopic access are well recognized. These include a shorter hospital stay and recovery time and lower postoperative analgesic requirements. We tried laparoscopic access for sterilization reversal and decided to continue using an operation microscope through a minilaparotomy incision. Our experience demonstrates that access by a minilaparotomy incision, using the technique described earlier in this text, provides the same advantages. We perform tubal anastomosis for reversal of sterilization, tubocornual anastomosis for pathologic tubal occlusion, and other more complex reconstructive microsurgical procedures via minilaparotomy. Patients are admitted to hospital on the morning of surgery and most are discharged a few hours postoperatively. Each surgeon must balance patient factors, his or her expertise, and the resources of the center in deciding how to approach such procedures.

The ASRM's committee opinion in regard to sterilization reversal supports the position we have held for more than three decades and is as follows: *"There is good evidence to support the recommendation for microsurgical anastomosis for tubal ligation reversal... it can be accomplished by mini-laparotomy as an outpatient procedure." Comparable results may be obtained by laparoscopy if the procedure is performed "in an identical fashion to open microsurgical tubal anastomosis.... Operating times are prolonged.... Only surgeons who are very facile with laparoscopic suturing and who have extensive training in conventional tubal microsurgery should attempt this procedure."*

Tubocornual Anastomosis for Proximal Tubal Disease

Various disease processes can affect the proximal tube and occlude the region of the uterotubal junction. On the basis of histologic studies on resected tubal segments, these occlusive lesions in order of frequency are as follows: obliterative fibrosis, chronic inflammation, salpingitis isthmica nodosa, intratubal endometriosis, and, rarely, ectopic gestation and tuberculosis. All of the published series report a varying but usually low percentage of cases with no demonstrable lesions. This may be related to tubal spasm (at the time of HSG or laparoscopy) or to the presence of tubal plugs or synechiae. Such conditions, as opposed to occlusive disease, are amenable to treatment with selective salpingography and tubal cannulation, as was discussed earlier in this chapter.

The management strategy in proximal tubal occlusion must take into account other variables, including the condition of the distal tube, the extent and nature of pelvic adhesions, the presence of associated pelvic disease, and the status of other fertility parameters, especially male factor infertility. This strategy must also respect the following principles: simplicity, reproducibility, and cost-effectiveness.

The selection of treatment must be individualized according to the investigative findings, the wishes of the couple, the expertise of the surgeon, and the results achieved by the center in which the couple will be managed.

Figure 21.31 diagrammatically summarizes a process to manage proximal tubal occlusion.

The traditional surgical treatment of occlusive proximal tubal disease was uterotubal implantation. The application of microsurgery has made it possible to perform an anastomosis instead, after removal of the affected tubal segment. Central to this approach is the complete excision of the affected portion of the tube, whether it is intramural or isthmic. In cases

P.393

of pathologic occlusion, a portion of healthy intramural tube is usually spared, permitting the conservation of sometimes all but more often a part of this segment. In other instances, the whole intramural segment is involved in the disease process and must be excised. In such cases, microsurgery permits an anastomosis to be performed between the uterine tubal ostium and the healthy portion of the isthmus. Depending on the extent of intramural tube that is excised and thus the site at which the anastomosis is performed, tubocornual anastomosis may be juxtamural, intramural, or juxtauterine (**Fig. 21.32**).

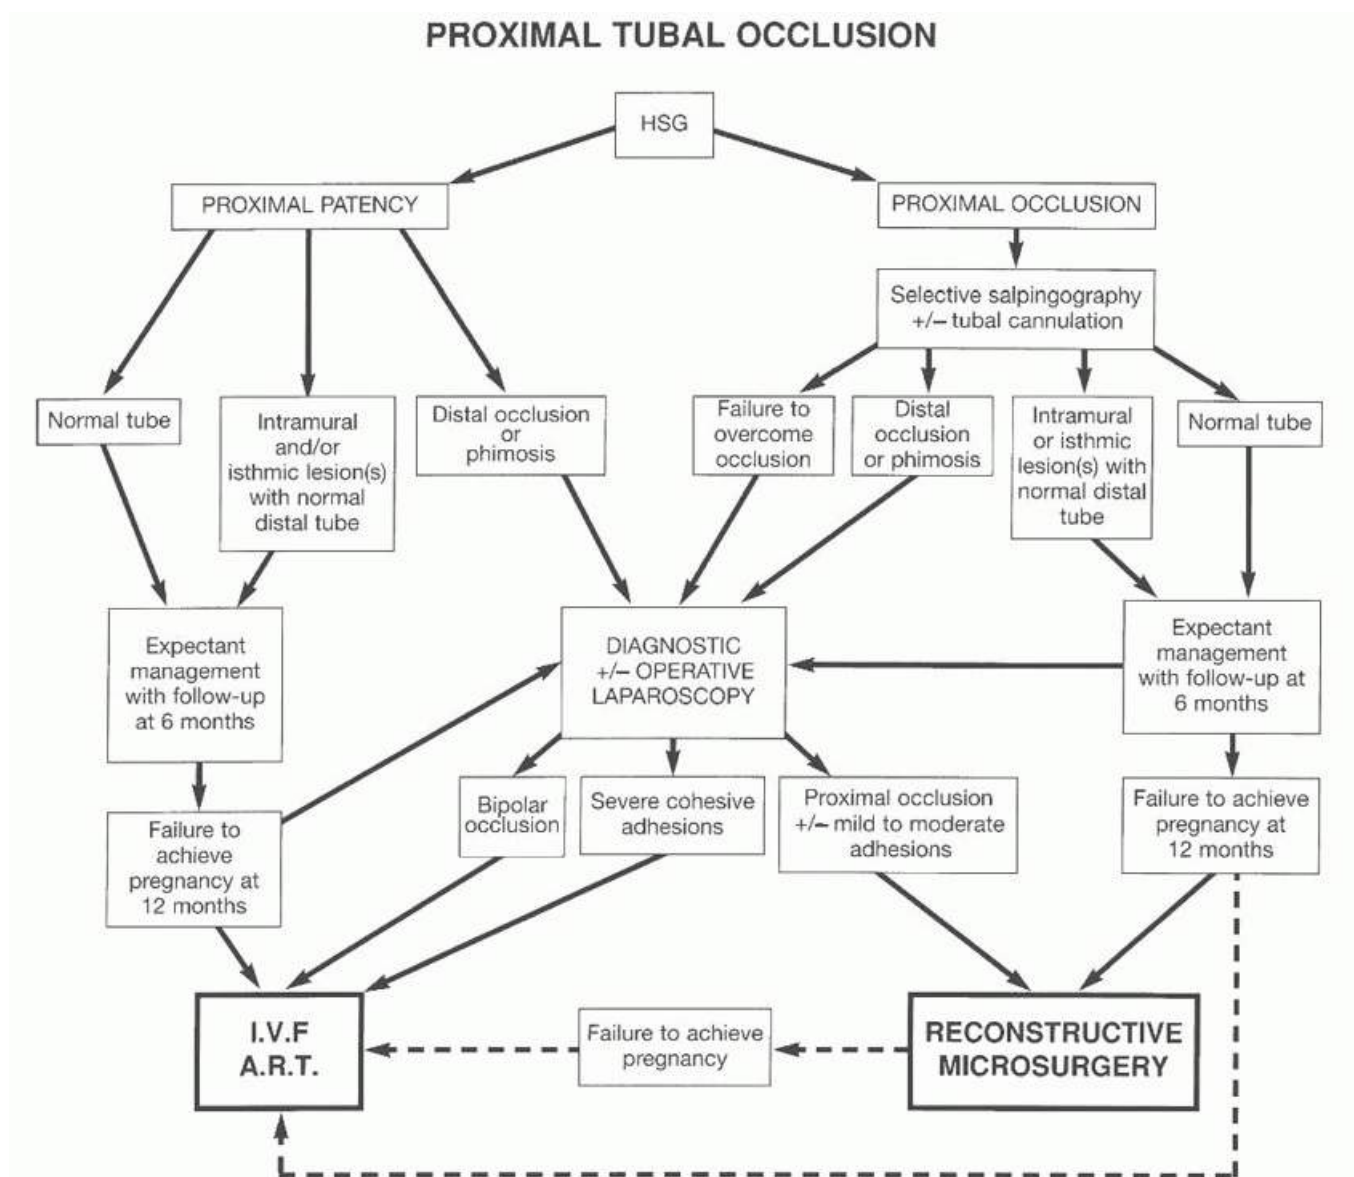

FIGURE 21.31 Management of proximal tubal occlusion. HSG, hysterosalpingogram; IVF, in vitro fertilization; ART, artificial reproductive technology. (Modified from Gornall V, Dubuisson JB. *References en gynécologie et obstétrique*. Poulnoy, France: SPEI, 1995:251.)

The cornual region of the uterus is infiltrated with dilute vasopressin solution. This is done by injecting 2 mL of this solution in a circular fashion under the serosa 1 cm medial to the uterotubal junction with the use of a 30-gauge needle on a 3-mL syringe. The vasoconstriction that follows is recognized by the blanching of the serosa. The tube is then incised at the uterotubal junction, with care taken not to divide the arteriovenous arcade at its mesosalpingeal margin. After transection of the tube, patency of the intramural segment is assessed by transcervical chromopertubation, and the normalcy of the cut surface is evaluated under high magnification (**Fig. 21.33A**).

FIGURE 21.32 Types of tubocornual anastomosis.

FIGURE 21.33 Microsurgical tubocornual anastomosis for proximal tubal disease. **A:** The tube is transected at the uterotubal junction (UTJ). Commencing at the UTJ, serial cuts are made on the isthmus until patent and normal tube is identified. **B:** The intramural tube is dissected electrosurgically, by using a microelectrode, from the surrounding uterine muscle, 1 to 2 mm at a time, and (**C** and **D**) transected until patent and normal tube is reached. **E:** The first anastomotic suture of the inner musculoepithelial layer is placed at the 6 o'clock position. **F:** Subsequent sutures are placed with a single strand of suture. **G:** After the apposition of the inner layer, the seromuscularis of the uterus is joined to the serosa of the tube and the mesosalpinx is joined to the lateral aspect of the uterus.

If the intramural tube is found to be occluded or abnormal at this site, its musculature is dissected further from the surrounding uterine muscle, 1 to 2 mm at a time, toward the uterine cavity (**Fig. 21.33B, D**). The small portion of the tube thus dissected is transected, and the cut surface is reassessed. If the intramural tube is still occluded or abnormal, the same procedure is repeated until normal patent tube is reached. Dye solution will spurt from the open lumen. It is essential that dissection of the intramural tube from the surrounding uterine muscle be effected at the level of the immediate periphery of the tubal muscularis. The preoperative HSG usually provides

information about the length of the normal intramural segment and the extent of excision required. Transection of successive portions of the intramural tube can be achieved with either curved microscissors or especially designed cornual blade (Gomel cornual blade,

P.395

Spingler-Tritt, Jestetten, Germany). By limiting the excised tissue to the intramural tube, there is little risk of creating a large defect at the cornu.

After the preparation of the cornual end, the occluded or abnormal isthmic segment is prepared by making serial cuts 1 to 2 mm apart, beginning at the initial transection site at the uterotubal junction and continuing until normal patent tube is identified (**Fig. 21.33A**). Patency of the distal segment is confirmed by descending hydropertubation, with injection of a few milliliters of dye or irrigation solution through the fimbriated end. Hemostasis of the cut end of the normal distal tube is obtained by precise electrocoagulation of bleeders located between the muscularis and serosa. The intervening abnormal tubal segments are excised from the mesosalpinx mechanically or electrosurgically, avoiding the vascular arcade beneath the tube.

The intramural and isthmic segments are approximated in two layers as follows: The initial suture of the first layer, which incorporates the muscularis and epithelium of the two segments, is placed at the 6 o'clock position (**Fig. 21.33E**). If the anastomosis is superficial (juxtamural type), the suture is tied.

With anastomoses located deep in the cornua, as in intramural or juxtauterine types, the 6 o'clock suture is held with a clip until the remaining sutures have been placed, because tying this initial suture would make placement of the subsequent sutures difficult if not impossible. In such cases, the subsequent sutures are placed with the use of a continuous strand of suture, as described earlier (**Fig. 21.25**). This approach facilitates suture placement and prevents the individual sutures from becoming tangled. Three additional sutures, placed at cardinal points, are usually sufficient to join the inner layer. If the cornual crater is deep and the placement of sutures is difficult, this task can be facilitated by making a small coronal incision on the uterus, above the cornual crater. The edges of this incision must be properly approximated at the end of the procedure.

If the distance between the two segments of the tube is significant or if there is undue tension, it is necessary to hold the distal tubal segment close to the intramural segment while tying the sutures. Alternatively, a single no. 7-0 Vicryl suture is passed through the mesosalpinx below the cut end of the distal segment of the tube and then through the border of the uterus immediately beneath the cornual crater. The suture is tied to bring the two segments into close proximity. The 6 o'clock suture is tied first. Then, the loop between each succeeding suture is divided and tied in turn. After approximation of the first layer, the seromuscularis of the uterus is joined to the serosa of the tube with no. 8-0 sutures. The defect under the tube is closed by approximating the mesosalpinx to the lateral edge of the uterus (**Fig. 21.33F, G**).

Compared with tubouterine implantation, microsurgical tubocornual anastomosis offers several advantages: It largely maintains the integrity of the uterine cornu; preserves a longer tube; obviates the need for a cesarean section, except for obstetric reasons; and yields better results (**Fig. 21.34**).

FIGURE 21.34 Microsurgical tubocornual anastomosis for proximal tubal disease. **A:** Serial cuts are made through the intramural segment to reach normal tube. **B:** Normal-appearing tube; methylene blue solution coming through. **C:** Subsequent to the 6 o'clock sutures the other sutures are in process of being placed. **D:** The procedure is completed by apposing the seromuscularis of the uterus to the serosa of the tube and the mesosalpinx to the lateral aspect of the uterus.

P.396

FIGURE 21.35 Cornual polyp.

Cornual polyps, when large, may cause infertility (**Fig. 21.35**). They can be removed placing a small coronal incision in the cornual region to access the tube at the site of the polyp. The polyp is excised, and the incision is closed in layers.

Results of Tubocornual Anastomosis

Microsurgical tubocornual anastomosis for the treatment of occlusive cornual disease yields fairly good results in centers experienced with this procedure. The published series report live birth rates between 33% and 56% and ectopic pregnancy rates between 5% and 7% (Table 21.7). This table makes it clearly evident that there has been a paucity of reports regarding this procedure for more than a decade. Tubocornual anastomosis for pathologic proximal occlusion is the most difficult type of tubal anastomosis. This procedure is performed less and less with such patients referred for IVF. We continue to perform this procedure in Vancouver and continue to obtain live birth rates of approximately 50%. It is imperative to confirm the cornual obstruction with selective salpingography and/or tubal cannulation, before recommending this procedure.

The ASRM's committee opinion states: "Unless the proximal blockage on HSG is clearly due to SIN, selective salpingography or tubal cannulation can be attempted... Before performing this procedure, there should be confirmation of normal distal tubal anatomy."

"In these cases, IVF is preferred to resection and microsurgical anastomosis... However microsurgery may be considered after failed tubal cannulation if IVF is not an option for the patient, but it should be attempted only by those with appropriate training."

Rare Procedures and Technically Difficult Cases

Rare circumstances may be encountered that are amenable to microsurgical correction. Some of these circumstances are discussed in this section.

The technical difficulty of a procedure must be differentiated from the prognosis that the procedure offers. Furthermore, difficulty is a relative term because what is commonplace work for some may be difficult or even impossible for others to achieve. From the patient's standpoint, what is important is the prognosis, the yield associated with the surgical procedure. Furthermore, the prognosis is not necessarily inversely proportional to the difficulty of the procedure. For example, microsurgical tubocornual anastomosis to treat occlusive cornual lesions is one of the technically more difficult reconstructive tubal operations. However, centers experienced in this procedure achieve excellent results. An even more technically difficult operation is tuboovarian transposition.

Tubo-Ovarian Transposition

In the case of a unicornuate uterus without an ipsilateral tube and ovary, the contralateral tube and ovary, if present, may be transposed while preserving their vascular pedicle.

P.397

We performed such a procedure in a woman with a single left unicornuate uterus whose ipsilateral tube and ovary were removed subsequent to a left tubal pregnancy. On the right side, placed high on the pelvic sidewall, were an ovary and a short oviduct, composed of infundibulum and ampulla only (Fig.21.36A).

TABLE 21.7 Results of Microsurgical Tubocornual Anastomosis for Occlusive Proximal Tubal Disease

INVESTIGATORS	YEAR	PATIENTS	INTRAUTERINE PREGNANCIES	LIVE BIRTHS	ECTOPIC PREGNANCIES

^aOf the 32 operated patients who did not deliver within 2 years after surgery, 21 were treated with 66 cycles of IVF, resulting in live births for 12.

FIGURE 21.36 Microsurgical tubo-ovarian transposition. **A:** Schematic drawing of the findings. **B:** The uterus was centered by moving the left round ligament and attaching it to right inguinal fossa. The intramural segment of the left tube is identified. **C:** The right adnexa is mobilized, with its vascular pedicle intact. The right tube is rotated clockwise to bring its ampullary stump in proximity of the left intramural segment, and permit a two layer anastomosis to be performed. **D:** the anastomosis is completed by apposition of the cornual seromuscularis to the serosa of the tube. All peritoneal incisions are closed. The *dotted lines* indicate the peritoneal incisions made during the procedure. (L = left side.) (From Gomel V, McComb P. Microsurgical transposition of the human fallopian tube and ovary with subsequent pregnancy. *Fertil Steril* 1985;43:804, with permission. Copyright 1985 American Society for Reproductive Medicine. Published by Elsevier Inc. All rights reserved.)

The uterus was mobilized centrally as follows: The left round ligament was divided near its inguinal insertion and dissected from the broad ligament with its vascular supply intact (**Fig. 21.36A**). The divided end of the round ligament was then affixed to the right inguinal region (**Fig. 21.36B**). Microsurgical transposition of the right ovary and tube with preservation of their vascular supply permitted anastomosis between the left intramural and right ampullary tubal segments (**Fig. 21.36C**). The ovary was mobilized further to achieve the proper spatial relation with the fimbrial extremity of the tube (**Fig. 21.36D**). In the third postoperative cycle, the patient was successful in achieving an intrauterine pregnancy, which resulted in a normal live birth. Subsequently, she had two additional pregnancies resulting in live births. Since the publication of this report in May 1985, there have been at least five case reports of successful transposition of the fallopian tube without the ovary. These reports clearly illustrate the potential of surgery, even though technically difficult, in restoring fertility in the face of unusual pelvic anatomy.

Other Unusual Procedures

The following procedures are of historic interest and have little place—excepting very unusual circumstances—in view of the results ART presently offers.

Correction of Bipolar Tubal Disease

The results associated with surgical correction of bipolar (both proximal and distal) tubal occlusion are dismal. A report from the Mayo Clinic included 31 such patients: bipolar tubal occlusion of both tubes ($n = 13$) or their only remaining tube ($n = 5$), bilateral distal and unilateral proximal occlusion ($n = 7$), and bilateral proximal and unilateral distal occlusion ($n = 6$). Despite a mean follow-up period of more than 3 years, pregnancies occurred in only three patients. Furthermore, two of these were ectopic, and one was a spontaneous abortion.

P.398

FIGURE 21.37 Microsurgical anastomosis of contralateral tubal segments. **A:** Isthmic segment of the tube on the left and ampullary-infundibular segment on the right. **B:** The uteroovarian ligaments are approximated with nonabsorbable sutures behind the uterus; the left isthmus segment of the tube is anastomosed to the right ampullary-infundibular segment.

Anastomosis of Contralateral Tubal Segments

A patient may have a healthy proximal segment of tube on one side and an ampullary-infundibular segment on the other. In such a circumstance, microsurgical reconstruction of one functional tube can be achieved by anastomosis of the contralateral tubal segments behind the uterus, maintaining the physiologic relation between the tubal infundibulum and ovary. In the presence of both ovaries, the utero-ovarian ligaments are first approximated with interrupted, nonabsorbable no. 4-0 or 5-0 Nylon sutures. This brings the ovaries together and helps reduce tension in achieving the subsequent tubal anastomosis ([Fig. 21.37](#)). Successful delivery after such a procedure has been reported.

Approximation of the Fimbriated End of the Oviduct to the Contralateral Ovary

When a single ovary exists on the side opposite the patient's only tube, simple approximation of the fimbriated extremity of the tube to the ovary may be possible. The ovary is mobilized, and the mesovarium is fixed to the posterior surface of the uterus with nonabsorbable sutures. The contralateral oviduct is mobilized, and its mesosalpinx is sutured to the posterior aspect of the uterus. The nonabsorbable sutures are placed on the mesosalpinx approximately 1 cm from the tube. This will effectively place the infundibulum in close proximity to the ovary. Alternatively, the ovary can be transposed to the contralateral side with its vascular pedicle kept intact.

Iterative Reconstructive Surgery

Except in rare circumstances, there are no data to support the undertaking of an iterative surgical procedure

when a prior reconstructive operation has failed. Rare exceptions include cases of tubotubal anastomosis that failed for purely technical reasons, provided sufficient lengths of healthy tube are available for reconstruction. In such instances, an iterative microsurgical anastomosis may be undertaken if tubal cannulation fails to restore patency.

Tubal cannulation, performed at the time of the postoperative control HSG that demonstrates an obstruction at the anastomosis site, may prove beneficial in a small percentage of cases by breaking down synechiae or dislodging debris that may be present at this site.

Iterative surgery yields a modest success rate if the initial procedure was performed with the use of conventional techniques. However, the success rate of iterative procedures is disappointing when they are undertaken after a failed microsurgical intervention. Most of the available data on iterative surgery concern salpingostomy. Of the 119 such cases reported in the literature, 18 (15.1%) achieved live births, 5 had spontaneous abortions, and 7 (5.9%) had ectopic gestations. All of these 119 patients had their first procedure performed by conventional techniques and their second intervention performed by microsurgery.

The first report on laparoscopic salpingostomy by Gomel in 1997 included, except for one case, iterative procedures on patients who had previously undergone surgery with conventional techniques. This fact may explain the satisfactory rate of success that was obtained.

The conception rate after iterative microsurgical fertilitypromoting procedures is significantly lower than that obtained with primary microsurgical interventions. Thie et al. (1986) reported a conception rate of 51% after various primary microsurgical procedures in 161 patients. This rate was only 18% at 3-year follow-up in a similar group of 21 patients who had microsurgery after a failed primary operation performed by conventional techniques.

The preceding data strongly suggest that iterative surgery may be indicated in selected, rare instances and that most of these patients may be better served with IVF.

Observations on Current Practice

The enormous progress in IVF and ART in the past 20 years has been accompanied with the commercialization of this technology and its services all over the world. In parallel fashion, there has been a significant decline in the practice and teaching of reconstructive surgery. There is a paucity of publications on this subject. In vitro fertilization is offered now, as a primary treatment option, in most cases of tubal factor infertility. These changes have occurred despite the greater acceptance of laparoscopic access to perform many of the reconstructive tubal operations and the use of minilaparotomy incision for more complex anastomotic procedures, which represents a major progress in gynecologic surgery. These changes have occurred despite the satisfactory results

P.399

yielded by reconstructive surgery in appropriately selected cases and despite the fact that surgery offers the couple the opportunity to attempt a pregnancy over a long period of time and to conceive more than once. Furthermore, as already stated before, the presence of a credible alternative with IVF permits the reproductive surgeon to operate on cases with better prognosis, which translates in superior outcomes as has been well demonstrated.

In addition, training in microsurgery renders the gynecologist much more conscious of avoiding peritoneal trauma and more careful in tissue handling and tissue care. It makes him/her more conscious of conservation and overall a better surgeon. Skills that may well be lost with lack of teaching of reconstructive microsurgery.

The evidence suggests that surgery should retain its place in the treatment of tubal infertility. Preservation of the place of surgery will require a concerted effort on the part of the teaching institutions. We are pleased to note the

recommendations in support of this approach in ASRM's recent "Committee Opinion: Role of Tubal Surgery in the Era of Assisted Reproductive Technology."

Surgery and ART are complementary approaches that can be used singly or in combination to improve the outlook of couples suffering from tubal infertility. This was clearly demonstrated in a study by Tomazevic published in 1996. Fifty-nine women with pathologic cornual occlusion were treated by microsurgical tubocornual anastomosis; 27 of these (45.8%) had live births. The 32 women in whom the surgery did not yield a birth were offered IVF treatment; 21 of them had a total of 66 cycles of IVF. Twelve of these had a live birth, bringing the total of women with a baby to 39 (66.1%). The reader must be reminded that the success rate with IVF in the late 1980s and early 1990s was fairly low compared to current outcomes.

In the preface of the book *Microsurgery in Female Infertility*, published in early 1983, it is stated: "This manuscript has been completed during a time of rapid change and expansion with the understanding that it represents not an end point but merely an accounting at a given point in time. Further developments are also occurring in the area of IVF and embryo transfer (IVF & ET), which will undoubtedly produce improved results. Nonetheless, I do not consider the techniques of microsurgery on the one hand and IVF & ET on the other as competitive; on the contrary, I see them as complementary, enabling us to achieve a greater success rate among those patients presenting with complex fertility problems." This statement is still valid today.

Chapter 22

Endometriosis

John S. Hesla

John A. Rock

DEFINITIONS

Adenomyoma—A manifestation of adenomyosis characterized as localized, encapsulated disease of the uterine wall, as compared with the more common diffuse pattern of extension of endometrial glands and stroma in the myometrium.

Adenomyosis—Heterotopic endometrial glands and stroma located deep within the myometrium, with glandular extension below the endometrial-myometrial interface of at least 2.5 mm.

American Society for Reproductive Medicine (ASRM) classification of endometriosis—A scoring system to quantify the location and extent of endometriosis with a scalar rather than numeric terminology. This documentation has been proposed to allow direct comparison of patient responses to medical and surgical treatments and to identify factors predictive of disease outcome.

Atypical peritoneal implants of endometriosis—Lesions of varying appearance, including vesicles, flat plaques, raised blebs, polypoid structures, areas of fibrosis and adhesion formation, and peritoneal defects. May be clear, yellow, brown, blue, or black in color, as compared with the readily recognized red or gray implants.

Cancer antigen 125 (CA-125)—A high molecular weight glycoprotein expressed on the cell surface of some derivatives of embryonic coelomic epithelium. CA-125 is often elevated in cases of mild-to-severe endometriosis, as well as other conditions, including acute pelvic inflammatory disease, adenomyosis, uterine leiomyoma, menstruation, pregnancy, epithelial ovarian cancer, pancreatitis, and chronic liver disease.

Endometrioma—A solitary, nonneoplastic mass containing endometrial tissue and blood.

Endometriosis—The presence and growth of functioning endometrial tissue containing glandular and stromal elements in places other than the uterus that often results in severe pain and infertility.

Hydrodissection—Forceful injection of physiologic irrigant through a small defect created in the surfaces to be separated, such as the peritoneum from the retroperitoneal tissue. This may aid in establishment of the plane of dissection.

Presacral neurectomy—Division of the superior hypogastric plexus; useful as an adjunctive procedure to eliminate the uterine component of dysmenorrhea that results from endometriosis.

Reflux menstruation—Reflux of menses through fallopian tube to ectopic site, especially the peritoneal cavity. Proposed by John Sampson as a mechanism for the origin of endometriosis in many women.

Uterine suspension—Surgical technique of elevation of the adnexa to reduce adhesion formation at denuded peritoneal surfaces of the posterior cul-de-sac, uterine serosa, and broad ligament.

FIGURE 22.1 Anatomic locations of endometriosis implants in 182 consecutive infertility patients found to have endometriosis by laparoscopy. The rates shown indicate the percentage of all patients with implants in a given locale (Redrawn with permission from Jenkins S, Olive DL, Haney AF. Endometriosis: pathogenic implications of the anatomic distribution. *Obstet Gynecol* 1986;67:335. Copyright © 1986, The American College of Obstetricians and Gynecologists).

Endometriosis is a clinical and pathologic entity initially described by von Rokitansky in 1860 that is characterized by the presence of tissue resembling functioning endometrial glands and stroma outside the uterine cavity. These ectopic implants can be located throughout the pelvic cavity, including the ovaries, uterine ligaments, rectovaginal septum, parietal peritoneum, intestinal serosa, and appendix. Less common sites of involvement include the cervix, hernial sacs, the umbilicus, laparotomy and episiotomy scars, and the pleural and pericardial cavities (Fig. 22.1).

Although endometriosis has been extensively investigated over the past century, it remains an enigmatic disease process. The association between endometriosis and infertility is still undefined, and there are insufficient data to support many of the hormonal and surgical therapies that have been proposed. In addition, the often subtle and varied appearances of endometriosis can make recognition of lesions and surgical staging difficult, thereby casting doubt on the utility of the classification systems that have been developed. Nevertheless, the findings of well-designed clinical trials and recent studies that have elucidated the pathogenesis of endometriosis have enabled a more rational approach to the medical and surgical management of this disease.

PREVALENCE

The estimated prevalence of endometriosis among population groups varies depending on the presenting symptoms. Endometriosis affects 6% to 10% of reproductive-age women. Among women with pelvic pain, the prevalence of endometriosis ranges from approximately 30% to 80%. The disease has been diagnosed in 40% to 52% of women with severe dysmenorrhea and 70% of patients with chronic pelvic pain. Cramer and colleagues, in a multicenter study, diagnosed endometriosis in 17% of women with primary infertility, and in other series, the prevalence varied from approximately 9% to 50%. Verkauf prospectively identified endometriosis in 38.5% of infertile women and 5.2% of fertile women. Other studies have confirmed the odds that infertile women are seven to 10 times more likely to have endometriosis than are their fertile counterparts. However, any postmenarchal woman is at risk, because endometriotic implants have been identified in postmenopausal women, in women with primary amenorrhea secondary to müllerian anomalies, and in 69.6% of teenagers

who underwent diagnostic laparoscopy for chronic pelvic pain. Twin and family studies suggest a genetic component. Simpson and colleagues reported a 6.9% occurrence rate in first-degree female relatives, which compared with 1% for the non-blood-related control group. Genes involved in implantation of tissue, fibrinolysis, or ovarian steroidogenesis may be aberrantly expressed at a higher frequency in family members with endometriosis. Other risk factors include alcohol use, smoking, and low body mass index.

HISTOGENESIS

The mechanism by which endometriosis develops is unknown, although there has been much discussion as to its origin (Table 22.1). Variations in the location and presentation of implants have compromised a complete understanding of the histogenesis of the aberrant endometrial cells. Four major theories have been proposed:

1. The reflux and direct implantation theory suggests that viable endometrial cells reflux through the fallopian tubes during menstruation and implant on surrounding pelvic structures.
2. The coelomic metaplasia theory suggests that the multipotential cells of the coelomic epithelium may be stimulated to transform into endometrial-like cells.
3. The vascular dissemination theory suggests that endometrial cells enter the uterine vasculature or lymphatic system at menstruation and are transported to distant sites.
4. The autoimmune disease theory suggests that endometriosis is a disorder of immune surveillance that allows ectopic endometrial implants to grow.

P.404

Metaplasia of urothelium
Hereditary factor
Immunologic factor

Reflux and Direct Implantation Theory

John Sampson first postulated that endometriosis arose from retrograde flow of fragments of endometrial tissue through the oviducts and into the peritoneal cavity. Much evidence validates this theory. The anatomic distribution of endometriosis as noted at laparoscopy is consistent with a reflux pattern of development; the most common sites of disease in the infertile woman are the ovary and uterosacral ligament, followed by the posterior uterus, posterior cul-de-sac, and posterior broad ligament. Endometriosis developed in monkeys when the uterus was surgically inverted to cause menstruation to occur

intraperitoneally. Exposure of abraded peritoneum to endometrial cells has resulted in the growth of endometriotic implants in rabbits and rats. Endometriosis has developed in laparotomy, episiotomy, and cesarean section scars after surgical entrance into the endometrial cavity, and anomalies of the müllerian tract are associated with an increased occurrence of endometriosis. Endometriosis is a common finding in women with stenosis of the external cervical os. Epidemiologic data suggest that women who menstruate more frequently, more heavily, or for a longer duration have an increased likelihood of disease development. Prolonged lactation and multiparity are protective.

Peritoneal implants of endometriosis and the presence of endometriomas are more common on the left side of the pelvis than the right. The position of the sigmoid colon creates a sequestered microenvironment around the left adnexa, which facilitates implantation of endometrial cells regurgitated through the left tube. The large intestine does not provide the right hemipelvis with this anatomical shelter, because the cecum lies more cranial in position. In addition, the retrograde menstruation theory is supported by the finding of a higher prevalence of endometriosis in the subphrenic region, since the falciform ligament may trap refluxed endometrium in the right hypochondrium.

Focal endometriosis has been identified in 16% to 63% of proximal tubal segments after cautery or Pomeroy tubal sterilization, perhaps as a consequence of recurrent bathing of the healing terminal area with menstrual products. Nevertheless, bloody peritoneal fluid has been observed in 90% of women with patent fallopian tubes undergoing laparoscopy during the perimenstrual time period, a figure much greater than the estimated 2% to 5% prevalence of symptomatic endometriosis in women of reproductive age. Additionally, peritoneal implants have been identified in women who had a prior tubal ligation procedure and were undergoing laparoscopy for the evaluation of pelvic pain. Hence, other factors evidently are present to promote the ectopic implantation.

Coelomic Metaplasia Theory

The germinal epithelia of the ovary, endometrium, and peritoneum all originate from the same totipotent coelomic epithelium. The metaplasia theory postulates that these totipotent cells are transformed by repeated exposure to hormonal or infectious stimuli. This may explain the development of endometriotic lesions in unusual locations and in the odd cases of male patients in whom endometriosis develops after prostatectomy, orchiectomy, or prolonged treatment with estrogen. Reports of endometriosis in women with primary amenorrhea and an absence of functioning uterine endometrium and of endometriosis identified in mature teratomas also lend support to the metaplasia theory.

Vascular Dissemination Theory

Endometrial cells can be transported to extrauterine sites by blood vessels or the lymphatic system or by contamination of the pelvis or abdominal wall incision if the uterine cavity is surgically entered. Retroperitoneal endometriosis is hypothesized to arise from lymph vascular spread; 29% of patients with pelvic endometriosis documented on autopsy had pelvic lymph nodes that contained endometriosis. Theories of vascular dissemination help explain how endometriosis can develop in the lung or pericardium.

Autoimmune Disease Theory

Alterations in cellular immunity can facilitate the successful implantation of translocated endometrial cells. Compared with control subjects, monkeys with spontaneous endometriosis had both a lowered cell-mediated response to autologous endometrial tissue, as determined by skin testing, and a decreased in vitro blastogenesis response. Similar studies performed in women demonstrated that lymphocytes obtained from control patients were significantly more efficient in cytolysis of isolated endometrial stromal cells than were lymphocytes obtained from patients with endometriosis. This decreased cytotoxic response to endometrial cells may be due to a defect in natural killer cell activity, such as a decreased lytic effect toward stroma that allows ectopic development of endometrial fragments. In addition, there may be an increased resistance of endometrium in women with endometriosis to natural killer cytotoxicity.

Promoting Factors

Clinical and laboratory studies support the concept that endometriosis is an estrogen-dependent condition. Estradiol concentrations greater than approximately 60 pg/mL have been identified as necessary for proliferation of endometriotic lesions. Nevertheless, estrogen and progesterone receptors are found in much lower concentrations in endometriotic tissue than in normal endometrium tissue; such endometriotic tissue also frequently fails to show cyclic variations of development in response to hormonal changes. Early data from primate studies suggested that endometriosis required no steroidal supplementation to become initially established, but later studies demonstrated that chronic exposure to ovarian steroids is

Growth factors can originate from the peritoneal environment to stimulate endometrial development. Platelet-derived growth factor, a macrophage secretory product, enhance endometrial stromal cell proliferation in a dose-dependent manner. Similarly, macrophage-conditioned media promote mouse endometrial stromal cell proliferation in vitro, and this activation is enhanced with the addition of estrogen. Increased concentrations of macrophage-derived growth factors, including vascular endothelial growth factor, have been identified in the peritoneal fluid of women with endometriosis. This suggests that changes in the vascular permeability and angiogenesis play an important role in the pathophysiology of this disease.

Molecular alterations in steroidogenic enzyme function have been implicated in the pathogenesis of endometriosis. Endometrial tissue from patients with endometriosis expresses aromatase P-450, whereas endometrium from control women without identifiable endometriosis does not. The presence of aromatase within endometriosis results in higher local production of estrogen necessary to support the growth and metabolic activity of the lesion.

Menstrual effluent contains factors that induce alterations in the peritoneal mesothelium, facilitating adhesion of endometrial cells. Attachment of endometrial cells is enhanced by induction of adhesion molecules and their receptors and the overexpression of matrix metalloproteinases and plasminogen activators. These factors ensure local destruction of the extracellular matrix. Suppression of matrix metalloproteinase production by progesterone decreased ectopic implantation of endometrium in the nude mouse, implicating these proteinases in the pathogenesis of endometriosis.

In summary, no single theory explains all cases of endometriosis, although the direct implantation mechanism seems the likely cause for most disease locations. Immunologic factors, inducing substances, or other mediators may explain the development of endometriosis in more distant sites.

NATURAL HISTORY

The natural history of endometriosis is not clearly understood. The disease appears to progress in most untreated patients, although spontaneous regression can occur in as many as 58% of milder cases. Falcone and Lebovic analyzed the findings of follow-up laparoscopies performed 6 to 39 months following the initial diagnostic procedure among 162 patients in several previous endometriosis surgical trials that were randomized to the placebo control group rather than surgical excision/ablation. There was nearly equal distribution of those with progressive disease (31%), unchanged (31%), and improvement in extent of lesions (38%).

Surgical and medical therapies may promote a temporal regression but may not effectively eliminate microscopic, retroperitoneal, and hormonally resistant disease. Dmowski and Cohen described persistent disease in 15% of patients treated with danazol, and Henzl and associates noted a progression of disease during the course of treatment in 4% to 8% of patients receiving danazol or an analogue of gonadotropin-releasing hormone (GnRH). When conservative surgery was combined with danazol or GnRH agonist therapy, the overall recurrence rate at 36 months was between 13.5% and 33%.

The effect of pregnancy on the clinical course of endometriosis is uncertain. Although Sampson proposed that pregnancy induces involution of implants, other authors recently described a variable response of endometriosis to pregnancy. McArthur and Ulfelder analyzed the clinical effect of pregnancy on endometriosis in 24 patients. They found that the behavior of endometriosis during the gravid state was extremely variable and that the regression of disease appeared to be due to decreased tissue responsiveness to hormonal stimulation rather than to actual necrosis of the lesions. More patients in their series experienced disease persistence than permanent regression. Monkey studies have confirmed these findings; the response of endometrial implants to pregnancy varied from total regression to significant progression.

Approximately 2% to 4% of early postmenopausal women suffer from endometriosis. These cases are usually associated with exogenous intake of estrogens or tamoxifen. Nevertheless, there are reports of symptomatic endometriosis in women older than 60 years of age who have not received steroid replacement therapy. Such cases presumably are secondary to the responsiveness of the residual lesions to low levels of estrogens that arise from peripheral conversion of ovarian and adrenal androgens.

PATHOPHYSIOLOGY

Gross Appearance

Signs of endometriosis may be evident on physical examination. Endometriosis can form tender nodules on the

uterosacral ligaments that are readily palpable on rectovaginal examination. It may infiltrate the deepest portion of the rectouterine pouch and cause pain with defecation and, rarely, cyclic rectal bleeding. Lesions of endometriosis have been identified in the umbilicus, in the vulva, and in episiotomy scars. Complete ureteral obstruction has been reported. This can be temporarily reversed with the administration of GnRH agonists, progestogens, and danazol. Diaphragmatic involvement can lead to chronic, recurrent pneumothorax at the time of menstruation. Lesions have been identified in the upper and lower extremities, the pericardium, and the lung.

The gross appearance of endometriosis is extremely variable. On entering the abdomen, the surgeon may find a small, adherent nodule on one or both sides of the pelvis, usually attached to the posterior cul-de-sac and posterior surface of the uterus. Frequently, release of ovarian adhesions to mobilize the adnexa results in an egress of chocolate-colored or dark red fluid that is highly suggestive of endometriosis. Examination of the ovary may disclose a cyst that is rarely larger than 10 cm and has a dark, hemorrhagic lining. Endometriomas develop over a time span of a few months as a result of extensive intracystic hemorrhage. Reddish blue, fibrinous areas that represent small islands of endometriosis may be present on the ovarian cortex. Peritoneal implants vary in appearance from black, puckered lesions surrounded by a variable extent of fibrosis, to red polypoid material, to clear vesicles. Other appearances include yellow-brown peritoneal discoloration, white plaques, or scarring. The strong inflammatory stimulus of superficial lesions of endometriosis may promote fibrosis and invagination of adjacent peritoneal surfaces. Red lesions are the most metabolically active and are found mainly in younger patients.

The fallopian tube is usually nonobstructed and free of gross disease, although peritubal adhesions can extend to adjacent structures, particularly in patients with extensive disease. Deeply infiltrating endometriotic nodules extend more than 5 mm beneath the peritoneum and may involve the uterosacral ligaments, bladder, ureters, or vagina. The depth of invasion has been correlated with pain symptomatology. Endometrial invasion of the rectal or sigmoidal wall can simulate malignancy or produce complete obstruction.

P.406

Microscopic Appearance

The essential diagnostic criterion is the presence of endometrial tissue, both stroma and glandular elements. This aberrant tissue resembles the uterine mucosa both histologically and physiologically. Secretory change and decidualization are seen in response to hormone influences in the luteal phase, and estrogen stimulates proliferation of the ectopic implants. Nevertheless, these functional changes are less uniform for implants than for the uterine mucosa.

The ultrastructural features of endometriosis are consistent with an incomplete response to the hormonal milieu. Endometriotic implants contain lower concentrations of progesterone receptors than do corresponding normal endometrium, so the histologic response to progesterone is less profound. Gould and colleagues reported that the nucleus of endometriotic stromal cells had a marked degree of estrogen binding throughout the menstrual cycle, whereas stromal binding sites in the uterine endometrium were present only during the proliferative phase and not the secretory phase of the cycle. The differing responses of the two tissue types to steroid hormones were reflected by the modulation of estrogen binding and changes in glandular histology. Estrogen receptors did not undergo downregulation during the luteal phase of the cycle in endometriotic foci, despite an increase in endogenous progesterone concentration. Alterations in the quantity, activation, or function of the progesterone receptor may be responsible for this lack of change in estradiol receptors, the abnormal response of the ectopic endometrium to progesterone, and the failure of hormonal therapy in some patients.

Estrogens play a primary role in the establishment and maintenance of endometriotic tissue. There is evidence of local estrogen production within endometriotic cells. Pellegrini and colleagues observed an overexpression of estrogen receptors α and β , which belong to the nuclear receptor family and act as activated transcription factors. Cyclin D1 and c-myc are estrogen-related genes implicated in cell cycle control that are overexpressed in endometriotic cells.

Because of the pressure of retained blood in the cyst cavities of endometriomas, a large concentration of endothelial leukocytes heavily laden with hemosiderin (pseudoxanthoma cells) may be found, and the glandular lining may be nearly absent and replaced by reactive connective tissue elements. Biopsy may fail to yield histologic proof of the endometrial glands and stroma in approximately one third of all cases of typical clinical endometriosis, even if many tissue sections are analyzed.

The "chocolate cyst" description of the ovary is used synonymously with endometrial cyst or endometrioma. Nevertheless, other types of ovarian cysts may have a similar fluid content, including the hemorrhagic follicle, corpus luteum, or cystadenoma. Pathologic confirmation of the diagnosis is always advised.

Approximately 0.7% to 1.0% of patients with endometriosis have lesions that undergo malignant transformation. Atypical glandular changes have been found in 3% to 6% of cases of ovarian endometriosis. Several histologic tumor types have been described (**Table 22.2**). Endometrioid adenocarcinomas account for 69% of reported lesions, with the ovary being the primary site in most cases. Rapidly enlarging endometriomas or those measuring greater than 10 cm should be sectioned carefully to search for malignant foci. Tumors arising in endometriosis are predominantly of low grade and confined to the site of origin. Progestogen therapy is recommended after surgical resection of these lesions.

Clinical Characteristics

The clinical features of endometriosis are varied, and the presentation depends on the site of growth and the severity of disease. The classic triad of dysmenorrhea, dyspareunia, and infertility has been described as characteristic of the disease (**Table 22.3**). Nevertheless, patients with extensive endometriosis may be clinically symptom-free, and women with only minimal involvement may manifest disabling pelvic pain. Dysmenorrhea is a common symptom that most likely is associated with endometriosis if it develops after age 20 years, is

P.407

progressive, and is not well relieved by nonsteroidal antiinflammatory agents or oral contraceptives. Spasmodic pain beginning before the onset of menstrual bleeding is another common symptom of patients with endometriosis. When the rectovaginal septum or uterosacral region is involved, the pain is often referred to the rectum or lower sacral and coccygeal regions because of premenstrual and menstrual swelling of ectopic implants. Dyschezia and constipation may be present. Dyspareunia is common, especially in cases of uterosacral or vaginal infiltration, fixed retroversion of the uterus, or ovarian fixation by adhesions. Again, there is no absolute correlation between the amount of visible endometriosis as seen at surgery and the extent of symptoms; minor disease involvement may result in severe pain, whereas massive areas of superficial endometriosis may cause no discomfort.

Infertility

Other presenting symptoms can include signs of urinary tract involvement, such as hematuria or ureteral obstruction, unusual abdominal or adnexal masses, cyclic sciatica, catamenial pneumothorax or hemoptysis, and swollen and painful scars. Premenstrual spotting can occur for 3 to 7 days before the start of menses; this is a poorly recognized but relatively consistent sign of endometriosis. An endometrioma can leak, causing considerable pain, or it can rupture and produce a clinical picture much like that seen with a ruptured ectopic pregnancy or acute appendicitis. Nearly 10% of patients with endometriosis present with acute symptoms that require exploration for diagnosis and treatment.

Approximately 20% to 40% of women with endometriosis are infertile. Vercellini and colleagues report the monthly fecundity rate for those with endometriosis is 2% to 10%, as compared to 15% to 20% in fertile couples. When extensive pelvic scarring or large endometriomas are present in the patient with endometriosis, the associated infertility can be clearly attributed to anatomic distortion. Also, the oxidative stress associated with endometriomas may lead to follicular depletion and vascular compromise of the ovarian cortex. However, the pathophysiology of infertility in patients with less advanced disease is more controversial.

Endometriotic implants within the fallopian tube or ovary may promote a local inflammatory response that has a direct, deleterious effect on tubal function ([Table 22.4](#)). Oocyte capture by the fallopian tube may be prevented despite the normal process of oocyte maturation and ovulation. Endometriosis and especially adenomyosis are associated with impeded hyperperistaltic and dysperistaltic uterotubal transport capacity. Chronic salpingitis was detected in 29 of 87 (33%) fallopian tubes of patients undergoing laparotomy for ovarian endometriosis; tubal obstruction was demonstrated in only one of these cases, although adhesions were present in 24%. Endometriosis has been identified in the resected segments of fallopian tubes in women undergoing tubocornual anastomosis for proximal tubal obstruction when there was no evidence of implants elsewhere in the pelvis. Others have reported a correlation between tubal endometriosis and chronic salpingitis in similar cases, although this finding has not been uniform.

Altered folliculogenesis or ovulation has been described in endometriotic patients who have undergone serial sonogram studies. An abnormal follicular growth rate and total growth period may disturb the normal synchronization of oocyte maturation, uterine receptivity, and ovulation. Tummon and coworkers reported that women with minimal endometriosis had more, yet smaller, follicles and lower preovulatory estradiol levels at the time of midcycle luteinizing hormone (LH) surge.

TABLE 22.4 Possible Mechanisms by Which Endometriosis Causes Infertility

Mechanical interference

Pelvic adhesions

Chronic salpingitis

Altered tubal motility

Distortion of tuboovarian relations

Impaired oocyte pickup

Alterations in peritoneal fluid

Increased concentration of prostaglandins

Increased number of activated macrophages

Increased production of cytokines

Enhanced phagocytosis of sperm

Abnormal systemic immune system response

P.408

Luteinized unruptured follicle (LUF) syndrome, a condition of normal ovulatory hormone secretion and luteinization of the follicle without the expected occurrence of ovulation, has been reported to be more common in patients with endometriosis. Mio and colleagues performed transvaginal ultrasound at least every other day from cycle day 8 through the third day after human chorionic gonadotropin (hCG) administration on 47 patients with endometriosis, predominantly minimal and mild, and 28 control patients with male factor infertility. Luteinized unruptured follicle syndrome was diagnosed in 20 of 81 (24.7%) monitored cycles in endometriosis patients and in only 3 of 44 (6.8%) monitored cycles in control patients, a difference that achieved statistical significance. Schenken and associates also noted an increased rate of LUF and associated luteal phase deficiency in monkeys with surgically induced moderate-to-severe endometriosis. An absence of sonographic evidence of midcycle follicular collapse in patients with mild endometriosis has ranged from 4% to 35% in the literature.

Luteal phase function has been evaluated by endometrial biopsy and peripheral progesterone concentrations. There is insufficient evidence to conclusively link endometriosis with a deficiency of corpus luteum activity, although some studies have suggested the existence of a shortened luteal phase, delayed increase in progesterone secretion after ovulation, decreased progesterone secretion in the late luteal phase, and lowered serum estradiol levels during the early follicular phase.

The effect of endometriosis on fertilization and preimplantation development is widely debated. Peritoneal fluid from patients with endometriosis had a deleterious effect on sperm-oocyte interaction in homologous mouse and hamster

fertilization assays. In vitro studies involving human zona pellucida confirmed an adverse effect of peritoneal fluid on sperm binding in this patient population, although others reported that peritoneal fluid from women with low-stage endometriosis had no detrimental effect on sperm motility characteristics. Peritoneal fluid from women with moderate and severe endometriosis caused declines in sperm motility and velocity. Exposure of two-cell mouse embryos to the peritoneal fluid or serum of patients with endometriosis has resulted in a decreased rate of cleavage and development to the blastocyst and hatching stages as compared with control nonendometriotic specimens. However, this association was not verified by similar studies of mouse embryo development and apoptosis.

Aberrant gene expression in eutopic and ectopic endometrium may be related to infertility or the establishment of the disease. Integrins are ubiquitous cell adhesion molecules that undergo dynamic alterations during the normal menstrual cycle in the human endometrium. The $\alpha v \beta 3$ vitronectin receptor integrin is normally expressed in endometrium during the periimplantation period; such expression may be lost in women with mild endometriosis, which may affect uterine receptivity. The endometrium of infertile women with endometriosis may synthesize low levels of L-selectin, a protein that coats the trophoblast on the surface of the blastocyst. This may be another mechanism for impaired implantation. Women with lower levels of expression of *HOXA10* have lower implantation rates. This gene is involved in endometrial regeneration in each menstrual cycle.

A high frequency of spontaneous abortions in infertile women with endometriosis has been reported, although the relation was questioned because of potential control group bias. Naples and coworkers found that patients with endometriosis who refused treatment had the same abortion rate before and after diagnosis (26% and 25.5%). Studies of the last decade with appropriate control groups have demonstrated no substantial increase in the incidence of spontaneous abortion in women with endometriosis.

Mechanisms Influencing Symptoms

Because of the uncertain mechanisms causing infertility and pelvic pain in patients with minimal and mild endometriosis, many investigators have attempted to identify specific alterations in the peritoneal environment that would explain these symptoms. Significant increases or decreases in peritoneal fluid volume that are due to increased production by the ovaries, altered mesothelial permeability, or increases in the colloid osmotic pressure have been hypothesized to inhibit ovum capture by the fallopian tube or to adversely affect tubal transport. Koninckx and associates reported elevations in peritoneal fluid volume during cycle days 1 through 5 in patients with mild and moderate endometriosis. The quantity of fluid was comparable to that in control subjects during the remainder of the follicular phase. These authors described reduced volumes in the early luteal phase, which directly contrasts with findings reported by Oak and colleagues. Rock and associates evaluated patients during cycle days 8 through 12 and measured no difference in fluid vols in patients with endometriosis compared with that in control subjects. Similar findings were noted by Rezai and associates. Hence, it appears unlikely that fluid volume alone plays a role in the establishment of infertility.

Peritoneal fluid from patients with minimal and mild endometriosis has been shown to increase macrophage proliferation in vitro. In addition, several studies have described increases in total macrophage number in the peritoneal fluid of patients with endometriosis. Hill and coworkers measured significant elevations in total leukocytes, macrophages, helper T cells, lymphocytes, and natural killer cells in women with stages I and II endometriosis. Activated macrophages may affect the reproductive process by altering sperm motility, fimbrial ovum capture, sperm-oocyte interaction, and early embryonic growth. Increased sperm phagocytosis by macrophages has been demonstrated by in vivo animal and in vitro human studies. Suginami and Yano demonstrated the presence of an ovum capture inhibitor in peritoneal fluid from patients with endometriosis, which reduces fimbrial activity for ovum capture in vitro. This macromolecule may prevent contact between the fimbrial cells and cumulus oophorus.

Prostaglandins, interleukins, and other substances produced by macrophages may be harmful to reproduction. Fakhri and colleagues demonstrated that interleukin-1 was present in the peritoneal fluid of almost all patients with endometriosis, but not in the fertile control group. Interleukins have been shown to adversely affect mouse embryo growth in vitro. In addition, interleukin-1 stimulated fibroblast proliferation, collagen deposition, and fibrinogen formation; hence, elevated concentrations of such lymphokines may account for the development of fibrosis and adhesions in advanced stages of endometriosis. Interleukin-6 secretion in vitro is up-regulated in ectopic and eutopic endometrial stromal cells from women with endometriosis. Nevertheless, not all studies have confirmed the existence of a difference in interleukin activity between endometriosis patients and control groups. Decreased plasminogen activator activity in endometriotic implants may also be a cause for increased adhesion formation.

Bleeding from ectopic endometrial implants may promote the formation of free oxygen radicals. The iron in hemoglobin

may be the catalyst of free radical reactions. Free radicals may damage proteins, carbohydrates, nucleotides, and lipids, resulting in tissue damage and de novo adhesions.

P.409

Chronic elevations in the level of peritoneal prostaglandins have been hypothesized to interfere with ovulation, to alter tubal mobility such that the embryo may arrive in the uterus at a suboptimal time for implantation, or to diminish corpus luteum function. Drake and associates measured the metabolites of prostacyclin and thromboxane A₂ in peritoneal fluid and noted a 10-fold increase in these levels in patients with endometriosis. Ylikorkla and colleagues confirmed these observations, although the increase in prostanoid metabolites in the patients with endometriosis was less than twice that of the controls. When cycle stage was experimentally controlled, Rock and coworkers, Rezai and associates, and others failed to demonstrate a significant change in prostaglandin levels in peritoneal fluid from patients with endometriosis as compared with control groups. In addition, prostaglandin concentrations did not vary between the follicular and luteal phase in either endometriosis patients or controls. Variations in collection of samples during the menstrual cycle, selection of control groups, and collection techniques have compromised the interpretation of data regarding the relative importance of prostanoid content in peritoneal fluid in the studies that have been published on this topic.

Alterations in the systemic immune response of endometriosis patients may influence fecundity. Cellular and humoral abnormalities have been reported in the peripheral blood and peritoneal fluid of women with endometriosis. Translocated endometrial cells may implant only in patients with an inherent defect in cell-mediated immunity. Functional changes in monocytes and macrophages, natural killer cells, cytotoxic T lymphocytes, and B cells suggest decreased surveillance, recognition, and destruction of misplaced endometrial cells and possible facilitation of their implantation. The endometrial proteins of menstrual fluid may be recognized as foreign by the host and trigger an autoimmune response. This host reaction can be variable, thus explaining why some women with a weak autoimmune response and varying extent of disease can conceive with no difficulty. Other investigators have confirmed a high prevalence of autoantibodies against endometrial and ovarian tissues in the sera and cervical and vaginal secretions of women with endometriosis.

Nonspecific polyclonal B-cell activation has been postulated to exist in endometriosis, but there is a lack of substantive data to demonstrate that this association contributes significantly to endometriosis-associated subfertility.

Dioxin, a pollutant that is known to decrease cell-mediated cytotoxicity by reducing the number of helper T cells, has been suggested as a causative factor in the high incidence of endometriosis in developed countries. Heilier and associates documented an increase in dioxin-like compounds in the serum of women with peritoneal endometriosis and deep endometriotic (adenomyotic) nodules. Moreover, a dose-dependent relation existed between dioxin exposure and the subsequent development and severity of endometriosis in the rhesus monkey after a latent period of more than 5 years.

Nevertheless, other studies have suggested that endometriosis may not be associated with immunologic alterations in the pelvis. In a retrospective analysis of the cell count and volume of peritoneal fluid in 135 infertile women with endometriosis, Haney and colleagues found a negative correlation between total cell numbers and extent of disease and no significant correlation between fluid volume and extent of disease. Similarly, in the rabbit model of endometriosis, there was no difference in peritoneal fluid volume, macrophage numbers, or macrophage activation in treated versus control animals.

Hence, the exact cause-and-effect relation between endometriosis and infertility in the absence of a distortion in pelvic anatomy remains unknown. In a recent study using an adhesion-free rabbit model of endometriosis, peritoneal implants did not adversely affect the number of corpora lutea, the oocyte recovery or fertilization rates, tubal transport, embryonic development and cleavage, or nidation index. Similarly, Mahmood and Templeton were unable to detect differences in hormonal patterns of the menstrual cycle, follicular growth, preovulatory peritoneal fluid volume and sex steroid concentration, rate of LUF, oocyte maturity, fertilization rate, or cleavage rate between patients with minimal and mild endometriosis and control women.

Little is known about the mechanisms by which endometriosis induces pain symptoms. Dyspareunia may be related to stimulation of pain fibers by stretching of scarred, inelastic tissue or by direct pressure on nodules of endometriosis embedded in fibrotic tissue. Endometriosis implants may secrete inflammatory substances such as prostaglandins, cytokines, and growth factors that initiate the sequence of events that result in the development of pain. Moreover, the extravasated debris and blood from endometriotic implants may stimulate an inflammatory reaction within the peritoneal cavity with production of the aforementioned substances.

DIAGNOSIS

Symptoms

Dysmenorrhea, dyspareunia, and pelvic, back, and rectal pain—the more common symptoms of endometriosis—have been assumed to be caused by endometrial implants. However, the development of such symptoms is not diagnostic of the disease state. In one random survey of women in the general population, more than 60% reported dyspareunia at some point in their lives, and 33% had persistent discomfort. The prevalence of laparoscopically diagnosed endometriosis in patients with chronic pelvic pain has ranged from 4% to 52% in published series. Leibson et al. reported the age of peak diagnosis of endometriosis based on presenting symptom is pelvic pain, age 15 to 24 years; infertility, age 25 to 34 years; and dysfunctional uterine bleeding, age 35 to 44 years.

Some authorities have suggested that the symptoms may be dependent on the location of the implants, the presence of adhesions, distortion of ovarian anatomy by endometriosis, and involvement of other organs, such as the ureter or rectum. However, Fedele and colleagues found no significant association between the American Fertility Society (AFS; now known as the American Society for Reproductive Medicine) classification of stage and the presence and severity of dysmenorrhea, pelvic pain, and dyspareunia in a prospective study of 160 women. The pain profiles of the patients with ovarian lesions were similar to those of the patients with peritoneal or ovarian and peritoneal disease. Conversely, in a later study by the same group, ovarian endometriomas were the only lesions significantly associated with severe dysmenorrhea and pelvic pain in infertile women. In a more recent prospective study of symptoms experienced by women diagnosed with histologically proven endometriomas, Chapron et al. showed no correlation of the intensity of the pain with the size of the endometrioma. In this study, severe pelvic pain was significantly associated with the secondary finding of deeply infiltrating endometriotic lesions.

Koninckx and coworkers demonstrated that the presence of pelvic pain did not correlate with the total area of endometriosis, type of lesion, or volume of disease. The only significant discriminator proved to be the depth of infiltration; endometriotic lesions greater than 1 cm in depth were associated with

P.410

severe discomfort ([Fig. 22.2](#)). This supports earlier data that strongly linked pain with deep infiltration of the fibromuscular tissue of the pelvis. Hsu and colleagues found dysuria and midline anterior pain were the only symptoms associated with the location of superficial endometriosis lesions.

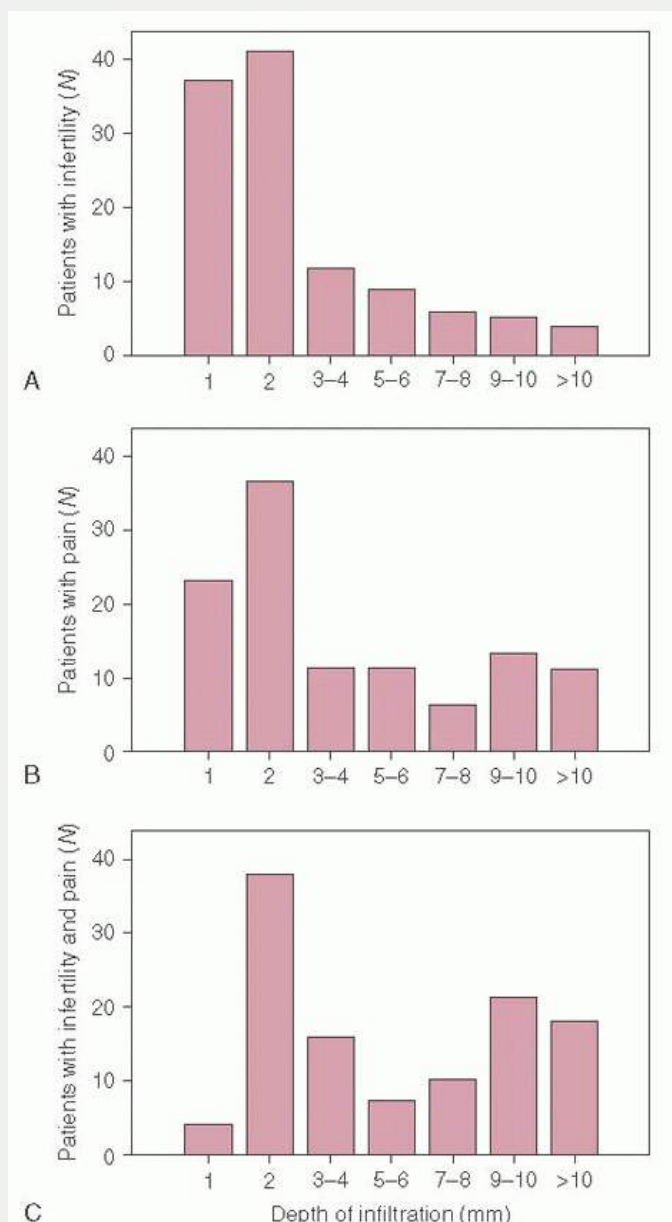

FIGURE 22.2 Frequency distributions of depth of infiltration of pelvic endometriosis in women with (A) infertility ($N = 283$), (B) pain ($N = 119$), or (C) infertility and pain ($N = 48$) (Redrawn with permission from Koninckx PR, Mueleman C, Demeyere S, et al. Suggestive evidence that pelvic endometriosis is a progressive disease, whereas deeply infiltrating endometriosis is associated with pelvic pain. *Fertil Steril* 1991;55:759. Copyright © 1991, Elsevier).

Pain symptoms generally correlate with fluctuations in steroid hormone concentrations. In response to cyclic stimulation by ovarian estradiol and progesterone, endometriotic lesions undergo epithelial and stromal proliferation, variable secretory changes, stromal pseudodecidual reaction, and periodic regression in a manner more disorganized than, yet similar to, that of normal endometrium. Surgical castration and ovarian hormonal suppressive therapy result in diminution of pain in most patients.

Physical Findings

Bimanual pelvic examination may reveal tender uterosacral ligaments, cul-de-sac nodularity, induration of the rectovaginal septum, fixed retroversion of the uterus, adnexal masses, and generalized or localized pelvic tenderness. The adherent tube and ovary may constitute a tender, irregular mass that is similar in characteristics to the mass palpated in cases of chronic salpingo-oophoritis. Uterosacral nodules occasionally reach 1 cm or more in size. Lesions implanted in the retrocervical area or rectovaginal wall are frequently more easily felt than seen and can be missed if the physical examination is omitted. A perceptible, painful swelling of the implant before and at menstruation remains a classic and reliable clinical sign of active rectovaginal or retrocervical endometriosis.

Cancer antigen 125 (CA-125), a high molecular weight glycoprotein expressed on the cell surface of some derivatives of embryonic coelomic epithelium, is often elevated toward the end of the luteal phase and during menstruation in patients with AFS stages II to IV endometriosis. Barbieri and colleagues reported that a value higher than 35 U/mL had a positive

predictive value of 0.58 and a negative predictive value of 0.96 in establishing the presence of endometriosis. Many other conditions have been associated with an elevated CA-125 concentration, including acute pelvic inflammatory disease, adenomyosis, uterine leiomyoma, menstruation, pregnancy, epithelial ovarian cancer, pancreatitis, and chronic liver disease. Pittaway and colleagues reported that 80% of women with pelvic pain and endometriosis had a CA-125 titer greater than 16 U/mL, whereas only 6% of patients with pelvic pain and without endometriosis had an increased serum concentration of this cell surface antigen.

Increased concentrations of CA-125 and placental protein 14 (PP14) have been related specifically to the presence of endometriotic cysts and deep endometriosis. The results of most studies, however, suggest that CA-125 is not sufficiently sensitive to identify lesser stages of endometriosis and is therefore not reliable as a screening test.

Somigliana and colleagues report transvaginal ultrasonography has high sensitivity (84% to 100%) and specificity (90% to 100%) in identifying ovarian endometriomas as based upon characteristics of low-level, homogeneous internal echoes. Doppler sonographic evaluation of resistance indices in the vessels of adnexal masses increases the sensitivity and negative predictive values of two-dimensional sonography and CA-125, but this yields many false-positive results because of the neovascularity of benign tumors. Magnetic resonance imaging (MRI) may be helpful in assessing deep pelvic and extrapelvic endometriosis, including lesions that involve the bladder, vagina, or sigmoid (**Table 22.5**). Small studies have indicated that transrectal sonography or rectal endoscopic sonography is useful for detecting rectal wall involvement if performed by a skilled radiologist or gastroenterologist.

Visual Findings

The patient with unexplained lower abdominal pain or a presentation suggesting endometriosis requires laparoscopy for definitive diagnosis. Ultrasonography and other noninvasive procedures cannot provide the specific information needed to diagnose or classify the extent or severity of disease. For proper laparoscopic evaluation, a double puncture technique is essential. The ancillary probe or forceps placed through the lower abdominal sheath permits mobilization of the tubes and ovaries. A methodical regimented approach should be used to thoroughly inspect the lateral sidewalls, all ovarian surfaces, both sides of the broad ligaments, the

P.411

bladder and bowel serosa, and the inferior aspects of the cul-de-sac. Uterine manipulation with a cannula fixed to the cervix facilitates evaluation of the uterosacral ligaments and rectal serosa. Photography and video recording are useful for documentation of findings.

TABLE 22.5 Accuracy of MRI for the Diagnosis of Adenomyotic Endometriosis According to Location

Awareness of the wide range of visual appearances of endometriosis is necessary for accurate diagnosis and appropriate surgical therapy of the disease. Although darkly pigmented lesions are readily recognizable and are considered a classic presentation of endometriosis, less discernible yet common forms of implants were described as early as the 1920s,

when Sampson noted “red raspberries, purple raspberries, blueberries, blebs, and peritoneal pockets.” The black or blue puckered “powder-burn” implant is a late consequence of cyclic growth and regression of the lesion, to the point that bleeding and hemosiderin staining of the tissue have occurred. Biopsy of such areas reveals inactive endometrial glands and fibrous stroma.

Distinctive morphologic variations include vesicles, flat plaques, raised lesions, polypoid structures, areas of fibrosis and adhesion formation, and peritoneal defects (**Table 22.6**). Yellow, brown, blue, or black coloration is proportional to the amount of hemosiderin deposition. Red polypoid lesions share the closest histologic characteristics with native endometrium and are thought to have the greatest metabolic activity, as is suggested by their high concentrations of prostaglandin metabolites. Biopsy of nonpigmented implants (i.e., implants that are the same color as adjacent peritoneum) may reveal active endometriotic glands and stroma. White lesions are predominantly fibromuscular scarring with scattered glandular and stromal elements, and brown lesions are mainly hemosiderin deposits. Peritoneal defects and subovarian adhesions contain endometriosis in 40% to 70% of cases. Because other peritoneal lesions share morphologic features similar to those of endometriosis, the differential diagnosis is broad and includes old suture locations, epithelial malignancies, endosalpingiosis, hemangioma, inflammatory reaction to infection or oil-based hysterosalpingogram dye, and carbon deposition from laser surgery. Rectovaginal endometriotic lesions consist of smooth muscle with active glandular epithelium and scanty stroma. They share similar characteristics to adenomyomas. Small endometriotic lesions become more visible during the premenstrual and menstrual phases of the cycle, because during this time, microfoci of peritoneal disease become congested with blood and debris. In addition, vascular dilatation, superficial hemorrhage, and ecchymosis formation cause accentuation of the more typical features of endometriosis. Performance of laparoscopy at a time when ovarian steroidogenesis is suppressed by medications such as GnRH analogues or progestogens can lead to inaccuracies in the assessment of extent of disease.

Jansen and Russell reported the presence of nonpigmented lesions in 38% of their 202 patients with biopsy-proven endometriosis; 15% had only nonpigmented implants. Most areas of pigmented endometriosis are surrounded by nonpigmented endometriosis. These subtle lesions may represent the first stage of development of peritoneal disease. Recognition of nonpigmented endometriosis may be enhanced by “painting” the peritoneum with the patient’s blood or by filling the pelvis with irrigation fluid and submerging the laparoscope to appreciate the three-dimensional configuration of clear lesions. Subtle lesions are likely to originate from microscopic glands; they appear and disappear like blebs on the peritoneal surface. With progressive fibrosis, these implants become the classic pigmented, scarred lesions, and finally, when fibrosis replaces the stroma, they appear as white, inactive disease.

The ability to detect subtle lesions of endometriosis increases with the experience of the surgeon and is reinforced by histologic confirmation. Although depth perception is impaired when the monocular lens of the laparoscope is used to view the pelvic cavity, the magnification ability of this lens when closely approximated to the peritoneum may allow identification of subtle surface irregularities present in occult disease. Magnification up to 10× power can be obtained with the laparoscope, depending on the working distance. Microscopic implants of endometriosis not visible even with 10× magnification have been documented by scanning electron microscopy in peritoneal biopsies of patients with unexplained infertility who had no evidence of disease at the time of laparoscopy. A scanning electron microscopy study of samples of supposedly normal tissue from endometriosis patients has documented the presence of endometriotic foci in 25% of cases. Lesions as

P.412

small as 200 µm have been identified through this technique. Hence, surgical treatment of all visible disease is more accurately described as cytoreductive rather than ablative.

Martin et al. (1989)	94	80	75	66	39	22	39

An ovarian endometrial cyst is usually formed by an inversion of the ovarian cortex. The frontal surface of the ovary in proximity to the hilus is the most common site for the invagination process to occur. Repetitive bleeding from the endometrial implants on the surface of the ovary may promote the growth of such lesions. Alternatively, invaginated epithelial inclusions may form endometriomas through coelomic metaplasia. Adhesions are common from the ovary to the fossa ovarica or to the posterior leaf of the parametrium.

Preoperative sonographic evaluation is a useful screening test for the presence of small endometrial cysts; their identification may affect the disease categorization to which the patient is assigned. Sonographic patterns may indicate purely cystic features, cystic features with few septations or minimal debris, complex combinations of cystic and solid elements, and largely solid features. More recently, fat-saturated MRI has been shown to be an acceptable tool for detecting endometriomas larger than 4 mm in diameter.

An adnexal mass in a patient with known pelvic endometriosis cannot be assumed to be an endometrial cyst of the ovary. Ovarian malignancy must remain in the differential diagnosis; the size of the mass has been correlated with malignancy. In a study of 180 women, 1% of masses smaller than 5 cm, 11% of masses between 5 and 10 cm, and 72% of masses larger than 10 cm were malignant. Most of these malignant tumors were adenocarcinoma.

The rules that apply to the management of all women in whom an adnexal mass develops also apply to patients with endometriosis with an adnexal mass. Among women of reproductive age, unilateral adnexal masses that are cystic and unilocular with regular borders on ultrasound examination are likely to be benign, whereas masses with solid areas, septa, papillations, or irregular borders have a greater likelihood of being malignant. Endometriomas vary in their appearance but usually have regular borders and slightly thickened and diffuse internal echoes unless fresh hemorrhage is present. Sensitivity and specificity of transvaginal ultrasound have been reported by Eskenazi and colleagues to be 84% to 100% and 90% to 100%, respectively.

Recognition of deep ovarian endometriosis is necessary for correct surgical staging. Small endometriomas were diagnosed in 48% of infertile women with mildly enlarged ovaries (3.5 to 5 cm in diameter) when the ovaries were punctured with a 16-gauge needle. The ovarian surfaces were without gross disease in this series of patients. Deep ovarian endometriosis is frequently associated with the presence of intestinal or more extensive pelvic disease.

Vercellini and colleagues studied the visual diagnostic parameters of ovarian endometriomas at laparotomy in 245 women with ovarian cysts. The gross characteristics that established the diagnosis included a size smaller than 12 cm in diameter; adhesions to the pelvic sidewall, to the posterior broad ligament, or to both; the presence of powder-burn lesions; superficial endometriosis with adjacent puckering on the surface of the ovary; and tarry, thick, chocolate-colored fluid content. These criteria yielded a sensitivity of 97%, a specificity of 95%, and an accuracy of 96%.

The depth of peritoneal infiltration by endometriosis cannot be evaluated by inspection alone. Deep endometriosis, which is almost exclusively localized to the posterior cul-de-sac and the uterosacral ligaments, is better detected by palpation and becomes even more apparent during excision. Deep endometriosis has been recognized to become smaller with increasing depth, although in some women, the largest volume is hidden under an adhesion involving the bowel or is buried in the rectovaginal septum. Diagnosis is enhanced if clinical examinations are performed during menstruation in women with chronic pelvic pain, severe dysmenorrhea, or deep dyspareunia. In most cases, a nodule is more palpable at this time. Koninckx and Martin have described three types of infiltrating endometriosis. Type I is characterized by a large pelvic area of typical or subtle lesions surrounded by white sclerotic tissue. During excision, deep disease becomes obvious and grows progressively smaller with deeper sectioning of tissue (like a cone). Type II is formed by retraction of the bowel and is recognized clinically as a small classic lesion associated with retraction. In some women, no implant is visible, but induration is associated with the retraction. Excision usually reveals the presence of a nodule. Type III is nodular endometriosis of the rectovaginal septum. This category is clinically suspected at the time of rectovaginal

examination when painful nodularities are noted. Occasionally, nodular endometriosis presents as small, typical lesions at laparoscopy or as dark blue cysts at the vaginal fornix during speculum examination. Type III disease is the most severe and often spreads laterally to involve the ureter.

CLASSIFICATIONS

Many endometriosis classification systems have been introduced to allow direct comparison of patient responses to medical and surgical treatments and to identify factors predictive of disease outcome. No system has yet been devised that is entirely satisfactory. The AFS (renamed the American Society for Reproductive Medicine) organized a panel of experts in 1979 to develop a classification system that might serve as a basis for evaluating various therapies. The committee devised an innovative scheme based on the natural progression of the disease. Three anatomic areas—the peritoneum, ovary, and fallopian tube—were examined for the presence of endometriosis or adhesions, with allowances made for unilateral involvement. However, the system was not weighted for depth of infiltration of peritoneal implants. A point system instead assigned values to each area of disease involvement based on the presumption that implant area and adhesion characteristics were most often associated with disease prognosis. The stage of disease was determined by the cumulative score of the assigned points. This classification system was criticized for its arbitrary division of endometriosis into categories that did not necessarily reflect the true relative risk of disease sequelae, pain, and infertility.

The AFS classification was revised in 1985 to provide a more standard assessment of endometriosis for correlation of surgical treatment with distribution and severity of implants ([Table 22.7](#)). The point range of mild disease was expanded, and greater weight was given to deep endometriosis, dense adhesions, and cul-de-sac obliteration by adhesive disease. Although the revised staging system appropriately acknowledges the importance of adhesive disease and endometriomas, most women with extensive peritoneal disease in the absence of ovarian involvement, particularly deeply invasive implants, receive a very low score on laparoscopic inspection of the lesions.

This revised AFS classification has been widely used by investigators to categorize disease states. Nevertheless, direct comparison of treatment outcome is compromised by inconsistencies in the application of the staging criteria and by the great variations in medical and surgical therapeutic options being applied in the management of endometriosis. Evaluation of the extent of disease by laparoscopy may be limited by a lack of recognition of atypical implants, particularly if the patient is hypoestrogenic as a result of recent discontinuation of medical therapy for endometriosis. Furthermore, the divisions between stages of endometriosis remained arbitrary, the

P.413

point score for ovarian involvement was weighted too heavily, and the classification scheme did not address disease involving the fallopian tubes, intestines, or urinary tract. Also, there were no parameters to indicate the present activity and state of evolution of the disease.

^a Determination of the stage or degree of endometrial involvement is based on a weighted point system. The following categories have been established: stage I (minimal disease) 1-5 points, stage II (mild disease) 6-15 points, stage III (moderate disease) 16-40 points, and stage IV (severe disease) >40 points.			
^b If the fimbriated end of the fallopian tube is completely enclosed, change the point assignment to 16.			

The Endometriosis Classification Subcommittee of the American Society for Reproductive Medicine (ASRM) released new recommendations in 1996 for the documentation of the extent and location of disease. One concern over the reproducibility of the scoring system was directed at the variability in assessing ovarian endometriosis and cul-de-sac obliteration. The subcommittee indicated that an endometriotic cyst should be confirmed by histology or by the presence of the following features: (a) cyst diameter less than 12 cm, (b) adhesion to pelvic sidewall and/or broad ligament, (c) endometriosis on the surface of the ovary, and (d) tarry, thick, chocolate-colored fluid content. Cul-de-sac obliteration should be considered partial if some normal peritoneum is visible below the uterosacral ligaments, but adhesions or endometriosis has obliterated part of the cul-de-sac. Complete obliteration exists when no peritoneum is visible below the uterosacral ligaments. Because information is accumulating to suggest that the morphologic appearance of the endometriotic implants may correlate with biologic activity and consequently fertility, the newly revised classification scheme requests the categorization of lesions as red, white, and black. The percentage of surface involvement of each implant type is to be documented.

This revised ASRM classification system is oriented toward the infertile population. Muzii and colleagues, using a pain questionnaire administered to women before surgery, found a significant correlation between the severity of dysmenorrhea and total revised ASRM score, partial score for deep disease, and partial score for adhesions. However, they found no correlation between the pain score for dysmenorrhea and the partial score for superficial disease, number of typical and atypical implants, or the total number of implants. Limited knowledge of the specific pathophysiologic alterations by which endometriosis can cause these symptoms has so far prevented any precise categorization of disease based on response to conventional therapies for these symptoms.

The Enzian classification was developed in 2005 and subsequently revised in 2010 and 2011 to provide a means to characterize deeply infiltrating endometriosis, retroperitoneal structures, and the involvement of other organs. In 2003, Haas et al. observed a correlation was observed between the rASRM severity grade and the location of lesions in the Enzian classification, and pain and dysmenorrhea correlated strongly with the Enzian staging system score. The Enzian classification has thus far not been widely accepted and applied in clinical settings outside of Europe.

THERAPIES

Although women with endometriosis can present with a range of symptoms, therapy is usually initiated for the correction of pain, infertility, or a persistent pelvic mass. Pain and infertility can coexist in a patient; nevertheless, many women with

P.414

endometriosis-associated infertility have relatively little or no discomfort. Treatment options vary depending on the clinical history and findings at the time of surgery.

Expectant Management

Treatment of mild and moderate endometriosis with hormonal preparations does not offer any advantage over expectant management in promoting conception in women with infertility. A Cochrane review of 13 randomized controlled trials that included almost 800 infertile women with endometriosis found no evidence that medications that suppressed ovulation were superior to placebo in women who wished to conceive. In studies by Seibel and colleagues, Hull and associates, and Telimaa, patients assigned to expectant management conceived earlier than the medically treated group, and the cumulative pregnancy rate was not higher for women receiving progestogens or danazol. This lack of enhancement of fecundity may be related to the lower number of estrogen, progesterone, and androgen receptors in endometriotic lesions as compared with normal endometrium. Nevertheless, patients who have pelvic pain or dysmenorrhea and minimal or mild disease do benefit from hormonal therapy.

The age of the patient and the duration of her infertility are important factors to consider in determining the appropriate therapy for the symptomatic individual. Laparoscopic laser ablation of milder stages of endometriosis appears to lessen the interval to conception, although the cumulative pregnancy rate may not be greater than that of women managed expectantly. Surgical therapy for more advanced disease results in a higher pregnancy rate than does expectant management or hormonal treatment, partly because of correction of mechanical factors that may be inhibiting ovulation or tubal function.

There is no direct evidence to support the contention that surgical treatment of minimal or mild endometriosis in the asymptomatic patient will hinder future disease progression and sequelae. The potential benefits of cytoreductive therapy must be weighed against the risk of adhesion formation through surgical devitalization of peritoneal surfaces.

Medical Treatment

Mild pain symptoms associated with endometriosis may be effectively treated with nonsteroidal anti-inflammatory agents and oral contraceptives (Fig. 22.3). Additional endocrinologic therapies include progestogens, GnRH agonists, and danazol.

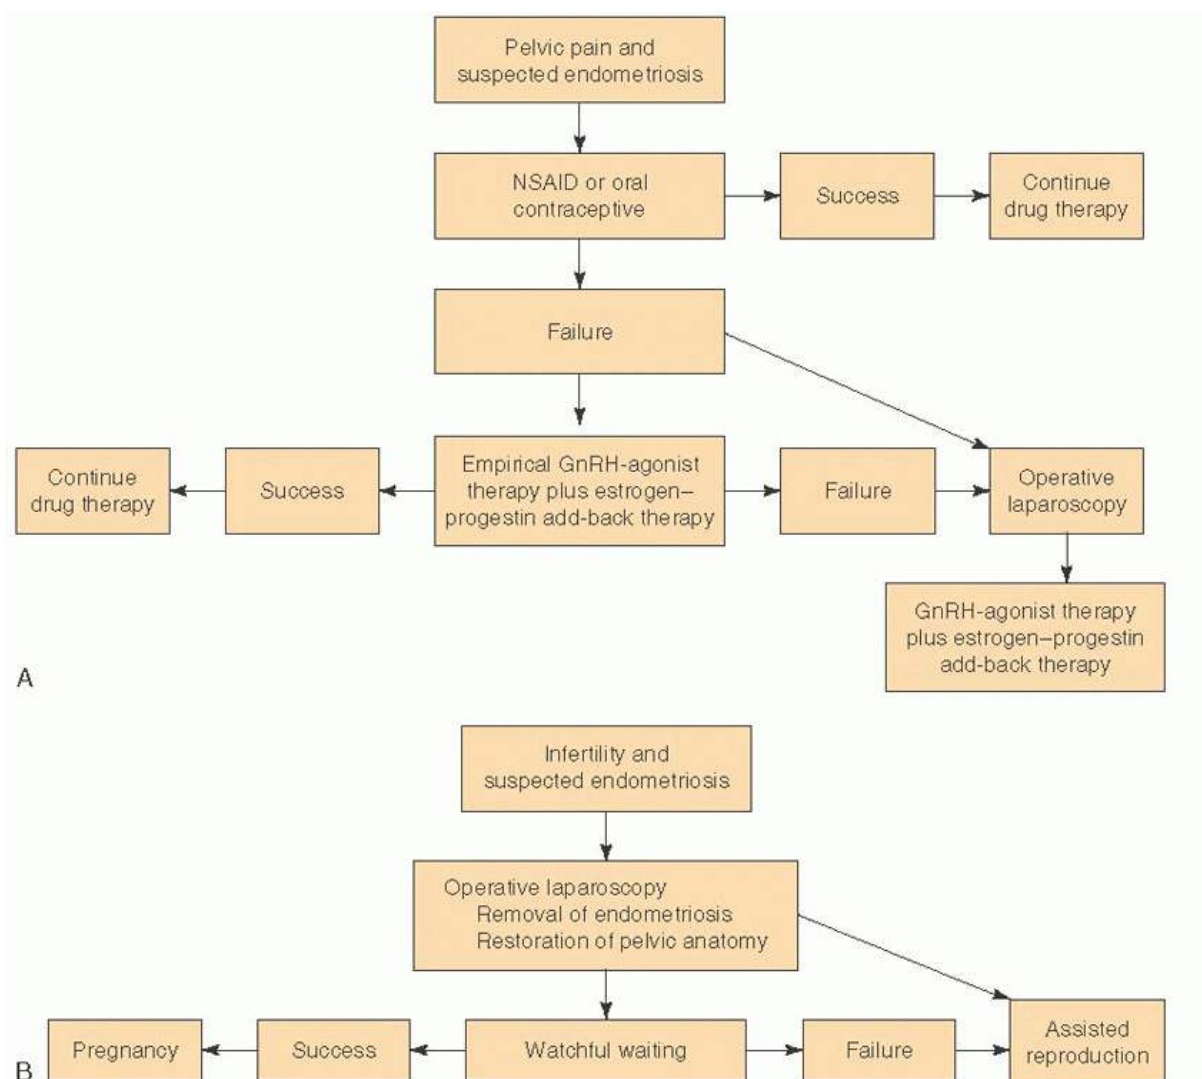

FIGURE 22.3 Algorithm for treatment of endometriosis-associated pain (**A**) and infertility (**B**). Where multiple pathways are shown, the path is guided by medical judgment and patient preference. In the infertility pathway, some practitioners dispense with the operative laparoscopy and recommend assisted reproductive technologies directly (From Olive DL, Pritts EA. Drug therapy: treatment of endometriosis. *N Engl J Med* 2001;345:267, with permission. Copyright © 2001, Massachusetts Medical Society).

P.415

These agents have similar degrees of efficacy in the relief of pain symptoms; side effects vary depending on their mechanism of action. At restoration of ovulation and of physiologic levels of estrogen, both eutopic and ectopic endometria resume metabolic activity. Therefore, medical therapy is symptomatic rather than curative, and most patients experience pain relapse at suspension of treatment.

Progestogens

By inhibiting the pituitary release of LH, progestogens suppress ovarian steroidogenesis and promote endometrial glandular atrophy, apoptosis, and extensive decidual transformation of the stroma. Progestogens oppose the growth-promoting effects of estrogens on the endometrial tissue by altering the clearance of the nuclear estrogen receptor and inducing 17 β -hydroxysteroid dehydrogenase, which converts estradiol to the weaker estrone. Moreover, by eliminating cyclic bleeding and suppressing uterine contractility, progestogens prevent reflux menstruation, a potential stimulus for continued endometriosis development. Progestogens may prevent implantation and growth of regurgitated endometrium by inhibiting the expression of matrix metalloproteinase and plasminogen activators. Moreover, progestogens have anti-inflammatory properties.

Luciano and colleagues administered medroxyprogesterone acetate, 50 mg daily for 4 months, to symptomatic women with moderate-to-severe endometriosis. Improvement of pain, pelvic nodularity, and tenderness on examination occurred in 80% of patients. Twenty percent of women experienced breakthrough bleeding, and an additional 10% reported persistent cyclic bleeding. Minor weight gain, edema, and increased irritability were other described side effects, which were generally well

tolerated. A lower daily dose of 30 mg may provide equivalent relief of symptoms. Bergqvist and Theorell administered this dose to patients for 6 months and found a similar improvement in quality-of-life scores as that achieved with the GnRH agonist nafarelin. Compared with the cost of GnRH agonists and danazol, which are the other commonly prescribed agents, the low cost of the medroxyprogesterone acetate is a notable advantage.

Norethindrone acetate, a 19-nortestosterone progestin, has been shown to be effective in achieving amenorrhea and controlling disease symptoms, even with rectovaginal endometriosis. When used to treat moderate or severe pelvic pain after unsuccessful conservative surgery for symptomatic rectovaginal endometriosis, a dose of 3.5 mg per day for 12 months resulted in a 73% satisfaction rate (33/45). In 2005, Vercellini and colleagues reported a substantial reduction in dysmenorrhea, deep dyspareunia, nonmenstrual pelvic pain, and dyschezia scores. Low-dose norethindrone acetate could be considered an effective, tolerable, and inexpensive first-choice medical alternative to repeat surgery in those with recurrent pain. More recently, Vercellini et al. compared the effect of conservative surgery at laparoscopy with daily oral norethindrone acetate 2.5 mg per day. The progestin group took longer to respond to therapy, but the laparoscopy group started to experience a return of symptoms before the end of the study. At 12 months, surgery and progestin therapy were equally effective in the treatment of deep dyspareunia in women with rectovaginal endometriosis, whereas medical therapy performed significantly better than excisional treatment in those without deeply infiltrating lesions (33% vs. 63%; adjusted odds ratio [OR], 0.23; 95% confidence interval [CI], 0.07 to 0.76; $P = 0.02$).

A similar response rate can be obtained with megestrol acetate. Doses of 40 mg per day for up to 24 months resulted in significant relief of dysmenorrhea, noncyclic pelvic pain, and dyspareunia in 86% of subjects.

Parenteral depot medroxyprogesterone acetate has also been used to produce long periods of amenorrhea and elicit direct progestational changes of the endometrial tissue. A regimen of 150 mg intramuscularly every 3 months for 1 year has been used to manage endometriosis patients with moderate-to-severe pelvic pain. Twenty-nine of 40 subjects (72.5%) were satisfied with their pain relief after 1 year of therapy. An alternative regimen is 104 mg subcutaneously every 3 months. Frequent breakthrough bleeding can be troublesome to correct.

The rate of recurrence of symptomatic endometriosis after progestogen therapy appears to be related to the length of follow-up. Riva and colleagues reported an 18% rate after an average of 11 months, whereas Moghissi and Boyce described a 42% recurrence rate during a 2-year interval after discontinuation of medication.

Cyclic administration of low-dose oral contraceptive pills may result in relief of pelvic pain, particularly cramping associated with menstruation. This line of therapy should be considered for the woman with mild symptoms who is not attempting to conceive. A randomized, controlled trial by Harada and colleagues showed the superiority of combined oral contraceptives over placebo in decreasing baseline pain scores for dysmenorrhea (by 45% to 52% vs. 14% to 17%) and the volume of ovarian endometriomas (by 48% vs. 32%). Long-term continuous oral contraceptive use has been proposed for women with symptomatic endometriosis and menstruation-related pain who have failed a cyclic pill regimen. With such a regimen, the endometrium remains thin on sonogram studies, and endometriotic plaques subjected to a progestin-dominant pill are less active and usually less painful and will undergo apoptosis.

Low-dose (20 to 35 mg ethinyl estradiol) combination oral contraceptives may be given daily for 6 to 9 months without break to relieve pain or more severe dysmenorrhea. The dose may be increased to two or more tablets per day for several days to alleviate episodes of breakthrough bleeding. In a study by Vercellini and colleagues in 2003, 80% (40/50) of patients were satisfied or very satisfied with continuous use of an oral contraceptive containing ethinyl estradiol (0.02 mg) and desogestrel (0.15 mg) for 2 years, and 96% experienced pain relief, although spotting and breakthrough bleeding were frequent side effects.

The levonorgestrel intrauterine device (IUD) has proven effective in relieving pelvic pain symptoms caused by peritoneal and rectovaginal endometriosis and in reducing the risk of recurrence of dysmenorrhea after conservative surgery. In a study by Lockhat and colleagues, an improvement in symptoms was observed in 96% throughout the 36 months of use, with only 11% experiencing pain symptoms at 18 months. A recent randomized study by Tanmahasamut showed that the immediate postoperative placement of a levonorgestrel-releasing IUD after conservative surgery significantly prevented recurrence of moderate-to-severe dysmenorrhea, pelvic pain, and dyspareunia and improved the quality-of-life scores of the patients in the treatment group at 1 year postlaparoscopy. The progestogen released by the IUD is rapidly absorbed by the subendometrial vascular network, which reduces menstrual flow by 70% to 90%.

Danazol

Danazol is a synthetic (2,3-isoxazole) derivative of 17 α -ethinyl testosterone that was introduced into clinical practice by Greenblatt and colleagues in 1971 after good performance in uncontrolled trials. The drug gained rapid acceptance because of its effectiveness in relieving pain associated with endometriosis and in enhancing fertility. All of the progestational and

P.416

the weak androgenic effects of the drug result from retention of the methyl group in the 19 position of the steroid nucleus, whereas the oral activity of danazol is ascribed to the ethinyl group at position 17.

The pharmacologic action of danazol is complex. By directly inhibiting GnRH secretion, the midcycle LH surge is ablated, although basal gonadotropin concentrations are maintained. The drug interacts with endometrial androgen and progesterone receptors, suppresses the activity of multiple enzymes necessary for ovarian and adrenal steroidogenesis, and displaces androgens from sex hormone-binding globulin, thereby augmenting androgen action on endometrial receptors. The decline in sex hormone-binding globulin induced by danazol lowers estradiol binding, increases estradiol clearance, and promotes a decline in the circulating level of this hormone. Hence, the derivative has direct androgenic and antiprogestational action on endometrial implants and creates a hypoestrogenic, hypoprogestational environment antagonistic to endometriosis. Moreover, by producing amenorrhea, danazol prevents peritoneal seeding of refluxed endometrial tissue. In addition, danazol is capable of suppressing elevated autoantibodies in several autoimmune diseases and has been shown to decrease immunoglobulin and autoantibody levels in women with endometriosis. In contrast to GnRH agonists, danazol use maintains a normal estrogenic state and increases bone mineral density over baseline.

The adverse effects of danazol reflect its anabolic, androgenic, and antiestrogenic properties and may be dose related. Weight gain, muscle cramps, decreased breast size, and vasomotor symptoms are noted in 50% or more of patients maintained on doses of 400 to 800 mg per day. In Buttram's 1985 series, 41% of patients treated with the standard dose of 800 mg per day gained more than 10 pounds during the course of therapy. The threefold increase in free testosterone can cause acne, oily skin, and deepening of the voice in a small percentage of recipients. High-density lipoprotein (HDL) cholesterol declines by 50% or more in response to the altered steroid concentrations; an 80% decrease in the HDL₂ subfraction has been reported. Most series have described a concomitant increase in low-density lipoprotein (LDL) cholesterol; the alteration in the ratio of HDL to LDL cholesterol may be an unacceptable risk to some patients. Because danazol is metabolized by the liver, modest elevations in serum glutamic oxaloacetic transaminase and serum glutamate pyruvate transaminase may arise. Reported idiopathic drug reactions include gastrointestinal disturbances, weakness, dizziness, skin rashes, headaches, and muscle cramps. Bothersome side effects occur in as many as 85% of patients, and at least 10% of women receiving danazol discontinue pharmacologic treatment because the adverse effects are intolerable. Combining danazol therapy with aerobic exercise appears to reduce the incidence of many of these androgenic side effects. Preliminary data from trials using danazol vaginal rings and insertion of daily 200 mg vaginal tablets suggest that this route of administration may result in symptomatic improvement of pain while avoiding the androgenic side effects noted with oral administration.

Because of the potential androgenic action of this hormone on the developing fetus, the patient must not be pregnant when initiating therapy. Barrier contraception has been recommended for the entire course of treatment to eliminate the possibility of conception, although high doses of danazol usually cause anovulation.

The amenorrhea induced by danazol has been found to benefit patients with dysmenorrhea, dyspareunia, and cyclic pelvic pain associated with endometriosis. Young and Blackmore reviewed the effects of different dosages of oral danazol with respect to relief of symptoms in 452 patients. At a dose of 800 mg, 95% of patients noted relief of dysmenorrhea, and 89% reported relief of pelvic pain. At a dose of 400 mg, posttherapeutic relief was reduced by 10%. Moore and associates reported that pain associated with minimal and moderate pelvic endometriosis appeared to respond well to doses of danazol of 400 mg or less per day, whereas severe endometriosis was best treated with doses greater than 400 mg per day. A 6-year prospective study that evaluated the effectiveness of danazol at two doses (400 and 800 mg) in carefully classified patients concluded that there was no difference in side effects between the two doses and that gross resolutions of disease at second-look laparoscopy were similar. However, ovarian endometriosis greater than 1 cm did not respond as well to either dose of danazol as did peritoneal or ovarian disease less than 1 cm.

Recurrence of pain symptoms within 4 to 12 months of discontinuation of danazol therapy approached 50% in most studies. Lower daily doses of medication or courses of treatment less than 4 months in duration may result in a shorter symptom-free interval.

Clinical trials designed to assess the efficacy of medical therapy of minimal, mild, and moderate stages of disease refute the notion that danazol may enhance conception. Furthermore, conception is delayed while the patient is receiving danazol.

Gonadotropin-Releasing Hormone Agonists

Gonadotropin-releasing hormone (GnRH) agonists are available for use in the treatment of estrogen-dependent diseases such as endometriosis. Some of the more frequently studied analogues include leuprolide, nafarelin, buserelin, and goserelin. Alteration of the amino acid at position 6 and ethylamide replacement of the C-terminal amino acid of the native decapeptide hormone results in a GnRH agonist with increased resistance to lysosomal degradation. Pituitary receptor binding is enhanced, resulting in a decline in the number of receptors available for further occupancy. Continued administration of the GnRH agonist leads to a desensitization of the pituitary gonadotrope receptor and a reversible down-regulation of the pituitary-ovarian axis. Ovarian estrogen secretion may reach castrate levels.

The initial response to GnRH agonist administration is a markedly increased secretion of pituitary stores of folliclestimulating hormone (FSH) and LH. If therapy is begun in the follicular phase of the menstrual cycle, the developing follicle may respond to the flare in circulating gonadotropin levels with a rapid increase in estradiol production. Estradiol levels may remain elevated for 3 weeks before declining. GnRH agonist administration in the luteal phase leads to a more rapid decline in estrogen secretion, although FSH and LH levels remain elevated for 1 and 4 weeks, respectively.

Gonadotropin-releasing hormone agonist treatment results in improvement or resolution of pain symptoms in all stages of disease. Lemay and colleagues reported resolution of pain in 70% and improvement in discomfort in 15% of 24 subjects after 2 to 4 months of treatment with the agonist buserelin. Dyspareunia improved in 9% and disappeared in 91% of patients studied. The depot formulation of leuprolide acetate has also been shown to significantly reduce dysmenorrhea, pelvic pain, and pelvic tenderness in patients with endometriosis.

Henzl and associates, in a double-blind, multicenter study, treated 213 patients with either danazol or nafarelin. After 6 months of treatment, more than 80% of patients in all groups experienced a significant reduction in visible implants. A 43% reduction in AFS score was noted for each treatment

P.417

group; there was no difference in response among patients receiving the 0.4- and 0.8-mg daily dose of nafarelin. Most patients continued to demonstrate some visible implants at the time of follow-up laparoscopy, and, as with danazol, there was some diminution in size of endometriomas but no effect on preexisting adhesions.

The optimal interval of GnRH analogue administration has been widely debated. Six months of medication has been traditionally prescribed, although a significant reduction in implant volume occurs as early as 2 weeks after initiation of treatment in the rat model. A maximal effect was measured after 4 weeks of therapy in this animal study, suggesting that short courses of drug may be as efficacious as 6 months of continuous therapy. The regrowth of lesions after estrogen therapy has been reported years after the menopause; hence, hypoestrogenism results in inactivation rather than resolution of the disease.

Response to therapy may be dependent on route of administration. Donnez and colleagues reported that buserelin administration by a long-acting subcutaneous implant led to a greater reduction in endometriosis score, mitotic index, and endometrial cyst diameter than when given in an intranasal form. This may have been due to a greater consistency in hormonal release by the injected preparation.

As occurs with danazol and progestogen regimens, symptoms recur at variable periods after discontinuation of GnRH analogue therapy. Subjective return of pain occurred in 57% of patients within 6 months of discontinuing leuprolide, although 37% with moderate or severe pelvic pain at baseline were still improved at 1 year. Franssen and colleagues noted a lasting and significant amelioration of dysmenorrhea and dyspareunia 6 months after completion of treatment; however, scores for chronic pelvic pain had nearly reached their pretreatment level once this time had elapsed. Patients with a higher disease stage at the onset are more likely to experience recurrence and to experience it earlier than patients with minimal disease. One treatment option for such patients may be a second 3-month course of GnRH analogue. Henzl reported a significant decrease in mean pain scores and essentially no change in compact bone density in most patients when nafarelin was readministered for 3 months after a treatment-free interval of 6 months or more.

Most of the side effects associated with GnRH analogue therapy are related to hypoestrogenism. Hot flashes are common and can lead to sleep disturbances and chronic fatigue in extreme cases. Vaginal dryness, superficial dyspareunia, headaches, and depression have been reported. In general, these adverse effects are better tolerated than those experienced with danazol use. In addition, there are no undesirable changes in HDL, LDL, or total cholesterol throughout the prolonged period of hypoestrogenism induced by GnRH analogue, unlike the changes accompanying danazol intake.

A decline in trabecular bone mineral content and an increase in urinary calcium excretion to menopausal levels occur during the course of GnRH analogue therapy in approximately two thirds of patients. Quantitated computed tomographic (CT) studies consistently show significant loss of trabecular bone of the vertebrae and hip with GnRH analogue exposure. Restoration of normal estrogen production after cessation of therapy appears to at least partially reverse these bone changes. In a study of the GnRH agonist goserelin, an 8.2% decline in density of the lumbar spine was measured after completion of 6 months of treatment; this improved to a mean loss of 5.4% at 6 month after cessation. Others found no significant change from baseline after a 6-month course of GnRH analogue when bone density was assessed 6 months after treatment.

Concomitant administration of a progestogen during the course of GnRH analogue therapy has been examined to ameliorate vasomotor symptoms and retard both urinary calcium excretion and radiologic evidence of loss of bone mineral density. Cedars and coworkers reported a diminution in the side effects mentioned earlier when medroxyprogesterone acetate was administered at a dose of 20 to 30 mg per day during the 6-month course of agonist therapy; however, laparoscopic evaluation after completion of therapy failed to reveal any improvement or suppression of active endometriosis with the combination regimen, and the regimen failed to significantly reduce symptoms of pelvic pain. Conversely, Makarainen and colleagues reported that medroxyprogesterone acetate, 100 mg per day, diminished hot flashes and the urinary excretion of calcium in women treated with goserelin acetate, 3.6 mg monthly, for 6 months. Second-look laparoscopy revealed equivalent diminution in extent of endometriosis when compared with the goserelin-progestin placebo group.

Norethindrone, the 19-nortestosterone progestin, has been shown to suppress both the painful symptoms of endometriosis and the extent of disease at laparoscopy when used in daily doses of 1.4 to 10 mg during GnRH agonist therapy. A randomized, double-blind study has demonstrated that GnRH agonist therapy may be safely and effectively extended for up to 1 year in the management of endometriosis-associated pelvic pain when prescribed in conjunction with low-dose sex steroid hormones. Hornstein et al. reported that norethindrone acetate, 5 mg, alone or in combination with conjugated equine estrogens, 0.625 mg daily, from the onset of depot leuprolide acetate therapy alleviated hypoestrogenic symptoms and preserved bone density while resulting in equivalent pain relief to that achieved by the placebo estrogen-progestin patient group. Others have treated a limited number of patients with a similar regimen for up to 10 years without detecting an adverse effect on bone mineral density. For women with relapse of endometriosis-associated pain, GnRH agonist with “add-back” progestin or progestin/estrogen therapy provides patients with a better quality of life than GnRH analogue alone or oral contraceptive regimens.

The addition of calcium carbonate and alendronate or etidronate sodium, which are organic bisphosphonates, to the low-dose norethindrone acetate add-back therapy in patients with symptomatic endometriosis receiving prolonged GnRH agonist treatment may further minimize the adverse side effects of hypoestrogenism.

In a review of randomized clinical trials of the Cochrane Menstrual Disorders and Subfertility Group register, there was no difference in pain relief between GnRH agonists, levonorgestrel, and danazol. Additional controlled studies will better establish the optimal medical management of this condition.

Conservative Surgery

Surgery is indicated for correction of pain, infertility, or other symptoms in patients with extensive pelvic endometriosis or when hormonal manipulation fails to adequately diminish pain symptoms in women with lesser stages of disease. Surgery is successful in relieving pain in a very high percentage of cases and offers a better prognosis for pregnancy than does endocrine therapy in many cases of advanced disease.

The surgeon who has mastered the specialized techniques of operative laparoscopy can treat a wide range of pathologic findings at the time of diagnosis. Therapeutic planning depends on many factors, including the age of the patient, her desire for fertility or pain relief, the duration and intensity of her symptoms, the extent of disease, and previous treatments that have been undertaken. Preoperative rectoscopy-sigmoidoscopy and intravenous pyelography are recommended in patients with

P.418

symptoms suggestive of deeply invasive endometriosis of the posterior cul-de-sac and rectovaginal septum. Magnetic resonance imaging or sonography may also be helpful in predicting the extension of disease ([Table 22.5](#)).

The decision of whether to perform surgical resection of endometriosis through the laparoscope or open abdomen is not entirely dependent on the stage of disease that is encountered. Laparoscopy can be considered for all cases unless there is difficulty in establishing the appropriate tissue planes of dissection or unless improved access is necessary for atraumatic manipulation of the involved organs. Specific endoscopic procedures include ablation of endometriotic implants, adhesiolysis,

ovarian cystectomy, oophorectomy, and salpingectomy. Although the results and complications are similar, the cost savings with respect to decreased hospital expenses and loss of work time favor laparoscopy over laparotomy when other factors regarding risks and outcome are equal. Laparoscopy provides superior visualization of the posterior cul-de-sac and allows a high degree of magnification of peritoneal surfaces, which aids in the identification of subtle disease.

Conservative resection of disease by laparotomy is most valuable in cases of extensive, dense pelvic adhesions, or endometriomas greater than 5 cm in diameter. In addition, deep involvement of the rectovaginal septum with fibrotic extension into the perirectal fossa, invasion of the bowel muscularis, and endometriotic infiltration in the region of the uterine vessels and ureter is generally best approached through the open abdomen for all but advanced endoscopic surgeons. The objective of the laparotomy procedure is complete excision of all endometriosis and associated adhesive disease to restore normal functional anatomy of the reproductive tract. The usual surgical approach is through a transverse suprapubic incision. A Maylard incision provides adequate exposure for presacral neurectomy and reconstructive surgery of ovarian endometriomas of almost any size.

Principles of Microsurgery

Microsurgical technique, or the philosophy of gentle manipulation of tissue in an attempt to avoid trauma, is the major tenet of pelvic reconstruction. The inflammation, trauma, coagulation, and foreign materials associated with conventional macrosurgical technique lead to tissue ischemia and adhesion formation because of local failure of the intrinsic peritoneal fibrinolytic system. Adhesion formation can be reduced by the application of loupe magnification or use of the operating microscope; reconstruction with fine, nonreactive sutures; precise hemostasis; and frequent irrigation of tissues with warmed lactated Ringer solution. Nevertheless, there are no definitive data to suggest that use of the particularly costly ancillary laser and the operating microscope has appreciably improved the reproductive prognosis in the surgical management of endometriosis through laparotomy. The magnification provided by laparoscopy in a closed surgical field matches these microsurgical principles.

Several basic techniques are available for the endoscopic ablation of endometriosis, including excision, coagulation, and vaporization. Coagulation can be achieved by monopolar or bipolar cautery, thermocoagulation, or, in some circumstances, laser, depending on the wavelength of energy applied. The extent of tissue penetration in electrocautery is related to the power and type of current, the duration of application, and the size of the electrode. Less tissue damage is achieved with bipolar than with monopolar cautery. The carbon dioxide (CO₂) laser is more precise than the fiber lasers, although CO₂ laser energy is strongly absorbed by water molecules and is rendered ineffective in the presence of blood. Meticulous technique that maintains serosal integrity may reduce the incidence of de novo adhesion formation.

Sites of Conservative Surgery

Peritoneum

Small lesions of superficial peritoneal endometriosis less than 5 mm in diameter are easily treated with laser or bipolar coagulation while under a constant stream of irrigation. Deep lesions or more extensive peritoneal disease must be excised with a tissue margin of at least 2 to 4 mm, because, as noted previously, microscopic lesions are commonly present in tissue adjacent to visible implants ([Fig. 22.4](#)). Ablation of deep disease by monopolar microdiathermy or CO₂ laser vaporization rather than excision of the disease may result in inadequate resection and a greater amount of ischemic damage to the tissue, heightening the propensity toward adhesion formation. Immobilizing adhesions can be merely divided during the preparatory phase of the procedure; precise excision is more easily accomplished after the involved organs are freed. Before dissection of the pelvic sidewall, the ureter must be identified and isolated; it frequently is displaced from its normal location by endometriotic adhesive disease. A Lucite, Teflon, or laparoscopic titanium probe can be used to isolate adhesions and protect adjacent structures during separation of the tissue planes. Suture placement can lead to foreign body reaction, tissue anoxia, and fibrosis and should therefore be avoided. Covering hemostatic, deperitonealized surfaces with an absorbable, oxidized, regenerated cellulose barrier (Interceed) significantly reduces the incidence, extent, and severity of postsurgical pelvic adhesions, even in patients with severe endometriosis. Alternatively, application of the Gore-Tex surgical membrane has been shown to result in a statistical reduction in adhesion score; this barrier can be removed at the time of a second-look laparoscopic procedure if its presence would impair tuboovarian function.

Estimations of the depth of endometrial implants at the time of laparoscopic resection relate well with histologic measurements. Superficial implants can be destroyed by bipolar cauterization; however, 25% of patients have lesions greater than 5 mm in

depth. Deep (<5 mm) and very deep (< 10 mm) lesions represent an active form of the disease and occur almost exclusively in patients who report pain. The superficial action of nonvaporizing modalities such as bipolar or thermal coagulation is not sufficient for deep disease. The diagnosis of retroperitoneal endometriosis is suggested by preoperative digital rectovaginal palpation and laparoscopic blunt probe palpation. The depth of infiltration of deep lesions appears to correlate poorly with the visible surface area of involvement. The laparoscopic treatment of deep disease is often complicated by the proximity of implants to vital structures such as the ureter, bladder, and vessels (**Table 22.8**).

Laparoscopic forceps are used to elevate and isolate the tissue to be excised. Instruments should be placed with care, because surgical manipulation of tissue that will not be resected may result in de novo adhesion formation. The diseased peritoneum may also be separated from underlying tissue by the technique of hydrodissection, which forcefully injects physiologic irrigant retroperitoneally through a small defect created in the peritoneum (**Fig. 22.5**). This retroperitoneal placement of fluid acts to dissipate CO₂ laser energy and, in so doing, promotes safer dissection or vaporization of the peritoneal surface. Coagulation or vaporization of disease in the ovarian fossa or near the uterosacral ligament should be undertaken only after clear identification of the ureter. Uterine manipulation with a Valtchev retractor or other uterine manipulator may be used while treating lesions of the posterior cul-de-sac.

P.419

FIGURE 22.4 Excision or CO₂ laser vaporization of peritoneal implants. **A:** Superficial implants are vaporized by use of power densities between 1,000 and 3,000 W/cm², with a spot size of 0.8 to 1 mm, or they are cauterized with microbipolar forceps. More extensive peritoneal disease is excised. Very large defects can be closed with 5-0 or 6-0 polyglactin or polydioxanone sutures. Adhesion barriers can be placed. **B:** Endometriosis can be associated with extensive adnexal adhesions. **C:** Wide adhesion bands can be retracted with a glass rod or similar nonconductive probe and completely excised with a monopolar microelectrode.

TABLE 22.8 Suggested Surgical Procedure According to Classification of Deeply Infiltrating Endometriosis (DIE)

DIE CLASSIFICATION	OPERATIVE PROCEDURE
	http://obgynebooks.com

A: Anterior DIE	
AI: Bladder	Laparoscopic partial cystectomy
P: Posterior DIE	
P1: Uterosacral ligament	Laparoscopic resection of USL
P2: Vagina	Laparoscopically assisted vaginal resection of DIE infiltrating the posterior fornix
P3: Intestine	
Solely intestinal location	
Without vaginal infiltration (V-)	Intestinal resection by laparoscopy or by laparotomy
With vaginal infiltration (V+)	Laparoscopically assisted vaginal intestinal resection or exeresis by laparotomy
Multiple intestinal location	Intestinal resection by laparotomy
USL, uterosacral ligament.

P.420

FIGURE 22.5 Hydrodissection.

It is difficult to evaluate the depth of tissue damage with electrocauterization; however, laser vaporization allows visualization of the three-dimensional boundaries of every lesion. The laser beam should be applied until the bubbling of retroperitoneal areolar tissue is noted. The zone of thermal necrosis is minimal with the CO₂ laser, particularly when applied in the superpulse mode. In the region of the ureter, urinary bladder, colon, or large blood vessels, a single or repeat pulse mode of 0.05 to 0.1 second allows a depth of penetration of 100 to 200 µm. Irrigation of the pelvis washes off debris and carbon deposition and better exposes the base of the site of laser impact. A 2- to 4-mm clear margin is desired around each lesion treated. Excision of the involved peritoneum is superior to vaporization of implants when the extent of tissue penetration cannot be recognized.

Dissection of retroperitoneal disease can be facilitated by placing a bougie probe in the rectum and a sponge forceps in the vagina (**Fig. 22.6**). Traction in either direction opens the rectovaginal and perirectal spaces. Initial dissection of the anterior rectum provides a landmark of the rectovaginal space and permits posterior mobilization of the nodule. Subsequent lateral dissection is performed, followed by anterior dissection, which permits retrieval of the involved tissue.

Resection of deep posterior cul-de-sac nodules requires great endoscopic expertise. A combined laparoscopic-vaginal approach may be necessary to effectively remove these implants (**Fig. 22.7**). It is often helpful to have an assistant place his or her fingers deep in the vaginal fornices or a bougie probe in the rectum to indicate the sites of the nodules to ensure their complete removal. The direct palpation made possible through laparotomy may be required to recognize all indurated, deep lesions. A complete bowel preparation is mandatory in all cases of suspected deep endometriosis.

Electrosurgery should be avoided when extensive dissection is performed because it may be associated with widespread thermal damage and difficulty in recognizing tissue planes. Superficial invasion of the muscularis of bowel or bladder can be treated with laser vaporization or endocoagulation because of the precision and lack of penetration of these energy sources. Anterior cul-de-sac treatment should be accompanied by continuous bladder drainage.

Tubal endometriosis may distort the normal anatomic relationship of the distal tube to the ovary and in severe cases may cause complete fimbrial obstruction. Short pulses of CO₂ laser may be used to vaporize lesions while minimizing thermal damage. Endoscopic adhesiolysis of the distal tube may be accomplished with fine scissors or careful application of laser. Unipolar electrocautery should not be used on this tissue.

Defects in the parietal peritoneal surface are frequently associated with endometriosis and are most commonly found in the posterior cul-de-sac region. These defects should be explored and ablated even if they appear grossly normal because of the frequency of microscopic disease.

Ovary

Superficial endometriosis of the ovary usually presents as small, dark, punctate lesions located on and immediately beneath the cortical surface. This disease can be readily treated with laser or bipolar forceps under constant irrigation. Occasionally, however, the small, visible lesion may be merely the tip of a large endometrial cyst. If there is any doubt, the implant should be excised and the ovary explored to determine the extent of disease. Care should be taken to minimize thermal injury to surrounding ovarian tissue. This is particularly important near the fimbria ovarica, because postoperative adhesion formation could compromise distal tubal function. Inability to elevate the ovary is usually a sign of adhesions and endometriotic implants of the inferolateral surface of the ovary and the peritoneum of the ovarian fossa. Excising the fibrotic pelvic sidewall and/or uterosacral ligament lesions to which the ovary was attached will reduce disease recurrence.

RECONSTRUCTION BY LAPAROTOMY

Extensive ovarian endometriosis is often associated with periovarian and peritubal adhesions. These adhesions may become apparent while manipulating the ovary to visualize the lateral surface adjacent to the broad ligament. Filmy adhesions are elevated with delicate tissue forceps and can be resected with fine-needle cautery, a scalpel, or the laser. Care must be taken to maintain the integrity of the ovarian capsule. After the appropriate adhesiolysis is accomplished, the posterior cul-de-sac is packed with moist, lint-free packs, and a silicone surgical platform can be placed to stabilize the adnexa. The ovary should be carefully

examined for extent of disease involvement before creation of the initial incision. Peritoneal spillage of the contents of the endometrioma can be avoided by placement of a lint-free pack around the platform.

FIGURE 22.6 Laparoscopic therapy for endometriosis. **A:** Dorsal lithotomy positioning for surgery, with multiple puncture sites marked for placement of ancillary instruments. **B:** Traction on bougie in rectum and sponge forceps in vagina mobilize rectovaginal and perirectal spaces. Uterine manipulation cannula, bladder drainage, and multiple transabdominal instruments facilitate safe dissection. **C:** CO₂ laser division of endometriosis-associated adhesions extending from lower uterus to rectal serosa.

The cortical incision should be made in a way that will preserve the normal anatomic relations of the ovary with the uteroovarian ligament and fimbria ovarica (**Fig. 22.8**). This is best accomplished by making a shallow longitudinal incision over the endometrioma with the monopolar microneedle, scalpel, or laser. The surgeon should attempt to remove the endometrioma in an intact state; however, if the cyst cavity is inadvertently entered, an elliptical incision around the site of rupture is useful for exposure. The intact endometrioma can be transfixated with a traction suture of 2-0 nylon to facilitate creation of a cleavage plane between the cyst and normal ovarian tissue. Blunt, curved scissors or a flat probe or knife handle is used for dissection. Particular care must be taken when dissecting the hilar region to maintain hemostasis and preserve primordial follicles. An attempt should be made to preserve as much of the normal ovarian cortex as possible; pregnancies have been achieved with only a small fraction of remaining ovary.

The ovary is reconstructed by placing one or two purse-string sutures of 4-0 or 5-0 polyglactin, polyglycolic acid, or polydioxanone to eliminate the dead space and maximize hemostasis. This may be followed by placement of a running subcortical 5-0 suture of the same delayed absorbable material (**Fig. 22.8**), if necessary. In some circumstances, less tissue distortion can be achieved by placing a deep layer of interrupted mattress sutures followed by additional layers of running sutures (**Fig. 22.8**). Suture on or extruding through the surface should be strictly avoided because of its adhesiogenic properties.

After the ovary has been carefully approximated, the posterior surfaces of the uterus and broad ligament are inspected for hemostasis wherever the ovary was previously adhered. Microbipolar cauterization may be necessary. Placement of an adhesion barrier is useful in separating raw peritoneal surfaces during the healing process.

ENDOSCOPIC THERAPY OF OVARIAN ENDOMETRIOSIS

Surgical treatment of endometriosis less than 4 to 5 cm in diameter can be accomplished with relative ease. However, endoscopic resection of larger lesions may be compromised by the presence of dense, cohesive adhesions and by difficulties removing the entire cyst wall because of the inability to find the plane of attachment of the fibrotic endometrioma to the ovarian cortex. When performing a cystectomy, the experience and skill of the surgeon influence the extent to which healthy ovarian tissue is removed and the ovary is devascularized. A recent histologic study of endometriomas by Romualdi et al. indicated that more follicles are involuntarily removed when smaller cysts are excised, particularly when the capsule is less defined due to fibrosis.

P.422

FIGURE 22.7 A: Deep laparoscopic dissection of the rectovaginal space, in combination with colpotomy, for the excision of a large endometriotic nodule of the rectovaginal septum. **B:** Initial laparoscopic dissection of nodule. **C:** Completion of dissection by way of colpotomy incision. **D:** Vaginal suture placement to reapproximate the rectovaginal septal defect.

The endometrioma can be excised in an intact or ruptured state during the laparoscopic procedure. In either case, the technique is initiated by longitudinally incising the cortex overlying the cyst after achieving full mobilization of the ovary by adhesiolysis. The incision is generally made along the inferior pole on the opposite side to the hilus in such a manner as to preserve the apposition of healthy ovarian tissue to the fimbria. Laser, scissors, or a unipolar needle electrode may be used for this purpose. Hydrodissection may be used to separate the cyst wall from the ovarian stroma. If the cyst is entered, its contents are immediately drained with the suction cannula, and the cavity is irrigated and inspected for papillary structures or other suspicious features. Often, the cyst ruptures during dissection of adhesions that bind the ovary to the pelvic sidewall. Under this circumstance, the plane of dissection between the cyst wall and the ovarian cortex can be established after identifying the site of rupture. The endometriosis tissue typically penetrates the cyst wall less than 2 mm. The opening can be extended with the use of the needle electrode or laser.

With larger endometriomas, the normal ovarian cortex is stabilized with atraumatic forceps, and the cyst wall is grasped with a second pair of 5-mm forceps and stripped from the bed of normal ovarian tissue (**Fig. 22.9**). As demonstrated by Muzii et al., dissection may be facilitated by removing a small circular rim of tissue around the adhesion site to begin the stripping

procedure in a clearer field, where the endometrioma wall is less adhered to healthy ovarian tissue. Judicious use of the needle electrode or hydrodissection may facilitate separation of the tissue planes. Remaining fragments of the cyst wall near the hilum should be vaporized with CO₂ laser, if possible, rather than electrocautery to destroy the mucosal lining and reduce the extent of thermal damage to the vasculature. If necessary, hemostasis may be achieved with minimized application of bipolar cautery. The key to successful surgery is to avoid bleeding, since the application of energy to control bleeding results in loss of functional ovarian tissue.

An alternative technique involves sharp and blunt dissection to remove the cyst in an intact state. Hydrodissection is particularly useful with this approach. The cyst contents are carefully drained in a plastic laparoscopy pouch to facilitate clean removal from the peritoneal cavity.

Very small endometriomas less than 1 to 2 cm in size may be effectively treated by electrocoagulation of the mucosal lining. Because CO₂ laser is absorbed by fluid, complete ablation of the cyst wall with this energy source may be compromised in an environment rich in blood and hemosiderin, although laser ablation may be less harmful to healthy ovarian tissue than electrocoagulation.

The ovarian defect is usually left to heal spontaneously. Ischemia associated with suture placement can provoke adhesion formation after laparoscopic ovarian reconstruction. Low-power continuous CO₂ laser or bipolar coagulation can be applied to the inside wall of the redundant ovarian capsule

P.423

to cause an inversion of the incised cortex. Most authors have reported excellent results with this no-suture technique.

FIGURE 22.8 Excision of ovarian endometrioma through laparotomy. **A:** The ovarian cortex is gently incised so that the endometrial cyst is not entered. The incision is made along the longitudinal axis of the ovary. **B:** The endometrioma is then peeled out with the blunt knife handle. **C and D:** The ovarian defect is closed with two layers of purse-string sutures of 4-0 or 5-0 absorbable, nonreactive material. **E:** In the case of a deep defect, a more superficial running suture may be necessary before the cortical edges are approximated with 5-0 nonreactive, delayed absorbable sutures.

Under the rare circumstances of persistent bleeding or poor apposition of ovarian tissue, the cortex may be reapproximated with sutures. If fine absorbable suture is used, the knot should be placed internally to minimize the possibility of it becoming a nidus for adhesion formation. The high incidence of adhesion formation after surgery for endometriosis, particularly at the site of the ovary or where dense adhesions were divided, underscores the importance of optimizing surgical techniques to

potentially reduce adhesion formation.

Extensive cauterization of ovarian tissue can lead to a rise in FSH levels postoperatively and should be avoided. Goksever Celik et al. demonstrated that laparoscopic removal of endometriomas by the stripping technique causes a decrease in ovarian follicular reserve at 6 months after surgery as measured by serum antimüllerian hormone levels. This change in serum markers of ovarian reserve was not different whether laparoscopic suturing or bipolar coagulation was used to achieve hemostasis in a recent randomized trial by Ferrero et al. Postsurgical ovarian failure after laparoscopic excision of bilateral endometriomas is a rare but possible complication. There were three cases of premature ovarian failure among 126 patients who underwent laparoscopic excision of bilateral endometriomas in a recent series by Busacca and colleagues, corresponding to a rate of 2.4%. This may be caused by irreversible trauma to ovarian vasculature by electrocoagulation, excessive removal of ovarian tissue, and an autoimmune reaction caused by a severe, local inflammatory process. Coccia et al. found the mean age of menopause is lower in patients who have undergone surgery for bilateral endometriomas.

Fayez and Vogel prospectively evaluated four laparoscopic methods for the treatment of endometriomas. Patients were treated postoperatively with danazol and underwent a secondlook laparoscopy 8 weeks after their initial surgery. Complete excision with scissors successfully eliminated recurrence of the cysts, but adnexal adhesions had developed postoperatively in all cases. Mere incision and drainage of the cyst contents, followed by stripping or CO₂ laser vaporization of the lining, resulted in adhesion formation in only 25% to 37% of cases, but endometrioma cysts recurred in 21% to 22%. Other authors have used the potassium titanyl phosphate laser to photocoagulate or remove the cyst lining of large endometriomas and have reported a very low rate of recurrence at 6 months after the procedure.

In a prospective study by Beretta and colleagues, patients were randomly allocated at the time of laparoscopy to undergo either cystectomy or drainage of the endometrioma and bipolar coagulation of the inner lining. No preoperative or postoperative adjunctive medical therapies were administered. The excision technique resulted in a lower 24-month cumulative recurrence rate of dysmenorrhea, deep dyspareunia, and

P.424

nonmenstrual pelvic pain. The median interval between the operation and the recurrence of moderate-to-severe pelvic pain was longer in the cystectomy group (19 months) versus the drainage and coagulation group (9.5 months). In addition, the 24-month cumulative pregnancy rate was statistically significantly higher in the former group than in the latter group (66.7% vs. 23.5%, respectively).

FIGURE 22.9 Laparoscopic ovarian cystectomy after fenestration of the cyst. **A:** The cut edges of the ovarian cortex and cyst wall are held and teased apart. **B:** The cyst wall can be stripped off by twisting it around the grasping forceps. Hydrodissection may be helpful. **C:** Large defects can be closed with laparoscopic suturing. Most incisions are left to heal by second intention.

In a 2004 prospective, randomized clinical trial by Alborzi and associates, the rate of recurrence of pelvic pain and dysmenorrhea over a 2-year postoperative period was significantly less for those who underwent cystectomy (15.8%) as compared with those undergoing fenestration and coagulation (56.7%). Moreover, the rate of reoperation was 5.8% in the former group and 22.9% in the latter group. The cumulative pregnancy rate was significantly higher in the cystectomy group (59.4%) than in fenestration/coagulation group (23.3%) at 1-year follow-up.

If there is evidence of functional destruction of the ovary or if the patient has chronic, incapacitating pelvic pain secondary to ovarian endometriosis and does not plan to become pregnant in the future, appropriate therapy may consist of oophorectomy. The infundibulopelvic and utero-ovarian ligaments can be ligated with an Endoloop ligature, bipolar coagulation, the harmonic scalpel, or surgical staples before excision of the structure. The ovary is retrieved by morcellation, minilaparotomy, or posterior colpotomy. This type of surgery must be performed carefully when adnexal adhesions are present to avoid ovarian remnant syndrome.

Intestines

Intestinal involvement has been estimated to occur in 3% to 15% of women with endometriosis and in up to 50% of patients with severe disease. The most common areas of intestinal involvement are the rectum and rectosigmoid colon, followed by the sigmoid colon, cecum, terminal ileum, proximal colon, and appendix. The incidence of appendiceal endometriosis has been estimated at approximately 0.8% of all appendectomies; 3% to 5% of patients with endometriosis have appendiceal

involvement.

Symptoms that should arouse suspicion of colorectal involvement include constipation alternating with diarrhea,

P.425

rectal pain, tenesmus, dyspareunia, and dysmenorrhea. Cyclic rectal bleeding is seen in as many as one third of women with rectosigmoid involvement, but the mucosa is rarely invaded. Small intestine disease accounts for up to 16% of gastrointestinal endometriosis and most often involves the terminal ileum. The most common symptom associated with disease in this location is midabdominal cramping pain. Ten percent of small bowel involvement presents with obstruction requiring surgery. The more common large bowel disease results in clinical obstruction in only 1% of cases.

The differential diagnosis of intestinal endometriosis includes primary carcinoma, metastatic carcinoma, diverticulitis, inflammatory bowel disease, irritable bowel syndrome, pelvic inflammatory disease, radiation colitis, and ischemic stricture. Endometrial adenocarcinomas have been reported in the colon and rectum but are exceedingly rare in comparison with the relatively large numbers of patients with colorectal endometriosis.

Preoperative or intraoperative rigid sigmoidoscopy may be helpful in ruling out primary colorectal malignancy. An intact mucosa effectively rules out primary colorectal malignancy. The greatest chance of diagnosing colorectal endometriosis occurs when the examination is performed at the time of menstruation. Although endometriosis rarely invades the intestinal mucosa, mucosal distortion is possible secondary to infiltration of the submucosa.

Pelvic and rectal pain is the major symptom that leads to colorectal resection in patients with advanced endometriosis. Bowel resection should be undertaken in the symptomatic patient or when there is a suspicion of malignancy; however, the frequency of such indications is small. In a series authored by Prystowsky and colleagues of 1,573 consecutive patients with endometriosis, only 11 women (0.7%) required bowel resection. Bowel resection is usually undertaken for lesions producing partial obstruction because most of these lesions are fibrotic and unresponsive to hormonal manipulation. This would include those with bowel occlusion of greater than 50% of the circumference, lesions of greater than 2 to 3 cm in size, or when muscularis involvement of disease is greater than 7 to 8 cm. Recommended approaches for less extensive lesions include CO₂ laser vaporization of superficial serosal disease of the rectum or large intestine, excision without entering the mucosa, and oophorectomy or hormonal suppression. A harmonic scalpel may be used laparoscopically to shave an endometriotic nodule in the prerectal fascia. As demonstrated by Koninckx et al., most recurrences occur at the posterior fornix of the vagina, and complete excision is important in this area, particularly since the vaginal cuff heals well following resection of deep endometriosis in this area. The use of electrocautery or fiber lasers should be avoided because of their greater risk of causing transmural thermal damage.

A full mechanical and antibiotic bowel preparation is carried out preoperatively. A technically difficult and prolonged surgery is expected when the nodule is greater than 3 cm in diameter, firmly attached to the ischial spine, and localized in the sigmoid or when adhesions are present because of previous incomplete surgery or past in vitro fertilization (IVF) procedures that resulted in perforation of the nodule with the aspiration needle. When the nodule of deep endometriosis is attached to the ischial spine or ischiosacral ligament, dissection should be performed carefully because of the risk of extensive bleeding that may be difficult to control.

Lesions less than 2 cm in size or less than one third of the rectal circumference can be excised in a full-thickness manner either transabdominally or laparoscopically. In cases of large lesions that encroach on the mucosa, full-thickness excision of involved bowel can be undertaken either by disk excision of small, isolated lesions or by segmental resection for larger lesions, particularly those invading the bowel lumen. During the dissection of the nodule from the bowel, a layer of fibrosis may be left in situ to avoid entering the mucosa. The anastomosis can be hand sewn with a continuous single layer of absorbable monofilament suture or created with surgical staples; however, patients with cul-de-sac disease must be in the lithotomy position to allow transanal placement of the stapler. A circular end-to-end stapler has limitations to the amount of rectal wall that can be resected. The risks of rectovaginal fistula may be reduced by the interposition of a pedicled omentoplasty between the two suture lines and performance of a defunctioning stoma and pelvic drainage.

Excision of a sigmoid nodule is difficult without sigmoid resection, since the nodule is often localized mesenterically, thus impairing blood flow after excision, and the mobility of the sigmoid makes discoid resection and suture repair technically challenging. These procedures have been performed by or with the assistance of general surgeons.

A one-time dose of antibiotic is administered intraoperatively if the vagina is entered; a course of 4 to 7 days is recommended for muscularis defect with single-layer suturing or full-thickness resection and double-layer suture repair, respectively.

The short-term complications associated with bowel resection for endometriosis include leak at the anastomosis site, pelvic abscess and fistula, and bowel and bladder dysfunction. The lower the anastomosis, the higher the probability of postoperative leakage and rectovaginal fistula formation. Bowel perforation is usually identified within the week after surgery and may be treated with suturing and lavage if laparoscopy is performed within 24 hours after perforation. Later diagnoses associated with peritonitis necessitate colostomy. For those who have undergone low rectal resections, 15% or more experience leaks. Urinary retention usually resolves within a few weeks. Local excision with transmural discoid excision is associated with a lower risk of short- and long-term complications than rectal resection and has acceptable clinical outcomes for most patients.

Appendectomy should be considered when there is physical evidence of peritonitis, when implants are large and active, when associated adhesive disease to adjacent bowel may result in partial or complete angulation and obstruction, or when the benign nature of the lesion is in doubt. Spontaneous perforation of the appendix that is due to endometriotic involvement is very rare. The technique of incidental endoscopic appendectomy is similar to that performed through laparotomy, although the stump need not be buried in the cecum. The tip of the appendix is grasped and elevated. The appendiceal vessels are bipolar cauterized or occluded with surgical clips near the base of the appendix before being excised. Two loop ligatures are placed immediately next to each other at the base, and a third Endoloop is then secured approximately 5 mm distal to the first two. The appendix may then be transected between the second and third ligature and placed in a surgical pouch for safe retrieval from the abdominal cavity. Judicious application of bipolar cautery at the stump sterilizes the raw surface of the pedicle without causing damage to the adjacent cecum.

Coronado and colleagues reported a complete relief of pelvic symptoms in 49% and an improvement in 39% of patients who underwent full-thickness resection of the colon; 39% of patients in the series achieved a term pregnancy. In a later series by the same colorectal surgeons of 130 patients who underwent aggressive, conservative surgical management for advanced disease, the operative procedures performed included low anterior resection with anastomosis to the extraperitoneal

P.426

rectum ($n = 109$), sigmoid resection ($n = 10$), disk excision of the rectum ($n = 7$), ileocecal resection ($n = 2$), and small bowel resection ($n = 2$). Twenty-four of forty nine patients (49%) who attempted to conceive delivered a viable child.

Ferrero and colleagues compared open-bowel resection to laparoscopic resection in women with rectosigmoid endometriosis. They showed improved pregnancy rates when the procedure was performed laparoscopically. However, Vercellini et al., in a nonrandomized study in 2006, showed no higher rate of conception following resection of deeply infiltrating rectovaginal endometriosis via laparotomy over that achieved with expectant management among 105 women who were followed over a 2-year period. The cumulative 24-month probability of becoming pregnant was 44.9% in the surgery arm and 46.9% in the expectant management arm.

The sequelae of intestinal endometriosis may not appear until the patient is postmenopausal. Although the endometriosis can become inactive, the resulting cicatrization can lead to a decrease in the bowel lumen and to symptoms of obstruction.

Urinary Tract

Endometriosis involving the urinary tract is relatively rare. The spectrum of disease severity varies from incidental findings at laparoscopy, laparotomy, or cystoscopy to more significantly associated hematuria, flank pain, hypertension, and ureteral obstruction. Bladder and ureteral involvement represent 85% and 15% of cases, respectively. Cystoscopy and intravenous pyelography are helpful studies in documenting the extent of disease. Magnetic resonance imaging may further delineate the extent of involvement. Vesical endometriosis can be treated by hormonal suppressive therapy or partial cystectomy. These nodular lesions develop within the muscularis and are typically seen with partial or complete obliteration of the anterior cul-de-sac. Fedele et al. demonstrated conservative surgical treatment of bladder endometriosis is effective in ensuring long-term relief in most cases of endometriosis affecting the vesical dome, whereas success rates for deeper lesions involving the vesical base and the vesicouterine septum are lower, depending on the degree of surgical radicalness. The bladder wall is sutured in two layers, and a bladder catheter is left in place for 7 to 10 days postoperatively.

Extrinsic ureteral compression by endometriosis presents four times more frequently than intrinsic involvement and is most likely to occur in the distal third near the region of the ovarian fossa. The left ureter is more commonly affected. Patients with paracervical and extensive uterosacral ligament disease are also at risk. In patients with deep endometriosis, hydronephrosis should be excluded before surgery because it requires preoperative placement of a ureteral stent. The preferred treatment for ureteral obstruction is ureterolysis or resection of the involved segment followed by ureteroneocystostomy or

ureteroureterostomy. When hydronephrosis is present, the stricture can be removed over the stent with resection of a defined lesion in greater than 80% of patients.

Involvement of peritoneum overlying the ureter is amenable to resection by laparotomy or laparoscopy. An incision is made in normal peritoneum adjacent to the involved area. The inferior margin of the incision is grasped and deviated medially, and the ureter is separated from the peritoneum bluntly or by hydrodissection. The peritoneal lesion can be excised or vaporized. Periureteral vessels must remain intact to prevent ischemia and resultant fistula formation. If the peritoneum is adhered and the lesion cannot be dissected, the ureter is likely involved in the disease process. Ureteroneocystostomy should be considered.

Incisional Scars

Surgical scars are occasionally the sites of endometriotic implantation. Perineal, vaginal, and vulvar scars, particularly episiotomies, colporrhaphies, and Bartholin gland excisions, are likely areas for involvement by endometriosis. There is often a history of delayed wound healing of the incisional scar infiltrated with endometriosis. These implants typically appear as either deep-lying or subcutaneous nodules infiltrating the fascia and muscle. Bleeding into the tissues at the time of menstruation can cause cyclic local pain, tenderness, and discoloration; however, the nodule may lie too deep for detection of any color change through the skin. If the nodule is superficial, cyclic bleeding or ulceration may be apparent.

In most instances, incisional endometriomas have followed surgical procedures that violated the uterine cavity and allowed the endometrium to be transplanted. Wespi and Kletzhändler suggested that the frequency might approach 5% among patients having cesarean section or hysterectomy. Metroplasty and myomectomy also increase the risk of incisional endometriosis. Indeed, endometriosis has been reported along the needle tracts after amniocentesis or saline injection for abortion. Careful flushing and irrigation of the abdomen and of the incision during closure should minimize the chance of contamination when incision into the uterine cavity is required.

Episiotomy scars and cervical and vaginal lacerations also serve as implantation sites after delivery. The chance is significantly increased when postpartum curettage is performed. Paull and Tedeschi reported 15 instances in 2,208 deliveries when curettage was carried out and no instances in 13,800 deliveries without curettage.

Management, usually best accomplished by local excision, is both diagnostic and curative. Various hormonal regimens may be appropriate if it is imperative to avoid surgery. However, malignancy can occur in each area of ectopic endometriosis, and histologic confirmation of the tentative diagnosis is recommended.

Thorax

Thoracic endometriosis is an uncommon disease with varying clinical presentations. The diagnosis is almost always established on clinical grounds. In a report of 65 cases of thoracic endometriosis by Foster et al., pleural and lung parenchymal disease presented with different clinical features. Ninety-three percent of women with pleural disease developed pain with right-sided pneumothorax or pleural effusion. Because numerous right diaphragmatic defects were noted in patients with pleural involvement, pleural implants are believed to be secondary to tubal regurgitation and transport of endometrial tissue through the diaphragmatic defects. Other symptoms may include upper quadrant abdominal pain or referred pain to the shoulder. Disease involving the lung parenchyma produced hemoptysis rather than the pleuritic symptoms. Previous pelvic surgery was more common among women who had parenchymal endometriosis; however, pelvic endometriosis was found more often in those with pleural disease.

Catamenial pneumothorax or hemoptysis should alert the physician to the possibility of thoracic endometriosis. The chest roentgenogram is usually of little value in diagnosing this disease; however, cytology, aspiration biopsy, and pleuroscopy may be useful. Chest CT scan may reveal pulmonary or pleural nodules, particularly if performed during menses. Massive effusion and bleeding can occur, but this presentation is more commonly associated with a malignancy. GnRH agonist or surgical treatment may be effective in the symptomatic patient. Chemical pleurodesis or surgical pleural abrasion may be superior to hormonal treatment in the long-term management of pneumothorax.

Sciatic Nerve

Endometriosis may compress the sciatic nerve within the pelvis, at the sciatic notch, in the gluteal region distal to the notch, or within the sheath of the sciatic nerve. The

lesion may be identified with magnetic resonance neurography. Patients present with pain in the hip and the buttock radiating

down the back of the leg to the foot. The discomfort begins a few days before menstruation and becomes progressively more severe before subsiding 2 or 3 days to 2 weeks after cessation of menstruation. Over time, the sciatica may be constantly present, with excruciating exacerbation during menses. Neuropathic injury and muscle denervation may lead to progressive weakness of the leg. Two thirds of patients with sciatic nerve endometriosis have right-sided lesions. CT-guided biopsy is possible to confirm the diagnosis. Surgical exploration of the sciatic nerve is not necessary in most cases. Patients may experience remission of symptoms with GnRH agonist administration or during pregnancy.

Adjunctive Procedures of Conservative Surgery

Uterine Suspension

Uterine suspension techniques have been devised to reduce adhesion formation at denuded peritoneal surfaces of the posterior cul-de-sac, uterine serosa, and broad ligament. Elevation of the adnexa may prevent adhesion reformation of the ovary or fallopian tube at a site where existing adhesions have been excised. This procedure may be particularly useful in the case of a posterior or retroflexed uterus. It is indicated in selected cases of dyspareunia after resection of posterior cul-de-sac endometriosis. There is no evidence to suggest that uterine suspension is detrimental to subsequent pregnancies, although it is of unproven efficacy in enhancing fertility or as an adjunct in the treatment of endometriosis-associated pelvic pain. The modified Gilliam procedure offers certain advantages over other uterine suspensions because of its maintenance of normal anatomic relations. Shortening the round ligament through the internal inguinal ring eliminates the opening that is made lateral to the point of the ligament's attachment to the abdominal wall in the Olshausen suspension procedure.

When a modified Gilliam suspension is performed via laparotomy, the uterus is elevated, and a 2-0 absorbable suture is placed around each round ligament approximately 3 to 4 cm from its insertion into the uterus (**Fig. 22.10**). The edge of the rectus fascia is grasped by a Kocher clamp at the level of the anterosuperior spine of the ileum. The adjacent peritoneal edge is grasped with a Kelly clamp. The rectus fascia is separated from the underlying musculature with blunt dissection. A long Kelly clamp is inserted between the fascia and muscle to the level of the inguinal ring while displacing the peritoneum superiorly. This clamp is inserted through the ring and along the round ligament by gently opening and closing the instrument. The insertion is facilitated by placing traction on the suture to stabilize the round ligament. The peritoneum overlying the ligament is then incised at a point adjacent to the suture, and the suture is grasped by the Kelly clamp. By withdrawing the clamp, the round ligament is brought through the internal ring and outside of the peritoneal cavity; it can then be sutured to the rectus sheath with 2-0 interrupted delayed absorbable sutures. These sutures must be placed through the round ligament without encircling the ligament and thus occluding its blood supply. This procedure is repeated on the opposite side.

At the end of the suspension, the surgeon's hands should be introduced into the abdomen to ascertain whether there is a loop of round ligament lateral to the point where the ligament has been withdrawn from the peritoneal cavity. If so, this should be corrected to prevent strangulation of the involved segment lying between the ligament and abdominal wall. In addition, the fallopian tube should be inspected to ensure that its course has not been disturbed. This can occur if the traction suture has been placed through a segment of round ligament too close to the uterus.

Laparoscopic suspension is possible after placement of a trocar and sheath approximately 5 cm lateral to the midline and 3 cm above the inguinal ligament. The anterior rectus fascia in this site is tagged with suture. The round ligament is grasped at the usual site with laparoscopic forceps to elevate the ligament to the tagged anterior fascia, where it is sutured in place with nonabsorbable suture. The desired positioning of the uterus is confirmed laparoscopically.

Presacral Neurectomy

Presacral neurectomy, or division of the superior hypogastric plexus, is useful as an adjunctive procedure to eliminate the uterine component of dysmenorrhea that results from endometriosis. Sixty to eighty-five percent of patients with secondary dysmenorrhea experience complete relief of symptoms. There is no evidence that presacral neurectomy enhances fertility.

A significantly greater relief of midline pelvic pain is achieved when endometriosis resection is combined with presacral neurectomy as compared with conservative resection alone. In a series by Tjaden and colleagues, all 17 patients undergoing presacral neurectomy noted a complete resolution of midline pelvic pain, and only two of these had a recurrence of pain within the 42-month follow-up period. Endometriosis rarely provokes exclusively midline pelvic pain, however, and lateralizing adnexal pain and deep dyspareunia are not affected by this procedure. Careful patient selection is necessary if the desired outcome is to be achieved.

The hypogastric plexus consists of fine strands of nerves embedded in a delicate areolar tissue. The plexus is formed as a

continuation of the aortic and inferior mesenteric plexuses and passes over the bifurcation of the aorta. It then continues below the promontory of the sacrum before dividing into the right and left inferior hypogastric nerves. The presacral neurectomy procedure can be performed through a transverse Maylard incision or longitudinal incision that adequately exposes the region of the bifurcation of the aorta (**Fig. 22.11**). At the time of laparotomy, the descending colon is packed superiorly and to the left to expose the left margin of the hypogastric plexus. The posterior peritoneum overlying the sacrum is elevated and incised with the scalpel. The incision is extended caudally with scissors for approximately 5 cm to the third or fourth sacral vertebra and cranially to just below the bifurcation of the aorta. The margin of the posterior peritoneum can be drawn upward and outward by a stay suture or an Allis clamp. A Kittner sponge is then used to dissect the areolar tissue and associated nerve fibers off the posterior aspect of the peritoneal flap. The right ureter is readily visible and can be retracted laterally, and the areolar tissue is dissected from it without disturbing its blood supply. The common iliac artery, which lies just below the ureter, is freed superiorly from the adjacent tissue. A right angle clamp or probe can be introduced medially next to the promontory to elevate the sheath and allow blunt dissection underneath it. Care must be taken to avoid the middle sacral vessels that may be left intact on the surface of the promontory. Injury to the middle sacral vein can result in significant blood loss. Hemorrhage is controlled with cautery, suture ligation, hot packs, hypogastric vessel ligation, use of an absorbable gelatin sponge (Gelfoam) or microfibrillar collagen (Avitene), or packing with bone wax.

The areolar tissue is taken off the left flap of peritoneum until the superior hemorrhoidal vessels are exposed. These vessels should remain on the peritoneum but are bluntly freed from the overlying tissue. By elevating the sheath, several vessels that feed into the left common iliac vein can be identified. These branches are isolated, clamped, and tied as they are visualized. When the plexus has been isolated, a Babcock clamp

P.428

can be used to elevate the sheath. Two 2-0 absorbable or silk sutures are placed around the proximal and distal aspects of a 5-cm segment of the plexus and are loosely tied. The tonsil clamp is applied to each end of the nerve bundle. As the clamps are removed, the sutures are slipped down over the crushed areas and tied securely. The intervening portion of the plexus is then excised. The peritoneum may then be approximated with absorbable suture.

FIGURE 22.10 Modified Gilliam suspension. **A:** A chromic suture is placed around the round ligament approximately 3 to 4 cm from the uterine cornu. **B:** The rectus fascia is grasped with Kocher clamps and separated from the belly of the rectus muscle bluntly with the index finger or knife handle. **C:** The parietal peritoneum is grasped with Kelly forceps. A long Kelly forceps is introduced through the internal inguinal ring as it passes over the belly of the rectus. **D:** The Kelly clamp is brought through the internal inguinal ring and along the round ligament to a point adjacent to the chromic stay suture. A knife is used to open the peritoneum. The ends of the chromic suture are grasped by the Kelly clamp. **E:** As traction is applied to the suture, a knuckle of the round ligament passes through the internal ring. **F:** Three sutures of 2-0 delayed absorbable or silk suture are placed, fixing the ligament to the rectus fascia in a manner that will not interrupt the blood supply.

FIGURE 22.11 Presacral neurectomy. **A:** Location of incision in relation to anatomic landmarks. A Maylard incision can also be used in some cases. The descending colon is displaced superiorly and to the left for good exposure of the left margin of the hypogastric plexus. **B:** A Kittner sponge is used to dissect the areolar tissue medially and off the posterior aspect of the peritoneal flap. The right ureter can be identified easily. **C:** The areolar nerve-bearing tissue is dissected from the peritoneum on the left side, exposing the left internal iliac vessels and superior hemorrhoidal vessels. **D:** The plexus is isolated and elevated off the sacral promontory. A segment of plexus approximately 5 cm in length is isolated with 2-0 silk sutures. **E:** The plexus is excised. Note the relation between pedicles of the nerve bundle and adjacent structures.

In less than 10% of cases, the pelvic mesocolon is inserted in front of the interiliac trigone and the nerve bundle cannot be reached by simple incision of the peritoneum. In these cases, the chief branches of the inferior mesenteric artery must be moved

P.430

to the left to expose the triangular space between the two common iliac arteries. Unless there is adequate exposure and meticulous dissection, incomplete resection of the superior hypogastric plexus can occur, resulting in suboptimal denervation.

A laparoscopic approach to presacral neurectomy has also been described. This technique involves insertion of a 10-mm trocar sheath 3 cm above the symphysis pubis and placement of two accessory ports in each iliac fossa. Steep Trendelenburg position with a left lateral tilt is required to allow displacement of the intestines cephalad to expose the bifurcation of the aorta and sacral promontory. After retraction of the sigmoid colon and vasopressin infiltration of the sacral promontory area, the parietal peritoneum is grasped and elevated, and a transverse incision is performed from the major vessels or ureter on the right to the mesentery of the sigmoid on the left. The presacral nerve is isolated by developing the avascular space between the nerve and right internal iliac artery down to the periosteum via blunt dissection. Segments of the superior hypogastric

plexus are removed by sharp dissection after thorough diathermy. The entire length of removed nerve plexus should not exceed 3 to 4 cm. Venous bleeding is controlled with bipolar cautery. Meticulous hemostasis must be ensured at the completion of the operation. This technique should only be performed by experienced laparoscopic surgeons because the vascular complications can be serious. In a review of 655 laparoscopic presacral neurectomy procedures, Chen and Soong reported a 0.6% rate of major complications, including one case of injury of the right internal iliac artery and three cases of chylous ascites.

Polan and DeCherney reported that the combination of presacral neurectomy and conservative surgery in women with chronic pelvic pain, endometriosis, and pelvic inflammatory disease increased total postoperative pain relief from 26% to 75%, although only a small number of patients were included in this laparotomy series. Lee and coworkers performed presacral neurectomy via laparotomy in 50 women with chronic pelvic pain. Dysmenorrhea resolved in 73% of the cases, dyspareunia lessened in 77%, and acyclic pain improved in 63%. The uterosacral ligaments were resected in half of the subjects in this study, but this did not seem to affect the overall rate of pain relief. In a randomized clinical trial of women with moderate-to-severe endometriosis and pelvic pain undergoing conservative surgical therapy, Candiani and colleagues reported a recurrence of midline menstrual pain in 23% of women who underwent presacral neurectomy versus a 42% recurrence in those who did not. This difference reached the limit of statistical significance ($P = 0.06$).

In an uncontrolled laparoscopic study by Nezhat and associates of 100 women subjected to vaporization of endometriosis and presacral neurectomy, the symptoms of pelvic pain, dysmenorrhea, and dyspareunia were reduced by more than 50% in 74, 61, and 55 patients, respectively, over the 1-year follow-up period. The stage of endometriosis did not correlate with the degree of pain improvement achieved. More recently, in a prospective, randomized, double-blind, controlled trial, Zullo and colleagues reported that the performance of laparoscopic presacral neurectomy improved the cure rate in women treated with conservative laparoscopic surgery for severe dysmenorrhea caused by endometriosis as compared with those who underwent mere ablation of endometriosis (85.7% vs. 57.1% at 12 months, $P < 0.05$). A significant improvement in the quality of life was observed after surgery in both groups.

Two common side effects of the presacral neurectomy procedure have been observed. Constipation may require laxatives or stool softeners for a period of 3 to 4 months. The vaginal dryness that develops in as many as 10% to 15% of patients is transient and usually resolves within 6 months. Difficulty with micturition is an infrequent complication that rarely lasts for more than 1 or 2 months. A painless first stage of labor has been reported in women who have undergone presacral neurectomy.

Uterine Nerve Ablation

The technique of uterosacral neurectomy was initially described by Ruggi in 1899. Later popularized by Doyle, it has since been adapted for performance during laparoscopic procedures for the alleviation of dysmenorrhea. Sympathetic fibers T10 to L1 are contained within the inferior hypogastric plexus and course along the inferior vena cava and sacrum to enter the uterus through the nerves of the uterosacral ligaments and accompanying uterine arteries. The parasympathetic components of the paracervical nerves originate from S1 through S3 or S4, travel within the nervi erigentes, and emerge in the lateral pelvis to form the Frankenhäuser ganglia lateral to the cervix. Division of the uterosacral ligaments at a point approximately 1.5 cm distal to the cervix should interrupt many sensory nerve fibers of the cervix and uterine corpus.

Lichten and Bombard published a small randomized, prospective, double-blind study of laparoscopic uterosacral nerve ablation for the treatment of severe or incapacitating dysmenorrhea unresponsive to oral contraceptives and nonsteroidal anti-inflammatory agents. None of the control patients noted improvement, whereas 9 of 11 in the treated group had almost complete relief at 3 months, and 5 of 11 described complete relief from dysmenorrhea 1 year after surgery. Patients with endometriosis were not included in this small series.

Surgical resection of pelvic endometrial implants may be all that is necessary to alleviate discomfort in most endometriosis patients. In a double-blind, randomized controlled laparoscopic trial, Johnson and colleagues found that uterine nerve ablation was effective in reducing dysmenorrhea in the absence of endometriosis, but the addition of this procedure to the surgical treatment of endometriosis was not associated with a significant difference in any pain outcomes. Similarly, Vercellini and colleagues could not demonstrate the efficacy of this procedure.

Uterine nerve ablation by laparotomy fell from favor before it was revived as an endoscopic technique. The potential neurologic, intestinal, orthopedic, and psychological components of pain should be considered before subjecting the patient to a procedure that, although now performed endoscopically, carries some surgical risk and whose effectiveness has been questioned because of the small number of cases evaluated. Complications associated with transection of the uterosacral

ligaments include ureteral damage, bowel damage, and postoperative hemorrhage, which, if undetected, may result in death. Uterine prolapse has been described as a potential longterm side effect of the procedure.

Second-Look Laparoscopy

Second-look laparoscopy has been suggested as an appropriate procedure for additional lysis of pelvic adhesions in patients who have undergone a laparotomy or a laparoscopy for the resection of endometriosis. If scheduled 8 days to 6 weeks after the initial dissection, second-look laparoscopy allows separation of de novo adhesions that are still relatively filmy in consistency. In addition, laparoscopy after pelvic reconstructive surgery provides an opportunity to assess future prognosis for fertility.

Early second-look laparoscopy after endoscopic treatment of endometriomas has revealed a recurrence rate of endometriomas of 15% to 20%. Equally significant are the nearly 20% incidence of de novo adhesion formation and the 40% to

P.431

82% recurrence rate of dense adhesions. Second-look laparoscopy allows treatment of these findings; however, there is little direct evidence that this secondary surgical procedure will increase the cumulative pregnancy rate.

Some surgeons have proposed a three-step protocol to both surgically and medically treat large endometriomas more than 5 to 6 cm in size. During the initial diagnostic laparoscopy, the endometrioma is opened, drained, and biopsied. The patient is then treated with GnRH agonists for 12 weeks, and the second-look laparoscopy is performed. The endometrioma is opened, and the interior wall of the cyst is laser vaporized. The epithelial lining of the cyst is atrophic and thinned, and the use of the CO₂ laser results in minimal thermal damage to the normal ovarian tissue. This three-step approach may result in less compromise to ovarian follicular reserve than stripping of the cyst wall.

Surgical Outcomes

No classification schedule for endometriosis provides an accurate correlation between extent of disease and pregnancy rate. Nevertheless, point categorization through the revised ASRM classification does provide a framework in which to report outcomes of therapy.

Fertility

In a review of the surgical outcome expected through laparoscopic therapy for minimal and mild endometriosis, Cook and Rock found the crude pregnancy rate following cautery or laser ablation of implants was 54% to 58%. Life table analysis showed similar conception rates following laparoscopy and laparotomy to excise minimal or mild stages of endometriosis. Hence, the performance of a laparotomy is not warranted for lesser stages of disease.

Treatment of mild endometriosis via laparoscopic excision or electrocoagulation resulted in similar reproductive outcomes in a retrospective study by Tulandi and Al-Took. The total pregnancy rate was 53.5% in the excision group and 57.1% in the electrosurgery group. The mean interval between surgery and conception was 10.7 months in the electrosurgery group and 13.3 months in the excision group. Excision of tissue may result in more complete removal of infiltrating endometriosis, which should be of particular benefit to patients with deep nodules.

The stage of disease as categorized by the modified ASRM classification of endometriosis did not predict subsequent reproductive performance in a 2006 study by Vercellini and colleagues. Five hundred and thirty-seven infertile women with endometriosis undergoing first-line conservative laparoscopic surgery were followed for a mean of 32 months postoperatively. The cumulative probability of pregnancy at 3 years following laparoscopy was 47% (51% at stage I, 45% at stage II, 46% at stage III, and 44% at stage IV; log-rank test, $[\chi^2] = 1.50$, $P = 0.68$).

Expectant management of mild-to-moderate endometriosis after diagnosis by laparoscopy yields a crude pregnancy rate of approximately 50%, which has brought into question whether surgical therapy of lesser stages of disease actually enhances fertility. In a retrospective study comparing the efficacy of electrosurgical treatment of endometriosis with the efficacy of expectant management in minimal and mild endometriosis-associated infertility, Tulandi and Mouchawar reported that the cumulative probability of conception was significantly higher among patients treated surgically. Moreover, meta-analysis of the two randomized prospective trials showed that laparoscopic electrosurgery or laser to resect or ablate stages I-II endometriosis implants and adhesions resulted in a significantly higher fecundity rate as compared with the control group undergoing diagnostic laparoscopy only. The largest trial, conducted by Marcoux et al. in 1997, clearly supported this outcome, with an

increased chance of pregnancy (OR 2.03, 95% CI 1.28 to 3.24) and ongoing pregnancy rate after 20 weeks (OR 1.95, 95% CI 1.18 to 3.22) (Fig. 22.12), but the smaller trial, by Parazzini in 1999, did not show benefit (pregnancy OR 0.76, 95% CI 0.31 to 1.88; live birth OR 0.85, 95% CI 0.32 to 2.28). When the ongoing pregnancy and live birth rates from these two studies were combined, Jacobson et al. found a statistically significant increase with surgery (OR 1.64, 95% CI 1.05 to 2.57). The findings suggest that for every 12 patients having stage I or II endometriosis diagnosed at laparoscopy, there will be one additional successful pregnancy if ablation or resection of visible endometriosis is performed, compared with no treatment. This number needed to treat applies only to those patients who are found to have endometriosis. Approximately 70% of patients with otherwise unexplained infertility and no signs or symptoms to suggest endometriosis would be found to not have endometriosis during diagnostic laparoscopy.

Operative treatment of moderate or severe disease does offer a greater likelihood of conception than expectant management, in part because of correction of mechanical factors such as adhesions. The overall crude pregnancy rate reported by various studies of conservative laparotomy for endometriosis that stratified reproductive results by disease severity was 38%, with a monthly fecundity rate averaging 1.4% to 1.5%. Laparoscopic treatment of severe endometriosis offered a mean crude pregnancy rate of 47.6% in a small compilation of series. Hence, expert laparoscopists have reported results that appear to be as good as those obtained through the open abdomen, although there are inadequate data for direct comparison of outcomes of the two surgical modalities, and the correct identification and classification of disease may vary between laparotomy and laparoscopy groups. A 2012 Cochrane review of two randomized control trials concluded that excision of ovarian endometriomas was superior to ablative therapy of endometriomas in improving the chance of spontaneous pregnancy, with an odds ratio of 5.21. Life table analysis demonstrated that pregnancy is most likely to occur during the first 36 months after surgery. Furthermore, the duration of

P.432

infertility and, perhaps, patient age may have a greater impact on cumulative pregnancy rates than the actual stage (revised ASRM stages I through IV) of the disease.

FIGURE 22.12 Cumulative probability of a pregnancy carried beyond 20 weeks in the 36 weeks after laparoscopy in women with endometriosis, according to study group (From Marcoux S, Maheux R, Bérubé S. Laparoscopic surgery in infertile women with minimal or mild endometriosis. *N Engl J Med* 1997;337:217. Copyright © 1997, Massachusetts Medical Society).

Rectovaginal endometriosis is usually associated with pain symptoms, but the effect of disease in this location on fertility is uncertain. According to the results of 11 selected studies reviewed by Vercellini et al. in 2012, the mean postoperative conception rate in all women desiring pregnancy was 39% (223/571), irrespective of the preoperative fertility status and whether the patient pursued IVF after surgery. This rate dropped to 24% (123/510) in infertile patients who attempted to conceive spontaneously after surgery.

Pain

In a prospective, randomized, double-blind, controlled trial of laser laparoscopy in the treatment of pelvic pain associated with minimal-to-moderate endometriosis, Sutton and associates found that 62.5% of the laser-treated women reported symptom improvement at 6 months as compared with 22.6% of those treated expectantly. Symptom relief continued at 1 year in 90% of those who initially responded. Moreover, in a more recent randomized, blinded, crossover study by Abbott et al., 80% percent

of patients who underwent excisional surgery had symptomatic improvement as compared with 30% of the placebo group. A 2010 Cochrane analysis concluded that laparoscopic surgery for pelvic pain associated with endometriosis was superior to diagnostic laparoscopy alone, with an odds ratio of 7.72.

The technique of surgically treating lesser stages of endometriosis may not significantly influence pain relief, as long as the surgeon is aware of the depth of extension of the lesions. In a recent randomized study by Wright and colleagues, both excision and ablation of mild endometriosis produced good symptomatic relief and reduction of pelvic tenderness (67%).

Long-term improvement in quality of life can be achieved with laparoscopic excision of endometriosis. In a prospective, observational cohort study of 176 women with chronic pelvic pain with surgically diagnosed endometriosis, pain scores were highly significantly reduced at 2 to 5 years following resection in the categories of dysmenorrhea, dyspareunia, nonmenstrual pain, and dyschezia. The chance of requiring further surgery was 36%. Of note, almost one third who had further surgery had no evidence of endometriosis, either macroscopically or histologically, at the time of reoperation.

Aggressive and complete or near-complete excision of deep endometriosis is justified. Resection of deep endometriosis relieved dyspareunia in 40% and dysmenorrhea in 60% of cases. Nezhat and associates noted moderate-to-complete relief of pain in 162 of 175 women; however, some patients in this series had several surgical interventions. Preliminary analysis of the surgical results in 250 women in whom deep endometriosis had been excised with CO₂ laser showed a cure rate of pelvic pain in 70% and a recurrence rate of less than 5% over a 5-year follow-up period. Vercellini and colleagues reported that conservative surgery for rectovaginal endometriosis in infertile women did increase the pain-free survival time, although it did not modify the reproductive prognosis over expectant management. Recurrence of symptoms after surgery requiring reoperation may be dependent on surgeon experience and the use of postoperative suppressive therapy. It is progressive with time and is reported to by Falcone and Lebovic be approximately 15% at 1 year, 36% at 5 years, and 50% at 7 years. After bowel resection in patients with extensive endometriosis, pain symptoms have been improved by at least 70%, with recurrence in 0% to 34% in published trials. Women under 30 years of age at the time of initial operation are more likely to undergo a second surgical procedure to treat recurrent pain.

Endometriosis is often not identified in patients with chronic pelvic pain who undergo reoperation following their initial surgery for endometriosis. Persistence of dysmenorrhea and nonmenstrual pain after optimal endometriosis surgery may indicate adenomyosis. In a recent study by Parker and colleagues, chronic pelvic pain was significantly more likely to persist with uterine junctional zone thickness greater than 11 mm on preoperative MRI.

Recurrent Surgery

Rock and colleagues have shown that 13.5% of patients initially treated with conservative surgery required subsequent operative procedures. Wheeler and Malinak noted a cumulative recurrence rate at 3 and 5 years after conservative surgery of 13.5% and 40.3%, respectively. Neither the initial staging nor the ability to conceive after the initial surgery greatly affected the recurrence rates. Repeat conservative surgery for pelvic pain associated with recurrent endometriosis has similar efficacy and limitations as primary surgery, with long-term cumulative recurrence rates ranging from 20% to 40% as reported by Belanda et al.

Laparoscopic excision of ovarian endometriomas by the stripping technique is associated with a lower reoperation rate than that of fenestration. In a study of patients who underwent laparoscopic cystectomy of ovarian endometriomas of greater than 3 cm in diameter, Busacca and colleagues reported a cumulative rate of ultrasonographic recurrence of 11.7% over 48 months. Two studies that evaluated patients up to 49 and 60 months following surgery for endometriomas noted recurrent rates of up to 57%.

A second cytoreductive procedure may benefit some infertile women who have undergone surgery in the past if they do not pursue assisted reproductive technologies. A cumulative pregnancy rate of 32.4% at 35.4 months was achieved by Fedele and colleagues in 2006 after a second conservative laparoscopic stripping procedure for recurrent endometriomas. The recurrence of pain (17.4%) was similar to that experienced after the primary laparoscopic stripping procedure. However, if the initial surgery fails to restore fertility in patients with stage III or stage IV endometriosis, IVF may be more beneficial than reoperation for those who are otherwise asymptomatic. Pagidas and colleagues compared the outcome of a second operation for stage III or IV endometriosis-related infertility versus proceeding directly to IVF. The cumulative pregnancy rate 9 months after surgery was 24.4%, compared with a pregnancy rate of 33.4% after one trial of IVF and a cumulative pregnancy rate of 69.6% after two trials of IVF.

Combination Medical and Surgical Treatment

Preoperative and postoperative medical therapies have been proposed as treatment adjuncts to conservative resection of endometriosis to enhance fertility. Preoperative suppression of disease with hormonal agents may facilitate the surgical procedure by reducing tissue vascularity, and the greater ease in tissue dissection may decrease adhesion formation during the postoperative period. The preoperative hormonal agents also eliminate the corpus luteum that might otherwise be mistaken for an endometrioma. However, they may also reduce the size of endometriosis implants, making them less recognizable after short-term drug therapy. In a controlled clinical trial by Muzii et al., a 3-month course of GnRH agonist treatment before laparoscopy for endometrioma excision failed to result in a reduction in operative time or recurrence rate of disease during a 1-year follow-up period. There are no substantive data to justify hormonal treatments before surgery to improve the success of surgery.

P.433

Initiation of postoperative medical therapy may inhibit the activity of any residual disease, suppress ovulation, and decrease the possibility of adverse effects of peritoneal spillage of disease at the time of resection. However, postoperative medical therapy has a serious drawback; the patient is unable to attempt conception for several months. Andrews and Larsen have noted that the best chance for postsurgical conception occurs during the first 6 months after conservative surgery by laparotomy. Thus, suppressing ovulation during that critical period may be counterproductive. Treatment with a GnRH agonist after surgery does not improve fertility as compared with expectant management.

Contemporary management of women with endometriosis-associated pelvic pain involves both surgical and long-term medical therapy. When cytoreductive laparoscopy is followed by a 6-month course of GnRH analogue, there is a significant delay in the return of endometriosis symptoms requiring further treatment. In a randomized, prospective study, Hornstein and colleagues found that this interval was more than 24 months in those receiving nafarelin versus 11.7 months in the placebo group. A shorter duration of hormonal therapy during the postoperative period may be inadequate in reducing recurrence risk. A 3-month course of nafarelin following surgical therapy of stages III and IV endometriosis was ineffective in reducing pain scores as compared with placebo. Postoperative administration of low-dose, cyclic oral contraceptives for 6 months delayed the recurrence of pain symptoms and endometriomas at 12 months, but no significant differences were detected at 24 months or 36 months following laparoscopic excision. A 2012 systematic review and meta-analysis by Vercellini et al in 2012 indicated that a more prolonged course of postoperative oral contraceptive use (≥ 12 months) dramatically decreased the risk of endometrial cyst recurrence and pain symptoms. Because of these data, patients should be advised of the potential benefit of regular contraceptive use following surgery until such time as pregnancy is desired.

Hysterectomy

The number and rate of hysterectomies performed for endometriosis increased steadily from the 1960s to the 1980s, more so than for other diagnoses. The reported rate for 1982 to 1984 was more than double the rate for 1965 to 1967, although the exact reasons for the increase remain uncertain. Although statistically significant increases for hysterectomy rates were observed from 1994 through 1998, the increase was limited, and the curve remained nearly flat. Endometriosis was the primary indication for 20.8% of white women and 9.7% of black women undergoing hysterectomy in the United States from 1994 to 1999. Because of concern over the risk of recurrence even after definitive surgical therapy, bilateral oophorectomy was performed at the time of hysterectomy in 52% of women 44 years of age or younger and in 81% of women 45 years of age or older.

Definitive surgery offers prompt, complete, and long-term relief of pain from endometriosis more often than do the various available medical regimens. Most hysterectomies for endometriosis are performed by the abdominal route; in selected cases, laparoscopy may allow lysis of complicating adhesions or large implants, thus allowing safe vaginal hysterectomy. When the posterior cul-de-sac is obliterated and extensive fibrosis is present deep in the pelvis, subtotal hysterectomy may be indicated.

The recurrence of cyclic pain associated with endometriosis after hysterectomy with preservation of normal ovaries has been estimated at 3% to 7%. Nevertheless, in a study of 138 women who underwent hysterectomy with the diagnosis of endometriosis at the Johns Hopkins Hospital, ovarian conservation was associated with a 6.1 times greater risk of development of recurrent pain and an 8.1 times greater risk of reoperation as compared with oophorectomy at the time of hysterectomy. Recent data from a 7-year follow-up study by Shabika et al. showed that in women undergoing hysterectomy, the reoperation-free rates at 2, 5, and 7 years for those with ovarian preservation were 95%, 86%, and 77%, respectively, as compared with 96%, 91%, and 91% for those patients without ovarian preservation. Hysterectomy does not improve symptoms

in 25% of cases of chronic pelvic pain when the uterus is believed to be the source of the pain.

Minute, hormonally active ovarian fragments may be detected in women with symptomatic endometriosis, even after total abdominal hysterectomy and bilateral salpingo-oophorectomy. Laparoscopic resection of invasive peritoneal and intestinal disease that persists after castration may result in an improvement in pain symptoms. Ovarian remnant syndrome is the result of incomplete excision of cortical tissue at the time of extirpative surgery for endometriosis or pelvic inflammatory disease. Most ovarian remnants are retroperitoneal in location, and they are often densely adhered to pelvic sidewall structures, including the ureter, hypogastric vessels, and bladder base. Complete surgical removal may be difficult.

Estrogen replacement therapy after total hysterectomy and bilateral oophorectomy is associated with less than a 10% rate of recurrence of endometriosis. A cause-and-effect relation between estrogen replacement and malignancy in endometriosis has not been established, suggesting that progestational agents need not be prescribed together with estrogens after hysterectomy for a diagnosis of endometriosis. However, administering both progestin and estrogen may be theoretically beneficial if the disease was incompletely resected or deeply invasive, contained atypical epithelial changes, or is recurrent. A study by Matorras et al. showed an endometriosis recurrence rate of 3.5% in women treated with cyclic estrogen and progestogen replacement during a mean 46 months of follow-up as compared to 0% recurrence rate in untreated controls. Women who begin estrogen replacement therapy immediately after total abdominal hysterectomy and bilateral salpingo-oophorectomy are at no greater risk of recurrent pain than those who delay estrogen therapy for more than 6 weeks postoperatively.

Women with endometriosis were shown by Modugno and colleagues to be at increased risk of developing ovarian cancer (OR 1.32; 95% CI 1.06 to 1.65). An analysis by Melin et al. of data from the National Swedish Cancer Register showed that complete surgical removal of endometriosis lesions, even when the ovaries are unaffected, as well as removing the affected ovary in case of ovarian endometriosis, may significantly decrease the risk of ovarian cancer. In addition, hysterectomy and the use of oral contraceptives for greater than 10 years substantially reduce this risk.

ENDOMETRIOSIS AND ASSISTED REPRODUCTIVE TECHNOLOGIES

If spontaneous conception is not achieved within 3 years of surgical resection of endometriosis or within 1 year of repair of tubal obstruction associated with endometriosis, the odds are poor that it ever will occur. Techniques in assisted reproduction have been widely used during the past three decades. IVF removes gametes and zygotes from a potentially harmful environment and may bypass pelvic adhesions associated with endometriosis. Endometriosis is the sole identifiable cause of infertility in 25% to 35% of women undergoing IVF/embryo transfer.

P.434

The impact of endometriosis on the outcome of IVF has been controversial. Several studies have noted that the responses to gonadotrophic stimulation, the numbers of preovulatory oocytes, the fertilization and cleavage rates, and the clinical pregnancy rates associated with stage I and stage II endometriosis have been equivalent to rates associated with tubal disease and unexplained infertility. Kuivasaari et al. reported that there was a significantly lower pregnancy rate and embryo implantation rate per fresh embryo transfer after pooled cycles (1 to 4) among women with stage III/IV endometriosis (22.6%) compared with stage I/II (40%) or tubal infertility (36.6%). However, when adjusted for confounding variables, Barnhart and colleagues in 2002 found that there was a significantly negative association between endometriosis of all stages and IVF outcome. This meta-analysis pooled data from 22 nonrandomized studies regarding IVF success rates in patients with endometriosis versus control patients without endometriosis and with tubal infertility. Most of these series included small numbers of subjects. The authors concluded that there was a 54% reduction in pregnancy rate after IVF in patients with endometriosis and that the success rate was even lower when the staging of endometriosis was higher. Subsequent studies have disputed these findings.

Poor IVF outcome in severe endometriosis may be related to oocyte or embryo factors rather than decreased uterine receptivity. Diaz and colleagues found that a history of severe endometriosis in recipients of donor oocytes had no effect on embryo implantation rates or clinical pregnancy rates as compared with recipients who did not have a history of endometriosis. Oocytes originating from women with endometriotic ovaries and donated to disease-free women led to reduced implantation rates.

In general, women with endometriosis have a lower ovarian response to gonadotropin stimulation. One reason for this response may be previous ovarian resection. Studies recruiting women with a history of surgical excision of a unilateral endometrioma and comparing subsequent ovarian responsiveness to gonadotropin stimulation in the affected and

contralateral intact gonad indicate that excision of endometriomas is associated with quantitative damage to ovarian follicular reserve. However, this lower oocyte yield following surgery has not necessarily led to decreased pregnancy rates.

Recent retrospective studies have suggested that routine laparoscopic cystectomy for endometriomas before commencing an IVF cycle does not improve IVF outcomes. Aside from a lower peak estradiol level on the day of hCG administration and a higher total gonadotropin dose administered to women previously operated on for an endometrioma, no significant differences were found between the resected endometrioma group and the intact endometrioma group among the different variables analyzed by Garcia-Velasco et al. Pre-IVF excision of ovarian endometriomas in symptomatic women did not impair nor enhance IVF or intracytoplasmic sperm injection success rates.

A 2005 retrospective study by Suzuki et al. indicated that women with a history of past or current endometriomas had fewer oocytes retrieved during IVF than tubal factor controls, but the fertilization rate, embryo quality, or pregnancy outcome was not affected. Conversely, Almog and colleagues found that the presence of an intact, unilateral ovarian endometrioma was not associated with a reduced number of oocytes retrieved from the affected ovary as compared to the opposite ovary or women without endometriomas.

Tinkanen and Kujansuu studied the effects of operative treatment of recurrent ovarian endometriosis on the pregnancy rate with IVF. They compared 45 patients with ultrasound-diagnosed ovarian endometriosis during IVF treatment, 36 of the cases being recurrences after previous operation, with 55 patients who had undergone past endometrioma resection and had no evidence of recurrence before IVF. Patients with endometriomas had significantly more embryos for transfer compared with women without endometriomas. The clinical pregnancy rate was 38% in the endometrioma group compared with 22% in the no-endometrioma group. The women who had surgery with no recurrent endometriosis may have had a more extensive resection as compared with those with recurrent endometriomas following initial surgery.

Hence, the hypothesis that surgical therapy of endometriosis increases IVF pregnancy rates is not clearly validated by the available evidence. Endometrioma resection may compromise or destroy adjacent normal ovarian tissue by removing part of the ovarian cortex and thus reducing ovarian reserve. On the other hand, larger endometriomas may interfere with follicular recruitment, may impose difficulties during oocyte retrieval, and may theoretically produce substances that are toxic to maturing oocytes and affect cell cleavage after fertilization. However, a systematic review by Benschoop et al. concluded that surgical intervention for women with endometriomas 3 cm or larger has no benefit over expectant management on the outcome of assisted reproductive technology. The European Society of Human Reproduction and Embryology recommends laparoscopic ovarian cystectomy before IVF if the patient has an endometrioma ≥ 4 cm in diameter in order to confirm the diagnosis histologically and to reduce the potential risks of transvaginal aspiration of follicles in women with large cysts.

In vitro fertilization offers a high cumulative pregnancy rate in patients with colorectal endometriosis who have not undergone prior surgery for deep infiltrating endometriosis. However, the subgroup of patients with concomitant uterine adenomyosis has a low pregnancy rate. Several studies have found that adenomyosis had no adverse effects on IVF outcome in infertile women with proven endometriosis when they were pretreated with long-term GnRH agonist.

The presence of significant pelvic pain symptoms, number of previous surgical interventions for endometriosis, the size of the cyst, accessibility of ovaries for transvaginal aspiration of follicles, and the patient's age and ovarian reserve must be taken into consideration in establishing an individualized treatment plan ([Fig. 22.3](#)). Resection of large cysts before IVF may reduce the risk of inadvertent needle puncture or drainage of endometriomas at the time of oocyte retrieval for IVF, which is associated with an increased risk of infection, even if prophylactic antibiotics are administered. Further randomized clinical trials are needed to elucidate the relative effects of mild peritoneal endometriosis and advanced stages of disease associated with endometriomas and pelvic adhesions on the outcome of IVF.

The relative value of initial medical therapy before use of assisted reproductive technologies remains controversial. Dicker and associates noted that 35 women with severe endometriosis who underwent 6 months of ovarian suppression with a GnRH analogue had a higher clinical pregnancy rate per cycle and per transfer than did 32 women who received ovarian stimulation for IVF without prior GnRH treatment (per cycle, 25% vs. 3.9%; per transfer, 33% vs. 5.3%). Sallam et al., in a Cochrane review of three randomized, controlled trials involving 165 participants, ovarian steroid suppression with GnRH agonist for 3 to 6 months before IVF in women with stages II to IV endometriosis led to a fourfold increase in clinical pregnancy rates. However, the very high reported clinical pregnancy rates in the treatment arms of two of these studies suggest that more data are necessary to better understand the relative value of this suppressive therapy.

IUI, intrauterine insemination; IVF, in vitro fertilization.

From the Practice Committee of the American Society for Reproductive Medicine. Endometriosis and infertility. *Fertil Steril* 2004;82 (suppl 1):S40, with permission. Copyright © 2004, Elsevier.

Controlled ovarian hyperstimulation (COH) with clomiphene citrate, letrozole, human menopausal gonadotropins, or FSH together with intrauterine insemination (IUI) has been proposed as a method to increase cycle fecundity of patients with endometriosis, although few series have been published to date ([Table 22.9](#)). By increasing the number of oocytes released at the time of ovulation and introducing a high concentration of spermatozoa into the female reproductive tract, the chance for conception is improved, merely because of the larger number of gametes available for fertilization. In addition, subtle abnormalities of folliculogenesis, corpus luteum function, tubal motility, or sperm function may be corrected with this therapy. Cycle fecundity rates associated with COH/IUI therapy in patients with endometriosis-associated infertility have ranged from 9% to 13%, although these series did not include a nontreatment control group. One recent prospective randomized study found a higher pregnancy rate with COH/IUI following at least 6 weeks of GnRH agonist suppression in patients with advanced stages of endometriosis.

Fedele and associates reported that superovulation with timed intercourse was not associated with a better cumulative, crude pregnancy rate than expectant management in infertile women with endometriosis stages I and II, although the cycle fecundity rate was improved. However, a more recent randomized, controlled trial of COH and IUI for infertility associated with stages I and II endometriosis demonstrated a live birth rate of 11% per cycle in the treatment group and 2% in the control group. Nuoja-Huttunen and colleagues reported that ovarian stimulation or induction using gonadotropins results in higher fecundity rates than no treatment, but the clinical pregnancy rate after treatment was still significantly lower in the endometriosis group (6.5%) than in women with unexplained infertility (15%). There was no surgical treatment of endometriosis before therapy with COH and IUI in these latter studies.

In a 2006 retrospective study by Webrouck and colleagues, the clinical pregnancy rate per cycle of COH and IUI in women with minimal or mild endometriosis who underwent laparoscopic excision of lesions within 7 months of onset of treatment was 21% or 18.9%, respectively, which was comparable to that achieved in patients with unexplained infertility, 20.5%. The mean age of the patients with endometriosis in this study was 31 years. The cumulative live birth rate of nearly 70% within four cycles suggests that COH and IUI may be appropriate first-line therapy in patients younger than 35 who have not become pregnant within 6 to 12 months after surgical treatment of minimal-to-mild endometriosis and who have no other infertility risk factors. In a 2012 study by Abu Hashim et al. of women with a mean age of 31 years who had undergone laparoscopic treatment of minimal-to-mild endometriosis 6 to 12 months earlier, the clinical pregnancy rates were 15.9% and 14.5%, respectively, with letrozole-IUI and clomiphene-IUI therapy.

Temporary exposure to very high estradiol levels in women during COH for IVF or IUI is not a major risk factor for endometriosis recurrence in women treated with assisted reproductive technology.

Women with endometriosis have been shown to have adverse obstetrical outcomes as compared to those without endometriosis. Preterm birth, preeclampsia, antepartum bleeding or placental complications, and cesarean sections were more common in women diagnosed with endometriosis in a Swedish cohort study by Stephansson et al. of data from the national medical birth registry. It is uncertain whether these associations were related to endometriosis, being infertile, or the antiretroviral therapy treatment that may have been undertaken to achieve the pregnancy.

ADENOMYOSIS

Adenomyosis is defined as heterotopic endometrial glands and stroma located deep within the myometrium associated by hyperplasia of the adjacent smooth muscle. This disease can be categorized as diffuse or local in its distribution. Diffuse adenomyosis can be relatively localized but is never encapsulated (**Fig. 22.13**). The uterus itself is usually mildly enlarged, rarely to more than twice-normal size, and is generally symmetric. Cut sections of the myometrium reveal a coarse trabecular pattern of interlacing musculature and fibrous tissue with small islands of endometrium that are often dark and hemorrhagic. Localized, encapsulated disease of the uterine wall is termed *adenomyoma*, to distinguish this manifestation of adenomyosis from the more usual diffuse pattern. An adenomyoma is always located mainly within the wall of the uterus but may project into the uterine cavity to become further known as a *submucous adenomyoma*. This encapsulated, submucous form of adenomyosis disease resembles the leiomyoma.

The most widely accepted theory of the origin of adenomyosis is that endometrial tissue within the myometrium is of müllerian origin. Its presence in this location is the result of a direct, downward extension of the endometrium of the uterine cavity.

FIGURE 22.13 Uterus showing three types of adenomyomatous growth: encapsulated intramural adenomyoma, submucous adenomyoma, and diffuse adenomyosis of walls.

Serial sectioning of tissue has revealed a direct continuity between the basalis portion of the endometrium and the endometrial islands within the areas of adenomyosis. Endometrial extensions sometimes are present through the full thickness of the myometrium to the serosal surface of the uterus. Occasionally, only subserosal adenomyosis is seen. Subserosal adenomyosis is often associated with pelvic endometriosis and may cause the lymphatic spread of endometrial fragments.

The intramural islands generally have the same histologic appearance as the basalis of the endometrium (**Fig. 22.14**) and often respond to estrogen stimulation by demonstrating a proliferative or, occasionally, cystic hyperplastic pattern. Cellular atypia is rare. The effect of progestational agents on the ectopic endometrium is less predictable. Secretory changes in the glands are uncommon except in pregnancy, when a decidual reaction of the stroma is anticipated. Unlike endometriosis, adenomyotic lesions are not characterized by a pronounced hemorrhagic tendency or inflammatory response. In the absence of hormonal stimulation, adenomyosis becomes atrophic. Adenocarcinomas involving adenomyosis are characterized by a history of prior exogenous estrogen use, by low histologic grades, and by an excellent prognosis.

Adenomyosis can be definitively diagnosed only through histologic sections of myometrium. The reported incidence of the disease varies widely among from 8% to 62%, depending on the criteria used for diagnosis and on the thoroughness with which the excised uterine tissue is studied. The usual criterion for diagnosis is glandular extension below the endometrial-myometrial interface of greater than 2.5 mm, whereas adenomyosis subbasalis can be defined as minimally invasive adenomyosis extending less than 2 mm beneath the basal endometrium. The incidence of adenomyosis begins to rise in the mid-30s and peaks in the fifth decade. Infertility is not common, although most patients are multiparous. Approximately 12% have coexisting external endometriosis. Adenomyosis is often discovered incidentally in patients undergoing surgery for uterine leiomyomata.

FIGURE 22.14 Area of adenomyosis. Compact stroma and proliferative, slightly hyperplastic glands surrounded by hypertrophied myometrium.

Symptoms

Adenomyosis is often an incidental pathologic finding, and approximately 35% of cases are asymptomatic. Dysmenorrhea is more likely to be reported when glandular invasion exceeds 80% or more of the myometrium. Pain can be severe, cramping, or knifelike and may occur up to 1 week before the onset of menstrual flow. The pattern of dysmenorrhea is likely associated with bleeding episodes within the deep-lying islands of endometrium. Menorrhagia can be a consequence of the increased surface area of the enlarged uterine cavity. In addition, extensive involvement of the myometrium can interfere with the normal contractility of the uterine musculature and can lead to excessive bleeding. Nevertheless, data collected from 1,851 hysterectomies for the prospective, multicenter Collaborative Review of Sterilization study indicate that adenomyosis occurs as often in asymptomatic uteri removed for prolapse (19%) as in uteri removed for excessive bleeding (22%) or pain symptoms (15%). Uterine adenomyosis is significantly associated with pelvic endometriosis, with a prevalence of up to 90%. By impairing uterine sperm transport, adenomyosis may be a leading factor of infertility in women with endometriosis.

P.437

Pelvic Findings

The uterus may be very firm to palpation and is usually enlarged to not more than twice its normal size. As it is classically described, the adenomyotic enlargement occurs in the anteroposterior dimension, a reflection of the more prominent involvement of the posterior uterine wall. In the more common diffuse type of adenomyosis, the uterus is a symmetrically enlarged, globular structure. Encapsulated adenomyomas may cause the uterus to be irregular or asymmetric, much as it is when leiomyomata are present. At times, particularly during menstruation, the enlarged uterus is tender on examination.

Diagnosis

Adenomyosis should always be suspected in a woman with dysmenorrhea and menorrhagia of increasing severity her fourth or fifth decade, particularly if the uterus is symmetrically enlarged, firm, and tender. An exact preoperative diagnosis is often difficult to establish because dysfunctional uterine bleeding and multiple small leiomyomata can present in a similar fashion. Gambone and colleagues reported that a presumptive diagnosis of adenomyosis was verified in only 38% of hysterectomy specimens. The diagnosis can be histologically established before hysterectomy only in the rare case in which excessive myometrium is removed during curettage or a polypoid submucous adenomyoma is excised. However, hysteroscopic myometrial biopsy of the posterior uterine wall with use of a 5-mm loop electrode has been shown to effectively establish the diagnosis in women with menorrhagia.

Hysterosalpingography of the adenomyomatous uterus with water-based media can occasionally demonstrate multiple spiculations or tuft defects leading from the uterine cavity to the myometrial wall; however, similar findings can occur in cases of vascular or lymphatic extravasation. MRI has proved to be highly accurate for distinguishing adenomyosis from leiomyomata; on T2-weighted images, adenomyosis appears as an ill-defined, relatively homogeneous, low-signal-intensity area embedded with sparse, high-intensity spots. The optimal junctional zone thickness value for establishing the diagnosis of adenomyosis is 12 mm or more. Several studies have shown that the sensitivity and specificity of MRI to diagnose adenomyosis range from 86% to 100% in a symptomatic patient population.

Recent studies have also suggested an important role for transvaginal ultrasound in distinguishing adenomyosis from leiomyomata. By using the diagnostic criterion of the presence of unencapsulated, heterogeneous, myometrial areas within round anechoic areas 1 to 3 mm in diameter, Fedele and colleagues noted a sensitivity of 80%, a specificity of 74%, a negative predictive value of 81%, and a positive predictive value of 73%. Nevertheless, when transvaginal sonography and MRI have been prospectively compared, the latter has been significantly more accurate in correctly establishing the diagnosis.

Hormone receptor studies have documented the presence of steroid receptors in adenomyotic foci. Estrogen receptors are more consistently present than are progesterone receptors, which are completely absent in 40% of cases evaluated. Progestins or cyclic estrogen-progestin combination preparations offer little aid in treatment, although recent reports indicated that adenomyosis-associated menorrhagia can be controlled with the insertion of a levonorgestrel-releasing intrauterine device or a danazol-loaded intrauterine device. GnRH agonist therapy for 6 months resulted in the disappearance of pain symptoms and a decline in uterine volume in 65% of cases of biopsy-proven adenomyosis, but the dysmenorrhea and menorrhagia recurred at the end of treatment. Nevertheless, extended intermittent use of these agonists can effectively relieve pain symptoms while having the significant advantage of preserving fertility between treatments.

Curettage does not aid in establishing the diagnosis of adenomyosis and is ineffective as treatment, although it may be required because of abnormal bleeding. The need for surgery, therefore, is based on continued menorrhagia and dysmenorrhea rather than on an estimation of uterine size or even the known presence of adenomyosis or leiomyomata. The definitive treatment for abnormal bleeding caused by adenomyosis is hysterectomy. The vaginal route is preferred if the size of the uterus is appropriate and no other pelvic abnormalities are present. Under certain circumstances, as with a younger patient who wishes to retain her reproductive capability, excision of an encapsulated adenomyoma should be considered instead of hysterectomy. Such situations arise infrequently because adenomyosis is generally diffuse and usually occurs in multiparous women who are no longer interested in childbearing. The precise efficacy of hysteroscopic endometrial resection, laparoscopic myometrial reduction, and myometrial excision as conservative surgical procedures for adenomyosis has yet to be proved. Endometrial ablation is ineffective as treatment for deep, subserosal adenomyosis that penetrates more than 2 mm. Attempting to resect deeper myometrial tissue carries the risk of increased bleeding. Thermal balloon and radiofrequency ablation has been used recently to treat excessive bleeding in women with adenomyosis. Ectopic, deeper endometrial glands not resected may persist under the scar and eventually proliferate through the area of ablation or resection to cause symptoms such as dysmenorrhea.

Excisional surgery of adenomyosis is best performed by laparotomy because of the value of palpating the uterus to assess the extent of disease and the greater ease in achieving hemostasis. Fujishita and colleagues described a modified approach called the transverse H technique, where one vertical and two crossing horizontal incisions are made. This allows easier removal of a more limited volume of adenomyotic tissue than classical reduction and resulted in a greater improvement in symptoms.

The use of GnRH analogues postoperatively may reduce the recurrence of symptoms in patients who undergo cytoreductive surgery. Wang et al. followed 165 women treated with surgery alone or surgery followed by a 6-month course of ovarian suppressive therapy with GnRH analogues. They found that the symptom-relapse rates in the surgical-medical group were significantly lower than those in the surgery-alone group (28.1% vs. 49.0%, respectively). There was no significant difference in the clinical pregnancy rates (79.5% vs. 74.1%, respectively) or the delivery rates (72.7% vs. 63.0%) among the 44 women in the surgical-medical group and the 27 patients in the surgery-alone group who tried to conceive upon completion of the course of treatment for adenomyosis.

In a recent series of 104 patients, Osada and colleagues described a technique of radical resection of adenomyomatous tissue along with a triple-flap method for reconstructing the uterine wall. All of the patients in the report had adenomyosis involving more than 80% of the anterior and posterior uterine walls with more than 6 cm of wall thickness as verified by MRI and ultrasound. A supracervical tourniquet was applied, and the uterus was bisected at the midline along the sagittal plane until the uterine cavity was opened. Adenomyotic tissues were excised from surrounding myometrium, leaving a myometrial thickness of 1 cm from serosa to endometrium. The endometrium was reapproximated with suture, and the myometrium was repaired with a triple-flap reconstruction. The serosal surface of the underlying flaps was stripped to ensure that only myometrial tissues apposed each other. Only four cases (3.8%) had recurrence of symptoms after 2 years. Sixteen pregnancies

P.438

were reported out of twenty six women who wished to conceive (61%) and three-fourths of these were achieved through IVF. The deliveries occurred through cesarean section.

There have been several reports of uterine rupture in the second and third trimester of women who have undergone cytoreductive surgery, so careful patient counseling and close obstetrical management are necessary if conservative surgery is being contemplated, especially if it entails significant resection of a portion of the myometrium.

Interventional radiologic techniques have been described to selectively embolize the uterine vessels in women with adenomyosis. Although short-term results from Pelage et al. of uterine artery embolization to treat adenomyosis appeared encouraging, midterm results were disappointing, with only 55% of treated patients showing clinical improvement after 2 years. In a review by Popovic et al. of 15 studies in which uterine artery embolization was performed to treat symptomatic adenomyosis in 208 women, 64.9% reported long-term satisfaction. Preliminary trials have suggested that magnetic resonance-guided focused ultrasound surgery may be used in the future to destroy focal adenomyosis.

Hysterectomy should be considered in the severely symptomatic patient when ultrasonography, MRI, or myometrial biopsy demonstrates deep adenomyosis. The surgical procedure may be performed abdominally, vaginally, or laparoscopically. Subtotal hysterectomy should be avoided, as adenomyosis may recur in the cervical stump or the rectovaginal septum.

BEST SURGICAL PRACTICES

- Surgery is indicated for correction of pain, infertility, or other symptoms in patients with extensive pelvic endometriosis or when hormonal manipulation fails to adequately diminish pain symptoms in women with lesser stages of disease. Surgical management of endometriomas has no significant effect on IVF pregnancy rates as compared to no treatment. Resection of large endometriomas (>5 cm in size) allows a histologic confirmation of the etiology of the cyst and may reduce the risk of bacterial seeding of the endometrial cyst during transvaginal aspiration of follicles for IVF.
- Preoperative rectoscopy-sigmoidoscopy and intravenous pyelography are recommended in patients with symptoms suggestive of deeply invasive endometriosis of the posterior cul-de-sac and rectovaginal septum. Preoperative ultrasound and MRI may help to categorize the extent of ovarian involvement and location of deeply infiltrating disease. A bowel prep before surgery may facilitate optimal performance and safety of the surgical procedure, particularly when deep disease is anticipated.
- Laparoscopy can be considered for all cases unless there is difficulty in establishing the appropriate tissue planes of dissection or unless improved access is necessary for atraumatic manipulation of the involved organs. Conservative resection of disease by laparotomy is most valuable in cases of extensive, dense pelvic adhesions or endometriomas greater than 5 cm in diameter. In addition, deep involvement of the rectovaginal septum with fibrotic extension into the perirectal fossa, invasion of the bowel muscularis, and endometriotic infiltration in the region of the uterine vessels and

ureter are generally best approached through the open abdomen for all but advanced endoscopic surgeons.

- The philosophy of gentle manipulation of tissue in an attempt to avoid trauma is the major tenet of pelvic reconstruction. Adhesion formation can be reduced by magnification of the surgical site, avoidance of suture unless clearly indicated, reconstruction with fine nonreactive suture, precise hemostasis, and frequent irrigation of tissues with warmed solution.
- Less tissue damage is achieved with bipolar than with monopolar cautery. Ablation of deep disease by monopolar microdiathermy or CO₂ laser vaporization rather than excision of the disease may result in inadequate resection and a greater amount of ischemic damage to the tissue, heightening the propensity toward adhesion formation. Deep lesions or more extensive peritoneal disease must be excised with a tissue margin of at least 2 to 4 mm, because microscopic lesions are commonly present in tissue adjacent to visible implants. Twenty-five percent of patients have lesions greater than 5 mm in depth.
- Coagulation or vaporization of disease in the ovarian fossa or near the uterosacral ligament should be undertaken only after clear identification of the ureter. Resection of deep posterior cul-de-sac nodules requires great endoscopic expertise. A combined laparoscopic-vaginal approach may be necessary.
- Inability to elevate the ovary is usually a sign of adhesions and endometriotic implants of the inferolateral surface of the ovary and the peritoneum of the ovarian fossa. When removing an endometrioma, the cortical incision should be made in a way that will preserve the normal anatomic relations of the ovary with the uteroovarian ligament and fimbria ovarica. Suture on or extruding through the surface should be avoided when possible because of its adhesiogenic properties. With larger endometriomas, the normal ovarian cortex is stabilized with atraumatic forceps, and the cyst wall is grasped with biopsy forceps and stripped from the bed of normal ovarian tissue. The dissection may be facilitated by removing a small circular rim of tissue around the adhesion site to begin the stripping procedure in a clearer field, where the endometrioma wall is less adhered to healthy ovarian tissue. The rate of recurrence of pelvic pain and dysmenorrhea over a 2-year postoperative period is significantly less for those patients who are managed by cystectomy as compared with those undergoing fenestration and coagulation. Moreover, the rate of reoperation is less and the cumulative pregnancy rate is higher in the cystectomy group. Extensive cauterization or resection of ovarian tissue can lead to a decline in follicle number and a rise in FSH levels postoperatively and should be avoided.
- Aggressive and complete excision of deep endometriosis is justified. The recurrence rate of clinically detectable endometriosis is higher when the depth of infiltration is greater than 5 mm at the time of initial surgery, no matter the site of the lesion. A second cytoreductive procedure may benefit some infertile women who have undergone surgery in the past, although assisted reproductive technologies would lead to a higher chance of conceiving for most patients who failed primary surgery. The hypothesis that surgical therapy of endometriosis increases IVF pregnancy rates is not clearly validated by the available evidence.
- Uterine suspension is of unproven efficacy in enhancing fertility or as an adjunct in the treatment of endometriosis-associated pelvic pain.
- Presacral neurectomy, or division of the superior hypogastric plexus, is useful as an adjunctive procedure to eliminate the uterine component of dysmenorrhea that results from endometriosis. Uterine nerve ablation may be effective in reducing dysmenorrhea in the absence of endometriosis, but the addition of this procedure to the surgical treatment of endometriosis has not been associated with a significant difference in any pain outcomes.

Chapter 23

Surgical Conditions of the Vulva

Ira R. Horowitz

Joseph Buscema

Bhagirath Majmudar

DEFINITIONS

Bubo—Enlarged, suppurative inguinal lymph node characteristic of chancroid.

Burow solution—A soothing aluminum sulfate solute that can be used as a soak or wet compress for inflamed or irritated skin or mucous membrane.

Cavitron ultrasonic surgical aspirator (CUSA)—An electromechanical surgical instrument that is useful in soft tissue dissection. Using focused ultrasound, superficial tissue is sheared off and aspirated through the wand tip. It has been used to treat condyloma and vulvar intraepithelial neoplasia.

Donovan body—An intracytoplasmic gram-negative, rod-shaped bacteria characteristically identified in histiocytes associated with granuloma inguinale.

Fournier gangrene—An older term for necrotizing fasciitis.

Keyes biopsy instrument—A pencil-like biopsy instrument with a sharp, hollow, cylindrical tip that is rotated while pressed against the skin. It cuts a small, cylindrical biopsy, which is then elevated with tissue forceps and cut off at the base with scissors or a knife.

Necrotizing fasciitis—A severe, rapidly progressive, life-threatening infection of the subcutaneous tissue and fascia that may involve the vulva. Synergistic bacterial infection with multiple organisms, it is associated with vascular thrombosis leading to necrosis of the skin and subcutaneous tissue of fascia. It is treated with aggressive broad-spectrum antibiotic coverage and wide surgical debridement.

P.446

Silvadene cream—A 1% silver sulfadiazine cream commonly used on the vulva following laser therapy or surgery to minimize the risk of cellulitis or wound infection and to soothe the postoperative wound site.

Vulvar intraepithelial neoplasia (VIN)—A preinvasive neoplastic condition of the vulva.

Vulvar vestibulitis—A painful condition of the vulva of uncertain etiology. It is characterized by (a) severe pain on vestibular touch or attempted vaginal entry, (b) tenderness to pressure localized within the vulvar vestibule, and (c) minimal physical findings consisting of slight erythema within the vestibule.

Word catheter—A small latex catheter with an inflatable balloon to hold it in place. It is inserted to drain a Bartholin duct abscess.

The vulva and the adjacent perianal skin are designated the anogenital area. These tissues are derived from ectoderm and are considered separately from the vagina and cervix, which are of mesodermal origin. Multifocal diseases, particularly human papillomavirus (HPV), can affect all of the aforementioned epithelia. A complete vulvar examination should, therefore, include the vulva, perineum, anal area, urethral meatus, buttocks, and thighs. It is difficult to appreciate subtle skin changes in patients with dark skin; therefore, an adequate light source is necessary.

VULVAR DERMATOSES

In 1987, the International Society for the Study of Vulvovaginal Diseases (ISSVD) revised the terminology to describe the nonneoplastic epithelial disorders of the vulva, which include psoriasis, lichen planus, lichen simplex chronicus, candidiasis, and condyloma acuminata. In their 1976 classification, the ISSVD categorized hyperplastic dystrophy with and without atypia. In the classification of 1987, squamous cell hyperplasia is without atypia, and lesions with atypia are considered vulvar intraepithelial neoplasia (VIN). In 2006, the ISVD published the Classification of Vulvar Dermatoses. The benign lesions were categorized as spongiotic, acanthotic, lichenoid, dermal homogenization/sclerosis vesiculobullous, acantholytic, granulomatous, and vasculopathic patterns. This was further simplified in 2011 when the ISSVD formulated a classification that would be easier for clinicians ([Table 23.1](#)).

TABLE 23.1 International Society for the Study of Vulvovaginal Diseases Classification of Vulvar Pain

A. Vulvar pain related to a specific disorder

- Infectious
- Inflammatory
- Neoplastic
- Neurologic

B. Vulvodynia

1. Generalized
 - a. Provoked (sexual or nonsexual)
 - b. Unprovoked (spontaneous)
 - c. Mixed (provoked and nonprovoked)
 2. Localized (i.e., vestibule, clitoris, vulva)

Provoked (sexual or nonsexual)

Unprovoked (spontaneous)

Mixed (provoked and nonprovoked)
-

The terms *kraurosis* and *leukoplakia* have been overused in the past. In 1877, Schwimmer reported that leukoplakia on the buccal surfaces of the mouth was a premalignant lesion, and Beisky later described kraurosis as an atrophic lesion similar to lichen sclerosus. Because of these early reports, every lesion on the vulva that

appeared white and constricted the vaginal outlet was called kraurosis. Moreover, conditions as varied as leukoderma and invasive cancer have been called leukoplakia. Other terms, such as *primary senile atrophy* and *atrophic leukoplakia*, have been used interchangeably. They are nonspecific and should be eliminated. The epidermis may be thickened and the skin markings accentuated (lichenification), but the extent of the epithelial proliferation cannot be assessed without biopsy. Usually a 3- or 4-mm Keyes punch biopsy is used to obtain a small biopsy in the office under local anesthesia (**Fig. 23.1**). The specimen is oriented with the epithelial surface up on a square of filter paper or Telfa before being placed in fixative. This allows correct orientation of the tissue so that a full-thickness, nontangential, microscopic section can be prepared. Occasionally, experienced clinicians make a tentative diagnosis based on history and physical examination. A trial of topical therapy may be used for 6 to 8 weeks to evaluate the response; if the response is less than satisfactory or if there is any suspicion of invasive cancer, a biopsy must be done.

Although some physicians have suggested that lichen sclerosus and kraurosis have different histopathologies, their microscopic appearance is similar. A safe approach would be for surgeons to describe the anatomic appearance (i.e., whether the vulva is shrunk and constricted or thickened and leathery), leaving it up to the pathologist, who is familiar with both histology and anatomy, to define the cellular and histologic abnormalities.

Hyperkeratosis

Both chronic infections and benign tumors, most commonly condylomata acuminata, appear white because keratin absorbs moisture, which reflects light back to the observer.

To avoid the ambiguous term *leukoplakia*, Jeffcoate, in 1966, introduced the term *dystrophy* into the nomenclature of benign epithelial lesions of the vulva. Predictions about the malignant potential of vulvar dystrophy vary; of all the types of dystrophy, the one most often benign is lichen sclerosus. As noted earlier, the terminology for vulvar dystrophies has been altered. Vulvar dystrophy has been classified in three categories: squamous hyperplasia, lichen sclerosus, and VIN. Typical squamous cell hyperplasia is characterized by a thickened, hyperkeratotic squamous epithelium, elongated rete pegs, and often an infiltration of the underlying tissue with chronic inflammatory cells. Typical hyperplasia is a benign form of chronic dermatitis with hyperkeratosis and acanthosis; thus, the designation “dystrophy” should be eliminated.

Depigmentation Lesions

Leukoderma and *vitiligo* are terms that are used interchangeably. Treatment is not required unless the symptoms of the commonly associated chronic dermatitis cannot be controlled by local medications. The hyperkeratotic lesions comprise a number of diverse entities that share a white to grayish white epithelial appearance in a moist environment. Biopsy is the only reliable criterion for accurate assessment.

Lichen Sclerosus

Lichen sclerosus is characterized by hyperkeratosis, thinning of the epidermis, loss of rete peg architecture, collagenization of the underlying tissue, and associated middermal inflammatory infiltrate (**Fig. 23.2**). In 2006, the ISSVD classified lichen

P.447

P.448

sclerosis as lichenoid pattern. It can occur at any age. The disease has been noted in the prepubertal child, and it occurs during the menstrual years. Nevertheless, it is seen most often in the postmenopausal woman when the lesions more commonly are symptomatic, perhaps because of the additional epithelial compromise caused by atrophy. The genetic aspects of lichen sclerosus have not been clearly identified, but the finding of lesions in both mother and child has been documented.

FIGURE 23.1 Biopsy of the vulva. **A:** The skin and subcutaneous tissue are infiltrated with local anesthetic using a small needle. **B:** A 3- or 4-mm Keyes punch biopsy instrument is firmly pressed against the skin to be biopsied and gently rotated. **C:** The small core of skin and subcutaneous tissue separated by the Keyes punch is elevated by small toothed tissue forceps and trimmed off at the base with curved iris scissors. Pressure is applied to the biopsy site, and the base is cauterized with silver nitrate sticks.

FIGURE 23.2 Vulvar dystrophy; lichen sclerosus. **A:** Distorted vulva with superficial ulcerations and extensive hyperkeratosis and loss of normal architecture. **B:** Microscopic picture of lichen sclerosus composed of epidermal diminution, subepidermal collagenization, and middermal lymphocytic infiltrate.

If biopsy specimens reveal lichen sclerosus, the patient should be treated with ultrapotent corticosteroids. Many series over the past few years have shown an excellent clinical response to 0.05% clobetasol proportionate topical ointment or cream. In a series of 81 women with biopsy-proven lichen sclerosus, Lorenz and coworkers reported that 77% had complete remission of symptoms and another 18% experienced significant improvement. Patients were treated with topical application of clobetasol cream twice daily for 1 month, at bedtime for another month, and, finally, twice a week for 3 months. They continued to use the cream on an “as-needed” basis once or twice a week. Many patients continue to require occasional episodic therapy for symptomatic flareups, but the long-term effects of these ultrapotent steroids on the vulva have not been well studied. Some experts recommend maintenance therapy with lower potency corticosteroids, such as triamcinolone or 0.1% betamethasone. Topical testosterone has been recommended in the past, but Bornstein and associates compared the results of 2% testosterone propionate with 0.05% clobetasol dipropionate; at 1-year follow-up, 80% of the clobetasol-treated patients reported symptomatic improvement compared with 40% of those treated with testosterone.

Many patients with chronic vulvar dermatitis, stenosis of the outlet specifically related to lichen sclerosus, and vestibulitis have an associated constriction of the vaginal outlet with resultant dyspareunia. Local intravaginal or vulvar applications of estrogen do not improve this condition. Plastic surgery to the outlet ([Fig. 23.3](#)) may be helpful. By excising a triangular area of skin beneath the fourchette, the surgeon can undermine and evert the adjacent vaginal epithelium, incise the transverse perineal muscle and fascia, and cover the denuded area with a flap of vaginal mucosa. The procedure is simple, and the use of delayed absorbable suture material lessens the incidence of wound breakdown that commonly occurs when absorbable suture is used. The results of this procedure have been most satisfactory; approximately 95% of patients are greatly relieved of dyspareunia. Breech and Laufer have reported good results in a few patients by suturing a protective covering of oxidized

regenerated cellulose gauze (Surgicel, Johnson & Johnson, Arlington, TX) to the raw surfaces of the inner labia and clitoris after division of intraoital adhesions to prevent recurrence.

VULVAR INTRAEPITHELIAL NEOPLASIA

The first two cases of carcinoma in situ (CIS) of the skin were described by Bowen in 1912. Bowen also stated that although stromal invasion had not developed in patients observed over periods of 12 to 16 years, curettage and cauterization did not eliminate recurrence of the lesions.

In 1958, Woodruff and Hildebrandt reported 13 cases of VIN. They suggested that because the histology varied from one area to another in the same section, the general term CIS should be used to designate the lesion. Today, the term VIN is commonly used, and vulvar intraepithelial lesions were originally subdivided into VIN I, corresponding to mild dysplasia; VIN II, similar to moderate dysplasia; and VIN III, corresponding to severe dysplasia or CIS, similar to the classification of cervical disease.

However, in 2004, the ISSVD changed the classification, eliminating the term *VIN I*. VIN I is thought to be secondary to viral changes and not a reproducible diagnosis. In addition to eliminating VIN I, they combined VIN II and VIN III as simply VIN, the expectation being that these lesions will be treated as high-grade preinvasive neoplasms. Jones and colleagues, in their review of 405 women with VIN, reported a decrease in the mean age of patients with VIN from 50 in 1980 to 39 in 2003. The increased prevalence of HPV infection as well as increased awareness by patients, clinicians, and pathologists have resulted in an increase in the diagnosis of VIN and, perhaps, a more common identification of these lesions in younger women. In an international study, de Sanjose and colleagues identified HPV 16, HPV 33, and HPV 18 in descending order.

Symptoms

Pruritus is the predominant symptom of most vulvar disease, including cancer, yet itching was the primary symptom in only 50% of patients with in situ cancer in a series reported by Buscema and associates. Other presenting symptoms were the presence of a lump, bleeding, and pain. In a small percentage of the cases, the lesion was discovered on routine examination; but in others, the diagnosis commonly was made in patients seen during follow-up of cervical neoplasia.

Diagnosis

The best technique for early diagnosis is careful inspection of the external genitalia—including perianal areas, thighs, and buttocks—under a bright light (**Fig. 23.4**). If suspicion is aroused either by history or preexisting neoplasia in the lower genital canal or by the suggestion of an abnormal configuration, magnification should be used. An experienced colposcopist can describe white lesions and areas of abnormal vasculature. As a screening procedure, however, colposcopy has not contributed to the early detection of vulvar neoplasia. The use of nuclear staining, specifically 1% toluidine blue and tetracycline fluorescence, has delineated foci of increased metabolic activity, but the false-negative and false-positive rates are high enough to make the results unpredictable.

Careful visual evaluation of the vulvar region should be directed at the focally white, hyperkeratotic areas and at the more important, slightly elevated, papillary areas of the skin. Atypical pigmentation, most significantly gray-white areas that are even minimally ulcerated or slightly elevated above the surrounding skin, should be viewed with suspicion (**Fig. 23.5**). Biopsy provides the final diagnosis.

Multifocal areas of neoplasia that involve the external genitalia, perineum, and the epithelium of the lower genital canal are common; in fact, more than half of the patients with intraepithelial disease in the lower genital tract have multifocal lesions. These lesions suggest an infectious, possibly viral, origin for the

neoplasia. In contrast, patients older than 60 years of age with invasive or in situ cancer more commonly have unifocal disease. Benedet and Murphy noted an increase in unifocal and diffuse disease in patients older than 50 years of age. When the vulva is the primary site of the lesion, the cervix, vagina, and perianal areas are frequent sites for associated neoplastic alterations. The combination of vulvar and cervical cancer comprises approximately 20% of all multicentric neoplasia in the lower genital tract.

The most pressing question about multifocal disease is whether invasive disease that develops from in situ lesions will arise in many foci or in only one focus. Only two of our patients with in situ neoplasia younger than 40 years of age have developed invasive cancer, and both cases appeared as

P.449

P.450

solitary perianal lesions. Because the vulva and the cervix are of different embryologic origins, the tendency to correlate the histopathology of one area with that of the other may be unrewarding. For example, the full-thickness changes that signal cervical intraepithelial neoplasia are not as comparable when they occur on the vulva. Keratinization at the rete tips with intraepithelial pearl formation may indicate, on the other hand, a preinvasive disease in the anogenital area anywhere.

FIGURE 23.3 Perineoplasty. **A:** The incisional line is identified. The incision must be sufficiently extensive to allow for postoperative retraction and subsequent constriction of the outlet. **B:** The vagina is undermined to allow for exteriorization without tension. **C:** The scarred skin of the fourchette is excised. The vaginal epithelium is preserved for exteriorization. The vaginal epithelium is sufficiently undermined for the margins to be approximated to the skin (**D**) without tension (**E**). Occasionally, a small incision is made into the midline of the exteriorized mucosa to allow for an adequate outlet without tension.

FIGURE 23.4 Multiple foci of CIS in a young patient. Note the vulvar and perianal involvement.

FIGURE 23.5 Carcinoma in situ of vulva showing multiple patterns, particularly atypical pigmentation.

Pathologic Diagnosis

Biopsy with a Keyes punch can be performed in the office with the use of local anesthesia. Knife biopsies often are tangential and contain only the superficial layers, which results in a less than accurate histologic interpretation. An alternative is to use a cervical biopsy forceps to obtain a small specimen that can be evaluated. Correct orientation of the tissue in the fixative is mandatory if accurate evaluation of the specimen is to be rendered. Such orientation can be obtained by placing the biopsy specimen on filter paper or Telfa with the epithelial surface exposed, so that the pathologist can embed the specimen accurately. Tangential cutting may result in the erroneous diagnosis of invasive disease. Cytology has not proved to be a satisfactory screening technique in the evaluation of the precursory cellular atypias in vulvar neoplasia.

The classic bowenoid changes vary from one microscopic section to another, but typical sections show loss of polarity, hyperchromasia, anaplasia, individual cell keratinization, corps ronds, and mitotic activity on the surface (**Fig. 23.6**). Abnormal mitosis may abound. Other gross variations include the erythroplastic lesion (erythroplasia of Queyrat) with immature cells extending from base to surface and lesions that appear almost normal, being marked only by intraepithelial pearl formation at the rete tips in a background of marked dysplasia. Papillary lesions showing changes of high-grade dysplasia were previously designated as *bowenoid papulosis*, a term discontinued by ISSVD.

Treatment and Results

Although *surgical excision* of VIN is favored, patients typically do not require total vulvectomy. Modesitt and colleagues found invasive cancer in 22% of patients with biopsies consistent with VIN III. Vulvectomy may be appropriate for selected patients who are elderly, particularly if they have extensive disease, or for patients with

obtain clear margins. The adjacent loose skin of the vulva provides sufficient extra skin to cover minor defects without a skin graft and without significant deformity. The incidence of recurrence is no greater with local excision than with total vulvectomy, but it still approaches 30% to 40%. Positive margins have been indicative of an increased risk of recurrence in some series. Unless invasive cancer is suspected in the area of the positive margins, immediate reexcision is usually not indicated, but careful follow-up is necessary because recurrence is common. Brown has suggested that CO₂ laser vaporization around the surgical margins will decrease the risk of recurrence.

FIGURE 23.6 Carcinoma in situ of the vulva. There is full-thickness alteration in the architecture with elongation and distortion of the rete pegs. At *arrow*, there is intraepithelial pearl formation (160×).

A *skinning vulvectomy*, in which the epidermis and underlying dermis of the vulva and often the perineal area are removed and replaced by a skin graft, has been used for the treatment of extensive or multifocal vulvar in situ disease. This procedure is usually recommended in younger women with extensive lesions in an attempt to restore normal anatomy and sexual function. However, the technique requires surgery at a donor site, which produces an additional scar in a patient who usually is young. Furthermore, it imposes prolonged bed rest, near-complete immobilization of the lower extremities, and indwelling bladder catheterization for 5 to 6 days while the skin graft heals.

The *carbon dioxide laser* has been successfully used in the treatment of in situ vulvar neoplasia. This approach is of particular appeal for the younger patient with multifocal, viral proliferative disease. This subset of patients with VIN is undoubtedly at lower risk for occult invasion. Emphasis in therapy should be directed toward preservation of maximum tissue and vulvar function. Given these considerations and the reality of recurrences, laser ablation provides an effective medium. Pretreatment requirements include careful examination of the lower genital tract and the liberal use of biopsies to identify areas of possible invasion and multicentric disease. The risk of invasive cancer is greater in the older patient. The desire for cosmetic results is less, so the use of surgical excision is favored in older women.

The laser itself is directed colposcopically after examination of tissues prepared by the application of dilute acetic acid. The latter may enhance detection of minimal viral changes not readily seen with the naked eye. Although

benign condylomata can be adequately treated by superficial vaporization (so-called first and second plane), laser treatment of VIN must address the extension of disease into the hair follicles (pilosebaceous ducts). This mandates deeper laser vaporization beyond the papillary dermis and into the upper reticular dermis (third plane). The colposcope permits recognition of landmarks that characterize these levels. Baggish and coworkers identified skin appendage involvement in 36% of cases of vulvar in situ carcinoma and predicted that laser vaporization to a depth of 2.5 mm would effectively treat involved appendages in 95% of cases. Shatz and associates advocated ablation of VIN to a depth of 1 to 2 mm in nonhairy and hairy skin to achieve similar success. In laser treatment of VIN, the use of appropriate power densities should be emphasized. Low-power densities lead to thermal conduction injury in adjacent and underlying normal tissue. The latter increases the risk of scarring. Power densities of greater than 750 W/cm² are recommended. However, the deeper extent of vaporization required for VIN III, particularly in hair-bearing areas of the vulva, results in considerably greater postoperative pain, a longer period of healing, and an increased risk of scarring and subsequent chronic pain and dyspareunia; therefore, many experts have abandoned the use of the laser in favor of surgical excision for VIN III. Bornstein and Kaufman have proposed combining laser ablation with surgical excision in the treatment of selected patients with VIN. Laser is used particularly in areas where excision hampers preservation of anatomy, such as in the clitoral region. Laser therapy for VIN should probably be reserved for experienced laser surgeons and colposcopists.

The *ultrasonic surgical aspirator* can assist the surgeon in ablating to depths comparable to those achieved with the CO₂ laser. The advantage of this instrument is its ability to obtain additional tissue that might identify an occult cancer. Ultrasonic surgical aspirator and laser ablation also may be used to treat perianal intraepithelial neoplasia. In this setting, two concerns should be kept in mind. This location appears to be associated with a greater risk for the development of invasive squamous cancer, and the likelihood of fibrosis, scarring, and stricture is heightened. As with all treatments for VIN, the potential for recurrence and the need for further follow-up must be appreciated. With ablative approaches such as laser, diligence must be exercised to exclude invasion.

Topical agents have been used in the treatment of VIN with inconsistent results. Most notable among these topical treatments has been 5-fluorouracil (5-FU, Efudex 5%). Efudex is not recommended by the manufacturer for this use, and they specifically recommend against its use in the vagina. The mechanism of action appears to be related to the inhibition of DNA and RNA synthesis; the latter is not specific to dysplastic or HPV-infected cells. Normal epithelium is susceptible to the agent, and a component of hypersensitivity reaction appears operative in its mode of action. For cases in which treatment is effective, denudation of the epithelium is a requisite for success. This understandably leads to localized discomfort and pain, often reported as intense burning. Treatment regimens with topical 5-FU are diverse, and no standardized administration protocol has been widely adopted. One technique is topical application on an alternate-night basis for as long as 6 weeks; patient compliance problems typically lead to earlier curtailment. Among young patients with erythroplastic VIN, a 50% to 60% complete response rate has been reported. The hyperkeratotic VIN lesion has not proved to be as responsive to 5-FU.

In a 41-year review of 405 women, Jones and colleagues observed that more than 50% of women treated with laser ablation or surgical resection required an additional procedure within 14 years. Fifty percent of patients with positive surgical margins required additional treatment within 5 years. In comparison with positive margins, women with negative margins had a 15% chance of requiring additional therapy. Brown and colleagues, in a small series of 33 patients, noted a decrease in recurrence with a combination of surgical excision and laser vaporization at the margins.

TECHNIQUE OF CONSERVATIVE (SIMPLE) VULVECTOMY

Conservative (simple) vulvectomy is recommended in many patients with widespread VIN when it may be difficult to rule out invasive cancer or Paget disease of the vulva. It may also be appropriate when premalignant lesions, such as granulomatous diseases, do not respond to medical therapy or wide local excision.

An outline of the surgical margins is made with a surgical marking pen (**Fig. 23.7**). The initial incision should be made at the vaginal outlet so that the urethral borders can be well demarcated and the vaginal epithelium undermined for a short distance. If the incision is begun at the lateral skin margins, bleeding can mask the area, making the incision at the outlet more difficult to define. When the first incision is made at the outlet, a small pack can be placed into the vagina to control the bleeding while the elliptic incision at the outer skin margins of

P.452

the lesion is made. The skin incision usually encompasses most of the labia majora, depending on the extent of the lesion. The incision through the skin is made with a knife to avoid tissue necrosis that occurs at the skin margins when an electrosurgical instrument is used. Minor vessels can be coagulated.

FIGURE 23.7 Conservative vulvectomy for vulvar CIS.

Major bleeding concerns may arise at the clitoris, particularly from the dorsal vein. Hemostatic sutures must be

used to control the bleeding. A second point of concern is the pudendal vessels, which enter at the lower one third of the vulva close to the opening of the Bartholin duct. Branches of the pudendal vessels extend down to the anus as the inferior hemorrhoidals, and bleeding may be rather profuse in this area.

Because the lesions for which conservative vulvectomy is performed are superficial, dissection does not need to extend down to the deep fascia or to the muscles of the urogenital diaphragm. Although it is unnecessary to remove the bulbocavernosus and ischiocavernosus muscles, they may be difficult to avoid when the vulva is quite atrophic. Removal of some of the adipose tissue, particularly in the obese patient, allows for better approximation of the skin edges to the vaginal mucosa. The incision can be carried almost to the anal orifice; careful dissection here is important so that the external anal sphincter is not damaged. If the disease extends onto the anal mucosa or the protruding hemorrhoidal tissue, the mucosa should first be carefully dissected from the underlying external sphincter, excised with the tumor-free margins, and sutured to the perianal skin with 3-0 delayed absorbable material. In the remaining vulva, the underlying tissues are

P.453

approximated in layers with absorbable sutures, and the skin edges are approximated with interrupted absorbable sutures (**Fig. 23.7**). If bleeding is a problem, a small suction drain can be placed at the lower end of the incision, but it is much better to achieve meticulous hemostasis and use a firm pack against the area for 24 hours.

During closure of the perineal defect above the anal orifice and posterior vaginal introitus, the surgeon should evert the vaginal epithelium over the perineum in approximation to the anal orifice rather than suture the lateral skin edges snugly across the perineum and fourchette. Everting the vaginal mucosa allows for satisfactory coitus, whereas tightly approximated skin across the posterior fourchette may constrict the vaginal introitus and predispose to pain, dyspareunia, and fissuring.

When the firm packing has been removed after 24 hours, the entire area should be exposed. Initial application of ice packs to the operative site for 24 to 48 hours seems to provide more comfort to the patient than heat. Later, warm air blown across the perineum is both comforting and therapeutic because it helps to keep the operative site dry and stimulates blood flow, enhancing the healing process. An indwelling urethral catheter or a suprapubic catheter is used while the suture line undergoes initial healing of the skin edges. The suprapubic catheter can be maintained for 4 to 5 days, if desired. A single dose of a cephalosporin such as Cefazolin (1 g) intravenously is recommended immediately before surgery. Infrequently, a local cellulitis may develop, necessitating antibiotic therapy; extended-spectrum cephalosporins and semisynthetic penicillins have proved effective.

VULVAR RECONSTRUCTION

Procedures performed for extensive VIN III or Paget disease include total or partial vulvectomy, skinning vulvectomy, and multiple wide excisions. These may occasionally result in large denuded areas, creating challenges for reconstruction. With the advent of laser ablation and the ultrasonic surgical aspirator, fewer procedures such as skinning vulvectomy are performed for VIN.

Reconstructive efforts for superficial excisions typically require split-thickness grafts. Such grafts are ill suited for reconstruction after radical excision because the depth of tissue defect is too great, and poor cosmetic and functional results ensue. A buttock donor site is preferred. Perioperative antibiotics are used. Bowel preparation and slow postoperative feeding minimize contamination of the graft site.

Split-thickness skin grafts can be procured with an air-driven dermatome. The size of the vulvar defect helps to determine donor site excision. Meticulous hemostasis should be sought before application of the graft. Fine absorbable sutures are used to secure the skin edges of the graft. The donor site should be covered with an occlusive dressing, such as Op-Site or Tegaderm, until significant healing occurs. A soft pressure dressing is

tied over the graft site and kept in place for 5 days, accompanied by an indwelling catheter for urinary drainage.

VULVAR PRURITUS

The most common symptom associated with vulvar dermatoses and many other vulvar conditions is pruritus. In most cases, pruritus is a symptom of an underlying disease process, and although treatment of this annoying symptom is important, the clinician should attempt to diagnose and treat the disease that causes the symptom of pruritus.

Before any therapy for vulvar lesions caused by chronic irritation is begun, an accurate tissue diagnosis must be established. All patients should be given detailed instructions to eliminate local irritants. A history of urinary incontinence may suggest a source of chronic vulvar irritation. Associated vaginitis should be treated vigorously. Topical medications for control of the symptoms must be given a satisfactory trial. Vulvectomy should not be performed for chronic dermatitis or for the benign dystrophies, including lichen sclerosus, before careful histologic evaluation is done. Systemic etiologies such as diabetes, anxiety, Sjögren syndrome, hepatic or renal diseases, or drug reactions may exist. Cutaneous etiologies, such as candidiasis, vaginitis, and contact or atopic dermatitis, can also occur.

Topical Agents

Topical agents have been effective in treating vulvar pruritus and should be tried initially. When they are ineffective, often, it is secondary to their inability to penetrate the thickened hyperkeratotic surface. Initially, treatment for a specific disease should be instituted. For example, topical steroids should be used for psoriasis, antifungals for candidiasis, and appropriate ablative therapy for molluscum contagiosum and condylomata acuminata. Vulvar dermatoses such as lichen sclerosus, lichen simplex chronicus, lichen planus, seborrheic dermatitis, and plasma cell vulvitis can be effectively treated with highpotency topical steroids such as betamethasone. Many of these patients also present with vulvar dysesthesia (vulvar burning) and can be treated with tricyclic medications such as amitriptyline and nortriptyline.

For historic purposes, no chapter on vulvar pruritus would be complete without mentioning alcohol injection and the Mering procedure. Before treatment with amitriptyline became popular, patients with recalcitrant pruritus and vulvar dysesthesia were treated with local alcohol injection. The anogenital area was prepped and draped in a sterile manner after the induction of general or regional anesthesia. The region was then divided into 1-cm squares with a marking pen of brilliant green. Absolute alcohol, 0.2 mL, was then injected subcutaneously at the intersection of these lines (**Fig. 23.8**). Postoperatively, the patients were treated with cold packs and cool sitz baths for 1 week.

Mering Procedure

Because of the effectiveness of topical high-potency steroid creams, the Mering procedure is rarely used to treat vulvar pruritus in the United States today. It requires hospitalization and careful surgical technique (**Fig. 23.9**). The skin is shaved and thoroughly cleaned, and the incision is outlined with a marking pencil. The incision is made on the outer surface of the labium majus. It extends to the fascia of the urogenital diaphragm from the level of the clitoris to slightly beyond the fourchette and may continue inferiorly to the level of the anal orifice, depending on the extent of the pruritus. The nerves in the adjacent tissue are severed with a finger placed on each side, moving from the lateral aspect of the clitoris toward the midline, over the clitoris, where the fingers meet. The procedure interrupts branches of the ilioinguinal and genitofemoral nerves (**Fig. 23.10**). Blunt dissection extends posteriorly to the lateral side of the rectum, outside the external anal sphincter. If the perianal area is involved, blunt dissection may extend to the posterior limit of the anal orifice, where the two fingers meet behind the anus in the midline breaking up the branches of the pudendal nerve.

FIGURE 23.8 A: Marking of external genitalia into 1-cm squares in preparation for alcohol injection. **B:** Depth of penetration of 25-gauge needle into the subcutaneous tissue. (From Woodruff JD, Thompson B. Local alcohol injection in the treatment of vulvar pruritus. *Obstet Gynecol* 1972;40:18, with permission. Copyright © 1972 The American College of Obstetricians and Gynecologists.)

It is important that hemostasis be meticulously maintained. A small, flat Jackson-Pratt drain should be placed under the flap on each side. The subcutaneous tissue is approximated with absorbable sutures, and the skin is sutured with polyglycolic acid or polyglactin 910 material. The area must be packed tightly for 24 hours, and the patient should use ice packs or cool tub baths. Domeboro sitz baths (Burow solution) may help to relieve edema.

FIGURE 23.9 The Mering procedure. **A:** The incisions are made at the lateral margins of the labia majora, extending to the level of the clitoris superiorly and the anal orifice inferiorly. The depth of dissection is the deep fascia, to incise the adipose tissue and the nerves. **B:** The finger dissects the underlying tissue, breaking up the fibers of the pudendal, ilioinguinal, and genitofemoral nerves. **C:** The underlying tissues are carefully approximated to attain good hemostasis. A small drain should be inserted at the most dependent aspect of the incision to avoid the accumulation of blood in the operative sites.

VULVAR PAIN AND VULVODYNIA

Vulvar pain is another common symptom of vulvar disease. It may be produced by a wide variety of vulvar conditions, or, occasionally, primary vulvodynia without any identifiable underlying diagnosis may be encountered. The ISSVD has defined vulvodynia as “vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder.” The classification of vulvar pain is presented in [Table 23.1](#).

There are many types of vulvar conditions that cause vulvar pain, including infections (candidiasis, herpes, etc.), inflammatory conditions (contact dermatitis), neoplasia (VIN, Paget disease, etc.), and neurologic conditions (herpetic neuralgia, neuroma, etc.). A careful diagnostic evaluation, usually including a biopsy of the vulva, is indicated to identify any of these lesions so that the correct therapy can be instituted. However, despite a careful and thorough workup, some patients will have vulvar pain for which an underlying diagnosis cannot be found. These patients are thus diagnosed with vulvodynia as defined above. The syndrome may be either localized to one area of the vulva or generalized, and the pain may be present all the time (unprovoked) or only when the vulva is touched or pressed (provoked). Vulvodynia involving the vulvar vestibule has been called *vulvar vestibulitis* or *vestibulodynia*. It is a clinical syndrome consisting of the following characteristics: (a) severe pain

on vestibular touch or attempted vaginal entry, (b) tenderness to pressure localized within the vulvar vestibule, and/or (c) physical findings confined to vestibular erythema of varying degrees. This syndrome is chronic and multifactorial. Etiologies include chronic or recurrent candidiasis, HPV infections, recurrent bacterial vaginosis, trauma, chemical and surgical destructive techniques, alterations of vaginal pH, irritants (soaps, detergents, douches, deodorants), and idiopathic causes. **Figure 23.11** summarizes the evaluation and management of vulvodynia.

Medical Treatment

A careful diagnostic evaluation is essential because of the apparent multifactorial etiology of vestibulodynia. If an infectious etiology is present, it is imperative to treat it. Recombinant alpha-interferon is efficacious in treating vulvodynia with a history of condylomata acuminata or subclinical HPV. Triamcinolone acetonide 0.1% and bupivacaine can also be injected monthly. An alternative combination is methylprednisolone and lidocaine submucosal.

Chronic recurrent candidiasis is treated with prolonged oral administration of ketoconazole or fluconazole. Topical anticandidal regimens should be prescribed when oral antifungal medications are discontinued.

In addition to being treated for the infectious etiology, all patients should be started on a course of topical steroids. Horowitz treats all patients with vulvodynia with hydrocortisone acetate 1% or 2.5% with 1% pramoxine hydrochloride ointment (Pramosone) for 2 to 3 months. After 3 months of this therapy, the patients are placed on desoximetasone 0.25% ointment (Topicort). Only after failing topical steroids are the patients considered for surgical treatment. Oral amitriptyline is also an important part of the therapeutic regimen. Doses of 25 to 75 mg taken 3 hours before bedtime are prescribed. Patients with vulva dysesthesia or interstitial cystitis benefit most from medical therapy with amitriptyline. Oral gabapentin is also helpful in some patients. It should be started with a gradual dose escalation and tapered off when discontinued.

Surgical Treatment

Carbon dioxide laser ablation of the vestibular glands has not been shown to be optimal and has resulted in scarring and increased dyspareunia in some patients. In 1995, Reid and associates reported long-term results with the flashlampexcited dye laser in nonresponders to medical therapy. Those with poor responses to laser vaporization were then treated with gland resection. Overall response rates were 62% to 80%, depending on the distribution of tenderness. However, long-term follow-up has been disappointing, and this approach remains controversial.

Primary surgical therapy has produced relief of symptoms in 75% to 90% of patients. This technique was initially described by Woodruff and associates in 1981 and Friedrich in 1987 and was modified by Marinoff and Turner in 1991 to include the periurethral Skene gland openings. The outer incision extends circumferentially from the periurethral glands along Hart line to the contralateral glands. The proximal vaginal margin is just inside the hymenal ring. This horseshoe-shaped epithelium is superficially excised and sent for histologic diagnosis. In almost all cases, the histology consists of nonspecific periglandular chronic inflammation, much less impressive than might be expected based on the severe symptoms reported. As in a perineoplasty, the vaginal mucosa is

undermined and the vagina advanced to approximate edges. The wound is closed in two interrupted layers of 3-0 polyglactin 910 (Vicryl) or polyglycolic acid (Dexon) sutures (Fig. 23.12). Postoperative treatment is the same as for perineoplasty. Coitus should be avoided for 2 to 3 months after surgery.

FIGURE 23.12 The minor vestibular glands exit lateral to the hymenal ring. They are very superficial and thus seldom produce definable “nodules,” even when chronically infected.

P.457

TABLE 23.2 CDC-Recommended Treatment of Sexually Transmitted Diseases

DISEASE	PRIMARY TREATMENT	ALTERNATE TREATMENT
Herpes		
First episode	Acyclovir 400 mg PO TID × 7-10 d Famciclovir 250 mg PO TID 7-10 d Valacyclovir 1 g PO BID 7-10 d	Acyclovir 200 mg PO 5 × day × 7-10 d
Suppressive	Acyclovir 400 mg PO BID	Famciclovir 250 mg PO BID

Valacyclovir 500 mg PO daily

Valacyclovir 1 g PO daily

Episodic Acyclovir 400 mg PO TID × 5 d

Acyclovir 800 mg PO BID × 5 d

Acyclovir 800 mg PO BID × 2 d

Famciclovir 125 mg PO BID × 5 d

Famciclovir 1,000 mg PO BID × 1 d

Famciclovir 500 mg once, followed by 250 mg
BID × 2 d

Valacyclovir 500 mg PO BID × 3 d

Valacyclovir 1.0 g daily × 5 d

BID, twice a day; PO, by mouth; TID, three times a day. Available at
<http://www.cdc.gov/STD/treatment/2010/STD-Treatment-2010-RR5912.pdf>

Several of Horowitz's patients (unpublished report) had severe levator spasm secondary to anticipation of activities associated with vulvar pain. This learned response has been treated successfully with biofeedback in several patients. Glazer and colleagues were the first to report the treatment of vulvar vestibulitis syndrome with electromyographic biofeedback of pelvic floor musculature. Seventy-eight percent (22 of 28) resumed coitus by the end of the treatment period.

VULVAR INFECTIONS

Although infections involving the vulva are treated with antibiotics rather than surgery, their appearance may resemble CIS or even invasive cancer of the vulva. An accurate diagnosis may require cultures, viral testing, or even biopsy. Appropriate therapy is based on a correct diagnosis. Treatment of vulvitis secondary to an infectious process varies depending on the infection present. Viral infections such as HPV are strongly associated with intraepithelial neoplasia and carcinoma. These lesions are discussed later in this chapter.

TABLE 23.3 Types of Genital Herpes Simplex Infection

- Primary infection: Initial infection with either HSV-1 or HSV-2 without evidence of prior exposure to either (i.e., antibodies)
- Nonprimary first episode: Initial clinical episode with HSV-1 or HSV-2 in patient with prior exposure to the other viral serotypes
- Recurrent infection: Reactivation of latent virus

HSV, herpes simplex virus.

From Sweet RL. Sexually transmitted diseases. In: Bieber EJ, Sanfilippo JS, Horowitz IR, eds. *Clinical*

<http://obgynebooks.com>

Molluscum contagiosum, a member of the pox family, requires accurate identification and resection of the umbilicated lesions with a dermal curette. These lesions are usually circular and umbilicated. *Molluscum contagiosum* in an adult may be an indicator of underlying human immunodeficiency virus (HIV) infection. Therefore, the patient's background should be appropriately discussed.

Herpes genitalis is caused by the herpes simplex virus (HSV). Between 500,000 and 1 million new cases are diagnosed annually in the United States, a ninefold increase between 1966 and 1997. More than 25% of women are seropositive for HSV type 2. The patients with primary herpes present with high fevers, malaise, myalgias, painful vulvovaginal lesions, and inguinal adenopathy. The ulcers are small but coalesce into larger ulcers. The primary treatment of these sexually transmitted diseases is presented in [Table 23.2](#). The three categories of HSV infection are outlined in [Table 23.3](#).

Granuloma inguinale (donovanosis) is caused by *Klebsiella granulomatis* and presents as painless papular nodules or ulcerations. These lesions can occur in the genital, perianal, oral, and inguinal regions. Fewer than 100 new cases are reported annually in the United States. When large and destructive, *Granuloma inguinale* can simulate malignancy. Cytology and biopsy accompanied with Warthin Starry stains may establish the true diagnosis. The condition should be considered in all cases in which clinically malignant lesions are repetitively negative by biopsies. No U.S. Food and Drug Administration (FDA)-approved polymerase chain reaction (PCR) tests are available to date. The 2010 Centers for Disease Control and Prevention (CDC)-recommended treatment regimen is doxycycline 100 mg orally twice daily for 3 weeks or until lesions have completely healed. Alternative treatment regimens include the following:

Azithromycin 1 g orally once per week for at least 3 weeks and until all lesions have completely healed

OR

P.458

Ciprofloxacin 750 mg orally twice a day for at least 3 weeks and until all lesions have completely healed

OR

Erythromycin base 500 mg orally four times a day for at least 3 weeks and until all lesions have completely healed

OR

Trimethoprim-sulfamethoxazole one double-strength (160/800 mg) tablet orally twice a day for at least 3 weeks and until all lesions have completely healed

Lymphogranuloma venereum (LGV) is caused by *Chlamydia trachomatis* types L1, L2, and L3.

Lymphogranuloma venereum presents with papular or vesicular lesions on the vulva that can also ulcerate. Lesions are usually painless and heal spontaneously. As with herpes, these patients present with headaches, myalgias, arthralgias, and inguinal adenopathy. The 2010 CDC treatment guidelines recommend doxycycline 100 mg orally twice daily for 21 days. Alternatively, the patient can be treated with erythromycin base 500 mg orally four times daily for 21 days.

Chancroid is caused by *Haemophilus ducreyi*. The chancroid lesions present as multiple papules that become pustular and ulcerate. These lesions are very tender and have a ragged edge sitting on an erythematous base (halo). More than 50% of these patients present with large inguinal lymph nodes called buboes. These lymph nodes may become suppurative. Lymph nodes and soft tissue in the inguinal area can also be involved

secondary to LGV and granuloma inguinale. The 2010 CDC treatment guidelines include the following recommended regimens:

Azithromycin 1 g orally in a single dose

OR

Ceftriaxone 250 mg intramuscularly in a single dose

OR

Ciprofloxacin 500 mg orally twice a day for 3 days (ciprofloxacin is contraindicated for pregnant and lactating women)

OR

Erythromycin base 500 mg orally three times a day for 7 days

Syphilis is caused by the spirochete *Treponema pallidum*. The primary lesions usually have a painless, coin-shaped ulcer with a raised border and an indurated base. They can present 10 to 90 days after exposure and resolve in 2 to 6 weeks. Untreated syphilis results in a secondary phase characterized by skin rash, generalized adenopathy, and moist, papular anogenital lesions called condyloma latum. This is followed by a latent phase leading to tertiary syphilis. The latter can involve the cardiovascular, musculoskeletal, or central nervous system. *Treponema pallidum* can also cross the placenta and result in syphilis in the newborn infant. More than one sexually transmitted disease can be seen in the same patient and can combine with acquired immunodeficiency syndrome. See [Table 23.4](#) for CDC 2010 guidelines.

Necrotizing Fasciitis

Necrotizing fasciitis of the vulva is a very serious destructive infection characterized by rapid progression and a high mortality rate ranging from 12% to 60%. It represents a surgical emergency. Multiple bacterial pathogens are implicated, including staphylococci, *A. streptococci*, *Escherichia coli*, *Peptostreptococcus*, *Prevotella* and *Porphyromonas* spp., *Bacteroides fragilis*, and *Clostridium* spp. Associated vascular thrombosis leads to skin and subcutaneous tissue necrosis. Fisher criteria have been emphasized in the diagnosis and help to exclude clostridial infections. Brook and Frazier isolated mixed aerobic-anaerobic flora in 68% of specimens, 10% facultative or aerobic bacteria, and 22% exclusively anaerobic organisms. Diabetes mellitus is the most common predisposing condition, although other factors, such as radiation, have been identified. The most common clinical findings are necrosis, fever tachycardia, leukocytes, edema, and foul odor.

Devascularization of the skin proceeds with sparing of underlying muscle and bone. Early skin changes include hemorrhagic bullous formation. Typically, the underlying fascial necrosis exceeds the boundaries of visible skin involvement. Inflammatory alterations and edema usually are present. Most patients present with fever, tachycardia, and signs of systemic toxic reaction. Crepitus is present in 37% to 50% of patients. Prompt diagnosis is important because this disorder progresses rapidly.

Treatment combines expeditious surgery, antibiotics, and maintenance of circulation and tissue oxygenation. Surgical treatment should include aggressive excision of nonviable skin, subcutaneous tissue, and avascular fascia. Extensive debridement down to and including the fascia must be performed until viable, well-vascularized tissue margins are identified. Wounds are packed, not primarily closed. High-dose broad-spectrum antibiotic coverage is administered, and associated medical conditions such as diabetes are managed aggressively. These patients are frequently very sick, and renal failure and acute adult respiratory distress syndrome commonly complicate their management. The operation for additional debridement or subsequent skin grafting is also common. *Fournier gangrene* presents in a manner similar to that of necrotizing fasciitis and nonclostridial myonecrosis. Infections develop in the labia and spread to the perineum, buttocks, and abdominal wall.

Treatment consists of a combination of surgery, broad-spectrum antibiotics, and hyperbaric oxygen ([Table 23.5](#)).

Hidradenitis Suppurativa

An infectious process commonly demanding extensive local surgery is hidradenitis suppurativa. Hidradenitis suppurativa was initially described by Aristide Verneuil in 1854. This pustular disease begins as an infection in the apocrine sweat glands. The early manifestations often are cyclic, because the secretory activity of the apocrine glands corresponds to the progestational phase of the menstrual cycle. Consequently, in the early stages of the disease or in the chronic pruritic phase (Fox-Fordyce disease), the use of hormonal therapy, such as oral contraceptives, may help to modify the secretory activity of the glands. Once the disease extensively involves the deeper tissues, local and systemic agents usually are ineffective. Isotretinoin (Accutane) has been effective in some cases, but care must be taken in prescribing this agent because it is a powerful teratogen. Antiandrogens such as cyproterone acetate have been successful in some patients. Dapsone and anti-TNF alpha drugs have also proven efficacious. Culturing exudates and treating with appropriate antibiotics may provide palliation and further delay surgery. The pustules often infect the entire area, so that pressure at one point may produce exudation of purulent material from sinus tracts ([Fig. 23.13A](#)). Multiple bacteria have been isolated from

P.459

patients with hidradenitis suppurativa ([Table 23.6](#)). Because the entire anogenital area is honeycombed by the underlying infection, simple incision into a few of the pustules is useless. Extensive debridement must be performed to allow healing from the base.

TABLE 23.4 CDC-Recommended Treatment of Syphilis in Adults, 2010

Primary and secondary syphilis

Recommended regimen

Benzathine penicillin G, 2.4 million units IM in a single dose

Penicillin allergy (nonpregnant)

Doxycycline 100 mg orally twice a day for 14 d

OR

Tetracycline 500 mg orally four times a day for 14 d

Latent syphilis

Early latent syphilis (<1 y)—recommended regimens

Benzathine penicillin G, 2.4 million units IM in a single dose

Late latent syphilis (>1 y)—recommended regimens

Benzathine penicillin G, 7.2 million units total, administered as three doses of 2.4 million units IM each, at 1-week intervals

Penicillin allergy (nonpregnant)

Doxycycline 100 mg orally twice a day

OR

Tetracycline 500 mg orally four times a day

Both drugs administered for 14 d if duration of infection known to have been <1 y; otherwise, administer for 28 d

Tertiary syphilis

Recommended regimen

Benzathine penicillin G, 7.2 million units total, administered as three doses of 2.4 million units IM, at 1-week intervals

Penicillin allergy (nonpregnant)—Infectious Disease Consultation

Doxycycline 100 mg orally twice a day

Neurosyphilis

Recommended regimen

Aqueous crystalline penicillin G 18 million to 24 million units per day, administered in 3 million to 4 million units IV every 4 hours, for 10-14 d

Alternative regimen (if compliance assured)

Procaine penicillin 2.4 million units IM daily

PLUS

Probenecid 500 mg orally four times a day, both for 10-14 d

Penicillin allergy (nonpregnant)

Ceftriaxone 2 g daily either IM or IV for 10-14 d (Consider Infectious Disease Consultation)

Syphilis during pregnancy

Recommended regimens

Penicillin regimen appropriate for the pregnant woman's stage of syphilis. Some experts recommend additional therapy (e.g., a second dose of benzathine penicillin 2.4 million units IM) 1 wk after the initial dose, particularly for women in the third trimester and for those who have secondary syphilis during pregnancy.

Penicillin allergy—Infectious Disease Consultation

IM, intramuscularly; IV, intravenously. Available at <http://www.cdc.gov/STD/treatment/2010/STD-Treatment-2010-RR5912.pdf>

The incision extends into the underlying fat, and the involved skin is removed in segments, leaving bridges of normal skin between the excised pustules. Loose approximation of the skin edges can be performed with polyglycolic acid or polyglactin 910 suture material; more commonly, the entire area is left open and treated locally to promote granulation (**Fig. 23.13B**). Results of therapy are rewarding in most cases, and skin grafting usually is unnecessary. The patient must be treated with antibiotics based on cultures obtained from the draining sinuses both before and after surgery. Radical vulvectomy is occasionally indicated for extensive disease of the vulvar, inguinal, and perineal areas, but generally, simple vulvectomy is usually effective. It is imperative that a thorough histologic evaluation be performed by the pathologist. Squamous cell carcinoma has been reported to arise in diffuse perineal hidradenitis suppurativa. Myocutaneous flaps or split-thickness skin grafts can be placed in a two-stage procedure. This will allow the infections to clear before the raw vulvar surface is grafted. Wet to dry dressings are used 48 hours to 2 weeks before grafting.

Harrison and colleagues have reported a 37% recurrence rate in patients with inguinal or perineal lesions. In their series of 106 patients, Rompel and Petres experienced 17.8% complication rate with surgery and only a 2.5% recurrence in the operative field.

TABLE 23.5 Antibiotic Regimens for Treatment of NSTI

ANTIBIOTIC	BACTERIAL COVERAGE AND DOSE
Piperacillin/tazobactam	Gram-negative and gram-positive facultative 3.375–4.5 g, q6 h
Ticarcillin/clavulanic acid	Facultative and obligate anaerobes 3.1 g, q6 h
Ampicillin/sulbactam	3 g, q6 h
Gentamicin	Effective against gram-negative facultative anaerobes, acts synergistically with penicillin against enterococci 5 mg/kg of body weight q24 h, or 2 mg/kg of body weight as a loading dose followed by 1.5 mg/kg of body weight q8 h
Clindamycin	Effective against obligate anaerobes Effective against 80% of <i>Streptococcus agalactiae</i> and MRSA 900 mg q8 h

Metronidazole

Effective against obligate anaerobes 500 mg q8 h

CROHN DISEASE

Crohn disease, a chronic granulomatous inflammatory disease of the bowel, affects the vulva and perianal area in about 25% to 30% of the cases in which there is classic intestinal involvement. The draining sinuses often communicate with the vagina or the rectum, thus resulting in the formation of fistulous tracts (**Fig. 23.14A**). On rare occasions, the vulva may be primarily involved, even though the small and large bowel apparently are not affected or affected subsequently. Crohn disease can also present as unilateral labial hypertrophy.

P.461

FIGURE 23.14 Crohn disease. **A:** Vulva showing multiple fistulae and fibrosis causing tissue contraction and distortion. **B:** Microscopic section to show noncaseating granuloma. No microorganisms were seen by special stains.

Before any surgical therapy is begun, the diagnosis can be confirmed by studying the bowel or by obtaining a biopsy specimen of the affected tissues in the perineum. The presence of noncaseating granuloma without

demonstrable organisms is characteristic of Crohn disease (**Fig. 23.14B**). Further deterioration of the tissue may result from attempts to excise a draining sinus produced by Crohn disease. Rectal incontinence can result from destruction of the anal sphincter or the development of a rectovaginal fistula. Approximately 9% of rectovaginal fistulas are secondary to Crohn disease.

Immunocytochemistry of Crohn lesions has documented *E. coli* and streptococcal antigens. In addition to short-term metronidazole, patients have responded to prolonged treatment (3 to 6 months) with broad-spectrum antibiotics such as ciprofloxacin. Methotrexate therapy is effective in reducing the requirement for prednisone in patients with chronically active Crohn disease. Other drugs used in the medical management of Crohn disease include 5-aminosalicylic acid, cyclosporine, azathioprine, 6-mercaptopurine, mesalamine, and infliximab (Remicade).

In addition to pharmacotherapy, a submucosal anal pullthrough procedure may bring relief. Layered surgical repair of a fistula caused by Crohn disease usually is unsuccessful, particularly without appropriate medical management. However, after appropriate medical therapy, surgical excision of the tract is usually effective (see **Chapter 39**). Results are difficult to predict because multiple areas of the terminal colon and small intestine may be affected, and any affected area may involve the vagina or perineum. Medical therapy should always be given during this type of surgical procedure and should be continued postoperatively for at least 2 months.

TRAUMA

Major trauma to the vulva most often occurs when young girls experience injuries as a result of sledding or bicycling accidents. Hematomas and occasionally lacerations can develop when the vaginal area forcefully comes in contact with the crossbar of a bicycle (as during a fall from a bicycle seat) or when the girl is thrown from a sled against an obstacle such as a tree or fence. Trauma also can result from sexual assault, and the gynecologist must be sensitive to this possibility even when the initial history suggests another etiology. Women or girls who are victims of sexual assault should receive testing for pregnancy and sexually transmitted diseases. These patients should be referred to counseling and encouraged to report the abuse to state officials. All minors should be reported to the state by the examining physician.

Most traumatic injuries do not require surgical attention. An examination under anesthesia may be useful to adequately evaluate the extent of the injury. If surgical repair is not required, patients should be treated conservatively with activity restriction and with the immediate and continued use of Burow solution (aluminum sulfate, calcium acetate; available as Domeboro tablets or powder) added to the sitz bath to reduce edema. Antibiotics may be used as prophylaxis against superinfection in damaged tissues. If a hematoma increases in size and extends well into the perineum or over the lower abdominal wall, incising the vulvar skin, evacuating the hematoma, and ligating the bleeding vessels may reduce the period of convalescence. An alternative would be to use selective arterial embolization. Goldman and coworkers reported 30% of patients with genital trauma not associated with parturition have a urologic injury. When a hematoma produces urethral obstruction, evacuation may reduce the time an indwelling urethral catheter is needed. If the hematoma is not expanding, it should be followed conservatively. Most vulvar hematomas resolve spontaneously; surgical intervention, on the other hand, can result in significant morbidity, including infection. Frequently, a distinct bleeding site is not identified. If, however, the clot becomes secondarily infected, it requires prompt

P.462

evacuation and drainage. Lacerations into the rectum or urethra should be repaired expeditiously.

CYSTS OF THE VULVA

Bartholin Duct Cysts

Obstruction of the Bartholin duct, usually near the orifice, is common. Although such obstructions can result from

gonococcal infection, other infections and trauma more commonly explain the occlusion. During a mediolateral episiotomy or a posterior colporrhaphy, for example, sutures can easily injure or even ligate the duct. The lining of the main cyst is transitional epithelium. The mucus-secreting glands are not affected by the obstruction but may be distorted by the infectious process. During the acute infection, which may precede the actual cyst formation, an abscess often develops with symptoms of tenderness, swelling, and erythema. Depending on the cause, secretion from the cyst may be mucoid or cloudy.

Incision and drainage bring almost immediate relief to the patient and can be accomplished under local anesthesia. A small wick can be left in the cavity to maintain adequate drainage. A small incision (2 cm) is made in the cyst wall in the area of the normal duct orifice, and a culture is obtained for *Neisseria gonorrhoeae*, *Chlamydia*, and aerobic and anaerobic bacteria. A Word catheter ([Fig. 23.15](#)) is inserted and the catheter bulb inflated with 2 to 3 mL of saline. If the catheter remains in place for 3 to 4 weeks, the tract becomes epithelialized, and the catheter can be removed. Broad-spectrum antibiotics are given before surgery.

Marsupialization seldom can be accomplished during the acute stage, but the procedure is useful for chronic or recurrent abscesses. Injection of an antibiotic into the abscess has been tried as treatment for the acute infection but has proved to be less effective than systemic antibiotic therapy.

Most Bartholin duct cysts are uninfected and asymptomatic. They are usually found during routine pelvic examinations. Patients may even be unaware of large cysts. When symptoms do occur, most patients report discomfort during coitus or pain while sitting or walking. These require marsupialization only if they are symptomatic. [Table 23.7](#) differentiates between a Bartholin cyst and abscess.

TABLE 23.7 Differentiation between Bartholin Abscess and Bartholin Cyst

BARTHOLIN ABSCESS	BARTHOLIN CYST
Enlarged gland	Enlarged gland
Erythema present in skin overlying and surrounding the gland	Erythema absent
Skin overlying the gland typically warm to the touch	No increase in temperature
Fever present, especially with tachycardia	Fever absent
Advancing cellulitis can be present.	Cellulitis absent
WBC count elevated	WBC count not elevated
Bacteria and WBCs are present in fluid (pus) contained within gland.	No bacteria or WBCs present in (serous) fluid contained within the cyst

WBC, white blood cell.

FIGURE 23.15 The Word catheter (*left*) is inserted into the Bartholin duct cyst through a vaginal incision. The bulb is inflated with saline solution (*right*), and the end of the catheter is placed in the vagina.

Technique of Marsupialization

Drainage of a Bartholin duct cyst by marsupialization is not as technically involved as excision and eliminates many complications. The procedure makes it possible to avoid excising the gland with the cyst and to preserve the secretory function of the gland for lubrication.

Marsupialization has had limited use since the Word catheter was introduced. The catheter accomplishes the same result as surgery with minimal or no trauma. The nipple of the catheter can be inserted into the vagina. There is essentially no

P.463

discomfort with the procedure, and coitus can be resumed normally. Because this procedure can be performed with local analgesia in the office setting and yields results comparable to those of marsupialization, its use should be encouraged.

FIGURE 23.16 A: Incision for marsupialization. **B:** Marsupialization. (From Tancer ML, Rosenberg M, Fernandez D. Cysts of the vulvovaginal [Bartholin's] gland. *Obstet Gynecol* 1956;7:609. Copyright © 1956, The American College of Obstetricians and Gynecologists.)

The marsupialization can be performed under local, regional, or general anesthesia. A wedged-shaped, vertical incision is made in the vaginal mucosa over the center of the cyst, just outside the hymenal ring, with a no. 15 blade (**Fig. 23.16A**). The incision should be as wide as possible to enhance the postoperative patency of the stoma. After the cyst wall is opened and the cyst is drained of its contents, the lining of the cyst is everted and approximated to the vaginal mucosa with interrupted sutures of 3-0 delayed absorbable material (**Fig. 23.16B**). Drains and packs are not necessary, but the patient's postoperative care should include daily sitz baths beginning on the third or fourth postoperative day.

As a result of closure and secondary fibrosis of the orifice after marsupialization, 10% to 15% of cysts recur. Abscess formation is another occasional sequela of marsupialization.

Technique of Excision

It is seldom necessary to excise a Bartholin duct cyst, particularly in the younger patient, unless there is induration at the base. The latter may signify deep-seated infection that is inaccessible by marsupialization. Conversely, this may represent neoplasm in the base of the gland, an issue of greater concern in the patient older than 40 years of age or in patients with coexisting Paget disease. An elliptical incision in the vaginal mucosa is made as close as possible to the site of the gland orifice with a no. 15 blade (**Fig. 23.17**). An incision on the mucosal side is preferable because an incision through the vulvar skin makes it difficult to dissect the cyst wall from the skin without incising or tearing the skin. If an opening is accidentally made through the skin, a permanent fenestration may result. Difficulty is not usually encountered during dissection of the cyst from the inner surface of the vulvar skin when the incision is made on the mucosal side. Excising a small ellipse of mucosa with the cyst allows the surgeon to have a site for traction and reduces the risk of rupturing the cyst. Because cyst formation usually is preceded by inflammation, the wall is adherent and cannot be easily enucleated with blunt dissection only. The blunt-pointed Mayo scissors serve admirably for sharp dissection of

the cyst from its bed (**Fig. 23.17C**). The cyst can be mobilized further with the handle of the scalpel. A large cyst may develop posteriorly and may approximate the rectum. The rectal wall can easily be distinguished from the cyst by inserting a finger into the rectum during dissection.

Complete removal of the gland tissue adherent to the cyst wall is essential because residual glandular tissue may result in the formation of a tender nodule or recurrent cyst. If the margins of the cyst have become obscured, the cyst can be opened and the wall dissected from the surrounding tissue.

Directly beneath the Bartholin duct is the vestibular bulb, which is composed of anastomosing venous channels. In the dissection of the gland from the vestibular bulb, additional care must be taken to avoid troublesome bleeding. To ensure permanent hemostasis, the entire cavity must be obliterated by approximating the walls with fine delayed absorbable suture material after excision of the cyst.

Approximation of the vaginal mucosa is best accomplished with a continuous or interrupted mucosal suture of 3-0 delayed absorbable material. Persistent bleeding from the labia or vestibular bulb may cause a postoperative hematoma of the labia, which can progress to include the mons pubis and the abdominal wall beneath the Scarpa fascia. Bed rest, ice packs, and a pressure dressing on the vulva are the methods of treatment for a hematoma; attempts to ligate the venous bleeding points are futile. Although the blood usually reabsorbs with time, sometimes, evacuation and drainage are necessary. If the bleeding deep in the bed of the gland seems uncontrollable, deep mattress sutures can be placed from the skin through the bleeding bed into the vagina. The sutures should not be tied too tightly because necrosis may result, with fenestration of the vaginal outlet. A small drain should be stitched into the bed with fine absorbable sutures to avoid the accumulation of blood and serous fluid.

FIGURE 23.17 Excision of a Bartholin gland cyst. **A:** An incision is made in the mucosa over the cyst. **B:** Dissection is begun, using the handle of the scalpel. **C:** Dissection has been continued by sharp and blunt dissection. **D:** Dissection is almost complete. **E:** Intact cyst after removal.

Hydrocele or Cyst of the Canal of Nuck

Hydrocele is an uncommon vulvar cyst. The cyst appears as a dilatation in the labium majus and adjacent labium minus and must be differentiated from a Bartholin duct cyst. **Figure 23.18** shows a hydrocele. The patient underwent two procedures for drainage of a Bartholin duct cyst, but the mass recurred after each procedure.

FIGURE 23.18 A hydrocele is caused by the extension of a peritoneal sac with the round ligament from the inguinal canal into the vulva.

A hydrocele is a cystic, fluid-filled hernia of the peritoneum that accompanies the round ligament and extends from the inguinal canal into the vulva. When this sac extends into the inguinal canal, it is known as a cyst of the canal of Nuck. On rare occasions, a loop of intestine may follow the pathway of the round ligament, forming a hernia in the vulva. When a hydrocele is treated as a Bartholin duct cyst by incision and drainage, peritoneal fluid may reaccumulate above the drainage site, and the hydrocele recurs.

Surgical treatment for a hydrocele begins with an incision into the cystic mass. The external inguinal ring is identified by inserting a finger in the cyst anteriorly to the inguinal canal. The peritoneal lining is excised from the cavity, and the external inguinal ring is closed along with the subjacent tissue in the anterior vulva. If a hernia is present, inguinal herniorrhaphy should be performed along with excision of the peritoneal covering of the round ligament.

SOLID TUMORS OF THE VULVA

The incidence of solid, benign tumors in the vulva is low, but a variety of benign tumors, including fibromas, fibromyomas, lipomas, hemangiomas, neurofibromas, and endometriomas, have been reported. These tumors can originate from any of the three germinal layers that constitute the anogenital area. One occasionally sees a solid vulvar tumor composed of benign breast tissue or a benign fibroadenoma (**Fig. 23.19**). Lactational changes can be seen in this tissue. Such an event is

P.465

accounted for by the embryologic milk line caudally ending in the vulvar area. Degenerative changes and necrosis often occur in the larger tumors and should not be confused with malignancy. Lipomas often are mistaken for cystic lesions because of their consistency, whereas hernias and hydroceles of the canal of Nuck must be differentiated from neoplastic growths because they require different surgical approaches.

FIGURE 23.19 Fibroadenoma of the vulva arising from the embryonic breast tissue, the caudal end of the milk line.

Most solid tumors should be excised, both to ascertain the diagnosis and to relieve the patient's discomfort. Small, pedunculated tumors can be removed by simple ligation of the stalk; the deeply situated lesions require more extensive local dissection. All nevi showing hemorrhage, sudden enlargement, and pruritus should be suspected to be melanomas and excised widely.

The boundaries of such mesodermal tumors are difficult to delineate, but most of the tumors are benign. Even recurrence does not signify malignant alteration; a fibromyoma may recur if incompletely excised, even when the original specimen had no histologic evidence of malignancy. Although a sarcoma rarely arises in the vulva, histologic studies must be carefully made because degenerating atypical multinucleated cells of a benign or reactive tissue can be mistakenly diagnosed as malignant.

As in any vulvar surgery, hemostasis is important because compression is difficult to obtain in these soft tissues. Extravasation of blood can dissect the fascial planes well out to the vulva, thigh, flanks, and abdominal wall. Closed suction drains should be used in the wounds if hemostasis is not complete.

Condyloma Acuminatum

Condyloma acuminatum is one morphologic manifestation of HPV infection in the lower genital tract. These polypoid lesions have an incubation period ranging from several weeks to 8 months; however, clinical infection usually is apparent 6 to 8 weeks after exposure. Transmission of the virus is attributed to coitus, and the process is efficient, because most sexual partners are affected subclinically if not clinically. The disease process continues increasing in prevalence. Interestingly, clinically apparent condyloma constitutes only a fraction of HPV infections. Most are undetected in asymptomatic patients with no clinical findings.

Numerous HPV subtypes have been identified. Human papillomavirus subtypes 6, 11, 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, and 69 account for most genital tract infections. Careful histopathologic and virologic study of vulvar lesions has demonstrated an association of HPV 6 and HPV 11 with approximately 90% of exophytic vulvar condylomata as well as flat cervical condylomas and some low-grade cervical dysplasias. The quadrivalent vaccine provides protection against HPV subtypes 6, 11, 16, and 18. It is not effective for the treatment of already existing condyloma or HPV infections. This vaccine is further discussed in [Chapter 46](#).

Condylomata acuminata that manifest on the vulva are frequently associated with cervical, vaginal, and anal

HPV infection. Careful clinical evaluation mandates vaginal/cervical cytology and colposcopy in patients who present with vulvar warts. This is appropriate not only to exclude cervical and vaginal dysplasia but also to define the extent of condylomatous involvement and permit appropriate tailoring of regional therapy.

Condylomata acuminata are small and usually multifocal lesions. They may be accompanied by pruritic discomfort or irritation. Warts initially may be reddish brown because of parakeratosis; however, with time and exposure to local trauma, they become gray or white. The latter appears to be associated with hyperkeratosis and the generalized keratin disturbance associated with viral infection (**Fig. 23.20**). Unless they are traumatized, bleeding is not a typical feature. In pregnancy, however, because of marked vascular alterations, condyloma of the vagina and perineum can be a source of abundant bleeding if laceration occurs. Massive vulvar and perianal condylomata may occur in certain circumstances, preventing identification of the introitus and anal orifice; conditions that foster this growth potential include immunosuppression and, less frequently, pregnancy (**Fig. 23.21**). Those lesions that were previously called *giant condyloma* are now regarded as *verrucous carcinoma*. In the spectrum of condylomatous growths, the dividing line between condyloma and verrucous carcinoma is indistinct because of the structural benignancy of both.

Various treatment approaches are available and are characterized by their inability to eliminate the offending agent: the virus. Interferon offers a nonspecific antiviral therapy. Flulike effects should be anticipated for at least several weeks. Efficacy has been demonstrated with this technique, although treatment is cumbersome, can be costly, and remains investigational. Its primary role has not been defined.

Topical Therapy

At the present time, only a variety of ablative approaches are available for the management of condyloma. These should be individualized with consideration of prior treatment, volume and location of disease, the presence or absence of associated dysplasia, and other idiosyncratic patient factors. The most common approach to vulvar condylomata is the local application of 25% podophyllum resin, often prepared in benzoin. This method, although reasonably well tolerated in the office setting, often requires numerous applications. Burning discomfort ensues after sustained contact, which is necessary for efficacy. Most recommend that the agent be left in place for 6 hours before tub baths, so compliance may be problematic. Podophyllum appears to be more effective on exophytic, rather than flat, condylomata. Use is restricted to the vulva in nonpregnant patients; vaginal application may lead to undesirable absorption and neurotoxicity. An alternative is halogenated acetic acid, either bichloroacetic or trichloroacetic acid (TCA). Our preference is 90% TCA. This agent quickly interacts with cellular proteins, inducing a coagulative effect, and rapidly turns lesions a brilliant white. Advantages include its ability to sustain a prompt chemical effect on the condyloma, its availability for intravaginal use and use during pregnancy, and the fact that it can be rapidly neutralized with sodium bicarbonate, which may be dissolved in water and applied as a cooling paste. The patient may apply the following to treat external vulvar warts: Podofilox 0.5% solution or gel, Imiquimod 5% cream, and sinecatechins 15% ointment.

FIGURE 23.20 A: Condylomata acuminata, gross. Condylomata acuminata involving labia majora and minora. Note exophytic quality and lack of pigmentation. **B:** Condylomata acuminata, microscopic. Epidermal hyperplasia featuring acanthosis and elongated, distorted rete pegs is evident. Keratin disturbances are present.

Excision or Ablation

Surgical excision, electrosurgical, destruction, and laser ablation are reserved for certain patients.

Criteria for selection may include the following:

- Extensive volume of condylomata exceeding what may be resolved with chemical agents
- Multicentric HPV infections, particularly with involvement of the vagina, urethra, or anus
- Failure of concerted office therapy with topical chemical agents
- Additional presence of significant intraepithelial neoplasia
- Immunocompromised state in some hosts

FIGURE 23.21 Massive condylomata acuminata now considered as verrucous carcinoma. Note abundant exophytic lesions producing confluent, cauliflower-like growth. Lesion is present on perineum and totally obscures anal orifice. Patient is 23 years old and is maintained on prednisone because of neurosarcoidosis.

One should certainly use biopsy liberally to evaluate presumed condylomata that are refractory to topical treatment or that have an atypical appearance. This helps prevent sustained, ineffective chemical treatment of high-grade VIN, often presenting as a flat and pigmented verrucous lesion in the younger patient, and helps exclude a frank cancer with warty features. Large, sessile condylomata or those that grow rapidly, bleed abnormally, or become necrotic or invasive should arouse the suspicion of malignancy.

Cryotherapy has been used on the vulva to eradicate warts. The freezing induces localized tissue necrosis. Although healing usually is satisfactory, and numbing effects induce analgesia, application is limited by delivery systems and probe-tip sizes. Larger condylomatous masses are more difficult to treat, as are vaginal lesions. Depth of apparent tissue destruction can be difficult to assess.

Electrocautery with a loop has been used effectively, particularly with massive lesions. Analgesic needs are definitely a factor in this approach. Smaller lesions may be fulgurated. Buildup of charred tissue can be removed by abrasion to identify residual warty tissue. The precision and depth of tissue injury can be problematic.

Colposcopically directed laser ablation performed by trained personnel in appropriately selected cases may afford effective treatment. Condylomatous lesions may be vaporized; starting at the center of the lesion causes the wart to collapse inward toward the beam. The level of the adjacent normal skin should be selected as a landmark. In treating condylomata, there is no need for deep laser vaporization into the dermis, exceeding the so-called first laser surgical plane. Issues of appropriate power density may be debated; however, the inexperienced

P.467

laser surgeon should use lower-power densities (larger spot size or lower laser output) to protect against unnecessarily deep laser injury. In experienced hands, higher laser output may be feasible, which speeds the procedure. Power densities of 500 to 800 W/cm² normally are used for vaporization. Lower-power densities are associated with undesirable thermal injury to adjacent tissues. Sites of laser vaporization should be wiped with

moistened gauze sponges to remove carbon and thermally coagulated tissue and to permit accurate assessment of depth and remaining disease. Large lesions can be dealt with by laser excision followed by vaporization at the base (see [Chapter 15](#)). Clinicians are advised to use protective eyewear during vaporization to prevent possible conjunctival condyloma.

Brush laser vaporization of the normal epithelium surrounding warty lesions is commonly done to destroy subclinical HPV and reduce the risk of clinical recurrence. This technique uses lower-power densities (200 to 300 W/cm²) to superficially denude 1 to 2 cm of adjacent epidermis. The rationale for this approach is the presence of HPV in tissue proximal to the condyloma, as demonstrated by Ferenczy and colleagues. Brush vaporization and laser treatment of so-called subclinical HPV infection that may be appreciated with the colposcope have been proposed to lessen the viral reservoir and reduce recurrence rates.

Even with vaporization of grossly normal tissue surrounding the visible lesions, recurrences must be anticipated in 25% to 50% of patients with extensive disease treated with the laser, particularly if the patient is immunocompromised. These patients require further treatment with either laser or chemical approaches, such as 5-FU topically. If disease is minimal, they can be observed.

Patients subjected to extensive laser treatment require considerable local care while healing proceeds. Cool tub or sitz baths with Burow solution followed by the application of silver sulfadiazine (Silvadene) cream and 5% lidocaine (Xylocaine) ointment often afford relief and protect against bacterial superinfection. Narcotics for pain management are appropriate short-term drugs. Prophylactic systemic antibiotics do not appear to be indicated. Weekly office follow-up is advised for 2 to 3 weeks to assess tissue healing, prevent undesirable areas of tissue agglutination, and allow potential early identification of recurrences, which can be managed with chemical ablation. Patients should be followed up carefully for several months after treatment to monitor for recurrences.

FIGURE 23.22 A: Hidradenoma of the vulva. **B:** Low-power magnification section of hidradenoma of the vulva. (A: From Novak E, Woodruff JD. *Obstetric and gynecologic pathology*. 7th ed. Philadelphia, PA: WB Saunders, 1974. Copyright © 1974 Elsevier.)

The Cavitron ultrasonic surgical aspirator (CUSA) has also been efficacious in treating condyloma. Tissue cell damage is 25 to 30 mm, which is similar to that caused by a cold scalpel. This contrasts with electrocautery at 75

to 100 mm. The tip vibrates at 23,000 cycles per second. Tissue is fragmented and aspirated, providing a specimen for histologic evaluation. Regardless of the selected approach to therapy, all patients should be advised to have their partners examined to lessen the risk of reexposure to lesions with a large viral burden. This theoretically helps diminish treatment failures. Patients with HIV or other types of immunosuppression need to be more closely followed up.

Hidradenoma (Sweat Gland Tumor) of the Vulva

A rare benign tumor of the vulva, hidradenoma, was first described by Schickele in 1902. The tumor is characterized by its intricate papillary adenomatous pattern, which may be readily mistaken for cancer.

Clinically, a hidradenoma is small, rarely more than 1 cm in diameter (**Fig. 23.22A**). Its consistency can range from firm to as soft as a sebaceous cyst, with which it is often confused. Most of these lesions are found in the interlabial folds, in the labia majora, or in the perineum. Because these tumors are apocrine in origin, the labia minora location is unusual. The occasional occurrence of reddish brown pulpy material on the surface results when the tumor is evulsed through the duct of the sweat gland.

These lesions have been carefully studied in numerous laboratories, and the complex microscopic patterns have been repeatedly stressed (**Fig. 23.22B**). The superficial papillary adenomatous pattern appears aggressive, but careful inspection shows that the glandular structures are lined by a single layer of well-organized cuboidal cells. In some parts of the tumor, the pink-staining secretory elements can be identified superficial to the basal layer. Beneath the epithelium is an indefinite layer of flattened myoepithelial cells. When the clear cell variant of the

P.468

myoepithelium proliferates, an ominous picture is created, yet this clear cell hidradenoma also behaves in a benign manner. Although hidradenocarcinoma occasionally does occur, a finding of distinct adenocarcinoma in the vulva should initiate a search to rule out a metastatic lesion from another primary site. Hidradenomas are classically asymptomatic, and most lesions are discovered during a routine pelvic examination. Curative treatment consists of local excision; recurrences result only from incomplete excision.

Granular Cell Tumors

Granular cell tumors (GCTs) were first described by Weber in 1854. It was not until 1926 that Abrikossoff coined the term *myoblastoma*. Later, the tumor was termed *granular cell schwannoma*. The current nomenclature recognizes the term *granular cell tumor*. Although frequently benign, GCTs can present as a malignant form that is multicentric and metastatic in vital organs. Horowitz and associates reported on 20 patients presenting with GCTs of the vulva over a 31-year period at the Emory University Teaching Hospitals. Seventy percent of the patients were African American, and the mean age was 50 years. Ninety percent of the lesions were on the labia majora, with lesion size ranging from 0.4 cm × 0.4 cm to 7 cm × 8 cm × 12 cm. Nineteen of twenty patients were treated with a wide local excision. The twentieth patient required radical excision because of the size of the lesion. This patient eventually died of pulmonary metastasis. Only two patients presented with multiple lesions. Twelve lesions were stained for S100. All were positive, which suggests a neural Schwann cell origin.

Sometimes, the overlying pseudoepitheliomatous changes are misinterpreted as invasive cancer (**Fig. 23.23**). Identification is possible with recognition of the granular cells dispersed within the underlying stroma or within the tumor. In a few patients, GCT has behaved in a malignant fashion, but an appearance of a second lesion at a site outside the vulva usually indicates multiple primary lesions rather than metastasis.

FIGURE 23.23 Granular cell tumor. Note the pseudoepitheliomatous hyperplasia, nests of large, pale “granular cells” beneath the epithelium (*arrow*).

Hemangioma

Hemangiomas are common vulvar lesions that usually do not require treatment. The lesions normally are small, are often multiple, and may bleed with trauma. On occasion, keratinization causes the superficial surface to appear white or graywhite (angiokeratoma). Hemangiomas should be differentiated from small varicosities, which commonly are seen in the postmenopausal patient.

An accurate diagnosis is imperative because a malignant melanoma can be misinterpreted as a hemangioma. The abrupt appearance of any pigmented lesion demands biopsy. In 2 of 11 melanomas seen in our clinic, the lesions were diagnosed as hematoma or angioma, and a correct diagnosis was provided only by histologic study. Angiokeratoma, a benign tumor, is a distinct clinicopathologic entity. Aggressive angiomyxoma, although structurally benign, is known for its large size and local recurrences. Some tumors, although benign, can be massive in size and thereby pose operative problems (**Fig. 23.24**).

The best treatment for congenital hemangioma is careful observation. The lesions regress spontaneously in almost all cases, and attempts at excision may be mutilating. If bleeding is a problem, the troublesome vascular channels can be treated by surgical ligation or embolization.

Varicocele and Varices

Varices are common on the vulva, and the larger lesions are almost routinely unilateral. As with most varicosities, treatment depends on size and symptoms. Whereas varicoceles in the scrotum arise from dilatation of the veins in the pampiniform plexus of the inguinal canal, the lesions on the vulva arise from the pudendal veins (**Fig. 23.25**). Careful evaluation usually demonstrates more extensive involvement of the tributaries of the hypogastric vein with varicosities of the gluteal vessels over the buttock.

If the patient experiences discomfort from the engorgement that follows exercise or standing for long periods, ligation is indicated with excision of the segment of vulvar skin that contains the varices. Knowledge of the intricate vascular system that supplies the external genitalia is necessary to ensure that surgery will result in long-term success and will prevent recurrences. Horowitz has treated several patients using selective embolization with success.

FIGURE 23.24 A benign angioliipoma noted for its massive size.

FIGURE 23.25 Vascular supply of the vulva.

BEST SURGICAL PRACTICES

- Vulvar diseases are multiple and may be difficult to diagnose. Many inflammatory conditions clinically resemble cancer.
- Bartholin gland abscesses are usually treated with antibiotics and insertion of a Word catheter. Marsupialization or excision is rarely used today. The possibility of cancer of Bartholin gland should be considered in the postmenopausal women with a new mass involving the Bartholin gland.
- Vulvodynia can be caused by infectious, inflammatory, neurologic, or neoplastic conditions of the vulva. When no underlying cause of vulvar pain can be demonstrated, oral amitriptyline and gabapentin as well as topical steroid creams should be tried. Local injection with triamcinolone and bupivacaine can also be used. If vulvar vestibulodynia is diagnosed, an extended perineoplasty has been effective in many patients.
- Vulvar condyloma are caused by some types of HPV (90% are due to types 6 and 11). These lesions may be self-limiting and resolve spontaneously. They do not undergo malignant transformation. If numerous, large, or symptomatic, they can be successfully treated with topical podophyllin, podofilox, or TCA. These lesions may also be destroyed or removed with electrosurgical desiccation, CUSA, CO₂ laser, or simple excision. These lesions may be difficult or impossible to eradicate in immunocompromised patients.
- Vulvar intraepithelial neoplasia should be diagnosed by biopsy. It may be caused by certain types of HPV, especially in younger women. If untreated, it may progress to invasive cancer. It can be treated by laser ablation, but surgical excision is usually recommended. A variety of techniques have been used, depending on the size and location of the lesion or lesions.

ACKNOWLEDGMENTS

The authors want to recognize the late Dr. J. Donald Woodruff, who has been a coauthor of this chapter for several editions and who has served as a mentor to the current authors.

Chapter 24

Surgical Conditions of the Vagina and Urethra

Y. Hernandez Suarez

John A. Rock

Ira R. Horowitz

DEFINITIONS

Genitoplasty—Surgical reconstruction of the external genitals.

Hematocolpos—A condition in which menstrual blood accumulates inside the vagina and distends it, most commonly associated with obstructing vaginal anomalies.

Hermaphroditism—A condition in which there is a combination of disparate or contradictory elements most commonly used to describe an individual who has both male and female sexual characteristics and organs (synonyms: intersex, androgyne).

Imperforate hymen—The hymen usually is perforated during embryonic life to establish a connection between the lumen of the vaginal canal and the vaginal vestibule, and it usually is torn early in the prepubertal years. If canalization fails and there are no perforations, the hymen is called imperforate.

Pseudohermaphroditism—A condition in which the gonads are of one sex (genetically XX or XY), but in which the physical/phenotypical appearance is of the opposite sex. Genetically female individuals (chromosomes XX, thus with female gonads/ovaries) presenting with significant male secondary sex characteristics and genetically male individuals (chromosome XY, thus with male gonads/testes) presenting with significant female secondary sex characteristics.

OBSTRUCTIVE LESIONS OF THE VAGINA

Imperforate Hymen

Imperforate hymen is the most common obstructive congenital lesion of the female genital tract. The hymen, the junction of the sinovaginal bulbs with the urogenital sinus (UGS), is a thin mucous membrane, sometimes cribriform in appearance, composed of endoderm from the UGS epithelium. The müllerian ducts meet the sinovaginal bulbs at the most cephalad tip of the invaginating UGS. The vaginal plate elongates and canalizes to form the vagina. If the vaginal plate does not canalize, a transverse vaginal septum is the result. Canalization of the most caudal portion of the vaginal plate at the UGS establishes a patent hymen. The hymen usually is perforated during embryonic life to establish a connection between the lumen of the vaginal canal and the vaginal vestibule, and it usually is torn early in the prepubertal years. If canalization fails and there are no perforations, the hymen is called *imperforate*. It is usually an isolated finding with no associated anatomic anomalies.

Although variations in hymen development occur, complete blockage by the hymen of the vaginal orifice is rare, occurring in approximately 0.05% to 0.1% of newborn girls. In 1986, Mor and colleagues described the types of hymeneal shape in the newborn infant from examination performed within

P.473

the first 24 hours of life. In 53.5%, a smooth hymen with a central orifice was observed; a folded hymen with a central orifice was seen in 27%; a folded hymen with an eccentric orifice occurred in 4.5%; an anterior opening of the hymen was found in 10.8%; a posterior opening was found in 0.6%. The researchers found that 3% had hymeneal bands and 0.3% of the newborns had imperforate hymens.

Stelling and colleagues have evaluated the genetic transmission of imperforate hymen and reported that the

occurrence of imperforate hymen in two consecutive generations of a family is consistent with a dominant mode of transmission, either sex linked or autosomal. Examination of newborns with a family history of imperforate hymen is of particular importance.

Symptoms

Cases that are recognized at birth present with a thin bulging membrane between the labia, which represents a mucocolpos. When the hymen is incised, the vagina is found to contain mucoid fluid that is the result of accumulated cervical secretion. This is caused by the stimulation of the infant's cervical mucous glands by maternal estrogen in the presence of an intact hymen. Prenatal diagnosis of imperforate hymen and mucocolpos has been described with second-trimester antenatal sonography demonstrating a thin membrane that distended the vagina and spread the labia majora.

Although by performing a careful inspection of the external genitalia, an imperforate hymen may be diagnosed at any age, most commonly imperforate hymen is not detected until puberty, with girls presenting at age 13 to 15 years when symptoms begin to appear with no external evidence of menstruation. In 2005, Posner and Spandorfer reported a bimodal distribution of age at diagnosis with 43% ($n = 10$) of girls diagnosed younger than age 8 and 57% ($n = 13$) at or older than age 8. Among older girls, 100% were symptomatic with abdominal pain and/or urinary symptoms. They found that in the young girls, in 90% of cases the diagnosis was incidental. On review of the older girls' medical records, they found that the majority lacked description of breast and pubic hair development, and almost half did not have menstrual history documented. The older group was more likely to present symptomatically and to undergo ancillary testing. They conclude that incorporating an examination of the external genitalia into routine practice of clinicians caring for children can prevent the significant delays in diagnosis of imperforate hymen, misdiagnosis, and potential morbidity associated with the latter group.

FIGURE 24.1 A: An imperforate hymen, membrane protrusion with a dark-tinged posterior representing a hematocolpos. **B:** Extrusion of accumulated blood at the time of incision into the membrane.

The symptoms of imperforate hymen after the onset of puberty are due to the accumulation of menstrual blood within the vaginal outlet tract. The blood of the first few cycles is collected in the vagina, which can hold a large volume of blood without undue stretching. This accumulated menstrual blood in the vagina is called

hematocolpos. The patient may feel slight fatigue and have cramping discomfort suggesting menstruation, but she has no history of any passage of menstrual blood through the vaginal outlet. **Figure 24.1A** shows bulging of the imperforate hymen, which may be dark in color because of occult blood showing through the stretched mucous membrane; **Figure 24.1B** shows extrusion of accumulated blood after the hymen is incised.

With continuing menstruation, the vagina distends, the cervical canal dilates, and hematometra (the filling of the endometrial cavity with blood) occurs. When the intrauterine pressure reaches a certain point, retrograde passage of blood into the tubes causes hematosalpinx. Rarely, blood passes freely into the peritoneal cavity (**Fig. 24.2**) causing all the symptoms and signs of peritonitis.

The most common symptoms of vaginal overdistention are lower abdominal pain, discomfort in the pelvis, and pain in the lower back. A tender mass may be palpable suprapubically, the result of uterine enlargement and upward displacement, bladder distention, or both. Hematocolpos should be included in the differential diagnosis of amenorrheic girls presenting with persistent lower back pain. Irritation of the sacral plexus is believed to be the etiology of this referred pain pattern. The lower abdominal discomfort often is aggravated on defecation, and if extensive blood accumulation occurs in the vagina,

P.474

constipation may result from pressure and obstruction of the underlying rectum. Urination can be difficult as a result of pressure of the distended vagina, which can compress the urethra and prevent emptying of the bladder; urinary obstruction can ensue. Bladder symptoms can present as cramplike pains in the suprapubic region, along with symptoms of dysuria, frequency, and urgency; overflow incontinence may eventually develop, and hydronephrosis is a rare complication. Girls presenting with severe dysmenorrhea and duplicate vagina and didelphic uterus should be evaluated for unilateral imperforate hymen.

FIGURE 24.2 Hematocolpos, hematometra, hematosalpinx, and hemoperitoneum consequent to an imperforate hymen.

Pelvic ultrasound should be performed in the evaluation of imperforate hymen particularly prior to surgical intervention. Concomitant diagnostic laparoscopy in patients with imperforate hymen has not demonstrated an association with pelvic endometriosis, and laparoscopy should not be included in the standard evaluation of imperforate hymen.

Treatment

Approach to the surgical management of imperforate hymen requires cultural sensitivity. The importance of hymeneal integrity varies among cultures and religions. Options should be carefully explained to patients and their families, and the choice of surgical approach should be reached through shared decision making. In the patient diagnosed in infancy, surgery may be delayed until adolescence to ensure optimum long-term vaginal functionality and reduce the small risk of repeat surgery. The goals of surgical management of imperforate hymen are both long and short term. In the short term, the obstruction of the vagina is alleviated. In the long term, satisfactory cosmesis, sexual function, and fertility are preserved.

In the standard approach, the hymenal membrane is incised in a stellate fashion, preferably at the 2-, 4-, 8-, and 10-o'clock positions. The quadrants of the hymen are then excised, and the mucosal margins are approximated with fine delayed absorbable suture (**Fig. 24.3**). To prevent scarring and stenosis, the hymenal tissue should not be excised too close to the vaginal mucosa. The vagina should be carefully drained with a suction probe. In patients in whom hematometra is present, all intrauterine instrumentation should be avoided (**Fig. 24.2**), as there is significant risk of perforating the thin, overstretched uterine wall. Patients should be followed for 2 to 3 weeks to ensure adequate resolution of the hematometra. Rarely, secondary dilatation of the cervix may be needed.

For patients in whom the perception of hymeneal “integrity” is important, the procedure may be modified to exclude the excision of the hymen. A simple vertical incision of the hymeneal membrane is performed with oblique suturing of the hymen to form an annular opening. Sutures may be avoided with the placement of a Foley catheter and topical estrogen cream for 2 weeks postoperatively. These approaches have anecdotally resulted in satisfactory cosmesis and defloration.

Rock and colleagues followed pregnancy success subsequent to the surgical correction of imperforate hymen between 1945 and 1981 at the Johns Hopkins Hospital. Twenty-two patients of mean age 14.7 years were admitted for surgical correction of imperforate hymens. Associated anomalies, including urinary tract anomalies, were rare. Thirteen patients subsequently conceived, and 10 patients were observed to have living children. Liang and colleagues in 2003 reported on the long-term postoperative evaluation of 15 patients with imperforate hymen. They conducted questionnaires and telephone interviews regarding sexuality, fertility, menstrual problems, micturition, and defecation. The mean postoperative follow-up was 8.5 years, with the mean age at diagnosis being 13.2 years. The women reported being markedly relieved of their presenting symptoms after hymenectomy. There were some who reported having irregular menstruation, and 6/15 reported dysmenorrhea. The authors reported that most patients fared well in terms of fertility and sexual function. It is important to counsel patients and their families about the favorable prognosis of fertility and pregnancy in women with correction of imperforate hymen.

FIGURE 24.3 Excision of imperforate hymen. Stellate incisions are made through the hymenal membrane at the 2-, 4-, 8-, and 10-o'clock positions. The individual quadrants are excised along the lateral wall of the vagina, avoiding excision of the vagina (**inset**). Margins of vaginal mucosa are approximated with fine delayed absorbable suture.

Transverse Vaginal Septum

Transverse vaginal septum is a rare cause of congenital vaginal obstruction. Presenting symptoms are identical to imperforate hymen, but diagnosis is frequently delayed in the setting of a normal vulvovaginal exam. Transverse vaginal septum is diagnosed on pelvic ultrasound with hematocolpos identified cephalad to the septum. Concomitant uterine and renal malformations have been described. Magnetic resonance imaging (MRI) may be helpful in identifying the anatomy. Joki-Erkila and Heinonen in 2003 identified 26 women with obstructive vaginal malformations. Thirteen underwent incision of an imperforate hymen and 3 excision of a complete transverse vaginal septum, with a mean follow-up period of 13 years. The remaining 10 had obstructive hemivagina and incision of a “longitudinal” vaginal septum with a mean follow-up period of 16 years. The women with transverse obstruction (imperforate hymen or transverse vaginal septum) were diagnosed within a month from their primary symptoms compared with 27 months for those with longitudinal obstruction. None with imperforate hymen required reoperation, but 2/3 with transverse vaginal

septum did for vaginal constriction, and 3/10 with longitudinal vaginal septum had reexcision of their septum. All of the 10 women with longitudinal obstruction had uterine and renal malformations, whereas in those with a transverse vaginal obstruction, only 6 underwent renal evaluation, and of these, 2 had double ureters. Dysfunctional uterine bleeding was reported by 19% of those in the transverse group and 40% of those in the longitudinal obstruction group, dyspareunia was reported in 30% of the transverse and none in the longitudinal, and dysmenorrhea was reported in 19% of transverse and 20% of longitudinal. No endometriosis was found in women who subsequently had a laparotomy or laparoscopy (18/26). In the 14 who were attempting to conceive, difficulty with fertility was not diagnosed. Twenty-five (89%) out of twenty eight pregnancies ended in delivery, the live birth rate of the longitudinal group being 82%, and 94% in those with transverse obstruction. The authors concluded that accurate diagnosis, along with adequate treatment, can reduce the need for reoperations and that no specific longterm clinical gynecologic symptoms were identified in these women with obstructing vaginal anomalies.

Sequelae of Female Genital Mutilation

Female genital mutilation (FGM) is defined by the World Health Organization as “all procedures that involve partial or total removal of the external female genitalia, or other injury to the female genital organs for non-medical reasons.” The WHO estimates that more than 100 million worldwide have undergone some type of FGM. It is estimated that approximately 250,000 girls and women with FGM are currently living in the United States. Female genital mutilation is practiced in Africa, Southeast Asia, and the Middle East, and is most commonly performed in puberty. Late complications of FGM include strictures, obstruction, and fistula formation. Complete obstruction of the vagina resulting in hematocolpos and hematometra has been reported. Women with FGM may seek gynecologic consultation to alleviate dyspareunia or dysmenorrhea or in preparation for childbirth. Defibulation is a vertical incision made to open scarring and reconstruct external genitalia. In a study by Nour et al. at the African Women's Health Center at the Brigham and Women's Hospital, 40 women were identified as having undergone defibulation between 1995 and 2003. Indications for defibulation were pregnancy (30%), dysmenorrhea (30%), apareunia (20%), and dyspareunia (20%). Almost 50% were found to have an intact clitoris underneath the scar. More than 90% of women stated they would highly recommend the procedure to others. 100% were satisfied with appearance and sexual function. The American Congress of

P.476

Obstetricians and Gynecologists has prepared a toolkit for clinicians caring for patients with FGM that includes photographs and detailed instructions.

Anomalies of the External Genitalia and Vagina

Sexually Ambiguous External Genitalia

Sexually ambiguous external genitalia defects of the UGS are remarkably constant in appearance, regardless of the etiology of the anomaly. Such genitalia differ only in their degree of malformation and occupy a range of positions somewhere intermediate to the genitalia of a normal female and that of a normal male. These anomalies can be anatomically identical to each other, whether their etiologic factor is congenital adrenal hyperplasia (CAH), male hermaphroditism, true hermaphroditism, or some other intersex syndrome. External genitalia proceeds along the female lines except in the presence of some virilizing influence acting on the developing embryo (i.e., androgens). The conversion of testosterone to dihydrotestosterone by 5 α -reductase activity occurs in the skin of the external genitalia and UGS in early gestation. Masculinization of the external genitalia ensues in the presence of functional androgens regardless of genetic sex. In the case of female pseudohermaphroditism—XX chromosomes in the presence of a virilizing influence—the fusion of the scrotolabial folds may be sufficient to obscure or conceal the vagina from the outside or even to entirely suppress its formation. The urethra can be formed for varying distances or along the entire length of the phallus. Therefore, the operative procedure for reconstruction of ambiguous genitalia into feminine genitalia does not vary in its essential elements, regardless of the cause of the intersexuality. The common goals for the female reconstruction of ambiguous genitalia include reduction of clitoral size, creation of labia minora, and exteriorization of the vagina.

Any reconstruction of the external genitalia with the objective of producing normal female appearance and function requires a full understanding of the surgical anatomy. It is essential to accurately identify the site of communication of the vagina with the UGS. In their classic paper in 1969, Hendren and Crawford recognized the variability of the communication of the vaginal insertion into the UGS. **Figure 24.4** illustrates the spectrum of vaginal communication with the urethra, with **Figure 24.4A** representative of a low distal communication (infrasphincteric) and **Figure 24.4B** representative of a high proximal communication (suprasphincteric). In 95% of cases, the vaginal communication is in relation to the caudal UGS derivatives (infrasphincteric) with the vagina communicating with that portion of the UGS that in a man gives rise to the membranous portion of the male urethra and that in the woman becomes the vaginal vestibule. If this usual relation is confirmed at surgery, the persistent, anomalous UGS may be incised to the vaginal communication without fear of disturbing the urinary sphincter. In less than 5% of cases, the vagina communicates high, with the portion of the UGS that becomes the prostatic urethra in the man or the entire urethra in the woman (suprasphincteric). Knowledge of the possible variants in communication of the vagina with the UGS is critical before entertaining surgical correction. Preoperatively, genitography showing the relationship of the UGS, urethra, vagina, and bladder may be helpful. Contrast is injected retrogradely through the perineal meatus of the UGS. Delineation of this anatomy can be elucidated at the time of surgery with the use of endoscopy to evaluate where the vagina communicates with the UGS. In 1989, Bargo and colleagues described the anatomic lesions in the intersexual states based on clinical and anatomic observations.

FIGURE 24.4 Illustration of the spectrum of vaginal communication with the urethra. **A:** Representative of a low distal communication (infrasphincteric). **B:** Representative of a high proximal communication (suprasphincteric).

One objective of the reconstruction procedure for external genitalia is to delay the procedure until the anomalous structures are of a size to permit easy identification of all structures. As observed by Azziz and coworkers, vaginal repair may be delayed until menarche, when maturity and the desire for sexual activity are usually well established. There is present debate in the need for early reconstruction for the sole purpose of cosmesis to prevent embarrassment or anxiety to the patient's family. Crouch and Creighton revisited the longstanding dictum of early surgical correction of ambiguous genitalia for intersex conditions. They report that some advocate the "one-stage" procedure in infancy, but that others advocate deferral of vaginal surgery until after puberty, especially given that many patients require further surgery at adolescence. It has been believed that the intersex child may be psychologically damaged by the "appearance" of uncorrected external genitalia if not performed at infancy, but unfortunately to date little research on this exists.

Most hermaphrodites reared as girls have a vagina or vaginal pouch, although in some instances, it is rudimentary. Only rarely is there no vagina, despite ambiguity of the external genitalia. The choice of operative procedure must conform to the observed anatomy. Thus, these choices are considered in the context of several categories based on

When the Vagina Is Present and the Vaginosinus Communication Is Low

The basic operation is, in essence, a modification of one described at length by Young that was previously performed successfully by various surgeons, notably in Europe. Patients with adrenal hyperplasia usually require only reconstruction of the external genitalia. However, when exploratory laparotomy is necessary to remove contradictory sex structures in other types of intersexuality or to establish the diagnosis, reconstruction of the genitalia may be considered at the same operation.

If an operation is deemed necessary at a very young age, the structures can be so small that it is impossible to introduce a finger into the UGS, and all tissues must be grasped throughout the operation with fine delicate tissue forceps. Operating loupes (2.5 to 3) are of great benefit to the surgeon. Small bipolar forceps and microscissors are also useful. Fine 5-0 or 6-0 synthetic absorbable sutures on an atraumatic needle are used throughout the procedure.

In cases of simple labial fusion, a cutback vaginoplasty (**Fig. 24.5**) would be sufficient to restore “normal” female genital anatomy. In cases of low vaginal confluence with the UGS (**Fig. 24.4A**), reconstruction may be done either by freeing the posterior vaginal wall and suturing up to the perineal external opening (**Fig. 24.6**) or—if a patient has copious subcutaneous fat and difficulty exists in approximating the vagina to the perineal skin—by use of a posterior flap technique, as used by Fortunoff and coworkers (**Fig. 24.7**).

Initially, the UGS may be thoroughly investigated with a small McCarthy panendoscope to determine accurately the position and size of the vaginal communication. If a sound or catheter can be easily introduced into the meatus of the UGS and into the vagina, use of the endoscope may be omitted. Special care is needed not to introduce the sound into the urethra. A sound accidentally introduced into the urethra poses the danger of incising the distal urethral meatus. After the UGS is incised (to within 2 or 3 cm of the anus), the urethral orifice may be identified (**Fig. 24.6A, B**). A small Foley catheter may then be introduced through the urinary meatus for purposes of identification throughout the remainder of the operation. To attach the edges of the vagina to the skin, it is usually necessary to free the vagina posteriorly and laterally to secure sufficient mobilization so that these structures meet with no tension. It is unnecessary to free the vagina anteriorly, because this requires its separation from the urethra. Sufficient mobilization can ordinarily be obtained by lateral and posterior dissection. When sufficient freedom has been attained, the edges of the vagina may be secured to the skin with interrupted 5-0 sutures on an atraumatic reverse cutting needle. In the infant, four or five sutures around the edge of the vagina are usually sufficient. The edges of the incised sinus membrane may then be sutured to the skin anteriorly (**Fig. 24.6D-G**). A small sponge impregnated with petroleum jelly may be introduced into the vagina to maintain its patency during the healing process. The indwelling catheter may be left in place for a few days until edema of the surrounding structures has subsided. An indwelling catheter is particularly useful in children with metabolic disorders that require accurate urine collection. A pressure dressing for 24 hours reduces the incidence of incisional hematoma.

FIGURE 24.5 In cases of simple labial fusion, a cutback vaginoplasty is sufficient to restore “normal” female genital anatomy.

Figure 24.7 illustrates vaginoplasty with a posterior flap as advocated by Fortunoff and is useful in cases with anticipated difficulty in bringing the vaginal orifice to the outside. Briefly, a posterior-based U-flap is drawn, with corners on either side of the perineal body near the rectum (**Fig. 24.7A-C**). This flap must be wide enough for tension-free anastomosis. This posterior flap is dissected in the midline and is carried out between the rectum and UGS.

Sutures are individually placed through the posterior-based flap and into the split posterior vagina. Sutures are tied after all have been placed. Because the anterior wall is not disturbed, no anterior flap is required. Finally, the phallic skin is divided in the midline and moved inferiorly to create the labia minora.

Surgical reconstruction of an enlarged clitoris has undergone significant evolution. Traditionally, the clitoris was simply amputated, and a nonfunctioning cosmetic clitoris was fashioned. Although several children so treated now have normal adult sexual function, the literature is lacking in followup data on large patient groups. Surgical efforts now focus on concealment, plication, resection, and reduction, with an attempt to provide a normal cosmesis without sacrificing sensation or vascularity of the glans.

The clitoral flap technique has provided a somewhat better cosmetic result than simple amputation. This procedure attempts to preserve a shell of the glans on a pedicle flap. The shaft of the clitoris is subtotally resected, and the stumps are reanastomosed (**Fig. 24.8**). The nerve supply to the glans is severed during this procedure, with the result that sensation in the glans is diminished. Sexual function, however, seems to be satisfactory.

Rajfer and colleagues have suggested a dorsal approach to the subtotal resection of the corpora (**Fig. 24.9**), which has the advantage of preserving the ventral nerve supply and which should preserve sensation in the glans. This approach is theoretically desirable and can be recommended for suitable cases. As mentioned earlier, however, lack of clitoral sensation does not seem to significantly affect the later sexual behavior of patients treated by procedures that sever the dorsal nerves to the glans.

In 1999, Baskin and colleagues described the anatomic studies of the human clitoris. As in the human penis, the

of the corporeal body with a nerve-free zone at the 12-o'clock position. The normal clitoris has corporeal bodies that are smaller but analogous to those of the penis. The surgeon should be mindful of their function if extensive resection is considered with care to preserve the dorsal aspect of the glans.

FIGURE 24.6 A: The external genitalia of an 18-month-old girl with CAH. The operation is the same, regardless of the etiology of the “virilizing” deformity. **B:** Beginning of the operation. Incision into the UGS. If the external meatus is large enough and the UGS will accommodate it, it is sometimes possible to introduce a catheter into the bladder through the urethra and introduce a sound into the vagina beside this. When the structures are large enough, this maneuver greatly facilitates the operative procedure by ensuring their identification. **C:** Lateral view showing the relations among the various structures. **D:** Situation after incision of the UGS. **E:** With the glass catheter in the bladder, the posterior vaginal wall is freed to make it possible to bring it to the skin edge without undue tension. **F:** The operative situation after the edges of the vagina are sutured to the skin and after the edges of the mucous membrane of the UGS are also sutured to the skin along the line of incision. **G:** Lateral view at the completion of the operation.

FIGURE 24.7 A posterior flap technique for when there is difficulty bringing the vaginal orifice to the outside.

FIGURE 24.8 Clitoral reduction via the clitoral flap technique. **A:** The initial incision. **B:** The flap must be as wide as possible at the base to preserve the circulation for the glans. The glans cannot be preserved completely because the blood supply will be insufficient to maintain it. It must be as thin a shell of the glans as possible. **C:** The shaft of the phallus has been removed. **D:** There has been some closure of the space from which the corpora were removed. **E:** The flap has been sutured into place.

FIGURE 24.9 Clitoral reduction with the corpora exposed through a dorsal incision (operation of Rajfer et al.). **A-C:** Corpora are approached and removed through a posterior incision in the phallus.

FIGURE 24.9 (Continued) D: Diagram of the excised portion of the corpora. E: The corpora are removed and stumps approximated.

Rink and Adams in 1998 reviewed feminizing genitoplasty. They advocated clitoral reduction without sacrificing sensation or vascularity of the glans, recommending a subtunical reduction of erectile tissue as described by Kogan and colleagues in the 1980s. The glans is preserved with its neurovascular supply intact along Buck fascia and the dorsal tunic of the corpora, yet the cavernous erectile tissue is excised. **Figure 24.10** illustrates this surgical management; additionally, the phallus is degloved, and this skin is used to create the labia minora. An incision is made around the corona of the phallus and continued inferiorly around the urethral meatus. Preservation of this meatal plate improves cosmesis and increases blood supply to the glans. The neurovascular bundle is identified, with lateral incisions into the tunica of the corpora along the phallus from the glans backward proximal to the corporal bifurcation. The cavernous erectile tissue is dissected from the inferior aspect of the dorsal tunic and excised, and the proximal and dorsal corpora are suture ligated. The glans is secured to the inferior aspect of the pubis or to the corporal stumps.

FIGURE 24.10 Surgical management of the clitoris with creation of labia minora and a posterior flap technique for vaginoplasty. **A:** Incision around the corona of the phallus continued inferiorly around the urethral meatus. **B:** Proposed incision into the posterior wall of the UGS. **C:** Degloving of the phallus. Sutures are individually placed through the posterior-based flap and into the split posterior vagina. **D:** The phallic skin is divided in the midline and moved inferiorly to create the labia minora. (From Rink RC, Adams MC. Feminizing genitoplasty: state of the art. *World J Urol* 1998;16:212. Copyright © 1998, Springer-Verlag Berlin Heidelberg. With kind permission from Springer Science and Business Media.)

In a pilot study of six women in 2003, Crouch and colleagues reported on genital sensation after feminizing genitoplasty for women with CAH. These women were assessed for thermal, vibratory, and light touch sensory thresholds in the clitoris and vagina using a genitosensory analyzer and Von Frey filaments. Highly abnormal results for sensation in the clitoris were found in the six women studied. In three who had an introitus capable of admitting a vaginal probe, the vaginal sensory data was considered normal. Given an abnormal clitoral sensation and normal vaginal sensation, the authors hypothesize that the abnormal clitoral findings may result from the surgical reconstruction rather than an effect of CAH. A self-administered sexual function assessment revealed that these women had sexual difficulties, particularly in the areas of infrequency of intercourse and anorgasmia. The authors voiced their concerns with the stated superiority of modern surgery. They stated that the vascularity of the glans remains vulnerable and that the risk of damage to the neurovascular bundles is inherent in any technique that

P.481

entails their separation from the corporal tissue. They concluded that even after seemingly successful clitoral reduction, the sensory function is significantly impaired, and this should be taken into consideration during counseling. Larger studies are presently under way to further evaluate these findings.

When the Vaginal Orifice Is Obscured

As mentioned previously, preoperative identification and catheterization or sounding of the vaginal orifice is key to the performance of a successful, one-stage procedure. When the vagina cannot be located by sounding, it sometimes can be seen by endoscopy. When sounding and vision both fail, an attempt before surgery to introduce a small (no. 4 or 5) ureteral catheter into the vagina by blindly probing through the endoscope along the posterior wall of the UGS may assist in the identification of the vagina. Sometimes, this catheter finds the orifice. If so, it may be left within the vagina as a guide during surgical exposure of the area (**Fig. 24.11**). If the vaginal orifice cannot be located, a planned two-stage operation is indicated. The objective of the first stage is to obtain cosmetically satisfactory female genitalia by reducing the clitoris and partially excising the UGS without exteriorizing the vagina. During the planned second stage, exteriorization of the vagina can be performed. The second stage should be postponed until identification of the vaginal orifice by sounding becomes possible. This may require waiting for puberty for estrogenization of the area. If dilators are needed for patency postoperatively, this surgery should be delayed until the girl is sufficiently mature for their appropriate use. This will maximize the success of the reoperation.

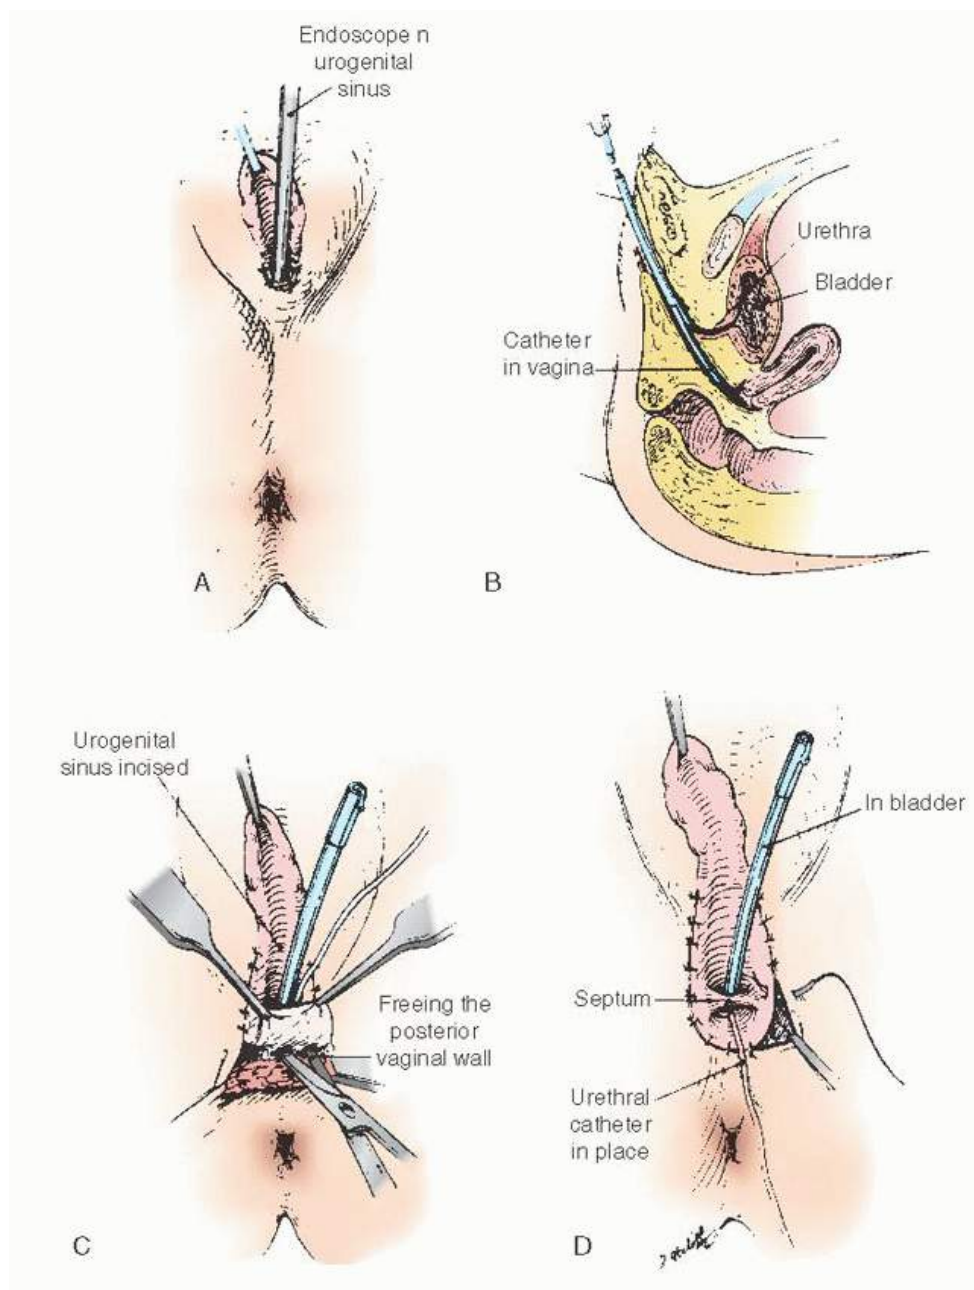

FIGURE 24.11 Operative procedure when it is difficult to locate vaginal orifice by sounding. An operative endoscope can be used to probe with a small ureteral catheter. **A:** The orifice is enlarged to accommodate the endoscope. **B:** The tip of the catheter has found the vaginal opening and entered the vagina. **C:** Freeing the posterior vaginal wall with the ureteral catheter in the vagina and a stiff catheter in the urethra. **D:** The vaginal portion of the operation is complete.

When the Vaginosinus Communication Is Blocked

Rarely does the vagina not communicate with the UGS. The vagina with the UGS is homologous with the hymenal area, and the hymen rarely is imperforate in an otherwise normal woman. For such a circumstance, we have found it helpful to pass a uterine sound downward through the fundus via hysterotomy into the vagina, thus forming a protrusion on the perineum. With such a guide, the edges of the vaginal epithelium can be located and sutured to the skin (**Fig. 24.12**). Until the uterus enlarges somewhat from its infantile state, the cavity is not large enough to accommodate even a uterine sound. Therefore,

P.482

if such an operation is contemplated, it should not be done until there is a palpable enlargement of the uterus at the onset of puberty. Evaluation of uterine volume sonographically as a predictor of uterine size adequacy may be helpful.

FIGURE 24.12 **A:** A situation in which the vaginal orifice is imperforate. **B:** A uterine sound has been passed through the fundus into the vagina. **C:** The tip of the sound can be palpated in the perineum. **D:** The completed procedure.

When the Vaginosinus Communication Is High

Hendren has been especially interested in patients whose vaginosinus communication involves the proximal urethra (suprasphincteric). He has advocated an operation that disconnects the vagina from the urethra and repositions the vaginal orifice in the perineum, the "pull-through" vaginoplasty. In his hands, this procedure seems to have been satisfactory for some patients. The procedure requires positioning the new vaginal orifice in the perineum (**Fig. 24.13**). The vast majority of patients with ambiguous external genitalia and a vagina have a vaginosinus communication well distal to the proximal urethra (infrasphincteric), and consideration of the procedure advocated by Hendren is not necessary. In patients in whom the vagina enters the UGS proximal to the external sphincter, the pull-through vaginoplasty of Hendren and Crawford or the method described by Passerini-Glazel can be used to prevent incontinence. Hendren and Crawford's vaginal pullthrough remains the basis for reconstruction today. Modification to this procedure has evolved in an attempt to decrease the complexity and decrease the tendency of an isolated vagina toward stenosis. Rink and coworkers have favored a one-stage procedure using a perineal prone approach with no division of the rectum.

Results of Revision of External Genitalia

Among 28 patients with adrenogenital syndrome and good follow-up treated at the Johns Hopkins Hospital, 22 (87.6%) needed further vaginal reconstructive surgery to achieve an adequate vaginal size to allow comfortable intercourse. Of the 22 patients, 5 had undergone more than 1 surgical attempt at reconstruction. The mean age of patients undergoing

repeat procedures was 7.1 years. The mean age at first surgery for the whole group was 23.6 months. Vaginal reconstructive surgery was performed on 18 of these patients and was successful in 13 (72%) of the procedures. It generally is recommended that exteriorization of the vagina be postponed until near puberty, when feminization occurs and the young woman is sufficiently mature to comply with a postoperative dilatation program. The results of exteriorization performed during infancy must be followed up carefully for evidence of narrowing. In 1997, Costa and colleagues evaluated the vaginal size and sexual activity after different techniques of feminization of external genitalia in patients with pseudohermaphroditism. In their series of patients, all who underwent clitoroplasty reported orgasms, and 29% of the patients who had clitoridectomy reported no orgasms. Fifty percent of the patients who submitted to neovaginoplasty reported pain or bleeding during sexual intercourse. Satisfactory sexual intercourse was reported by 87% after vaginal dilation with acrylic molds.

In 2000, Krege and colleagues reported on the long-term follow-up of female patients with CAH from 21-hydroxylase deficiency, with special emphasis on the results of vaginoplasty.

P.483

They reported that the main problem during the long-term follow-up was intravaginal stenosis, with all those affected—9 of 25 (36%)—having undergone a single-stage procedure early in life to correct ambiguous genitalia (mean age, 4.7 years; range, 2 to 9 years). The authors suggested that vaginoplasty should be undertaken at the beginning of puberty, because higher estrogen levels may prevent stenosis and dilatation may be performed. In addition, 16 patients answered questionnaires that included psychological profile, and the researchers found that 14 had problems with their overall body image. Patients with correction of vaginal stenosis were particularly anxious about sexual intercourse and had problems with orgasm. Creighton and colleagues in 2001 retrospectively evaluated the cosmetic and anatomical outcomes of 44 adolescent patients who had undergone feminizing surgery for ambiguous genitalia during their childhood. The authors reported that cosmetic results were judged as poor in 18 (41%) and that 43/44 (98%) required further treatment to the genitalia for cosmesis, tampon use, or intercourse. Of the genitoplasties planned as onestage procedures, 23/26 (89%) required further major surgery.

FIGURE 24.13 A perineal pull-through vaginoplasty according to Hendren. **A:** Sagittal view in diagram of high suprasphincteric vaginal communication to the UGS. A small Foley catheter is placed in the vagina to aid in its manipulation and localization. **B:** The location of the initial incision in relation to the balloon in the vagina. **C:** The flap is retracted posteriorly, and the dissection is carried along the anterior wall of the rectum until the vagina (as identified by the balloon) is approached. **D:** The vagina is identified by the Foley balloon catheter. The vagina is open. Care should be taken to pull a flap of vagina distal so that there will be no problem in closing the urethra.

Davies and colleagues in 2005 reported on urinary symptoms in adult women with CAH. The authors reported on

P.484

19 women with CAH, of whom 16 had childhood feminizing genital surgery, and compared them with age-matched women without CAH. The Bristol Female Lower Urinary Tract Symptoms (BFLUTS) questionnaire was given to all of the women. Sixty-eight percent of the women with CAH reported urge incontinence compared with 16% of controls ($P = 0.003$). Stress incontinence was present in 47% of CAH and 26% of the controls. Nine of the CAH women reported that their urinary symptoms had an adverse effect on their lives, whereas only one of the controls did ($P = 0.008$). The authors concluded that women with CAH are more likely to have urinary symptoms than controls. It is important to emphasize that it is not known whether these results are associated with the surgical procedures that the women underwent or an effect of CAH itself. For counseling purposes, this information is important because in two thirds of these CAH women, urinary symptoms persisted.

FIGURE 24.13 (Continued) E: The urethra is closed. Clips are placed on the vagina to bring it down to the perineum. **F:** The vagina is further mobilized. **G:** The edge of the vagina is attached to the original flap of perineal skin. **H:** Anterior and lateral flaps are attached. Note the use of a drain in the perivaginal space. (From Hendren WH. Reconstructive problems of the vagina and the female urethra. *Clin Plast Surg* 1980;7:207, with permission.)

Historically, it has been assumed that psychosexual development of infants with intersex disorders is mostly due to rearing rather than being intrinsic. Over the past decade, the role of testosterone imprinting of the fetal brain has been studied to evaluate the role of this hormone in determining male sexual orientation. Studies in the 1990s of girls with CAH have confirmed that such children engage in more rough-and-tumble

P.485

play than their affected peers and that difficulties with adjustment to their assigned sex may exist. Nonetheless, few studies have been conducted to address the social, psychological, and sexual outcomes for affected adolescents and adults, although it appears that most function in the normal range and are well adjusted. The majority of girls appear not to overtly demonstrate sexual identity problems.

Ozbey and coauthors reported on the experience of sex (re)assignment in genotypic female (46XX) patients with CAH when complicated by delayed presentation and inadvertent assignment. They reported on 70 patients with CAH who between 1983 and 2002 were counseled for sex assignment. They evaluated age at diagnosis and operation, the

degree of virilization, parental consanguinity, and the sex preference of the families as factors determining sex (re)assignment decision-making. Forty-one of 70 (59%) presented after the neonatal period, and in these cases, all of the parents had assumed or were advised of a sex based on external genitalia appearance. Forty-nine of 70 were reared as girls, and 21 were reared as “boys.” Of these 21 “boys,” only 9 could be reassigned as girls (mean age, 7.9 months), and the other 12, with mean age at presentation of 55.8 months, were reared as “boys” in compliance with the parents' and the study group's decision. These “boys” underwent appropriate masculinizing reconstructive surgery. They concluded that age of presentation was critical for the ability to correctly assign the sex of patients with CAH.

Secondary Operations

A secondary operation on the vaginal outlet may be required. This is generally the case if the basic operation is deliberately accomplished in two stages, whatever the reason. A secondary operation may be indicated, for example, when an infant's vaginal orifice is not readily identifiable, yet it seems desirable to construct cosmetically acceptable female genitalia at a very early age. Care should be taken when considering the appropriate age for performing a clitoroplasty. Some have recommended that this can be done in the newborn and that the vagina may be exteriorized at puberty as a second operation. Alizai and colleagues reported on the outcome of feminizing genitoplasty in 14 postpubertal girls (mean age, 13.1 years) with CAH. These girls were assessed under anesthesia by a pediatric urologist, plastic/reconstructive surgeon, and gynecologist. Thirteen of fourteen had previously undergone feminizing genitoplasty in early childhood. The authors reported that the outcome of clitoral surgery was unsatisfactory (clitoral atrophy or prominent glans) in six of the girls. Additional vaginal surgery was necessary for normal comfortable intercourse in 13 of the girls. In the girls with a history of vaginal reconstruction in infancy, fibrosis and scarring were prominent. The authors concluded that these results were disappointing, even in the girls who had their surgery performed by specialist surgeons. The authors highlighted the importance of late follow-up and the challenges in the prevailing assumption that total correction can be achieved with a single-stage operation in infancy. When the complete operation is attempted at an early age, the vagina is sometimes not satisfactorily exteriorized. Vaginal stenosis may require reconstruction at the time of puberty ([Fig. 24.14](#)). In this circumstance, there usually has been a failure to carry the midline incision far enough posteriorly, and a second procedure is required to complete the first one by continuing the midline incision far enough posteriorly.

In other cases, contraction at the vaginal outlet may occur even if the operation is adequately performed. A minor revision of the vaginal orifice is required to enlarge the vaginal orifice by making an incision in the midline and closing it at 90 degrees to the original axis of the incision ([Fig. 24.15](#)). In some instances, it may be necessary to create flaps to enlarge the vaginal orifice ([Fig. 24.16](#)).

FIGURE 24.14 External genitalia of a 15-year-old patient with vaginal stenosis. Revision of the external genitalia, including an exteriorization of the vagina, had been performed in infancy.

It should be emphasized that simple exteriorization of the lower vaginal tract can be combined with cosmetic correction of virilized external genitalia in infancy, but in most cases, it is best to defer definitive reconstruction of the intermediate or high vagina until after puberty.

Exstrophy-Epispadias Complex

Exstrophy-epispadias complex (ECC) is a rare congenital anomaly occurring in live births in a 1:25,000 to 1:40,000 ratio. There is a male predominance over females in a ratio of about 2:1. Classic ECC is characterized by (a) absence of the lower anterior abdominal wall, (b) absence of the anterior wall of the bladder so that the posterior bladder wall and the ureteric orifices are exposed, (c) a poorly defined bladder neck and urethra, and (d) wide separation of the pubic symphysis. A genital abnormality typically present in girls with bladder exstrophy is anterior displacement and narrowing of the vagina (**Fig. 24.17**) and separation of the clitoris into two distinct bodies (**Fig. 24.18**).

Bladder exstrophy, cloacal exstrophy, and epispadias are variants of the ECC. These defects have been attributed to failure of the normal process of ingrowth of mesoderm and the consequent lack of reinforcement of the cloacal membrane. The normal cloacal membrane is bilaminar and occupies the caudal end of the germinal disc. An ingrowth of mesenchyme between the ectodermal and endodermal layers of the cloacal membrane forms the lower abdominal wall musculature and the pelvic bones. After mesenchymal ingrowth occurs, descent of the urorectal septum divides the cloacal membrane into the bladder anteriorly and the rectum posteriorly. The urorectal septum eventually meets with the posterior remnant of the cloacal membrane, which perforates to form the anal and UGS openings. The paired genital tubercles migrate medially and fuse in the midline anterior to the

P.486

cloacal membrane before perforation. Without its normal support from mesenchymal derivatives, the cloacal membrane is subject to premature rupture. Depending on the extent of the infraumbilical defect and the stage of development when rupture occurs, bladder exstrophy, cloacal exstrophy, or epispadias develops (**Fig. 24.19**). Jones reviewed the records of all female patients diagnosed with bladder exstrophy at Johns Hopkins Hospital over a 20-year time span. Of 18 patients with adequately described external genitalia, 13 had small, anteriorly displaced vaginal orifices, and the remaining five patients had vaginal orifices of normal size and location. In this series, only a third of patients with ECC demonstrated the defect of narrowing of the vagina.

FIGURE 24.15 **A:** Repeated operation on the vaginal outlet when the operation was not completed at the first procedure. **B:** The posterior incision. **C:** The vagina is exposed. **D:** The closure.

FIGURE 24.16 Labial cutaneous flap. **A:** An incision is made through the labia skin and subcutaneous fat. **B:** The flap is rotated into the perineotomy incision. **C:** The flap is sutured in place by interrupted 3-0 delayed absorbable sutures. This may be repeated on the other side if required.

Exstrophy-epispadias complex may be associated with a wide range of both genital and extragenital abnormalities. Stanton reviewed 70 patients with bladder exstrophy and observed an increased incidence of various müllerian anomalies. Eleven patients were observed to have associated rectal

prolapse. Blakely and Mills observed various extragenital abnormalities in their series, including rectal prolapse, imperforate anus, exophthalmos, renal agenesis, and spina bifida.

FIGURE 24.17 Common gynecologic anomaly seen in women with bladder exstrophy. The vagina is rotated anteriorly and constricted over its distal portion.

Treatment

Our understanding of appropriate urologic management of bladder exstrophy has evolved greatly over the past few decades; improved management has markedly increased the life expectancy and quality of life of these patients. Historical methods of treatment involved bladder excision and a urinary diversion procedure such as ureterosigmoidostomy. These techniques were complicated by serious sequelae, including pyelonephritis, hyperchloremic acidosis, rectal incontinence, ureteral obstruction, and later development of malignancy. Modern care of the patient with complex pelvic congenital disorders mandates a multidisciplinary approach that includes gynecologic surgeons, urologists, neurologists, endocrinologists, pediatricians, and allied health professionals.

Urologic management of bladder exstrophy relies on a staged approach to functional bladder closure. The initial procedure consists of primary bladder closure with or without iliac osteotomies to aid closure of the pelvic ring and growth and improvement of bladder capacity. The second-stage procedures usually involve bladder neck reconstruction to improve continence and bilateral ureteral reimplantations to prevent reflux. Both failures and primary reconstruction have also been performed using continence urostomies, such as the Mainz II pouch. Mingin and coworkers and Gerharz and colleagues have reported their success using this technique.

FIGURE 24.18 Preoperative photograph of a patient undergoing reconstruction of the external genitalia. Note the bifid clitoris and small anterior vaginal orifice.

FIGURE 24.19 Anatomic features of (A) epispadias, (B) classic bladder exstrophy, and (C) cloacal exstrophy in females.

Genital anomalies in ECC can usually be sufficiently corrected to allow for sexual activity and pregnancy. The adjunctive gynecologic procedures in ECC attempt to correct the

P.488

anterior displacement and narrowing of the vagina and the bifid separation of the clitoris.

The surgical approach to the external genitalia in patients with ECC has evolved from that first described by Howard Jones Jr. in 1973. Particular emphasis is placed on attainment of an adequate vaginal diameter without further predisposing to subsequent prolapse. The first step is vertical incision into the posterior raphe of what resembles fused scrotolabial folds; next, Allis clamps are placed laterally for traction. Fine-needle point electrocautery is then used to further open the incision, with special care taken not to take this incision too far

posteriorly. The lateral portions of the incision are secured with 3-0 nonreactive absorbable sutures for further traction. The posterior vaginal edges are undermined to allow their mobilization to the exterior. The vaginal mucosa is then approximated to the perineal surface with interrupted and figure-of-eight sutures, incorporating the superficial perineal muscles into the closure. In the more posterior portion of the closure, 2-0 nonreactive absorbable suture is used, because this is the area of greatest tension. At completion, there is a significant increase in the diameter of the vagina, and the vaginal orifice usually accommodates two fingers.

Experience with management of ambiguous genitalia has shown a decrease in the incidence of postoperative vaginal stenosis if dilatation therapy is employed during the constrictive phase (the first 6 weeks) of healing. For this reason, following reconstruction of the external genitalia and exteriorization of the vagina, appropriately sized Lucite dilators are used once or twice a day for this 6-week period or until healing is complete. Patients who undergo surgical correction in early infancy are at risk for vaginal stenosis as they age. In a series by Cerveillone, one third of patients corrected in infancy underwent vaginoplasty by age 15.

Reapproximation of the bifid clitoris (**Fig. 24.20**) is primarily cosmetic and may disrupt erogenous sensitivity. The technique involves excising a diamond-shaped area of skin and subcutaneous tissue between the clitoral bodies. The medial aspect of each side of the clitoris is then denuded and undermined to allow a central reapproximation with a side-to-side closure.

Other surgical approaches have been described to optimize cosmesis. Stanton performed perineotomy in six patients with bladder exstrophy in which the labia and clitoris were reapproximated by a Z-plasty technique. Still others have described extraordinary efforts to restore the mons pubis and female escutcheon with skin flaps of hair-bearing areas. These latter reports, however, fail to mention correction of the vaginal anomaly.

FIGURE 24.20 Schematic depiction of procedure to reapproximate the clitoris. A vulvovaginoplasty has already been performed to exteriorize the vagina. **A:** A diamondshaped piece of skin and subcutaneous tissue between the clitoral bodies is excised. **B:** The clitoral bodies are then undermined and mobilized to the center for a side-to-side reapproximation.

Pregnancy and Exstrophy-Epispadias Complex

Several series have reviewed subsequent pregnancy outcomes in patients with bladder exstrophy. Clemetson extensively reviewed the literature in 1958 and found 45 patients who underwent 64 pregnancies. A very high incidence of uterine prolapse was observed both before and after pregnancy. In addition, there was a higher incidence

of premature labor and malpresentations (24%). Krisiloff and colleagues also reported a high incidence of uterine prolapse related to pregnancy, which occurred in 6 of 7 women. Burbige and coworkers reported on 14 pregnancies in patients with a history of bladder exstrophy. Uterine prolapse occurred in 7 of 11 patients, all of whom had undergone a previous urinary diversion procedure.

The mode of delivery in patients with prior urinary diversion procedures has primarily been spontaneous vaginal delivery. The increased incidence of premature labor and malpresentation, however, has warranted an increased rate of cesarean sections for obstetric indications. In patients with a prior bladder reconstruction, most surgeons advocate an elective cesarean section to eliminate stress on the pelvic floor and to avoid trauma to the delicate urinary sphincter mechanism.

Pelvic Prolapse and Exstrophy-Epispadias Complex

Several mechanisms have been proposed to explain the high incidence of uterine prolapse in patients with bladder exstrophy. These mechanisms include (a) a deficiency of the pelvic floor that is due to the wide separation of the pubic symphysis, (b) an inherent deficiency of the cardinal ligament complex, and (c) the abnormal axis and short length of the vagina.

Because wide separation of the pubic symphysis results in an enlarged genital hiatus and deficiency of the pelvic floor, it is possible that iliac osteotomy may be helpful in deterring pelvic organ prolapse by closer approximation of the levator ani and puborectal muscles. Although Gearhart and Jeffs suggest

P.489

that iliac osteotomies may not be necessary if primary bladder closure is performed in the first 72 hours of life, perhaps the procedure should be given increased consideration in female patients who present such a high risk for uterine prolapse later in life.

It appears important not to extend the midline perineal incision too far posteriorly in revision of the genitalia in these patients. As the incision proceeds posteriorly, the midline septum thickens to approximately 2 cm. At this point, the levator ani muscles may be severed, further enlarging the genital hiatus. It is prudent, therefore, to be more conservative; postoperative dilator therapy may aid in achieving further vaginal diameter if needed. A case referred to us illustrates this point. A 16-year-old nulliparous patient with bladder exstrophy and a history of staged bladder reconstruction underwent revision of the external genitalia. A large posterior incision into the perineal body had left a gaping introitus, and uterine prolapse had occurred several months after this procedure. Our initial approach was to reconstruct the perineal body to help contain the uterus and improve support to the pelvic floor. This reconstruction has been successful, without further prolapse 5 years after the procedure. Blakely and Mills, who observed uterine prolapse occurring very soon after enlargement of the vaginal introitus, reported a similar case.

Management of uterine prolapse associated with bladder exstrophy is particularly difficult when the patient desires preservation of childbearing. Sacrospinous fixation of the cervix may be considered, although an abnormally short vagina may produce difficulty in obtaining the suspension without significant suture bridges. An abdominal sacrocervicopexy may also be considered. Dewhurst and coworkers described this approach in 1980. They suspended the uterus to the sacrum using Ivalon sponge in a patient with procidentia following repair of bladder exstrophy.

Of note, the multiple operative and cystoscopic procedures performed on this group of patients have resulted in latex sensitization rates similar to that seen in health care workers. Ricci and coworkers evaluated 17 patients (15 children, 2 young adults) with bladder exstrophy for latex allergy. Twelve had latex sensitization, with five demonstrating serious symptoms.

Cosmetic Gynecologic Surgery

Women may seek surgical procedures to address the appearance of their external genitalia. It is the obligation of gynecologic surgeons to educate women on the wide range of normalcy of the female genitalia. Medical indications for labioplasty may include labial hypertrophy or asymmetrical labial growth. This procedure may be performed via simple linear removal, wedge resection, or Z-plasty. Some women may seek surgical procedures to enhance sexual function.

There are few long-term safety or efficacy studies to support these interventions, which include reduction of the clitoral hood, perineoplasty, vaginoplasty, and hymenoplasty, and are often bundled under the lay term “vaginal rejuvenation.” These procedures are not sanctioned by the American Congress of Obstetricians and Gynecologists and, like all vulvovaginal surgery, carry the risk of infection, dyspareunia, scarring, and unsatisfactory cosmesis.

Vaginal Trauma Post Sexual Assault

The National Violence Against Women Survey estimates that more than 300,000 women are the victims of sexual assault every year. Of these, about half are under the age of 18. Although the risk of surgical injury to the vagina is low in most cases of sexual assault, the risk increases under certain circumstances. These include when the perpetrator utilizes a weapon in the assault and/or is under the influence of drugs or alcohol at the time of the assault. Careful history and a judicious examination are needed to rule out acute genital trauma. In most urban settings, rape is initially evaluated in hospitalbased programs. Gynecologists who are called to evaluate the victims of sexual assault should be familiar with the forensic and legal implications of the examination.

THE URETHRA

The female urethra develops from the caudal end of the UGS after it separates from the vaginal canal between the eighth and twelfth week of embryologic life. Because the vagina and urethra are so closely integrated, the urethra shares many common disease processes and anatomic defects with the vagina. Bacteria in the lower genital tract frequently colonize in the outer urethra, harbor in the paraurethral glands, and enter the bladder to produce acute infections. A bacterial infection in the lower genital tract may not become clinically manifest for several years, until a Skene duct cyst or a urethral diverticulum develops. Estrogen deficiency causes atrophic changes of the vaginal mucosa and can have a similar effect on the urethral mucosa. Thinning of the epithelium and irritation of the sensory nerve fibers can cause urinary frequency and dysuria. Prolapse at the external meatus also may result from atrophic changes of the urethra.

Diverticulum of the Urethra

Urethral diverticulum is characterized by urethral mucosa herniating into surrounding tissues. The condition probably occurs more frequently than it is diagnosed; whenever an article reporting on urethral diverticulum appears in the literature, there is a coincident upsurge in the number of cases diagnosed. According to the National Hospital Discharge Survey (1979 to 1998), 27,000 inpatient procedures were performed for the repair of urethral diverticula in the United States over a 19-year period.

Etiology

In 1941, Parmenter suggested several congenital factors that could develop into a urethral diverticulum, including Gartner duct, a faulty union of primal folds, cell nests, and wolffian ducts or vaginal cysts that rupture into the urethra. Additional possible causes include trauma at childbirth, surgical trauma, urethral stone, urethral stricture, and infection of the urethral glands. Malignancy has been reported in a small percentage of cases.

The most probable etiology of urethral diverticulum is chronic infection of the suburethral tissue by vaginal flora. Huffman's experiments support the notion that a suburethral infection can develop into an abscess that becomes lined with epithelium. Huffman demonstrated periurethral openings by constructing wax models of infected urethras. The usual organisms cultured are *Escherichia coli*, *Aerobacter aerogenes*, and other gram-negative bacilli; *Staphylococcus aureus*; and *Streptococcus faecalis*.

Symptoms

Dysuria, urgency, frequency, and hematuria occurred together in 85% to 90% of 32 cases reviewed by Peters and Vaughn. Other frequently occurring symptoms are a lump in the vagina caused by protrusion of the diverticulum sac into the vagina,

dyspareunia (intermittent discharge from the urethra), and pain on walking. Pyuria and cystitis also occur,

depending on the location of the diverticular orifice. If the opening is sufficiently close to the outer end of the urethra, there may be no leakage of purulent exudate back into the bladder, which may explain the absence of symptoms of cystitis in 5% of cases. If the diverticulum is located in the posterior urethra near the urethrovesical junction, stress urinary incontinence may be a significant symptom. In a review of 70 cases from the Johns Hopkins Hospital, Ginsberg and Genadry found that 17% of the diverticula were located in the proximal (outer) urethra, 43% in the midurethra, and 31% in the distal (posterior) urethra; in the remaining cases, the site was not specifically identified. Urethral diverticulum should be considered in all cases of refractory urinary tract infection in women.

Diagnosis

Urethral diverticula usually are small, varying from 3 mm to 3 cm in diameter. Some of the larger sacs cover the entire length of the urethra. They are almost exclusively present on the distal two thirds of the posterior wall of the urethra. On palpation of a suburethral mass, tenderness commonly is found. Pressure on the mass may cause the escape of urine or exudate from the urethral meatus.

An examination of the floor of the urethra through the water cystoscope while suburethral pressure is being applied reveals an opening in 50% to 70% of cases. The pressure may force contents of the diverticulum into the urethra while it is being viewed. Some of the openings are extremely small and may be missed. Inflammatory swelling can result in edema of the orifice, which makes visualization difficult or impossible.

The diagnosis of urethral diverticulum is firmly established by means of positive-pressure urethrography (PPUG). A special catheter is used to block the urethra at both ends and to fill it and the diverticulum under pressure with water-soluble contrast medium (**Figs. 24.21, 24.22 and 24.23**). If the urethral orifice to the diverticulum is quite large, a voiding cystourethrogram together with a positive pelvic film may demonstrate the diverticulum. Although not as sensitive as PPUG, voiding cystourethrography (VCUG) may assist in identifying a urethral diverticulum. Wang and Wang compared VCUG and PPUG in evaluating 120 women. Twenty of 120 women demonstrated diverticulum. Thirteen were positive on PPUG and 10 with VCUG. If the surgeon's suspicion is high for urethral diverticulum, MRI should be considered if both the PPUG and VCUG studies are negative.

Gerrard and colleagues have shown that transvaginal ultrasound is effective for evaluating patients with suspected urethral diverticulum. The technique is accurate, low cost, readily available, and should be considered as an initial screening technique for women when one suspects a urethral diverticulum. Computerized tomography and MRI have better defined diverticular anatomy. Neitlich and colleagues have suggested MRI to be more sensitive than double balloon urethrography. These techniques should be considered after other conventional methods have not defined the diverticulum.

Occasionally, a diverticulum occurs with no clinical evidence of inflammation. If the diverticulum is diagnosed during a careful pelvic examination, and if the patient is completely asymptomatic except for a previous history of urinary tract problems, surgery is not necessary. With a complication rate of 15% to 20%, diverticulectomy should not be considered a quick and easy procedure. Removal of an asymptomatic urethral diverticulum may create more problems than it prevents, particularly if the sac is small

P.491

or located in the floor of the posterior urethra. Only if a patient experiences acute or recurrent symptoms should urethral surgery be performed. Leng and McGuire classify urethral diverticulum as true versus pseudodiverticulum (**Table 24.1**).

Treatment

A diverticulum that requires treatment must be completely excised before the defect in the urethra can be closed. Failure to remove the entire diverticulum results only in recurrence of the problem. Many techniques have been used to identify the anatomic boundaries of the diverticulum. One popular method is to pass a sound into the diverticulum through the urethral orifice. Another method is to distend the diverticulum by injecting it with fibrinogen and thrombin mixed in a syringe to form a firm fibrin clot. However, direct anatomic dissection of the diverticulum from the paraurethral fascia and vaginal wall without visual enhancement of the anatomic boundaries offers a better success rate. The smooth covering of a diverticulum protruding into the vagina can be easily distinguished from the rugal folds of the vaginal mucosa.

TABLE 24.1 Urethral Diverticulum

TRUE DIVERTICULUM	PSEUDODIVERTICULUM
No prior urethral surgery	History of urethral surgery
Chronic recurring symptoms of urgency, dysuria, dyspareunia, dribbling	Relatively few voiding symptoms
Chronic lower urinary tract infections	Cystoscopy demonstrates broad-mouthed ostium to diverticulum
Narrow-necked ostium not readily apparent on radiography or cystoscopy	More likely to have stress incontinence

If the wall of the diverticulum is left unopened until the dissection has reached the base of the diverticulum sac, its neck can be visualized directly while it is removed. Inadvertent removal of a portion of the urethral floor along the base of the diverticulum is too common an error; if the mucosa is closed with too much tension, a urethral stricture or a postoperative fistula may result.

Excision and Layered Closure

A midline incision is made through the vaginal mucosa, which is then separated from the wall of the diverticulum (Fig. 24.24A). The wall of the diverticulum also is dissected from the paraurethral fascia in as wide a circumference as can be developed.

The diverticulum is opened, and the interior of the cavity is inspected. If the orifice of the diverticulum is large, the opening of the urethra can easily be seen, especially if a catheter has been placed in the urethra and bladder (Fig. 24.24B). The rest of the thin, friable mucosa of the diverticulum is separated from the vaginal mucosa and fascia before the neck of the diverticulum is trimmed near the urethral orifice. The lining of the diverticulum is friable because of inflammatory changes and the thin layer fragments during the dissection. Meticulous sharp dissection is required to separate the lining completely from the vagina and from the floor of the urethra. We repeat, in caution, that the neck of the diverticulum should be carefully resected to avoid eversion and to prevent the removal of mucosa from the urethral floor.

The urethral defect is closed with 3-0 delayed absorbable sutures interrupted so that the edges can be inverted (Fig. 24.24C). After the interrupted sutures are tied, the paraurethral fascia is closed in a double-layer “vest-over-pants” technique in which the layer of fascia from one side of the urethra is sutured beneath the opposite and overlapping fascia and fastened to the urethral wall on that opposite side. The top layer of fascia is then sutured at its edge to the underlying fascial layer. The fascial margins are sutured by more durable 2-0 delayed absorbable sutures (Fig. 24.24D, E), and the vaginal mucosa finally is trimmed and closed, also with interrupted 2-0 delayed absorbable sutures. Faerber as well as Leng and McGuire have advocated diverticulectomy and placement of pubovaginal slings. Faerber uses the sling for intrinsic sphincter deficiency, whereas Leng and McGuire have recommended fascial slings to close the defect if it is too large for reinforcement.

The bladder is filled with 300 mL of distilled water, and a suprapubic Silastic catheter is inserted and left in place until the morning of the fifth postoperative day. A suprapubic catheter is used in preference to a urethral catheter for three major reasons: to avoid trauma to the operative site, to avoid the necessity for transurethral catheterization during attempts to initiate voiding, and to avoid the discomfort of a urethral catheter. On the fifth day after surgery, the patient should attempt to void with the three-way stopcock of the suprapubic catheter closed to allow the bladder to fill.

Urethrotomy

Urethrotomy has been used by Edwards and Beebe and by Kropp to treat diverticula. Splitting the floor of the urethra from the meatus down its full length to the site of the orifice of the diverticulum allows the sac to be well visualized during excision. As a rule, however, cases of urethral

P.492

P.493

diverticula can be successfully repaired without such an extensive incision that requires the floor of the urethra to heal along its entire length. Healing is particularly a problem if there has been recent infection in the diverticulum.

FIGURE 24.24 Suburethral diverticulum. **A:** A midline vaginal incision is made over the diverticulum. **B:** The diverticulum is dissected from the vaginal mucosa and surrounding fascia. Freed diverticulum is excised from the floor of the urethra, avoiding removal of an excessive amount of the urethral wall. **C:** The urethra is closed with interrupted 3-0 delayed absorbable sutures placed through the muscularis and mucosa to ensure mucosa-to-mucosa approximation. The paraurethral fascia is mobilized with sharp dissection from the vaginal mucosa. **D:** The paraurethral fascia is plicated beneath the urethral incision, using the vest-over-pants technique. The inner layer of fascia is sutured to the undersurface of the outer layer using horizontal mattress sutures of 2-0 delayed absorbable material. The inset is a cross-sectional view of suture placement. **E:** Completion of vest-over-pants plication of paraurethral fascia over the floor of the urethra. The free margin of the outer fascia is sutured to the inner fascial layer. The inset is a cross-sectional view of suture placement.

Marsupialization

In 1970, Spence and Duckett recommended marsupialization of the diverticulum to prevent recurrence, to minimize operating time, and to reduce blood loss. This procedure has been endorsed by Lichtman and Robertson and by Ginsberg and Genadry. Stress urinary incontinence has not been reported as a complication, but only, we suspect, because marsupialization is not used to treat lesions in the posterior urethra near the bladder base. Marsupialization is a useful procedure when diverticula occur in the outer third of the urethra, where a permanent opening in the outer floor of the urethra would not adversely influence intraurethral pressure.

Complications of Diverticulectomy

Complications arise in about 20% of cases treated for diverticula of the urethra. Urethral stricture can occur when too much urethral mucosa is removed, but strictures usually can be resolved by urethral dilatations. Urethral fistula, a serious and troublesome complication of diverticulectomy, occurs in about 5% of treated patients.

Postoperative fistulas frequently develop when acute or subacute infection in the walls of the diverticulum causes the urethral mucosa to become friable; the urinary incontinence that develops from urethral fistulas is far more troublesome than the initial symptoms of the diverticulum.

Closure of a urethral fistula is difficult because the blood supply to the floor of the urethra is delicate, and scarring and infection often develop with repeated efforts to close the urethra. A fistula in the outer part of the urethra may be asymptomatic and may not need to be repaired, but there normally are reports with an outer fistula of spraying of urine when voiding.

Urethral Prolapse

Although there have been few recent reports of urethral prolapse, nearly 400 cases have been published in the English literature since 1732. More than half of these cases occurred in infants and children; the remainder occurred in elderly patients.

Urethral prolapse is characterized by a sliding outward of the urethral mucosa around the entire urethral meatus. The urethra may become cyanotic, edematous, and infarcted (**Fig. 24.25**). Symptoms vary greatly. Prolapse may cause no discomfort, in which case it is detected only by bloody discharge of congested tissues that are breaking down, but more often there are reports of severe and continuous pain, urinary frequency, and tenesmus. Occasionally, in a small child, tissue reaction and edema of the outer urethra produces urinary retention rather than the more usual urinary frequency.

FIGURE 24.25 Prolapsed urethra.

FIGURE 24.26 Operation for urethral prolapse. **A:** The prolapsed mucosa has been excised. **B:** Completed operation. Cut edges of urethral and vaginal mucosa are sutured with 3-0 delayed absorbable sutures.

Urethral prolapse is thought to be the result of poor development of or atrophic changes in the collagen and elastic tissues of the submucosa. In infants, prolapse usually follows a severe coughing or crying spell. In some older patients, too, prolapse has followed paroxysms of coughing. In older patients, diminished tone and elasticity of tissue alone may be sufficient to cause some cases of urethral prolapse.

Treatment of urethral prolapse may be palliative or surgical. Hot, moist compresses provide temporary comfort. A small mass of tissue can be reduced, but recurrence is common.

Surgical Techniques

Several surgical procedures have been suggested, including the one advocated by Kelly and Burnam, in which the prolapsed mucosa is excised by a circular incision (**Fig. 24.26A**). The cut edges are then sutured with 3-0 delayed absorbable suture material, avoiding an excessive number of stitches, which can result in stricture of the urethral meatus (**Fig. 24.26B**). In most cases, this circumcision technique has proved to be the preferred method of correction.

Cryosurgery also has been used to treat urethral prolapse. The method is extremely effective in producing complete annular necrosis and healing of the prolapsed tissue (**Fig. 24.27**). The cryosurgery procedure can be performed without anesthesia, although for a young child, a local anesthetic is advisable. A suprapubic Silastic catheter is inserted and is left in postoperatively to permit bladder drainage until complete, spontaneous

P.494

voiding can occur. The catheter also helps to prevent postoperative trauma at the suture line around the meatus.

FIGURE 24.27 Cryosurgery in the treatment of urethral prolapse. **A:** Urethral prolapse in an elderly woman. **B:** Regression of urethral prolapse after cryosurgery. **C:** Repeated cryosurgery of urethral prolapse resulted in complete regression and healing of the urethral meatus within 8 weeks.

Carcinoma of the Vagina

Carcinoma of the vagina is uncommon, occurring in less than 2% of patients with gynecologic malignancies. The average age at presentation is 60 years. Vaginal carcinoma is most frequently secondary to metastases from tumors of the cervix and vulva rather than originating in the vagina. Lesions that encroach on the outer vagina from the vulva must be separated from lesions that originate in the vaginal canal to be considered a vaginal primary.

The International Federation of Obstetrics and Gynecology (FIGO) has agreed on the following exclusionary criteria for the classification of vaginal cancer:

- A vaginal growth extending to the portion of the cervix and reaching the area of the external os should always be considered a carcinoma of the cervix.
- A vulvar growth that has extended to the vagina should be classified as carcinoma of the vulva.
- A vaginal growth that is limited to the urethra should be classified separately as carcinoma of the urethra.

Clinicians now satisfy the staging criteria for the diagnosis of primary carcinoma of the vagina by showing a histologically negative cervix, urethra, vulva, and endometrium.

The criteria for the definition of primary carcinoma of the vagina were established after many clinicians reported the recurrence of vaginal lesions after treatment of carcinoma in situ of the cervix. Tumors recurred in 1% to 6% of cases. Today, extension of carcinoma in situ and invasive carcinoma of the cervix to the vaginal fornices or upper vagina can be easily identified with the use of colposcopy.

The clinical stages of carcinoma of the vagina agreed on by FIGO are listed in [Table 24.2](#). In 1973, Perez and coworkers proposed that stage II be divided into stages IIa and IIb to provide a more accurate definition of the extent of the lesion. In the proposed modified FIGO classification, stage IIa includes subvaginal infiltration not extending into the parametrial regions, whereas stage IIb includes parametrial or paravaginal infiltration not extending to the pelvic wall. This classification has not been accepted by FIGO. Creasman and colleagues queried the National Cancer Data Base (NCDB), a central registry of hospital case data, from 1985 through 1994. Of the 4,885 cases, 75% were invasive and 90% epithelial. Survival at 5 years was as follows: stage 0, 96%; stage I, 73%; stage II, 58%; and stage III to IV, 36%. The overall 5-year survival rate with melanoma was 14%.

Symptoms

The diagnosis of vaginal tumors frequently is delayed because of the lack of early symptoms. Progressive vaginal discharge and postmenopausal bleeding are the most frequent symptoms. Postcoital bleeding can also herald the presence of a vaginal or cervical carcinoma. More than 10% of patients are asymptomatic at the time of diagnosis. Women with a history of vaginal, vulvar, and cervical intraepithelial neoplasia have an increased risk of vaginal carcinoma. These patients should receive annual Papanicolaou smears even if they have undergone a hysterectomy. Having a hysterectomy for other than preneoplastic or neoplastic conditions does not increase the risk for developing vaginal carcinoma.

TABLE 24.2 International Federation of Obstetrics and Gynecology Classification of Vaginal Carcinoma

Preinvasive Carcinoma	
Stage 0	Carcinoma in situ, intraepithelial carcinoma
Invasive Carcinoma	
Stage I	Carcinoma limited to the vaginal wall
Stage II	Carcinoma involving the subvaginal tissue, but not extending onto the pelvic wall
Stage III	Carcinoma extending onto the pelvic wall
Stage IV	Carcinoma extending beyond the true pelvis or involving the mucosa of the bladder or rectum. Bullous edema that does not permit a case to be allotted to stage IV

Stage IVa Spread of the growth to adjacent organs

Stage IVb Spread to distant organs

From Pettersson F, ed. *Annual report on the results of treatment in gynecologic cancer*. Stockholm, Sweden: FIGO, 1988:174

The symptoms of vaginal carcinoma resemble those of cervical carcinoma, except that obvious bleeding occurs later than with neoplasms on the cervix. The overt bleeding eventually forces the patient to see her physician for diagnosis. The type of pelvic pain is frequently indicative of lesion location. The posterior vagina, the most common location of vaginal carcinomas, presents with tenesmus and other bowel symptoms. Anterior tumors, on the other hand, result in urethral and bladder symptoms.

Histopathology

The most common histologic type of primary vaginal tumor is squamous carcinoma, which accounts for 84% to 90% of all vaginal cancers (Table 24.3). Adenocarcinoma, including diethylstilbestrol (DES)-related cases, represents approximately 4% to 9% of vaginal cancers. Sarcomas, including leiomyosarcoma and sarcoma botryoides, account for 2% to 3% of vaginal lesions, and melanomas account for 1% to 2% of malignant neoplasms of the vagina. Rare tumors, such as endodermal sinus tumors or neoplasms originating in embryologic cloacal remnants, may form a transitional cell neoplasm that involves the vagina.

Squamous carcinoma of the vagina is discovered in 10% to 15% of cases after the finding of squamous cancer in other parts of the lower genital tract, such as the vulva or cervix. This has led to the theory of multicentric origin of squamous cancer in the lower genital tract. Woodruff and Parmley and others emphasize this correlation and have recommended that patients with squamous cancer in one area be categorized as high risk for the development of squamous carcinoma in other sites of the lower genital tract. A viral etiology, such as the human papillomavirus, is most likely responsible for these findings.

Carcinoma may arise in the neovagina lined with a splitthickness skin graft from the buttock or lateral thigh. Carcinoma of the neovagina is a rare cancer; only nine cases have been reported. The primary carcinoma seems to be related to the transplanted tissue. In three cases, adenocarcinoma was associated with the use of a large or small bowel intestinal graft for vaginal reconstruction. Five cases of squamous cell cancer arising from the graft have been documented. The transplanted epithelium in the vagina may be exposed to an unidentified carcinogen or mutagen, as has been documented with the vulva, and can undergo malignant transformation in

P.496

this environment. These observations underscore the need for regular pelvic examinations after operative vaginoplasty with either a bowel graft or a split-thickness skin graft.

TABLE 24.3 Histologic Types of Vaginal Cancer and Frequency of Occurrence

TYPE	FREQUENCY (%)
Squamous carcinoma	85-90
Adenocarcinoma (including DES related)	4-9

Sarcoma	2-3
Melanoma	2-3
Other	1-2
DES, diethylstilbestrol.	

Diethylstilbestrol, a nonsteroidal estrogenic hormone thought to enhance embryo implantation and placental development, was introduced into clinical obstetrics in 1944 in Boston and became popular and widely used during the next two decades. Women with a history of previous spontaneous abortions or other risk factors for early pregnancy loss of multiple gestations were given DES. It is known now that DES use during the first trimester of pregnancy may cause vaginal neoplasia. It was not until the late 1960s, however—when a cluster of cases of adenocarcinoma appeared in young women younger than age 25 years (all offspring of DES-treated women)—that Herbst and colleagues connected the result with the unusual cause.

From 1944 to 1970, approximately 1.5 to 2 million female offspring were exposed to DES. Fortunately, the incidence of vaginal adenocarcinoma in these young women has been quite low, ranging from 0.14 to 1.4 in 1,000 exposed women. More than 500 documented cases have been reported to the DES registry to date.

Observations of the development of vaginal adenosis and adenocarcinoma in teenage girls whose mothers were given DES before the eighteenth week of pregnancy brought new insights to the study of squamous tumor cells in the lower genital tract and greatly increased our understanding of the embryologic development of the vagina. The effect of the DES drug provided an indisputable histologic foundation for the development of an uncommon vaginal adenocarcinoma in women younger than 29 years of age. Twenty-five percent of women exposed in utero have anatomic cervical, vaginal, and urinary tract abnormalities.

The DES-associated adenocarcinoma originally was thought to arise from mesonephric remnants in the vagina, and the disease consequently was mislabeled as a clear cell carcinoma. However, electron microscopic analysis of the ultrastructure of both the adenocarcinoma and the vaginal adenosis allowed Fenoglio and colleagues to clearly define these lesions as composed of columnar epithelium, similar in all respects to endocervical epithelium, and of paramesonephric (müllerian) origin. The colposcopic studies of Staff and Mattingly and of others confirm these observations.

Vaginal adenosis has been found by colposcopic examination to occur in 34% to 90% of exposed offspring and vaginal adenocarcinoma in 50%. Although the hypothesis is still unproven, there is a strong possibility that the benign vaginal lesion is the cell of origin for vaginal adenocarcinoma. The risk of development of clear cell adenocarcinoma in an exposed woman between birth and age 34 is 1 in 1,000.

Etiology

During embryologic development, the vagina is formed from the columnar epithelium of the müllerian ducts and UGS. The tissue then transforms into squamous epithelium, so that the vaginal and cervical epithelium have a common embryologic origin. Squamous metaplasia within the vaginal adenosis has been observed with a colposcope, and transformation of the metaplastic tissue also has been demonstrated in the development of intraepithelial neoplasia. Although many agents have been postulated as carcinogenic factors, none have been positively demonstrated. It is quite possible that squamous carcinoma arises from the effects of an oncogenic agent on the transformation zone within the foci of vaginal adenosis. The studies now being done on the effects of DES may find some interesting causative factors that influence vaginal carcinoma.

Carcinoma of the vagina also may share a common causative denominator with cervical carcinoma. Because slightly

more than 50% of the cases occur in the posterior wall of the upper third of the vagina, which is the end point of vaginal coitus, vaginal carcinoma could be venereally induced. As with cervical carcinoma, primary carcinoma of the vagina usually occurs in sexually active women. Except for the cases of adenocarcinoma in young women exposed to DES, squamous carcinoma of the vagina is unquestionably associated with sexual activity. As with cervical intraepithelial neoplasia and carcinoma, the human papillomavirus is probably responsible for the majority of vaginal carcinomas.

Site of Lesion

Plentl and Friedman found that 51% of vaginal carcinoma lesions occur in the upper third of the vagina, 30% in the lower third, and 19% in the middle third. In the lower third, lesions most often occur in the anterior wall, whereas in the upper third, lesions most often appear in the posterior vaginal wall. Although the location is observed on diagnosis, the precise site of origin is difficult to pinpoint because the tumors usually have spread to various parts of the vagina by that time.

Pathways of Spread

The lymphatic drainage of the vagina takes place through different pathways. The upper third drains by way of the cervical lymphatics, the lower third passes by way of the vulvar lymphatics, and the middle third communicates with both the upper and the lower lymphatic channels. The vaginal vault and the anterior wall of the upper vagina drain to the interiliac pelvic lymph nodes, where they communicate with the external iliac, the hypogastric, and the common iliac nodes. The lymphatic drainage of the posterior vagina communicates directly with the deep pelvic nodes, including the inferior gluteal, sacral, and rectal nodes.

Because the major pathways of lymphatic drainage are to the superior and inferior gluteal muscles and the common iliac lymph nodes, the potential for extrapelvic spread of vaginal carcinoma is great. When extrapelvic spread occurs, prognosis usually is poor. The primary site of origin of the tumor is an important indicator of lymph node metastases, whether the tumor will metastasize to the inguinal-femoral chain or to the deep pelvic lymph nodes. When the disease involves the lower third of the vagina, 6% to 7% of patients have metastases to the inguinal-femoral lymph nodes.

Diagnosis

In general, invasive carcinoma of the vagina appears as either a raised exophytic lesion or an ulcerative, depressed lesion in the vaginal wall. Biopsy can be performed on both types of lesions easily, and diagnosis can be established without difficulty. Vaginal cytology usually is positive if an adequate cell sample is obtained from the exfoliated lesion, although, as often happens with cervical carcinoma, many cases of false-negative cytology occur even when an invasive lesion is present. Colposcopy, Lugol solution, or both can be used to demarcate the areas for biopsy, although iodine staining usually is unnecessary if the lesion is clearly visible.

Identifying vaginal carcinoma at an early stage can be a major problem because the first lesions appear within the epithelial cells, frequently indistinguishable from the remainder of the vaginal epithelium. Only by colposcopic examination or with iodine staining can alterations in the surface epithelium of the vagina be identified. Ng and associates have achieved an accuracy of 88% to 90% in detecting dysplastic lesions

P.497

in DES-exposed patients with adenosis, but their technique requires separate, four-quadrant vaginal smears from the walls of the vagina to increase the sensitivity of the Papanicolaou smear. Herbst and coworkers emphasize the advantage of iodine staining of the vagina to reveal occult lesions that may be associated with adenosis. Staffl and Mattingly reported an accuracy of 96% in detecting abnormal epithelial lesions of the vagina in DES-exposed women by careful examination and colposcopy.

Because the vaginal speculum can obscure surface lesions and delay early diagnosis, the instrument should be rotated during the examination so that the entire canal can be inspected. With iodine staining, the clinician can detect multifocal lesions, but the entire vagina also should be cytologically tested. A thorough colposcopic examination can be used to detect vaginal carcinoma if the clinician has that expertise.

Treatment

Primary vaginal carcinoma is treated either with surgery or with radiotherapy. The choice of treatment depends on three factors: the size of the lesion, the location of the tumor in the vagina, and the clinical stage of the disease.

Stage 1 Lesions

Easiest to treat by far is vaginal intraepithelial neoplasia **III** (VAIN **III**), and it offers the most hopeful prognosis. Either surgery or radiotherapy can be used, depending on the location of the lesion. If the disease is located in the upper vagina and the margins of the disease are distinct, a partial vaginectomy, with or without hysterectomy, is a practical and successful method of treatment.

The carbon dioxide laser has proved to be a simple, effective means of treating noninvasive vaginal carcinoma. Laser therapy offers conservative treatment for both focal and multicentric lesions without impairment of normal coital function. Because there is a risk of residual disease in 10% of lasertreated patients, careful colposcopic and cytologic follow-up are critical. Histologic study is difficult after the carbon dioxide laser vaporizes the treated lesions. An alternative ablative technique is the ultrasonic surgical aspirator, the tip of which vibrates 23,000 times per second, fragmenting and aspirating the tissue in contact with it. This technique permits histologic evaluation of the collected tissue fragments. The operative site also heals faster secondary to decreased thermal damage. Robinson and colleagues reported their experience in treating 46 patients with VAIN. Sixty-six percent (29) of those initially treated with ultrasonic surgical aspiration did not have recurrence. Fifty-two percent of patients treated for recurrent disease (17) did not experience a recurrence. The mean duration of follow-up was 21 months.

Nonsurgical methods such as administration of 5-fluorouracil vaginal cream have also proved efficacious in treating VAIN.

Radiation therapy is rarely used to treat VAIN. However, radiation is an excellent modality for suspected invasion when the medical risk for further evaluation by surgery is too great.

A vaginal cylinder, such as the Bloedorn applicator, can be used for radiotherapeutic treatment to deliver 70 Gy to the vaginal surface over a period of approximately 72 hours. If the lesion is confined to the vaginal fornices, vaginal colpostats can be used to deliver a similar dosage. Lesions in the lower third of the vagina may be treated by partial vaginectomy or by intravaginal irradiation using a variety of brachytherapy techniques.

Surgery, radiation, or both are the primary modalities for treating vaginal carcinomas. Lesions in the vaginal fornix can be treated with a radical Wertheim hysterectomy, partial vaginectomy, and bilateral pelvic lymphadenectomy. Treatment for this lesion is similar to that for stage Ib cervical carcinoma. If pelvic lymph nodes are histologically positive or if paraaortic lymph nodes look suspicious, a paraaortic lymphadenectomy should be performed. If the lymph nodes are histologically positive for carcinoma, pelvic radiation with or without paraaortic radiation should be administered. As with cervical carcinoma, the size of the lesion is prognostic of our ability to adequately treat these patients with primary surgery. Large lesions not permitting clear surgical margins (e.g., proximity to the bladder or rectum) should be treated with primary radiation therapy. Radical surgery also may require the replacement of the upper vagina with a split-thickness skin graft to reestablish normal vaginal length for a sexually active woman. Irradiation therapy is an alternative treatment for this stage of disease.

The radical Wertheim hysterectomy has been quite successful in treating stage I adenocarcinoma in young women who were exposed to DES in utero. More than 75% of patients are cured. Magrina and associates treated a patient with stage I disease at their institution with laparoscopic radical parametrectomy and pelvic and aortic lymphadenectomy. The role of laparoscopy in the treatment of vaginal carcinoma will continue to expand. Although its role in parametrectomy may be debated, laparoscopy to excise the pelvic and periaortic nodes before radiation may be beneficial to patients with advanced disease.

Sentinel Node Detection

Sentinel node detection in vaginal carcinoma has not gained universal acceptance. Gynecologic tumor—such as

cervical and vulvar—have been much more amicable to sentinel node detection and biopsy. Van Dam and colleagues used ^{99m}Tc -labeled nanocolloids in primary and recurrent vaginal carcinomas. Nodes were identified laparoscopically and resected. Three of four patients had nodes identified through sentinel node detection. Frumovitz and colleagues evaluated fourteen patients with pretreatment lymphoscintigraphy. Eleven patients had at least one sentinel node identified: five (45%) inguinal, four (36%) pelvic, and two (18%) inguinal and pelvic. Contrary to present beliefs, the location of positive sentinel nodes did not correlate to the location of the lesion. Radiation therapy is the preferable treatment for large proximal lesions or middle or distal vaginal tumors. A combination of teletherapy (external beam) and interstitial or intracavity therapy is used.

Stage II and Stage III Lesions

More extensive lesions of the vagina pose an extremely difficult therapeutic problem for the gynecologist. Because the levator ani muscles of the pelvic diaphragm surround the vagina, penetration of the lateral wall of the vagina by the invasive tumor frequently is associated with fixation of the disease to the adjacent pelvic musculature. Even radical surgery cannot effectively control the disease when it extends beyond the confines of the vagina into the paravaginal tissues. Instead, the major method of treatment for stage II and stage III lesions is radiotherapy.

When stage II lesions involve the anterior or posterior wall of the vaginal septum, an anterior or posterior exenteration with pelvic node dissection may be required. When the disease includes the lower third of the vagina, a groin dissection also is necessary. Because surgery must be so extensive, its usefulness is limited when the disease affects the paravaginal region (stage IIb) or the lateral vaginal wall (stage III).

P.498

Stage IV Lesions

When advanced lesions involve only the bladder or the rectum, exenteration may be required to control the disease effectively. Unfortunately, pelvic exenteration, either anterior or posterior, can be used only when there is no other extension of the disease, and it is rare for the bladder and rectum to be involved without involvement of the adjacent paravaginal tissues. If the patient is not an acceptable surgical risk for exenteration, external beam megavoltage irradiation therapy followed by intravaginal or interstitial irradiation can be used to control the local disease and to offer palliation. If the tumor does not respond after 5,000 cGY of irradiation treatment to the whole pelvis, an exenteration may be required to control the disease in properly selected patients. Exenteration is also recommended for central recurrences without lymph node metastasis.

Advanced/Recurrent Disease

Pelvic exenteration is the best treatment for patients who have failed primary irradiation therapy of vaginal carcinoma. As with cervical carcinoma, it is imperative that the recurrences be central and nodes radiographically negative. Before performing the exenteration, pelvic and periaortic nodes are sent for frozen section. Depending on the age of the patient, continent urinary diversions, neovaginal, and primary end-to-end colon anastomosis are performed when possible. Berek and colleagues reported on their 45-year pelvic exenteration experience at UCLA. Survival for cervical/vaginal cancers was 73% at 1 year, 57% at 3 years, and 54% at 5 years ([Fig. 24.28](#)). Positive margins had a deleterious effect on survival ([Fig. 24.29](#)).

Irradiation Therapy

Irradiation treatment of vaginal carcinoma is easily divided between lesions in the upper and middle thirds and the lower third of the vagina.

FIGURE 24.28 Survival of patients with recurrent cervical and vaginal cancers following pelvic exenteration. (Reprinted with permission from Berek JS, Howe C, Legasse LD, et al. Upper and Middle Thirds of the Vagina

Because the lymphatic drainage of the upper and middle vagina extends through the hypogastric and pelvic nodes, full

pelvic irradiation is necessary. Treatment usually includes a combination of techniques.

External beam megavoltage therapy using 4,500 to 5,000 cGY focused on the midplane of the pelvis is used to treat the full pelvis and to encompass the vagina. A vaginal implant of radium, cesium, or iridium follows, delivering an additional 3,000 to 4,000 cGY to a depth of 0.5 to 1.0 cm or more, depending on the thickness of the lesion.

At the MD Anderson Hospital, Brown and coworkers demonstrated the efficacy of using a radium needle implant for localized lesions. When the implant is used, high doses of radiation to the entire vagina, bladder, and rectum are avoided. Interstitial needles and iridium wires have been used as a primary treatment for localized vaginal lesions, and they can be used for persistent disease.

Lower Third of the Vagina

Lesions in the lower third of the vagina frequently metastasize to the inguinal-femoral lymphatics and must be treated with full external and intravaginal irradiation followed by external beam irradiation treatment to the inguinal-femoral lymph nodes. The inguinal-femoral regions require either a surgical groin dissection or the application of 5,000 to 6,000 cGY of electron beam teletherapy in addition to full pelvic irradiation. When vaginal lesions have metastasized to the groin lymph nodes, the cure rate is equally poor for both methods. In general, the presence of tumor in the groin nodes is a poor prognostic sign, suggesting that the deep pelvic nodes also may be involved in approximately 6% to 7% of cases. Because the incidence of vaginal cancer is so low, the exact frequency with which the deep pelvic nodes are involved has not been documented.

P.499

Chemoradiation for large bulky lesions may play a role in vaginal carcinoma, just as it does in cervical or vulvar lesions. Agents such as cisplatin, 5-fluorouracil, and hydroxyurea have been successfully used.

The number of patients with vaginal carcinoma reported to the FIGO registry by international clinics between 1979 and 1981 totals 547. Seventy-eight percent of these patients were treated by radiation. Only 38.6% of these patients were alive at 5 years. Results from other institutions that primarily have followed radiation therapy show that only stage I lesions have an adequate 5-year survival rate ([Table 24.4](#)).

In a retrospective analysis of 134 patients with carcinoma of the vagina treated at Washington University, Perez and Camel report an actuarial disease-free, 5-year survival rate of 85% for stage I lesions, 51% for stage IIa lesions, 33% for stage IIb lesions, 33% for stage III lesions, and 19% for stage IV lesions. The actuarial study demonstrated that beyond stage I of the disease, control is poor. For stage IIa lesions, local control of the disease was achieved in only 65% of cases at the University of Maryland because external irradiation was not used in all cases. Pelvic control was achieved in 48% of stage IIb and stage III lesions, but in none of the seven patients (0%) with stage IV disease.

Overall survival rates for stages I through IV from published reports are outlined in [Table 24.5](#). The highest survival rates are observed in stage I disease, whereas few patients survive for 5 years after the diagnosis of stage IV disease. Shah and colleagues reviewed the Surveillance, Epidemiology and End Results program (SEER) data on 2,149 women from 1990 to 2004. The average age at diagnosis was 65.7. The 5-year survivals were stage I (84%), stage II (75%), and stage III/IV (57%). Mortality decreased by 17% after the year 2000.

BEST SURGICAL PRACTICES

- Incorporating an exam of the external genitalia into routine practice of clinicians caring for children can prevent delays in diagnosing imperforate hymen, misdiagnosis, and potential morbidity. To prevent scarring, stenosis, and subsequent dyspareunia in women with imperforate hymen, the hymenal tissue should not be excised too close to the vaginal mucosa.
- Sexually ambiguous external genitalia defects of the UGS are remarkably constant in appearance regardless of the etiology and differ only in degree of malformation, ranging somewhere intermediate to that of a normal girl and that of a normal boy. Thus, operative procedure for reconstruction of ambiguous genitalia into feminine genitalia does not vary in its essential elements.
- The common goals for the female reconstruction of ambiguous genitalia include reduction of clitoral size, creation of labia minora, and exteriorization of the vagina. Any reconstruction of the external genitalia with the objective of producing normal female appearance and function requires a full understanding of the surgical anatomy.
- It is essential to accurately identify the site of communication of the vagina with the UGS in female reconstruction of ambiguous genitalia. Knowledge of the possible variants in communication of the vagina with the UGS is critical before entertaining surgical correction.
- One objective of the reconstruction procedure for external genitalia is to delay the procedure until the anomalous

structures are of a size to permit easy identification of all structures. Repair may be delayed until menarche, when maturity and the desire for sexual activity are usually well established.

- Surgical efforts of clitoral reduction focus on concealment, plication, resection, and reduction, with an attempt to provide

P.500

a normal cosmesis without sacrificing sensation or vascularity of the glans. Even after seemingly successful clitoral reduction, the sensory function is significantly impaired, and this should be taken into consideration during counseling.

- Preoperative identification and catheterization or sounding of the vaginal orifice is key to the performance of a successful, one-stage procedure.
- It generally is recommended that exteriorization of the vagina be postponed until near puberty because higher estrogen levels may prevent stenosis, and sufficiently, maturity in the patient is needed to comply with a postoperative dilatation program.
- When the complete operation is attempted at an early age, the vagina is sometimes not satisfactorily exteriorized. It should be emphasized that simple exteriorization of the lower vaginal tract can be combined with cosmetic correction of virilized external genitalia in infancy, but in most cases, it is best to defer definitive reconstruction of the intermediate or high vagina until after puberty.
- Preinvasive lesions of the vagina can be treated with excision or ablative techniques.
- Early stage I carcinoma of the vulva can be treated with radiation therapy and/or surgical excision. Radical vaginectomy and pelvic lymph node dissection has few complications and excellent 5-year survival. In more advanced-stage vaginal cancers, radiation therapy is superior.

Chapter 25

Surgery for Anomalies of the Müllerian Ducts

Lesley L. Breech
John A. Rock

DEFINITIONS

Hematometra—The distention of the uterus with blood or menstrual fluid.

Hematometocolpos—The distention of the uterus and vagina with blood or menstrual fluid; because the vaginal wall is more distensible, the vagina will preferentially fill before the uterus.

Hydrocolpos—The distention of the vagina with fluid; often seen in infants with complex reproductive anomalies.

Metropasty—Uterine reconstructive procedure.

Uterine anlagen—An underdeveloped uterine structure that is a remnant of a single embryologic müllerian duct.

Maldevelopment of the müllerian ducts occurs in a variety of forms, and each anomaly is distinctive. Nevertheless, some generalizations can be made. Classifications of vaginal anomalies based on certain anatomic findings are useful in organizing the type of malformation, but there usually are exceptions to each rule. Thus, what appears, after a preliminary diagnostic evaluation, to be an apparently isolated vaginal malformation may be found later to be associated with a uterine or renal anomaly. A comprehensive preoperative evaluation of patients with suspected malformations of the müllerian ducts is essential, but a clear understanding of the particular anomaly may not be established until the time of surgical correction. Reproductive surgeons must therefore be equally skilled in both uterine and vaginal reconstructions.

The patient with a uterovaginal anomaly often relies entirely on her physician to clarify the reproductive consequences associated with her diagnosis. The physician can help to allay her anxieties by making a prompt evaluation and giving a full and accurate description of the reproductive implications or the obstetric consequences of her particular uterovaginal anomaly.

CLASSIFICATION OF UTEROVAGINAL ANOMALIES

Classifications of uterovaginal anomalies originally were organized on the basis of clinical findings. Our improved understanding of the embryologic development of most uterovaginal anomalies has enabled categorization on this basis. The 1988 American Fertility Society (AFS) classification of müllerian anomalies ([Table 25.1](#)) offers an alternative based on the degree of failure of normal uterine development. Anomalies are grouped according to similarities of clinical manifestations, treatment, and prognosis for fetal salvage. The AFS classification system is weighted primarily toward disorders of lateral fusion and does not include associated vaginal anomalies, although the scheme does allow the user to describe anomalies involving the vagina, tubes, and urinary tract as associated malformations.

No classification of müllerian maldevelopment can focus entirely on the uterus; the vagina is often involved, and sometimes the tubes are involved as well. This discussion follows a suggested modification of the AFS classification of uterovaginal anomalies ([Table 25.2](#)) that comprises four groups based on embryologic considerations.

TABLE 25.1 American Fertility Society Classification of Müllerian Anomalies^a

Class I. Segmental, müllerian agenesis-hypoplasia

- A. Vaginal
- B. Cervical
- C. Fundal
- D. Tubal
- E. Combined anomalies

Class II. Unicornuate

- A. Communicating
- B. Noncommunicating
- C. No cavity
- D. No horn

Class III. Didelphys

Class IV. Bicornuate

- A. Complete (division down to internal os)
- B. Partial

Class V. Septate

- A. Complete (septum to internal os)

Class VI. Arcuate

Class VII. Diethylstilbestrol related

^aThis classification allows the user to indicate the malformation type and provides additional findings to describe associated variations involving the vagina, cervix, tubes (right, left), and kidneys (right, left).

Adapted from the American Fertility Society. The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, müllerian anomalies and intrauterine adhesions. *Fertil Steril* 1988;49:944, with permission. Copyright © 1988, Elsevier.

TABLE 25.2 American Fertility Society Classification of Uterovaginal Anomalies

Class I. Dysgenesis of the müllerian ducts

Class II. Disorders of vertical fusion of the müllerian ducts

- A. Transverse vaginal septum
 - 1. Obstructed
 - 2. Unobstructed
- B. Cervical agenesis or dysgenesis

Class III. Disorders of lateral fusion of the müllerian ducts

- A. Asymmetric-obstructed disorder of uterus or vagina usually associated with ipsilateral renal agenesis
 - 1. Unicornuate uterus with a noncommunicating rudimentary anlage or horn
 - 2. Unilateral obstruction of a cavity of a double uterus
 - 3. Unilateral vaginal obstruction associated with double uterus
- B. Symmetric-unobstructed
 - 1. Didelphic uterus
 - a. Complete longitudinal vaginal septum
 - b. Partial longitudinal vaginal septum
 - c. No longitudinal vaginal septum
 - 2. Septate uterus
 - a. Complete
 - 1) Complete longitudinal vaginal septum
 - 2) Partial longitudinal vaginal septum
 - 3) No longitudinal vaginal septum
 - b. Partial
 - 1) Complete longitudinal vaginal septum
 - 2) Partial longitudinal vaginal septum
 - 3) No longitudinal vaginal septum
 - 3. Bicornuate uterus
 - a. Complete
 - 1) Complete longitudinal vaginal septum

- 2) Partial longitudinal vaginal septum
- 3) No longitudinal vaginal septum
- b. Partial
 - 1) Complete longitudinal vaginal septum
 - 2) Partial longitudinal vaginal septum
 - 3) No longitudinal vaginal septum
- 4. T-shaped uterine cavity (diethylstilbestrol related)
- 5. Unicornuate uterus
 - a. With a rudimentary horn
 - 1) With endometrial cavity
 - a) Communicating
 - b) Noncommunicating
 - 2) Without endometrial cavity
 - b. Without a rudimentary horn

Class IV. Unusual configurations of vertical-lateral fusion defects

Modified from the American Fertility Society. The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, müllerian anomalies and intrauterine adhesions. *Fertil Steril* 1988;49:944.

Class I: Dysgenesis of the Müllerian Ducts

Dysgenesis of the müllerian ducts, which includes agenesis of the uterus and vagina (the Mayer-Rokitansky-Küster-Hauser [MRKH] syndrome), is an impairment of the reproductive system characterized by no reproductive potential other than that achieved by in vitro fertilization in a host uterus.

Class II: Disorders of Vertical Fusion of the Müllerian Ducts

Disorders of vertical fusion can be considered to represent faults in the junction between the downgrowing müllerian ducts (müllerian tubercle) and the upgrowing derivative of the urogenital sinus. Typically, these disorders are characterized by an atretic portion of the vagina that can be quite thick, extending through more than half the distance of the vagina, or it can be quite thin and limited to a small obstructing membrane.

Regardless of the length of the septum, a disorder of vertical fusion should be regarded as a transverse vaginal septum and classified as either obstructed or unobstructed. The so-called partial vaginal agenesis with uterus and cervix present is probably a misnomer for a large segment of atretic vagina. Cervical agenesis or dysgenesis is also included in the group of disorders of vertical fusion.

Class III: Disorders of Lateral Fusion of the Müllerian Ducts

Disorders of lateral fusion of the two müllerian ducts can be symmetric-unobstructed, as with the double vagina, or asymmetric-obstructed, as with unilateral vaginal obstruction. Obstructions associated with disorders of lateral fusion are particularly noteworthy in that they are observed clinically only as unilateral obstructions that almost invariably are associated with absence of the ipsilateral kidney. Bilateral obstruction is thought to be associated with bilateral kidney agenesis and subsequent nonviability of the developing embryo.

The three varieties of asymmetric obstruction with ipsilateral renal agenesis are:

1. Unicornuate uterus with a noncommunicating horn that contains menstruating endometrium
2. Unilateral obstruction of a cavity of a double uterus
3. Unilateral vaginal obstruction

The five groups of symmetric-unobstructed disorders of lateral fusion are:

1. The didelphic uterus
2. The septate uterus
3. The bicornuate uterus
4. The T-shaped uterine cavity, which may be hypoplastic and irregular and which is associated with diethylstilbestrol (DES) exposure in utero
5. The unicornuate uterus with or without a rudimentary horn

The first three groups are types of double uteri; differentiation between a septate uterus (second group) and a bicornuate uterus (third group) requires visualization of the fundus. The septum within the septate uterus is complete or partial. When the septum is complete, that inevitably involves the cervical region with a longitudinal vaginal septum that can extend to the introitus or partially down the vagina. The bicornuate uterus also can have a partial or almost complete separation of the uterine cavities. The term *arcuate uterus* is used primarily by radiologists to refer to a slight septum in the uterine fundus that forms no clear separation of the uterine cavities. This type of uterus is usually included in the category of partial septate uterus.

The unicornuate uterus may have an attached horn with a cavity that communicates with the unicornuate uterus, or there may be no uterine horn or a uterine horn with no cavity.

Some debate has focused on whether the unicornuate uterus with a communicating horn can represent a hypoplastic side of a bicornuate uterus.

Class IV: Unusual Configurations of Vertical-Lateral Fusion Defects

This final category includes combinations of uterovaginal anomalies and other disorders. Unusual uterovaginal configurations have been described that do not fit a particular category, and vertical and lateral fusion disorders can coexist.

Unusual configurations of vertical-lateral fusion defects can be seen with abnormalities of the lower urinary tract. Singh and coworkers have described a patient who was noted to have a persistent hymen and a longitudinal vaginal septum with a didelphic uterus. The patient was noted also to have a double urethra and bladder and left renal agenesis.

Obstructive lesions require immediate attention to relieve retrograde flow of trapped mucus and menstrual blood and increasing pressure on surrounding organs and structures. When no obstruction is present, attention may not be required immediately, but it will always be required eventually to establish or improve reproductive or coital function.

EMBRYOLOGY

The reproductive organs in the female (and in the male) consist of external genitalia, gonads, and an internal duct system between the two. These three components originate embryologically from different primordia and in close association with the urinary system and hindgut. Thus, the developmental history is complex (Figs. 25.1 and 25.2). Even in the 3.5- to 4-mm embryo, it is possible to recognize the bilateral thickenings of the coelomic epithelium known as the gonadal ridges medial to the mesonephros (primitive kidney) in the dorsum of the coelomic cavity. At approximately the 6th week of gestation, in the 17- to 20-mm embryo, the gonad can be distinguished as either a testis or an ovary.

In the female, the labia minora and majora develop from the labioscrotal folds, which are ectodermal in origin. The phallic portion of the urogenital sinus gives rise to the urethra. The müllerian (paramesonephric) duct system is stimulated to develop preferentially over the wolffian (mesonephric) duct system, which regresses in early female fetal life. The cranial parts of the wolffian ducts can persist as the epoöphoron of the ovarian hilum; the caudal parts can persist as Gartner ducts. The müllerian ducts persist and attain complete development to form the fallopian tubes, the uterine corpus and cervix, and a portion of the vagina.

Origin of the Müllerian Ducts

Approximately 37 days after fertilization, the müllerian ducts first appear lateral to each wolffian duct as invaginations of the dorsal coelomic epithelium. The site of origin of the invaginations remains open and ultimately forms the fimbriated ends of the fallopian tubes. At their point of origin, each of the müllerian ducts forms a solid bud. Each bud penetrates the mesenchyme lateral and parallel to each wolffian duct. As the solid buds elongate, a lumen appears in the cranial part, beginning at each coelomic opening. The lumina extend gradually to the caudal growing tips of the ducts.

Eventually, the caudal end of each müllerian duct crosses the ventral aspect of the wolffian duct. The paired müllerian ducts continue to grow in a medial and caudal direction until they eventually meet in the midline and become fused together in the urogenital septum. A septum between the two müllerian ducts gradually disappears, leaving a single uterovaginal canal lined with cuboidal epithelium. Failure of reabsorption of this septum can result in a septate uterus. The most cranial parts of the müllerian ducts remain separate and form the fallopian tubes. The caudal segments of the müllerian ducts fuse to form the uterus and part of the vagina. The cranial point of fusion is the site of the future fundus of the uterus. Variations in this site of fusion can result in an arcuate or bicornuate uterus. Complete failure of fusion can result in a didelphic uterus.

Isolated case reports continue to challenge established embryologic mechanisms of müllerian development. Dunn and Hantes reported a case of a double cervix and vagina with a blind cervical pouch challenging the theory of unidirectional fusion. Engmann and colleagues reported a unicornuate uterus with normal external uterine morphology, with bilateral fallopian tubes; however, only the right fallopian tube communicated with the uterine cavity. The patient suffered from pain because of the obstruction egress of the stimulated endometrial tissue. The patient was treated with removal of the obstructed cavity. The authors propose that this may represent failure of canalization of one of the müllerian ducts. Additional reports are necessary to fully evaluate potential variations in embryologic development.

Development of the Vagina

The vagina is formed from the lower end of the uterovaginal canal, which developed from the müllerian ducts and the urogenital sinus (Fig. 25.2). The point of contact between the two is the müllerian tubercle. A solid vaginal cord results from proliferation of the cells at the caudal tip of the fused müllerian ducts. The cord gradually elongates to meet the bilateral endodermal evaginations (sinovaginal bulbs) from the posterior aspect of the urogenital sinus below. These sinovaginal bulbs extend cranially to fuse with the caudal end of the vaginal cord, forming the vaginal plate. Subsequent canalization of the vaginal cord occurs, followed by epithelialization with cells derived mostly from endoderm of the urogenital sinus. Recent proposals hold that only the upper one third of the vagina is formed from the müllerian ducts and that the lower vagina develops from the vaginal plate of the urogenital sinus. Recent studies also suggest that the vaginal canal is actually open and connected to a patent uterus and tubes, even in early embryonic life, and that the vagina does not form and later become canalized from an epithelial cord of squamous cells growing upward from the urogenital sinus. Most investigators now suggest that the vagina develops under the influence of the müllerian ducts and estrogenic stimulation. There is general agreement that the vagina is a composite formed partly from the müllerian ducts and partly from the urogenital sinus.

At approximately the 20th week, the cervix takes form as a result of condensation of stromal cells at a specific site around the fused müllerian ducts. The mesenchyme surrounding the müllerian ducts becomes condensed early in embryonic development and eventually forms the musculature of the female genital tract. The hymen is the embryologic septum between the sinovaginal bulbs above and the urogenital sinus proper below. It is lined by an internal layer of vaginal epithelium and an external layer of epithelium derived from the urogenital sinus (both of endodermal origin), with mesoderm between the two. It is not derived from the müllerian ducts.

Anomalies in Organogenesis of the Vagina

Anomalies in the organogenesis of the vagina are easily understood. If there is failure in the development of the müllerian

P.508

ducts at any time between their origin from the coelomic epithelium at 5 weeks of embryonic age and their fusion with the urogenital sinus at 8 weeks, the sinovaginal bulbs will fail to proliferate from the urogenital sinus, and the uterus and vagina will fail to develop. Congenital absence of the uterus and the vagina, known as the MRKH syndrome, is the most common clinical example of this anomaly.

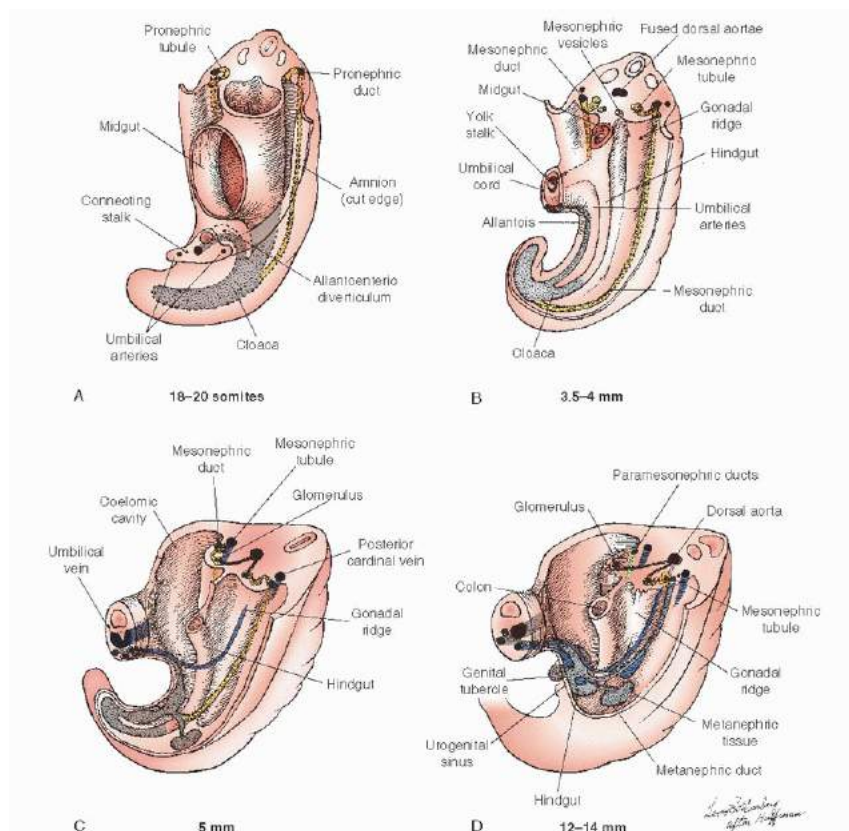

FIGURE 25.1 Diagrammatic representation of the development of the female reproductive organs and structures in early embryogenesis. **A:** At the 18- to 20-somite stage (4th week), the gonadal ridges have not yet begun to form. **B:** In the 3.5- to 4-mm embryo (5th week), the gonadal ridges can be recognized as thickenings of the coelomic cavity just medial to the mesonephric tubules. (Gonadal differentiation into either testis or ovary does not occur until the 6th week of development.) The allantoenteric diverticulum is joined caudally to the dilated cloaca. **C and D:** The genital tubercle and labial folds form in the region just anterior to the cloaca. The cloaca later divides into the ventral urogenital sinus and the dorsal rectum. The development of the urinary system closely parallels that of the reproductive system. The nonfunctioning pronephric tubules shown in **(A)** develop to form the mesonephric ducts shown in **(B)** and **(C)**. The permanent kidneys eventually develop from the metanephric tissue, and the urinary collecting system develops from the metanephric ducts. The paramesonephric (müllerian) ducts are apparent by the 12- to 14-mm stage **(D)**. (Their subsequent development is illustrated in [Figure 25.2](#).)

Transverse Vaginal Septum

A transverse vaginal septum can develop at any location in the vagina but is more common in the upper vagina at the point of junction between the vaginal plate and the caudal end of the fused müllerian ducts. This defect presumably is caused by failure of absorption of the tissue that separates the two or by

P.509

failure of complete fusion of the two embryologic components of the vagina. A large segment of vagina can be atretic. In past reviews, this has been termed *partial vaginal agenesis with a uterus present*. Elucidation of the cause of a high transverse vaginal septum is more difficult. A local abnormality of the vaginal mesoderm or failure of canalization of the epithelial vaginal plate can provide the answer, but why the abnormality should occur at this particular site is not evident. The proportion of the vagina originating from the urogenital sinus can at times be considerably more than one fifth, and a high transverse vaginal septum thus may represent the junction of an abnormally long urogenital sinus contribution and a short müllerian portion.

P.510

Alternatively, the high transverse septum could be the sequela of a local infection of the septum at the end of the vagina. Septa in other areas of the vagina are unexplained by this theory, which has not gained widespread acceptance.

FIGURE 25.2 Further development of the paramesonephric (müllerian) ducts and the urogenital sinus. **A:** Early development of the paramesonephric ducts. The cranial ends of the paramesonephric ducts develop first. These ends remain open to form the fimbriated ends of the fallopian tubes. The paramesonephric ducts grow caudally and cross the mesonephric ducts ventrally. **B:** Eventually, they fuse together to form the uterovaginal canal. **C:** Further caudal development brings this structure into contact with the wall of the urogenital sinus, producing the müllerian tubercle. The caudal ends of the fused paramesonephric ducts form the uterine corpus and cervix. Together with the urogenital sinus, they also form the vagina. The cranial point of fusion of the paramesonephric ducts marks the location of the future uterine fundus. The fallopian tubes form from the unfused cranial parts of the paramesonephric (müllerian) ducts. The proliferation of the lining of the uterovaginal canal above the upward growth of the sinovaginal bulb from below (**D**) forms the vaginal plate (**E**), which later becomes canalized to leave an open vaginal canal. Thus, the vagina is of composite origin. The mesonephric ducts in the female degenerate but can persist into adult life as Gartner ducts.

Disorders of Ineffective Suppression of Müllerian Ducts

When abnormal gonadal development is caused by ineffective suppression of the müllerian ducts, ambiguous external genitalia frequently are accompanied by a small rudimentary uterus or a partially developed vagina. Additionally, when there is a genetic loss of cytoplasmic receptor proteins within androgenic target cells, such as occurs in the androgen insensitivity syndrome (formerly called testicular feminization syndrome), the vagina is incompletely developed because the existing male gonads suppress the development of the müllerian ducts. Because these genetically XY patients have phenotypic female genital anatomy without a completely formed vagina, it is important that a vagina be nonsurgically (dilatation) or surgically created to ensure a satisfactory sexual experience.

Congenital anorectal malformations (imperforate anus with rectoperineal or rectovestibular fistula or more complex anomalies like cloaca or cloacal exstrophy) have been reported to occur with reproductive anomalies. These anomalies can be associated with maldevelopment of the müllerian and mesonephric duct derivatives.

Müllerian Duct Abnormalities

Abnormalities in the formation or fusion of the müllerian ducts can result in a variety of anomalies of the uterus and vagina: single, multiple, combined, or separate. Just as the entirely separate origin of the ovaries from the gonadal ridges accounts for the infrequent association of uterovaginal anomalies with ovarian anomalies (see this chapter), so do the close developmental relationships of the müllerian and wolffian ducts explain the frequency with which anomalies of the female genital system and urinary tract are associated. Failure of development of a müllerian duct is likewise associated with failure of development of a ureteric bud from the caudal end of the wolffian duct. Thus, the entire kidney can be absent on the side ipsilateral to the agenesis of a müllerian duct.

Depending on the timing of the teratogenic influence, renal units can be absent, fused, or in unusual locations in the pelvis. Ureters can be duplicated or can open in unusual places, such as the vagina or uterus. Jones and Rock have noted that failure of lateral fusion of the müllerian ducts with unilateral obstruction is associated consistently with absence of the kidney on the side with obstruction. Bilateral obstruction has not been observed clinically, presumably because it would be associated with bilateral renal agenesis, a condition that would not allow the embryo to develop. According to Thompson and Lynn, 40% of female patients with congenital absence of the kidney are found to have associated genital anomalies.

Much investigation has been undertaken to determine a genetic relationship in the development of disorders of the müllerian ducts. Familial aggregates of the most common disorders of the müllerian differentiation are best explained on the basis of polygenic or multifactorial inheritance. No information exists on the number and chromosomal location of responsible genes. Single mutant genes are responsible for the McKusick-Kaufman syndrome and the hand-foot-genital syndrome. Hand-foot-genital syndrome is a rare, dominantly inherited condition that affects both the distal limbs and the genitourinary tract. A nonsense mutation of the HOXA13 gene has been identified in several families. HOX gene mutations have been reported in several families with multiple müllerian abnormalities. Genital malformations may also be associated with heterozygous DNA sequence variations of the HOXA10, HOXA11, and HOXA13 genes. To date, involvement of the Y chromosome in the pathogenesis of müllerian anomalies has not been considered. The 2004 report by Plevraki and colleagues suggests the possible role of testis-specific protein 1-Y gene in patients with uni- or bilateral gonadal agenesis and uterovaginal dysgenesis. Timmreck and colleagues narrowed the genetic considerations by noting that in an evaluation of 40 women with developmental abnormalities of the uterus and vagina and 12 normal controls, no mutations of the WNT7A gene—a gene associated with murine Müllerian duct development—were found. Reproductive abnormalities involving the uterus and vagina may also be associated with other more complex malformation syndromes in which the molecular basis of many of the syndromes remains unknown.

CONGENITAL ABSENCE OF THE MÜLLERIAN DUCTS

The disorders of müllerian agenesis include congenital absence of the vagina and uterus. Often referred to in the literature simply as congenital absence of the vagina (vaginal

agenesis), this condition is more accurately labeled aplasia (or dysplasia) of the müllerian ducts because the lower vagina generally is normal, but the middle and upper two thirds are missing. Despite the absence of the uterus, rudimentary uterine primordia are found that are comparable to each other in size and appearance. Tubes and ovaries in patients with congenital absence of the müllerian ducts generally are normal. The syndrome, usually referred to as the MRKH syndrome, is associated with a heterogeneous group of disorders that have a variety of genetic, endocrine, and metabolic manifestations and associated anomalies of other body systems.

Characteristics of Women with Müllerian Agenesis

- Congenital absence of the uterus and vagina (small rudimentary uterine bulbs are usually present with rudimentary fallopian tubes)
- Normal ovarian function, including ovulation
- Sex of rearing: female
- Phenotypic sex: female (normal development of breasts, body proportions, hair distribution, and external genitalia)
- Genetic sex: female (46,XX karyotype)
- Frequent association of other congenital anomalies (skeletal, urologic, and especially renal)

Partial agenesis of the vagina with the uterus present and a transverse vaginal septum both are categorized as disorders of vertical fusion. These two disorders have a low incidence of associated urinary tract anomalies, another circumstance that sets them apart from the MRKH syndrome.

Realdus Columbus first described congenital absence of the vagina in 1559. In 1829, Mayer described congenital absence of the vagina as one of the abnormalities found in stillborn infants with multiple birth defects. Rokitansky in 1838 and Küster in 1910 described an entity in which the vagina was absent, a small bipartite uterus was present, the ovaries were normal, and anomalies of other organ systems (renal and skeletal) were frequently observed. Hauser and associates emphasized the spectrum of associated anomalies. Pinsky suggested that congenital absence of the vagina is part of a symptom

P.511

complex and not a true syndrome. Over the years, the disorder has come to be known as the MRKH syndrome, the Rokitansky-Küster-Hauser syndrome, or simply the Rokitansky syndrome (Fig. 25.3). Counseller found that the condition occurred once in 4,000 female admissions to the Mayo Clinic. Evans estimated that vaginal agenesis occurred once in 10,588 female births in Michigan from 1953 to 1957.

FIGURE 25.3 Typical findings in a patient with MRKH syndrome. Note the absence of the right kidney and right ureteral orifice. The uterus is represented by bilateral rudimentary uterine bulbs joined by a band behind the bladder. The ovaries appear normal although there is malposition of the right ovary.

Individuals with an absent vagina and the classic MRKH syndrome usually are first seen by a gynecologist at age 14 to 15 years, when the absence of menses causes concern. Such young women have a normal complement of chromosomes (46,XX) and usually have normal ovaries and secondary sex characteristics, including external genitalia. Menstruation does not appear at the usual age because the uterus is absent, but ovulation occurs regularly. There are some exceptions to the rule of normal ovaries. For example, polycystic ovaries and gonadal dysgenesis have been reported in patients with congenital absence of the vagina. Plevraki and colleagues reinforced the importance of consideration of such conditions, as one of the six women with MRKH evaluated over a 12-month period demonstrated hypergonadotropic hypogonadism that was due to the bilateral absence of gonadal tissue. Additionally, nested polymerase chain reaction demonstrated the presence of testis-specific protein 1-Y-linked (TSPY) gene in two women.

Etiologic Factors

An exclusively genetic etiology cannot be ascribed to vaginal agenesis because almost all patients have a normal karyotype (46,XX) and because the discordance of vaginal agenesis in three sets of monozygotic twins has been reported. The occurrence of complete vaginal agenesis in sisters with a 46,XX karyotype suggests an autosomal mode of inheritance for these patients. Shokeir investigated the families of 13 unrelated females with aplasia of müllerian duct derivatives. Similarly affected females were found in 10 families. Usually, there was an affected female paternal relative, suggesting female-limited autosomal dominant inheritance of a mutant gene transmitted by male relatives.

Other investigators point to the variety of associated anomalies as support for the etiologic concept of variable expression of a genetic defect possibly precipitated by teratogenic exposure between the 37th and the 41st gestational day, the time during which the vagina is formed. Knab has suggested five possible etiologic factors of the MRKH syndrome:

1. Inappropriate production of müllerian regressive factor in the female embryonic gonad

3. Arrest of müllerian duct development by a teratogenic agent
4. Mesenchymal inductive defect
5. Sporadic gene mutation

Knab believes that the teratogenic and the mutant gene etiologies are the most probable.

Anomalies Associated with Müllerian Agenesis

Many patients with müllerian agenesis have associated anomalies of the upper müllerian duct system together with associated anomalies of other organ systems. By gentle rectal examination, the physician can feel an absence of the midline müllerian structure that should represent the uterus. The physician instead feels a smooth band (possibly a remnant of the uterosacral ligaments) that extends from one side of the pelvis to the other. In MRKH syndrome, the uterus is represented by bilateral rudimentary uterine bulbs that vary in size, are not usually palpable, are connected to small fallopian tubes, and are located on the lateral pelvic side wall adjacent to normal ovaries. Depending on their size, these rudimentary uterine bulbs may or may not contain a cavity lined by endometrial tissue (Fig. 25.4). If present, the endometrial tissue can appear immature or, rarely, can show evidence of cyclic response to ovarian hormones. The endometrial cavity does not communicate often with the peritoneal cavity because the tube may not be patent at the point of junction between the tube and the rudimentary uterine bulb. In rare instances, however, active endometrium can exist within the uterine anlagen and the endometrial cavity, enabling communication with the peritoneal cavity through patent fallopian tubes. Reports have described several patients with functioning endometrial tissue in one or both rudimentary uterine bulbs (Fig. 25.4B). The patient can develop hematometra because of cyclic accumulation of trapped blood. Cyclic abdominal pain is relieved by excision of the active uterine anlagen. A patient with MRKH syndrome was reported who had a 4-cm endometrioma removed from the left ovary by laparotomy at the time of operation to create a vagina. Myomas have been reported to form in the muscular wall of inactive uterine anlagen, and dysmenorrhea has been attributed to their presence. A small myoma has been found, in addition to the tube and ovary, in the inguinal canal and in the inguinal hernia sac. Due to the rarity of the condition, interaction with the radiologist about the patient's history is important to make an accurate diagnosis.

FIGURE 25.4 Patients with congenital absence of the vagina can show variation in the development of the upper müllerian ducts. **A:** Bilateral rudimentary uterine bulbs without endometrium. **B:** Bilateral rudimentary uterine bulbs containing a cavity lined with functioning endometrial tissue. Crosssectional view shows presence of menstrual blood.

Chakravarty and colleagues and Singh and Devi have demonstrated that the rudimentary bulbs have the potential for function. These authors used these rudimentary uterine bulbs to reconstruct a midline uterus. The reconstructed uterus was then connected to a newly constructed vagina. A surprising number of patients who have undergone this procedure have experienced cyclic menstruation, although recurrent stenosis and obstruction of the rudimentary horns are the most common results of such efforts. The authors of this chapter have had no experience with this technique and question its usefulness. In the majority of cases, these rudimentary uterine bulbs usually are insignificant structures that cause no problems.

Associated Urologic and Renal Anomalies

Fore and associates reported that 47% of patients in whom evaluation of the urinary tract was performed had associated urologic anomalies. In other studies, approximately one third of patients with complete vaginal agenesis were found to have significant urinary anomalies, including unilateral renal agenesis, unilateral or bilateral pelvic kidney, horseshoe kidney, hydronephrosis, hydroureter, and a variety of patterns of ureteral duplication. A significant number of patients with partial vaginal agenesis also have associated urinary tract anomalies.

Associated Skeletal and Other Anomalies

Associated skeletal anomalies have been recognized since congenital absence of the vagina was first described. In a review of 574 reported cases, Griffin and associates found a 12% incidence of skeletal abnormalities. Most of these abnormalities involve the spine (wedge vertebrae, fusions, rudimentary vertebral bodies, and supernumerary vertebrae), but the limbs and ribs also can be involved. Other anomalies include syndactyly, absence of a digit, congenital heart disease, and inguinal hernias, although the latter are more often present in patients with androgen insensitivity syndrome than in patients with MRKH syndrome (Fig. 25.3). Consideration of cardiac anomalies is also important, as Pittock and colleagues reported a substantial incidence of cardiac defects (16%) when reviewing a group of 25 patients with MRKH at the Mayo Clinic.

The recognized association of absent vagina with imperforate anus and rectovestibular fistula will likely be diagnosed in infants and treated by the pediatric surgeon at the time of the rectal pull through (most commonly with sigmoid neovaginoplasty). However, the condition may not be noted or treatment may be deferred to young adulthood. Knowledge of this association can be important at the time of treatment as creation of an adequate neovagina with dilation may be impaired by scarring at the previous fistula site in the vestibule. Assessment of vaginal adequacy as a young adult is important as the neovagina created in childhood may need revision or augmentation.

Treatment for Disorders of Müllerian Agenesis

Pretreatment Considerations

If functioning endometrial tissue is present with the anlagen, then symptoms from cryptomenorrhea will begin shortly after female secondary sex characteristics develop. Prompt removal of the active uterine bulbs affords complete relief of symptoms.

Occasionally, older patients with the classic MRKH syndrome consult a gynecologist because of difficult or painful intercourse. The indication for operation in these patients is obvious. Of all patients, they are the most satisfied with the operative results.

Most commonly, patients aged 14 to 16 years are seen by a gynecologist because of primary amenorrhea. An examination may not have been performed by a previous physician because the patient was "too young," but various hormonal medications may have been given with the hope that menstruation would begin. An inaccurate examination may have led to the mistaken diagnosis of imperforate hymen. Futile attempts to incise the hymen may have resulted in scarring of the apex of the vaginal dimple before a correct diagnosis of congenital absence of the vagina was finally made. In the past, it was customary to advise delaying surgery to create a vagina for these young patients until just before their marriage. More recently, it has become usual to perform the procedure when patients are 17 to 20 years old and are emotionally mature and intellectually ready to manage the potential postoperative requirements for care, including manipulation of the vaginal form or the use of dilators.

Psychological Concerns

Insufficient attention has been given to the psychological aspects of this problem. The patient with congenital absence of the vagina cannot be made into a whole person simply by creating a perineal pouch for intercourse. Establishment of sexual function is only one concern and may be the easiest problem to correct. Evans reported that 15% of his patients have real psychiatric difficulty. He and David and associates suggest that psychiatric help should be initiated before the treatment to create a neovagina. Weijenborg and ter Kuile described the effect of a group program on women with Rokitansky syndrome. The authors held group sessions conducted by a gynecologist, a female social worker, and a woman with Rokitansky syndrome. Seventeen patients participated. Three women had elected not to create a vagina, six women created a vagina by dilatation or sexual activity, and eight women had undergone a vaginoplasty. Indices of psychological distress were measured before the program, at initiation of the program, and at the last group session. The results demonstrated that women with Rokitansky syndrome felt less anxious, less depressed, and less sensitive to interpersonal contact after participation in the semistructured program. These data support the value of group interaction in patients with Rokitansky syndrome.

Learning about this anomaly, especially at a young age, is a shock and is accompanied by diminished self-esteem. Such patients can be encouraged by having their gynecologist offer appropriate psychological and medical therapy with an experienced multidisciplinary team. The gynecologist can also point out that the patient will functionally be like other young women who have had a hysterectomy because of serious pelvic disease and who have satisfied their desire to be a parent through adoption or gestational surrogacy. When receiving this diagnosis, patients and families are looking for reassurance about the future. Liao and colleagues reported on women with Rokitansky (treated with dilation, no treatment, or surgery) who completed four questionnaires assessing health-related quality of life, emotional distress, and sexual function and underwent a vaginal examination. Of the 87 eligible participants, 56 (64%) took part in the study. Thirty-six women had used dilators in the past, and 7 (who were sexually active) had undergone vaginal surgery (laparoscopic Vecchietti 4, McIndoe 1, bowel 1, skin flap vaginoplasty 1). The range of time from surgery to participation in the study was 5 to 16 years. Twelve patients had no intervention to create a neovagina. The participants reported overall better physical health and poorer overall mental health compared with normative data. Anxiety levels were higher, especially for women who had treatment to create a neovagina (dilation or surgical treatment). Vaginal length had a positive correlation with overall sexual satisfaction but was not related to overall quality of life. Kimberley and colleagues in Australia reported on quality of life and sexual experience of patients with vaginal atresia or agenesis. Seventy patients were identified, but nine were excluded who were younger than 17 years, newly diagnosed, or developmentally delayed. Thirty-four women responded with 28 actual participants in the study. Of the 20 patients who completed the sexual satisfaction questionnaire, only four were treated surgically (Sheare procedure 3, McIndoe 1) and the remaining 16 created a neovagina with dilation. The quality-of-life outcomes as measured by the World Health Organization Quality of Life (WHOQOL-BREF) questionnaire showed overall quality of life to be comparable to that of the average Australian population. In addition to quality-of-life evaluation, psychosocial assessment is important as well. There was a strong correlation between the quality-of-life scores and sexual satisfaction, highlighting the importance of psychological and psychosocial supports in the management of young women affected by the condition. Time since diagnosis had a positive influence on overall sexual satisfaction, with 92% of women who received a diagnosis more than 5 years ago demonstrating satisfactory sexual function scores. Callens and her colleagues in the Belgian-Dutch Study Group on Disorder of Sex Development (DSD) attempted to evaluate the psychosexual and anatomical outcomes of patients after dilation or surgery to create a neovagina; however, only 7 of the 35 participants were noted to have a diagnosis of MRKH (all treated with skin graft neovaginoplasty). Of those patients, only two were examined to correlate the anatomic findings with the psychosexual responses. All of the patients completed at least some part of the Female Sexual Function Index (FSFI), a validated measure in the vaginal reconstruction population, with the mean score of 25.0, which falls below the 26.55 cutoff, implying that they are at risk for developing sexual dysfunction. The authors acknowledged that their population was not randomized for treatment, was recruited exclusively from a clinical sample, and may have been biased by including patients who created a sufficient vagina by coitus alone with those that followed a dilation program. Regardless, their results support that any treatment for vaginal hypoplasia may be of limited utility without psychological expertise to address other aspects of self-perception. More work in the

P.514

area of overall quality of life, well-being, and emotional/sexual wellness is needed in this population.

When counseling patients, gestational surrogacy should definitely be included in the discussion. Until recently, the literature had provided only sparse evidence regarding the use of this modality in this population. Beski and colleagues confirmed the use of gestational surrogacy in a small population. The treatment cycles resulted in six clinical pregnancies (42.9% pregnancy rate per embryo transfer and 54.5% per oocyte retrieval) and three live births (21.4% per embryo transfer, 27.3% per retrieval, and 50% per patient). Several authors have reported on the genetic offspring of patients with vaginal agenesis. Petrozza and colleagues reported a retrospective study in 1997, describing a large number of treatment cycles for patients with Rokitansky syndrome. The authors attempted to determine an inheritance pattern of the syndrome through a questionnaire sent to all centers performing surrogacy treatment in the United States. A total of 162 in vitro fertilization/surrogacy treatment cycles were reviewed for 58 patients with congenital agenesis of the uterus and vagina. The treatment resulted in 34 live births (17 girls, 17 boys). One child had a nonspecific middle ear defect and hearing loss. The authors concluded that congenital absence of the uterus and vagina was not commonly inherited in a dominant fashion. These findings suggest that inheritance of this disorder in children of affected mothers is likely via a polygenic mechanism. In this population, none of the 17 female infants born to affected mothers exhibited Rokitansky syndrome. Ovulation induction is similar to other patients; however, oocyte retrieval may be more challenging. Typically, oocytes are retrieved transvaginally; yet, after creation of a neovagina, the ovaries may not be as easily accessible. In addition, ovaries may be ectopically located, higher in the abdomen. Barton and colleagues reported success with a transabdominal approach without decrease in safety or efficacy. Five of the sixty-nine women who underwent abdominal follicular aspiration were noted to have congenital reproductive anomalies.

Patient Cooperation

Regardless of which operative technique is chosen, the patient must cooperate if the operation is to be successful. In many of the available vaginal reconstruction techniques, dilation or use of a vaginal mold will be necessary. For example, when a McIndoe operation is performed, patients must understand the need to wear a form continuously for several months and intermittently for several years until the vagina is no longer subject to constriction and until regular intercourse is taking place. No surgery should be performed until preoperative evaluation determines that the patient understands her essential role in its success. This is especially important when the patient is a younger teenager. The single most important factor in determining the success of vaginoplasty is the psychosocial adjustment of the patient to her congenital vaginal anomaly.

Laboratory and Diagnostic Testing

A complete chromosomal analysis should be considered in all patients. If there is a suspicion of ovarian dysgenesis, androgen insensitivity syndrome, or some aberration of the classic MRKH syndrome, then a consideration of additional SRY analysis should be entertained to assess the possible presence of any Y chromosome. A contrast study such as a magnetic resonance (MR) urogram or an intravenous pyelogram should be done preoperatively. This also provides an adequate survey for anomalies of the spine. If a pelvic mass is present, then additional special studies may be indicated to differentiate between hematometra, hematocolpos, endometrial and other ovarian cysts, and pelvic kidney. The MR urogram may facilitate the evaluation of the reproductive, urologic, and skeletal systems with one radiographic study.

Evaluation of Cyclic Pain

Some patients without a pelvic mass report cyclic pain. This pain can be ovulatory or possibly a result of dysmenorrhea originating in well-developed rudimentary uterine bulbs. The physician can differentiate between the two by asking the patient to keep a pain diary and reviewing the diagnostic imaging with an experienced reconstructive gynecologic surgeon or radiologist to ensure that an obstructed anlagen is not present. Occasionally, there is a question about whether a patient has congenital absence of the vagina or an imperforate hymen with cryptomenorrhea. The diagnosis is clarified before operative intervention by using radiographic imaging. Pelvic ultrasonography can often detect hematocolpos or an

obstructed uterine anlagen distended with menstrual blood. Magnetic resonance imaging (MRI) can differentiate the two diagnoses, if necessary.

METHODS OF CREATING A VAGINA

There is no unanimity of opinion regarding the correct approach to the problem of vaginal agenesis (Table 25.3). With the development of the Ingram method for vaginal dilatation, fewer patients require surgical vaginoplasty. The American Congress of Obstetricians and Gynecologists has supported nonsurgical creation of a neovagina as first-line therapy since 2006. Increased utilization of additional surgical techniques has broadened the discussion of surgical treatment of vaginal agenesis. The role of tissue expanders in vaginoplasty has been reviewed by Patil and Hixon. Labial expansion with an expander having a capacity of 250 mL provides a flap

P.515

10 cm long and 8 cm wide with a 4-cm projection. Thus, wellvascularized flaps can be available to provide an outlet for stenosis-free vaginoplasty. This approach has been suggested to maximize the success of surgical vaginoplasty. A review of the methods devised for the formation of a vagina follows. The editors of this book have found the modified McIndoe technique to give the most consistently satisfactory results.

TABLE 25.3 Classification of Methods to Form a New Vagina

Nonsurgical (intermittent pressure on the perineum)
Active dilatation
Passive dilatation
Surgical
Without the use of abdominal contents
Without cavity dissection
Vulvovaginoplasty
Constant pressure (Vecchietti)
No attempt to line cavity (now unacceptable)
Lining cavity with grafts
Split-thickness skin grafts (McIndoe operation)
Dermis grafts
Amnion homografts
Lining cavity with flaps
Musculocutaneous flaps
Fasciocutaneous flaps
Subcutaneous pedicled skin flaps
Labial skin flaps (can be created with tissue expander)
Penoplasty (transsexualism)
With use of abdominal contents (cavity lining with)
Peritoneum
Free intestinal graft
Pedicled intestine

Nonsurgical Methods

In 1938, Frank described a method of creating an artificial vagina without operation. In 1940, he reported remarkably satisfactory results in eight patients treated with this method. His follow-up study showed that a vagina formed in this manner remained permanent in depth and caliber, even in patients who neglected dilatation for more than 1 year. It has been emphasized that the pelvic floor itself is embryologically deficient in some patients. Indeed, the ease with which some patients are able to create a vagina with intercourse alone or with other intermittent pressure techniques can be explained on this basis. Five patients were reported to have developed enteroceles, one after coitus alone, three after a Williams vulvovaginoplasty, and three after a McIndoe operation. This complication can develop when the vaginal mucosa is brought in close proximity to the pelvic peritoneum, but a relative embryologic weakness or an absence of endopelvic fascia can also contribute to this complication. Rock, Reeves, and associates at the Johns Hopkins Hospital reported that an initial trial of vaginal dilatation was successful in 9 of 21 patients.

Prompted by the rewarding results of Broadbent and Woolf, Ingram has described a passive dilatation technique of creating a new vagina. Instructing his patients in the insertion of dilators (Fig. 25.5) specially designed for use with a bicycle seat stool, Ingram was able to produce satisfactory vaginal depth and coital function in 10 of 12 cases of vaginal

agenesis and 32 of 40 cases of various types of stenosis.

FIGURE 25.5 Vaginal dilators for use in Ingram passive dilatation technique to create a new vagina. The set from Faulkner Plastics consists of 19 dilators of increasing length and width.

The Ingram technique for passive dilatation has several advantages. The patient is not required to press the dilator against the vaginal pouch. A series of graduated Lucite dilators slowly and evenly dilate the neovaginal space. The patient should be carefully instructed in the use of dilators, as recommended by Ingram, beginning with the smallest dilator. The patient is shown and instructed with the use of a mirror how to place a dilator against the introital dimple. The dilator may be held in place with a supportive undergarment and regular clothing worn over this.

The patient is shown how to sit on a racing-type bicycle seat that is placed on a stool 24 inches above the floor. She is instructed to sit leaning slightly forward with the dilator in place for at least 2 hours/day at intervals of 15 to 30 minutes. Follow-up is usually at monthly intervals, and the patient can expect to graduate to the next size larger dilator approximately every month. An attempt at sexual intercourse may be suggested after the use of the largest dilator for 1 or 2 months. Continued dilatation is recommended if intercourse is infrequent. In our experience, functional success rates are outstanding. Roberts, Haber, and Rock previously reported the largest series of vaginal agenesis patients who used the Ingram method of dilatation to create a neovagina. The records of 51 patients with müllerian agenesis were reviewed: 37 patients attempted vaginal dilatation, and 14 young women underwent a surgical intervention. Functional success was defined as satisfactorily achieving intercourse or accepting the largest dilator without discomfort in the clinic visit. All patients were followed up for at least 2 years and for an average of 9.25 years. Functional success was achieved in 91.9% of those who attempted dilatation (Table 25.4). Thus, passive dilatation should be suggested as an initial therapy for vaginal creation. If dilatation is unsuccessful, operative vaginoplasty is indicated.

Edmonds and colleagues reported on their experience with managing 360 patients with MRKH from 1998 to 2010. Two hundred forty-five patients requested vaginal dilation for treatment. The mean age of dilating patients was 18.6 years (16 to 22 years). Success was defined as achieving sexual satisfaction and functional vaginal length (6 cm) and was achieved in 232 of 245 patients (94.7%). The mean time to complete therapy was 5.5 months (2 to 19 months). Despite having large number of patients in the study, the applicability outside of the United Kingdom could be questioned. The UK program consists of an intensive program in which patients have an identified clinical nurse specialist for teaching and support, one or two specific providers, and an inpatient admission (an average of 3 days) to teach dilation technique. Also, sexual satisfaction was not measured in a structured way for all patients; a subset of 60 patients were assessed using a sexual function questionnaire with the answers compared to a normal population. In the United States,

P.516

Gargollo and colleagues described their 12-year experience treating patients with vaginal agenesis. Rokitansky syndrome was the primary diagnosis in 64 of the 69 patients included in the retrospective review. The mean age at start of vaginal dilation was 17.5 years (14 to 35 years), and mean follow-up time was 19 months (0 to 100). Progressive perineal dilation was the treatment of choice. The total success rate was 88% achieving functional success (ability to achieve satisfactory vaginal intercourse, vaginal acceptance of the largest dilator, or vaginal length of at least 7 cm), during a mean of 18.7 months of therapy. Their work not only described an outpatient regimen that could be applicable in the United States but also highlighted the integral role that the multidisciplinary team plays in patient success. They also reinforced that dilating can be successful even in patients with a small vaginal dimple; thus, validating an attempt would be reasonable in almost all patients with vaginal agenesis.

TABLE 25.4 Outcomes of Patients with Vaginal Agenesis Who Attempted Dilatation

PATIENTS	TOTALS	PERCENT
Successful dilatation	34/37	91.9% ^a
Failed dilatation	3/37	8.1%

Surgical Methods

During the past three decades, experience has proved the Abbe-Wharton-McIndoe procedure (more popularly called the McIndoe operation) for dealing with complete absence of a vagina to be generally superior to others in most cases. In special circumstances, alternative methods of creation of a neovagina may be indicated.

Historical Development of Surgical Procedures

In 1907, Baldwin used a double loop of ileum to line a space dissected between the rectum and bladder, leaving the mesentery connected to the bowel. The continuity of the intestinal tract was reestablished by an end-to-end anastomosis. He reported that the new vagina was absolutely normal in every way. In 1910, Popaw constructed a vagina using a portion of the rectum that was moved anteriorly. This operation was modified by Schubert in 1911. The rectum was severed above the anal sphincter and moved anteriorly to serve

as the vagina. The sigmoid was sutured to the anus to reestablish the continuity of the intestinal tract. Both operations had soberingly high morbidity and mortality rates, and their popularity declined. Today, segments of sigmoid are used most often to create a vaginal pouch or extend vaginal length in patients who have lost vaginal function as a result of extensive surgery or irradiation for pelvic malignancy. Some patients who are treated for multiple genitourinary or gastrointestinal abnormalities may be treated with a bowel vaginoplasty during a combined procedure.

Less formidable procedures involving dissection of a space between the bladder and rectum and lining of this space with flaps of skin from the labia or inner thighs also were tried. Marked scarring resulted, and hair usually grew in the vagina. Extensive plastic procedures to construct a vagina are no longer necessary or desirable and have been discarded in favor of safer procedures unless there is the problem of maintaining a vaginal canal after an extensive exenterative operation for pelvic malignancy. In this case, the physician may want to consider using the gracilis myocutaneous flap technique described by McCraw and associates in 1976.

The Abbe-Wharton-McIndoe Operation

This operation for creating a new vagina began with simple surgical attempts to create a space between the bladder and the rectum. These early attempts were often made in patients with cryptomenorrhea. However, such a space usually would constrict because the surgeon would fail to recognize the importance of prolonged continuous dilatation until the constrictive phase of healing was complete.

At the Johns Hopkins Hospital in 1938, Wharton combined an adequate dissection of the vaginal space with continuous dilatation by a balsa form that was covered with a thin rubber sheath and was left in the space. He did not use a split-thickness skin graft. Instead, he based his operation on the principle that the vaginal epithelium has remarkable powers of proliferation and in a relatively short time will cover the raw surface. Recalling that a similar process occurs in the fetus when the epithelium of the sinovaginal bulbs and the urogenital sinus form the vaginal canal, Wharton merely applied this same principle in the adult. This simple procedure is entirely satisfactory as long as the space is kept dilated long enough to allow the epithelium to grow in. Occasionally, however, even after several years, the vault of the vagina remains without epithelial covering. Coital bleeding and leukorrhea result from the persistent granulation tissue, and there is a tendency for vaginas constructed by this method to be constricted by scarring in the upper portion. In Counsellor's 1948 report from the Mayo Clinic of 100 operations to construct a new vagina, 14 were performed by the Wharton method, with excellent results in all 14 patients. It was stated that the disadvantages of persistent granulation tissue with bleeding and leukorrhea were of no consequence. This has not been the experience of the editors of this book.

When inlay skin grafts were first used to construct a new vagina, the results were poor because the necessity for dilatation of the new vagina again was not recognized. Severe contraction, uncontrolled by continuous or intermittent dilatation, almost invariably spoiled the results. Although Abbe and others preceded him by many years in using a skin-covered prosthesis in neovaginal construction, it was Sir Archibald McIndoe, at the Queen Victoria Hospital in England, who popularized the method and gave it substantial clinical trial. He emphasized the three important principles used today in successful operations for vaginal agenesis:

1. Dissection of an adequate space between the rectum and the bladder
2. Inlay split-thickness skin grafting
3. The cardinal principle of continuous and prolonged dilatation during the contractile phase of healing

Other tissues such as amnion and peritoneum have been used to line the new vaginal space, but they have not had substantial success. However, Tancer and associates reported good results with human amnion. Karjalainen and associates stated that a more physiologic result was achieved with an amnion graft than with a skin graft. Nevertheless, concerns about the transmission of human immunodeficiency virus with human amnion now limit this option.

Technique of Abbe-Wharton-McIndoe Operation

TAKING THE GRAFT

After a careful pelvic examination is performed under anesthesia to verify previous findings, the patient is positioned for taking a skin graft from the buttocks. For cosmetic reasons, the graft should not be taken from the thigh or hip unless for some reason it cannot be obtained from the buttocks. Patients may be asked to sunbathe in a bathing suit before coming to the hospital so that its outline can be seen; an attempt should be made to take the graft from both buttocks within these borders. The quality of the graft determines to a great extent the success of the operation. We have found the Padgett electrodermatome to be the most satisfactory instrument for taking the graft. With relatively little experience and practice, the gynecologic surgeon can successfully cut a graft of controlled width and thickness (Fig. 25.6). The instrument is set and checked for taking a graft approximately 0.018 inch thick and 8 to 9 cm wide. The total graft length should be 16 to 20 cm. If the entire graft cannot be taken from one buttock, then a graft 8 to 10 cm long is needed from each buttock.

FIGURE 25.6 Section of split-thickness skin grafts. Grafts should be uniform in thickness. The Padgett electrodermatome is set to take a graft approximately 0.018 inch thick. A graft that is slightly thick is better than a thin graft.

The skin of the donor site is prepared with an antiseptic solution (povidone-iodine), which is then thoroughly washed away. The skin is then lubricated with mineral oil as assistants steady and stretch the skin tight. Considerable pressure should be applied uniformly across the dermatome blade. The thickness of the graft must have minimal variation. A graft that is a little too thick is better than one that is a little too thin. There should be no breaks in the continuity of the graft. The graft is placed between two layers of moist gauze, and the donor sites are dressed. The donor site is soaked with a dilute solution of epinephrine for hemostasis, and a sterile dressing is applied. A pressure dressing is then placed over the site; this dressing can be removed on the seventh postoperative day. The sterile dressing dries in place over the donor site and ultimately will fall off by itself. Moistened areas on the dressing can be dried with cool air. If there is separation and evidence of some superficial infection, then merbromin can be applied to these areas.

FIGURE 25.7 The McIndoe procedure. **A:** A transverse incision is made in the apex of the vaginal dimple. **B:** A channel can usually be dissected on each side of the median raphe. The median raphe is then divided. Careful dissection prevents injury to the bladder and rectum. **C:** A space between the urethra and bladder anteriorly and the rectum posteriorly is dissected until the undersurface of the peritoneum is reached. Incision of the medial margin of the puborectalis muscles will enlarge the vagina laterally.

CREATING THE NEOVAGINAL SPACE

The patient is placed in the lithotomy position, and a transverse incision is made through the mucosa of the vaginal vestibule (Fig. 25.7A). The space between the urethra and bladder anteriorly and the rectum posteriorly is dissected until the undersurface of the peritoneum is reached.

P.518

This step may be safer with a catheter in the urethra and sometimes a finger in the rectum to guide the dissection in the proper plane. After incising the mucosa of the vaginal vestibule transversely, the physician often is able to create a channel on each side of a median raphe (Fig. 25.7B), starting with blunt dissection and then dilating each channel with Hegar dilators or with finger dissection. In some instances, it may be necessary to develop the neovaginal space by dissecting laterally and bringing the fingers toward the midline. The median raphe is then divided, thus joining the two channels. This maneuver is helpful in dissecting an adequate space without causing injury to surrounding structures.

To avoid subsequent narrowing of the vagina at the level of the urogenital diaphragm, it may be helpful to incise the margin of the puborectalis muscles bilaterally along the midportion of the medial margin (Fig. 25.7C). Although useful in all circumstances, incision of the puborectalis muscle is more important in cases of androgen insensitivity syndrome with android pelvis, in which the levator muscles are more taut against the pelvic diaphragm, than in cases of gynecoid pelvis. Incision of the puborectalis muscle causes no difficulty with fecal incontinence, significantly improves the ease with which the vaginal form can be inserted into the canal in the postoperative period, and has eliminated the problem of contracture of the upper vagina caused by a poorly applied form. The dissection should be carried as high as possible without entering the peritoneal cavity and without cleaning away all tissue beneath the peritoneum. A split-thickness skin graft will not take well when applied against a base of thin peritoneum. All bleeders should be ligated by clamping and tying them with very fine sutures. It is essential that the vaginal cavity be dry to prevent bleeding beneath the graft. Bleeding causes the graft to separate from its bed, resulting in the inevitable failure of the graft to implant in that area and in local graft necrosis.

PREPARING THE VAGINAL FORM

Early skin grafts were formed over balsa, which has the advantages of being an inexpensive, easily available, light wood that can be sterilized without difficulty. It also can be whittled easily in the operating room to a proper shape to fit the new vaginal space. However, uneven pressure from the form can cause a skin graft to slough in places, and pressure spots are associated with an increased risk of fistula formation. The Counseller-Flor modification of the McIndoe technique (Fig. 25.8) uses, instead of the rigid balsa form, a foam rubber mold shaped for the vaginal cavity from a foam rubber block and covered with a condom. The foam rubber is gas sterilized in blocks measuring approximately 10 × 10 × 20 cm. The block is shaped with scissors to approximately twice the desired size, compressed into a condom, and placed into the neovagina (Fig. 25.8A-C). The form is left in place for 20 to 30 seconds with the condom open to allow the foam rubber to expand and conform to the neovaginal space (Fig. 25.8D). The condom is then closed, and the form is withdrawn. The external end is tied with 2-0 silk, and an additional condom is placed over the form and tied securely (Fig. 25.8E, F).

SEWING THE GRAFT OVER THE VAGINAL FORM

The skin graft is then placed over the form and its undersurface exteriorized and sewn over the form with interrupted vertical mattress 5-0 nonreactive sutures (Fig. 25.8G, H). Where the graft is approximated, the undersurfaces of the sutured edges are also exteriorized.

The graft should not be “meshed” to make it stretch farther, and the edges of the graft should be approximated meticulously around the form without gaps. Granulation tissue develops at any place where the form is not covered with skin. Contraction usually occurs where granulation tissue forms. After the form has been placed in the neovaginal space, the edges of the graft are sutured to the skin edge with 5-0 nonreactive absorbable sutures, with sufficient space left between sutures for drainage to occur. The physician must be careful not to have the form so large that it causes undue pressure on the urethra or rectum. A balsa form should have a groove to accommodate the urethra. With a foam rubber form, this is unnecessary. A suprapubic silicone catheter is placed in the bladder for drainage. If the labia are of sufficient length, then the form can be held in place by suturing the labia together with two or three nonreactive sutures.

REPLACING WITH A NEW FORM

After 7 to 10 days, the form is removed and the vaginal cavity is irrigated with warm saline solution and inspected. This is usually performed with mild sedation and without an

anesthetic. The cavity should be inspected carefully to determine whether the graft has taken satisfactorily in all areas of the new vagina. Any undue pressure by the form should be noted and corrected. It is especially important that there not be too much pressure superiorly against the peritoneum of the cul-de-sac. Such a constant upward pressure could result in weakness with subsequent enterocele formation. The new vaginal cavity must be inspected frequently to detect and to prevent pressure necrosis of the skin graft.

The patient is given instructions on daily removal and reinsertion of the form and is taught how to administer a lowpressure douche of clear warm water. She is advised to remove the form at the time of urination and defecation, but otherwise to wear it continuously for 6 weeks. A neoprene form, which is much easier to remove and keep clean than a foam rubber form, is substituted for the original form in 6 weeks. A new form is molded with a sterile sheath cover (condom) to fit the size of the vaginal canal. The patient is instructed to use the form during the night for the following 12 months. If there has been no change in the caliber of the vagina by that time, then it is unlikely to occur later, and insertion of the form at night can be done intermittently until coitus is a frequent occurrence. However, if there is the slightest difficulty in inserting the form, then the patient should be advised to use the form continuously again. Most patients are able to maintain the form in place simply by wearing tighter underclothes and a perineal pad. Douches are advisable during residual vaginal healing and discharge.

RESULTS AND COMPLICATIONS

Results with the McIndoe operation have improved over the years. Recently, reported percentages of satisfactory results have ranged from 80% to 100%. The serious complications formerly associated with the McIndoe operation have been significantly reduced by improvements in technique and greater experience. Serious complications do still occur, however, including a 4% postoperative fistula rate (urethrovaginal, vesicovaginal, and rectovaginal), postoperative infection, and intraoperative and postoperative hemorrhage. Failure of graft take is also still reported as an occasional complication. Failure of graft take often leads to the development of granulation tissue, which might require reoperation, curettage of the granulation tissue down to a healthy base, and even regrafting. Minor granulation can be treated with silver nitrate application. The functional result is more important than the anatomic result in evaluating the success of this operation. Although a vagina of only 4 cm is adequate for some couples, in most instances, a vagina smaller than 4 cm causes major problems.

P.519

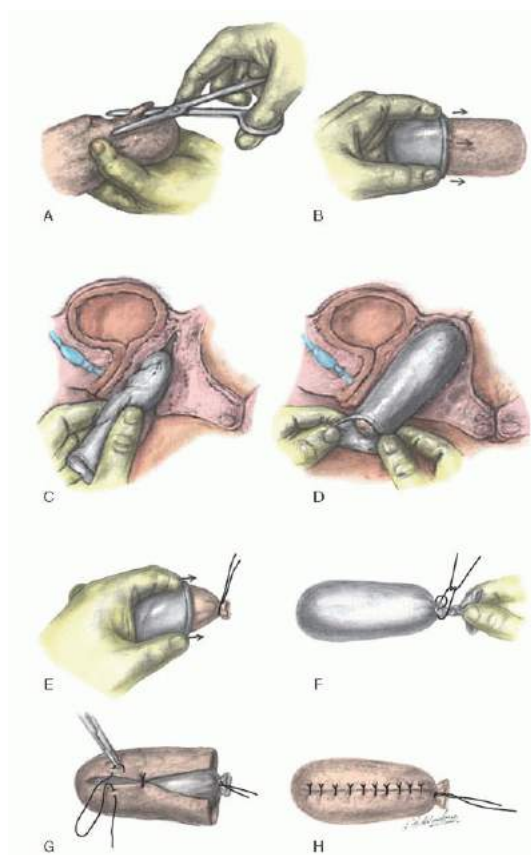

FIGURE 25.8 Counseller-Flor modification of the McIndoe technique. **A:** A form is cut from a foam rubber block. **B:** A condom is placed over the form. **C:** The form is compressed and placed into the vagina. **D:** Air is allowed to expand the foam rubber, which accommodates to the neovaginal space. The condom is closed and the form removed. A second condom is placed over the form (**E**) and tied securely (**F**). **G:** The graft is then sewn over the form with interrupted 5-0 nonreactive sutures. **H:** The undersurfaces of the sutured edges of the graft are exteriorized. The vaginal form is ready for insertion into the neovagina.

The postoperative results have improved significantly since the balsa vaginal form was replaced by the foam rubber form. Between 1950 and 1989, the McIndoe operation was performed on 94 patients at the Johns Hopkins Hospital. During these 39 years, 83% of the 94 patients had a 100% take of the graft; in only three cases was there a significant area over which the graft failed.

Urethrovaginal fistula has become even more infrequent since the introduction of the suprapubic catheter and the foam rubber form. The catheter is removed when the patient is voiding well and has no residual urine. In general, the patient is able to void without difficulty within the first few days of the procedure. Prophylactic broad-spectrum antibiotics started within 12 hours of surgery and continued for 7 days are of definite value in reducing the incidence of graft failures from infection in the operative site.

Because of the excellent results obtained after a modified McIndoe vaginoplasty, this operation is recommended as the procedure of choice for women unable or unwilling to obtain a neovagina with dilatation methods. Women with a flat perineum with no dimple or pouch have no alternative other than the McIndoe vaginoplasty to obtain a neovagina for comfortable sexual relations.

Desirability of the modified McIndoe procedure may be increased by the use of alternative graft harvest sites to conceal possible aesthetic concerns of the buttock site, as proposed by

P.520

Höckel and colleagues. The authors proposed the use of split skin harvesting from the scalp because thin (0.25-mm) split skin grafts do not seem to hamper hair growth at the donor site nor lead to hair growth at the recipient site. Because alopecia has been reported as a complication associated with technical errors, more experience is necessary before advocating the scalp as a potential graft harvest site.

It is important that a McIndoe operation be performed correctly the first time. If the vagina becomes constricted because of granulation tissue formation, injury to adjacent structures,

or failure to use the form properly, then subsequent attempts to create a satisfactory vagina are more difficult. The first operation has the best chance of success.

Ozek, like many other surgeons, modified the McIndoe procedure by describing an X-type perineal incision and the use of a perforated vaginal mold during the postoperative period. He postulated that this incision minimized stricture at the vaginal introitus and provided greater ease of dissection of the vaginal cavity. He reinforced that the overall procedure is simple with a generally uneventful postoperative course. Complications included infection, failure of skin graft take, stress urinary incontinence, partial graft loss, and vaginal stricture. All were treated satisfactorily except the patient with stress urinary incontinence.

Despite any minor modifications of the McIndoe vaginoplasty, the essential components of dissection of an adequate space, split-thickness skin grafting, and continuous dilatation during the contractile phase of healing remain unchanged. Recent reviews continue to support the safety and efficacy of the procedure. Hojsgaard and Villadsen reported 26 patients who underwent vaginoplasty, 18 of whom had Rokitansky syndrome. All patients were recorded as having a satisfactory result with complete graft take, adequate vaginal dimensions, and no strictures or fistulas giving symptoms. Complete take was achieved in 33% of patients within a week postoperatively, and after one further grafting procedure, an additional 38% had complete take. The intraoperative and early postoperative complications were perforation of the rectum in one patient (3.8%) and postoperative bleeding in three patients (11.5%). The late complications were vaginal stricture in three patients (11.5%), urethrovaginal fistula in two patients (7.7%), and rectovaginal fistula in one patient (3.8%). Alessandrescu and colleagues described the surgical management of 201 cases of Rokitansky syndrome. The surgeon substituted a modified transverse perineal incision and a perforated, rigid plastic mold. Intraoperative and postoperative complications consisted of two rectal perforations (1%), eight graft infections (4%), and 11 infections of graft site origin (5.5%). Sexual satisfaction was investigated with both objective and subjective criteria. Among the 201 cases, 83.6% had anatomic results evaluated as "good," 10% as "satisfactory," and 6.5% as "unsatisfactory." More than 71% of patients rated their sexual life as "good" or "satisfactory" and reported that they had been able to experience orgasms related to vaginal intercourse. Twenty-three percent reported the ability to have sexual intercourse but had no ability to achieve orgasm, and only 5% expressed dissatisfaction with their sexual performance. Strickland and colleagues reported on the coital satisfaction, perception of vaginal competence, and impact on lifestyle of adult women undergoing vaginoplasty as adolescents. Ten of twenty-two women responded to a questionnaire at a median of 18 years (range 5 to 13 years) following surgical intervention with a McIndoe vaginoplasty. All of the women had sexual experience, and 80% were sexually active at the time of evaluation. The most frequent difficulty reported was vaginal dryness and lack of lubrication with sexual intercourse. Ninety percent of the subjects expressed satisfaction that sexual ability was acceptable. This experience also supports the role of the McIndoe vaginoplasty in providing young women with vaginal agenesis long-term coital ability and minimal disabilities.

DEVELOPMENT OF COMPLICATIONS

Several case reports exist of malignant disease developing in a vagina created by various techniques; these reports were reviewed by Gallup and colleagues, as well as others. The authors reported a patient who was initially treated for intraepithelial malignancy by total vaginectomy combined with a split-thickness skin graft vaginoplasty to reconstruct a functional vagina. The authors noted a lesion in her vaginal apex 7 years later. These findings suggest that epithelium transplanted to the vagina can assume the oncogenic potential of the lower reproductive tract. The evidence supports a risk of neoplastic change in both skin and bowel grafts, with a reported average interval from vaginoplasty to diagnosis on the order of 19 years or greater. Epithelium transplanted to the vagina will assume the oncogenic potential of the lower reproductive tract. With less than 25 cases of primary carcinoma of the neovagina reported, it is presently unclear if transplantation of bowel or other graft tissue alone changes the malignancy risk. Consideration of a plan for surveillance and counseling regarding transmission risk for virally related dysplastic change in the lower genital tract is also extremely important for any patients undergoing neovaginoplasty. Neovaginal vault prolapse has also been reported in patients managed both medically and surgically. Without apical or lateral suspension by endopelvic fascial attachments, subsequent prolapse may develop with any type of neovagina. Prolapse in neovaginal segments created by dilation, McIndoe technique, skin flaps, and bowel segments is reported. Abdominal suspension via sacrocolpopexy, abdominal suspension to the Cooper ligament, vaginal resection of redundant prolapsed bowel neovagina, and sacrospinous ligament suspension have all been described as treatment. Kondo and colleagues report a recurrence rate after surgical treatment of 25%.

The Williams Vulvovaginoplasty

Construction of a perineal bridge to help contain the vaginal mold was a routine part of the operation described by McIndoe, but it was not adopted subsequently by others. However, Williams described a similar vulvovaginoplasty procedure in 1964 and advised that it could be used to create a vaginal canal (Fig. 25.9). In 1976, he reported that the procedure was unsuccessful in only 1 of 52 patients. Feroze and coworkers reported that the anatomic results were good in 22 of 26 patients. According to these authors, the advantages of the Williams operation are its technical simplicity, its absence of serious local complications even when performed as a repeat procedure, the ease of postoperative care, the absence of postoperative pain, the speed of recovery, the possible elimination of dilators and consequent applicability to patients who do not intend to have regular intercourse in the near future, and the higher success rates of primary and repeat procedures. The technique is not applicable to patients with poorly developed labia. It does result in an unusual angle of the vaginal canal, which is reported to straighten to a more normal direction with intercourse. If a very high perineum is created, urine can momentarily collect in the pouch after urination, giving the impression of postvoid incontinence. Failure of the suture line to heal by primary intention results in a large area of granulation tissue and most likely an unsatisfactory result.

Williams believes that if the urethral meatus is patulous, a vulvovaginoplasty should not be performed because the urethra might be stretched further by coitus. He suggests that varying deficiencies in muscular and fascial tissue can explain

P.521

why some patients with uterovaginal agenesis are able to develop a satisfactory vaginal canal with simple intermittent pressure with coitus, whereas others are prone to develop enteroceles.

FIGURE 25.9 The Williams vulvovaginoplasty. **A-C:** No. 3-0 polyglycolic acid sutures can be used throughout to close both inner and outer skin margins and the tissue between. **D:** The entrance to the pouch should not cover the external urethral meatus.

The Williams vulvovaginoplasty is a useful operation and should certainly be considered the operation of choice for patients needing a follow-up to an unsatisfactory primary operation to create a neovagina or a supplement to a small vagina resulting from extensive surgery or radiation therapy, when options are limited. It remains an option for the rare patient with a solitary kidney low in the pelvis who does not have room for dissection of an adequate vaginal space.

Alternative Techniques

Schätz and colleagues reported three patients who underwent the George modification of the Wharton-Sheares neovaginoplasty technique. Wharton combined an adequate dissection of the vaginal space with continuous dilatation by a balsa form that was covered with a thin rubber sheath and was left in the space. His operation was based on the principle that the vaginal epithelium will proliferate and, in a relatively short time, will cover the raw surface. This modification of an already simple procedure may provide an alternative in areas where multidisciplinary, reconstructive pelvic surgery teams are not available. Because the procedure includes the mere dilatation of the bilateral müllerian ducts and lining of the superior aspect with peritoneum, it eliminates some of the more complex aspects of the other surgical options. However, with a mean follow-up period reported as only 12 months (range of 2 to 23 months), reported long-term complications associated with the Wharton method (persistent granulation tissue, coital bleeding, leukorrhea, and scarring of the upper portion) cannot be fully evaluated. Longer follow-up and a larger patient experience are both necessary to consider this procedure as a primary option for patients with MRKH. Walch and colleagues from Austria reported the outcome of 10 patients with MRKH treated with the George modification of the Wharton-Sheares approach. Mean follow-up from surgery was 33.5 ± 22.4 months (range 3 to 77 months). Data collected on follow-up included cytologic smears of the neovagina, swabs, culture, and hybrid capture for human papillomavirus (HPV). The mean vaginal length was 8.3 cm (range 7 to 10 cm). Of the 8 patients from whom a biopsy was able to be obtained, all showed nonkeratinizing stratified squamous epithelium. The sexual function scores obtained by the Rosen FSFI questionnaire were comparable to previously published control patients. The authors propose that an important drawback of this technique may be the lifelong routine need for the use of vaginal dilators ([Table 25.5](#)).

P.523

Since the initial report of the use of oxidized cellulose material instead of a skin graft to line the neovaginal space, more than 30 cases have been reported using several different commercial products. No operative or postoperative complications have been reported and epithelialization was noted between 1 and 12 months after the procedure. Limited long-term data are available regarding this technique. Dornelas and colleagues in Brazil recently reported on 11 patients treated with this modality, eight of which had MRKH. The mean follow-up for the entire group was 14 months (6 to 24 months). Patients who were sexually active at the 6-month assessment were administered the FSFI, translated into Portuguese, with all the results in the “very good” range. The authors reinforced that if sexual intercourse is suspended for prolonged periods, vaginal dilation may be required to preserve vaginal length. The proposed advantages include the shorter operative times and easily available material that does not require additional surgical expertise. Several authors, including Adamyan, Soong et al., and Templeman and colleagues, have described the laparoscopic use of the peritoneum to create a neovagina in patients with vaginal agenesis. Adamyan and Soong et al. reported a group of 45 patients without significant postoperative complications. The most common postoperative problem involved the formation of granulation tissue at the vaginal vault. Templeman and colleagues described the laparoscopic mobilization of peritoneum for the creation of a neovagina in only one patient. The peritoneum was grasped through a perineal dissection and sutured to the introitus. A purse-string closure was placed at the apex. Stenting of the neovagina was continued for 3 months postoperatively followed by rigid dilator use. At 9-month follow-up evaluation, an 8- by 2-cm vagina was described, with squamous epithelialization present. Both groups describe the technique as safe and efficient, producing a neovagina with apical granulation tissue as the only complication. Bianchi and colleagues reported on eighty patients with Rokitansky syndrome. Forty patients underwent a Davydov procedure. The team highlighted that the Davydov procedure is a better choice in patients with female hypospadias but may have more risk in patients with a pelvic kidney or patients with previous pelvic surgery and adhesions. They also argued that the Davydov approach immediately achieves good functional results and there is less need for vaginal dilation than other methods to maintain the end result. They found a mean vaginal length of 7.25 ± 2.1 cm at discharge and 8.5 ± 1.6 cm at 12 months postprocedure. At 12 months postprocedure, the FSFI was completed by all the patients in the study with globally optimal results. No important complications occurred, although one patient experienced introital stenosis, which did not require surgery. However, they also again reinforced the risk of significant complications including rectal and bladder perforation. Lastly, they commented on potential limitation of the Davydov in the situation of postoperative failure. They suggest that this procedure yields poor chance of surgical correction due to the difficulty of recanalization of the urethrovesicorectal space. Giannesi and colleagues reported an assessment of sexuality via a self-report questionnaire after the laparoscopic Davydov procedure. The FSFI was also administered to both 28 women who underwent a laparoscopic Davydov procedure and 28 age-matched controls. The anatomical result was judged to be satisfactory (>6 cm) in 26 of 28 patients with a mean vaginal length of 7.2 ± 1.5 cm. No statistical difference was found between the subjects and the controls in all six domains of the FSFI; however, the authors note that 6 of the 25 (24%) operative subjects who completed the entire FSFI had a poor FSFI result. Of note, the areas of greatest concern were in the areas of lubrication and pain. Liao and colleagues reported on 31 patients with MRKH who underwent surgery with a laparoscopic Davydov procedure. Seven patients were lost to follow up, so only 24 patients completed the surgery and requested follow-up. The FSFI was administered to evaluate function of patients who became sexually active and compared them with 50 randomly selected, age-matched healthy women. There was no significant difference in the frequency of sexual intercourse between the control group and the 20 cases who were sexually active. There was no statistical difference in scores of all six domains of the FSFI between the cases and the control subjects. The data from both groups suggest positive functional results.

The Vecchiatti operation was first described in 1965 by Giuseppe Vecchiatti. He subsequently reported his cumulative 14-year experience in 1979 and 1980. Veronikus and colleagues reviewed the use of the technique and described a laparoscopic modification that uses cystoscopy to confirm bladder integrity. The Vecchiatti procedure is a surgical technique for the treatment of vaginal agenesis that constructs a dilatation-type neovagina in 7 to 9 days. The procedure uses specialized equipment including a traction device, a ligature carrier, and an acrylic-shaped olive. The process is in two steps, with essential operative and postoperative components. The operative phase involves positioning the olive at the perineum and the traction sutures extraperitoneally. Classically performed through a Pfannenstiel incision, the ligature carrier introduces the suture into a newly dissected vesicorectal space. The olive is threaded with suture at the perineum, and the suture is reintroduced at the abdomen. The suture is then guided lateral to the rectus muscles bilaterally in a subperitoneal fashion and advanced along the sidewall. The traction device, which provides constant traction on the olive, is positioned on the abdomen. During the postoperative invagination phase, the neovagina is created by applying constant traction to the olive. The process reportedly occurs at a rate of 1.0 to 1.5 cm per day, developing a 10- to 12-cm vagina in 7 to 9 days. Prior to being discharged, patients are instructed on how to use a vaginal obturator on an outpatient basis. Borruto reported on Vecchiatti's personal series of vaginal agenesis patients, comprising 522 consecutive patients. The surgical complications included one bladder and one rectal puncture with the ligature carrier and three cases of vaginal vault bleeding. At 100% follow-up at 1 month, dyspareunia was initially reported to be 12%, but resolved in all cases by 3 months. There were no reported failures of the neovaginal construction with 1- and 2-year follow-up of 70% and 30%, respectively.

Modifications of the Vecchiatti approach include the use of laparoscopy and elimination of the dissection of the vesicorectal space. The first description of a laparoscopic modification was published by Gauwerky and colleagues. The vesicorectal space was dissected laparoscopically. The threads of the olive device were positioned using a probe introduced into the abdomen through the perineum. Six small abdominal incisions were used for laparoscopic instruments and the traction springs of the specialized device. In 1995, Laffarque and others described a laparoscopic intervention, creating a neovagina in three patients without dissection of the vesicorectal space. At completion of the procedure, cystoscopy was used to confirm bladder integrity. Some experts believe the theoretical risk of bladder or rectal perforation without the dissection of the vesicorectal space is unacceptably high. Brucker and colleagues in Tübingen, Germany, reported on their experience with the Vecchiatti procedure in 101 patients with 93 treated for vaginal agenesis. They stratified their patients to three groups: Group 1 with conventional instruments and tunneling in the vesicorectal space, Group 2 included conventional instruments and no dissection in the vesicorectal space, and Group 3 combined both

P.524

specialized instruments and no vesicorectal dissection. Group 3 had the longest mean vaginal length immediately postprocedure (9.6 cm compared to 8.9 cm in Group 1 and 7.8 cm in Group 2) and shortest traction time (4.8 days compared to 11.7 days in Group 1 and 7.5 days in Group 2). Mean followup for Group 2 was 37.7 months compared to 15.5 months in Group 3. Without tunneling and the new specialized instruments, the mean operative time was decreased from 113.0 to 47.5 minutes with a significant reduction in complication rate for bladder lesions and no bowel lesions. Bianchi and colleagues also described their experience with 80 patients who underwent laparoscopic creation of neovagina. Forty of these patients underwent a laparoscopic Vecchiatti procedure. Mean operating room time was 30 ± 9.6 minutes. Their group did not perform a Vecchiatti procedure for patients with female hypospadias due to risks to the urethra with introital pressure. Preferentially, they performed a laparoscopic Vecchiatti for patients with a pelvic kidney, in lieu of other laparoscopic options. They noted that the Vecchiatti is easier as a laparoscopic procedure since the perineal approach is not necessary with the absence of dissection in the vesicorectal space. When comparing the outcomes to the laparoscopic Davydov procedure, they reported initially longer vaginal length with the Davydov approach (6.3 ± 0.7 cm for Vecchiatti, 7.25 ± 2.1 cm for Davydov), which persists at 12 months; however, both remain within the clinically normal range (7.5 ± 1.1 cm for Vecchiatti, 8.5 ± 1.6 cm for Davydov). Additionally, there were no important differences in sexual quality of life, as demonstrated by FSFI scores. Fedele and colleagues modified the approach to use a combined laparoscopic-ultrasonographic technique. The ultrasound assists in identifying the space of connective tissue between the bladder and rectum. The operating time for this modified procedure was only 40 minutes. After 10 days, the patient engaged in sexual intercourse. One-month evaluation confirmed a 12-cm vaginal length. Long-term follow-up outcomes are not available. This technique may even be considered in patients who have been treated for imperforate anus with vaginal agenesis who were not treated in childhood. Sexuality after the laparoscopic Vecchiatti procedure requires more data to fully assess. Fedele and colleagues provided the initial report, describing 50 of 52 cases (96%) with a vaginal length greater than 7 cm. All patients succeeded in having vaginal intercourse, 49 (82.6%) had a stable sexual relationship, and 49 (94.2%) were globally satisfied with their sexual life. Since then, the FSFI was introduced and validated as a tool to assess the sexual function in patients undergoing reconstruction. In 2008, Fedele reviewed the entire population, which at that time included 110 patients, including the 27 patients who completed the FSFI at 12 months after surgery. No significant difference was found between the patients and the controls

in the domains regarding desire, arousal, and satisfaction. The scores for the domains on lubrication, orgasm, and comfort, as well as in the total score, resulted in a statistically significant difference, with slightly lower scores for patients with Rokitsansky. The lowest scores were in patients who had low scores for desire and arousal, with the authors suggesting that this may actually reflect a more pervasive psychological aspect affecting the total score.

Urologic surgeons involved in urogenital reconstruction are familiar with the role of buccal mucosa in the reconstruction of the urethra and mucosally lined genital surfaces. More recently, gynecologic surgeons have reported the use of buccal mucosal grafts in surgical creation of a complete neovagina. Reports have described using buccal mucosa that was fenestrated prior to grafting to increase the size of the graft. Patients were initially hospitalized with the graft in place and then discharged to continue mold use at home for several weeks. Authors reported vaginal lengths greater than 8 cm; however, limited patient numbers and abbreviated follow-up have been reported. Perhaps, the most advantageous role for buccal neovaginal grafting may be in augmentation vaginoplasty for patients who have had prior suboptimal attempts at vaginal reconstruction or those with more complex reconstructive needs, such as DSD conditions or cloacal anomalies. Benefits of this procedure include the tissue similarities compared to native vagina, an easily accessible source with excellent healing and no visible scar. More data are necessary to weigh the possible disadvantages of numbness of the lip/cheek and difficulty opening the mouth due to scarring or contracture at the graft donation site.

Bowel vaginoplasty is a well-known alternative for creation of a neovagina. The Ruge procedure and others are characterized by the formation of a neovagina using sigmoid colon grafts. Advocates propose that scar formation and vaginal stenosis occur less often than with other procedures; however, the disadvantage is the necessity of an abdominal laparotomy. Ota and colleagues reported a laparoscopic-assisted Ruge procedure. Mesenteric dissection and sigmoid resection were performed laparoscopically. A 3.5-cm incision was used for appropriate bowel suturing. The segment of sigmoid colon was mobilized and brought to the introitus. The serosal layer of the pediculate end was stabilized to pelvic peritoneum. The patient remained hospitalized for 14 days. The benefit of this modification is certainly the accomplishment of a difficult surgical procedure endoscopically. Other advantages include the functional, ample vaginal length (12 cm) without postoperative dilatation. Disadvantages include the extended postoperative hospitalization period and the small number of patients evaluated.

Reported surgical outcomes by authors such as Hensle and colleagues and Communal and associates support the role of sigmoid neovaginoplasty, especially in patients with MRKH. Until recently, long-term data regarding sexual function had not been available. Parsons and colleagues retrospectively reviewed 28 cases at a mean of 6.2 years after sigmoid vaginoplasty. Seventynine percent of patients were reportedly "very satisfied" with sexual function, and 21% were "comfortable" with the outcome. Communal and colleagues administered the FSFI to 11 patients after creation of a sigmoid neovagina. The mean score of the 8 women who were attempting intercourse was reported to be equivalent to that of "normal" patients without vaginal agenesis. Carrard et al. reported on 59 patients with MRKH, 11 treated with the Frank method and 48 who underwent sigmoid vaginoplasty. The mean time after surgery was 6 years (10 months to 17.8 years). Forty patients (68%) answered the questionnaire, 35/48 (73%) who had surgery and 5/11 (45%) who were treated with dilation. The mean total FSFI score was 28 in the operated group: 21 patients of the 30 currently sexually active respondents (70%) had a score above the cutoff for sexual dysfunction. Women with MRKH syndrome treated with sigmoid vaginoplasty could be considered "normal" in terms of desire, arousability, lubrication, orgasm, and global sexual satisfaction. However, discomfort scores were higher in these patients. The only significant between-group difference was in terms of vaginal discharge discomfort. In comparison, in the group treated by the Frank method, the mean total FSFI score was 30 and each domain score was similar to "normal" women's score. Three patients (75%) had a score above the 26.55 cutoff. Hensle and colleagues provided additional information by reporting the sexual function of 57 patients who underwent creation of a bowel neovagina. Forty-two of the patients were reported to have MRKH. Eight patients underwent ileovaginoplasty; two patients were then subsequently treated with a colonic neovagina. The follow-up period varied from 18 months to 24 years with a mean of 8.8 years. Outcomes

P.525

were evaluated both by a retrospective chart review and the female sexual dysfunction questionnaire described as an Institutional Review Board-approved, validated instrument. Of the 36 patients who responded, 31 were sexually active. Seventy-eight percent of the entire group of patients, including additional diagnoses precipitating neovaginoplasty, reported sexual desire, 33% sexual arousal, 33% sexual confidence, and 78% sexual satisfaction. Also, 56% reported frequent orgasms, 22% occasional orgasms, and 22% no orgasms. Thirty-two patients (89%) reported adequate lubrication for sexual activity; 34 patients used home douching, and 20 required pads for mucus production. Djordjevic and colleagues reported on the use of the rectosigmoid in neovaginal replacement. They reported on 86 patients, of whom 54 had vaginal agenesis. The mean follow-up was 47 months (range 8 to 114 months). The mean vaginal length was 13 cm in patients with vaginal agenesis. Mucous production was reported in 19/54 (35%) in the first 6 months; however, after 6 months, only 2 (3.7%) patients noted the complaint. Introital stenosis and vaginal prolapse were each only reported in 2 cases (3.7%). Sexual outcome was evaluated with the FSFI with sexual function described as satisfactory in 46/54 patients (85.18%).

One of the long-term risks with colonic neovaginal replacement is the possible involvement of the neovagina in systemic inflammatory bowel disease. Only a handful of cases have been reported; however, involvement of the neovagina has been reported as significant, requiring reoperation and repeat vaginal replacement. Endoscopic surveillance with biopsy should be considered essential in patients with symptoms of unexplained discharge and pain.

Makinoda and colleagues reported a nongrafting method of vaginal creation. This group reported 18 women who underwent a two-step protocol. The initial step used noninvasive dilatation using a vaginal mold based on the technique of Frank. The second step was a surgical procedure via a perineal approach. The apex of the dilated vaginal space was incised, and further dissection between the bladder and rectum was carried to the peritoneal cavity. After peritoneal perforation, the uterine structures, when present, were pulled down and sutured to the newly created vaginal space. A firm vaginal mold was inserted and recommended for use for 6 months postoperatively. The authors propose a benefit of avoidance of grafting. The time course for success with the initial dilatation step may be unacceptably long in many patients (mean = 10.90 ± 9.8 months). No significant surgical complications were reported despite the theoretical risk of ureteral contortion and kinking when pulling the rudimentary uterine structures inferiorly. During the follow-up period, shrinkage of the vaginal length and diameter was noted in some patients who had been noncompliant with the mold or without coitus. The authors noted a minimal vaginal length of 5 cm in a patient who was noncompliant with the mold and not sexually active. The authors dispute the necessity of any lining of the neovaginal space. In their experience, significant narrowing or contraction of the margins did not occur. They maintain that the vaginal space is maintained by suturing the muscular buds of the uterus to the pressure-created neovaginal space.

A spatial W-plasty technique using a full-thickness unilateral groin graft has been described in a limited number of patients by Chen and others. The authors advocate an earlier intervention with the premise that a full-thickness graft may grow as the patient grows. This is recommended to eliminate psychological issues in patients who would be treated during the late teens, when sexual identity may be forming.

An exciting innovation is the use of autologous in vitro grown vaginal tissue. Panici and colleagues in Rome reported a two-step procedure. The first step involved acquiring a fullthickness biopsy of the vestibule. The tissue was processed and incubated. The time interval between the biopsy and the fully differentiated mucosal tissue for grafting was 2 weeks. When the tissue was ready for grafting, the vaginal canal was prepared in the Abbe-McIndoe technique and gauze was placed with the cell stratum facing the newly created vaginal canal walls. Surgical time was reported as 18 minutes for the second step, and estimated blood loss was less than 100 mL. The gauze was kept in place with a mold for 5 days; the mold was then removed, and the vagina was irrigated. Estimated success was 90%. Although this technique is in its infancy, the benefit of having the neovagina lined with physiologic vaginal tissue is significant both for function and psychological implications. Challenges include the logistics of the two-step procedure and the need for capabilities for tissue culture. Additional experience with this type of orthotopic vaginal grafting may lead to groundbreaking changes in the treatment of this condition.

Acquired Vaginal Insufficiency

Unusual types of infection and atrophy can rarely cause closure of part of the vagina, but acquired vaginal inadequacy most often is the result of treatment of various gynecologic malignancies with surgery or radiation, or a combination of both. Restoration and maintenance of vaginal function are important elements of the treatment plan for such malignancies, especially when the patient is young and otherwise healthy. The unique surgical challenges associated with creation of a neovagina in patients treated with radiation therapy require the experience and expertise of surgeons familiar with this population. The techniques of vaginal reconstruction in gynecologic oncology have been reviewed by Magrina and Masterson, by Pratt, and by McCraw and associates.

DISORDERS OF VERTICAL FUSION

The problems associated with vertical fusion include transverse vaginal septum with or without obstruction. Although imperforate hymen is a vertical fusion problem, the hymen is not a derivative of the müllerian ducts; therefore, this condition is discussed elsewhere (see [Chapter 24](#)).

Transverse Vaginal Septum

No reliable epidemiologic data exist regarding the incidence of transverse vaginal septum. Reported incidences vary from 1 in 2,100 to 1 in 72,000. It is probably less common than congenital absence of the vagina and uterus. It has been diagnosed in newborns, infants, and older adolescent girls. Its etiology is unknown, although McKusick has suggested that some and perhaps most cases are the result of a female sex-limited autosomal recessive transmission. There is a developmental defect in vaginal embryogenesis that leads to an incomplete fusion between the müllerian duct component and the urogenital sinus component of the vagina. The incomplete vertical fusion results in a transverse vaginal septum (AFS class IIA) that varies in thickness and can be located at almost any level in the vagina ([Fig. 25.10](#)). Lodi has reported that 46% occur in the upper vagina, 40% in the midvagina, and 14% in the lower vagina. Rock, Zacur, and associates have noted septa in the upper, middle, and lower thirds of the vagina in 46%, 35%, and 19% of patients, respectively. In general, the thicker septum is noted to be more common closer to the uterine cervix. In contrast to congenital absence of the müllerian ducts, the transverse vaginal septum is associated with few urologic or other anomalies. Imperforate anus and bicornuate uterus can be found, as

P.526

reported by Mandell and colleagues. The lower surface of the transverse septum is always covered by squamous epithelium. The upper surface can be covered by glandular epithelium, which is likely to be transformed into squamous epithelium by a metaplastic process after correction of the obstruction.

FIGURE 25.10 Positions of septum responsible for complete vaginal obstruction. High (**A**), mid- (**B**), and low (**C**) transverse vaginal septa. Note the position of the hematocolpos. Lower vaginal septa allow more blood to accumulate in the upper vagina. The vaginal mass shown in (**C**) is more accessible through rectovaginal examination.

In neonates and young infants, imperforate transverse vaginal septum with obstruction can lead to serious and life-threatening problems caused by the compression of surrounding organs by fluid that has collected above the septum. The fluid undoubtedly comes from endocervical glands and müllerian glandular epithelium in the upper vagina that have been stimulated by the placental transfer of maternal estrogen. Continued fluid collection in infants, even after the 1st year, has been reported; thus, the possibility of a fistula between the upper vagina and the urinary tract should be considered. The distended upper vagina creates a large pelvic and lower abdominal mass that can displace the bladder anteriorly, displace the ureters laterally with hydronephrosis and hydroureter, compress the rectum with associated obstipation and even intestinal obstruction, and limit diaphragmatic excursion to indirectly compress the vena cava and produce cardiorespiratory failure. Fatalities have been reported. The hydrocolpos develops along the axis of the upper vagina and therefore may not necessarily cause the outlet or perineum to bulge when there is compression of the mass from above. After careful preoperative radiologic and endoscopic investigations of the infant, the septum should be removed through a perineal approach. Bilateral Schuchardt incisions may be required to ensure that the septum has been removed. Because of the subsequent tendency for vaginal stenosis and reaccumulation of the fluid in the upper vagina, follow-up studies to assess the recurrence of urinary obstruction are important. Vaginal reconstruction may be required in later years to allow satisfactory menstruation and coitus.

A hematocolpos may not develop until puberty. Symptoms include cyclic lower abdominal pain, no visible menstrual discharge, and gradual development of a central lower abdominal and pelvic mass. Sometimes, a small tract opens in the septum, some menstrual blood escapes periodically, and symptoms are variable. A septum large enough to allow pregnancy to occur can still cause dystocia during labor. Cyclic hematuria may be present if a communication between the bladder and upper vagina exists. The pelvic organs of a woman with a transverse vaginal septum are shown in [Figure 25.11](#). The woman developed severe cyclic pain at the time of onset of menstruation, but there was no external bleeding until menstrual blood finally began to flow through the small sinus. Pelvic examination per rectum revealed a cervix and a normal-sized corpus. The ovaries were palpable but adherent, probably because of organized blood from hematosalpinx and hemoperitoneum. Remarkably, the woman had little dysmenorrhea after beginning to menstruate externally. Coitus was fairly satisfactory before surgical correction, but the shortness of the vagina was something of a handicap. The obstructing membrane was excised, and an anastomosis of the upper and lower vagina was performed.

The findings of 26 patients with complete transverse vaginal septum reported from the Johns Hopkins Hospital by Rock, Zacur, and colleagues have shown that associated congenital anomalies include urinary tract anomalies, coarctation of the aorta, atrial septal defect, and malformations of the lumbar spine. Vaginal patency and coital function were successfully established in all patients, and 7 of 19 patients

P.527

attempting pregnancy eventually had children. The incidence of endometriosis and spontaneous abortion was high. A lower pregnancy rate and more extensive endometriosis were present when the transverse septum was located high in the vagina, suggesting that retrograde flow through the uterus and fallopian tubes occurs earlier in these patients. More extensive dissection between the bladder and rectum was required to identify the upper vagina when the septum was thick and high. Exploratory laparotomy was necessary in five patients to guide a probe through the uterine fundus and cervix and to assist in locating a high hematocolpos.

FIGURE 25.11 Surgical correction of transverse vaginal septum. **A:** The upper end of a short vagina. The small sinus tract opening, through which the patient menstruated, is shown. The line of incision is drawn through the mucous membrane between the vaginal dimple and the sinus. **B:** Areolar tissue is dissected through to the pocket of mucosa that covered the cervix. The mucosa is incised. **C:** An anastomosis is made between the lower vagina and the upper vagina. **D:** Completed vagina. It is slightly shorter than normal but of normal caliber.

Surgical Technique for a Transverse Vaginal Septum

A transverse incision is made through the vault of the short vagina (**Fig. 25.11A**). A probe is introduced through the septum after a portion of the barrier has been separated by sharp and blunt dissection. The physician usually finds some areolar tissue in dissecting the space between the vagina and the rectum. Palpation of a urethral catheter anteriorly and insertion of a doublegloved finger along the anterior wall of the rectum posteriorly provide the proper surgical guidelines so that the bladder and rectum can be avoided during this blind procedure. After the dissection is continued for a short distance, the cervix can usually be palpated, and continuity can be established with the upper segment of the vagina (**Fig. 25.11B, C**). The lateral margins of the excised septum are extended widely by sharp knife dissection to avoid postoperative stricture formation. The edges of the upper and the lower vaginal mucosa are undermined and mobilized enough to permit anastomosis with the use of interrupted delayed absorbable sutures (**Fig. 25.11C**). **Figure 25.11D** shows the completed anastomosis with a vagina that is of normal caliber but has a length slightly shorter than average. A soft foam rubber vaginal form covered with a sterile latex sheath can be placed in the vagina and removed in 10 days for evaluation of the healing process. The form can be worn for 4 to 6 weeks until complete healing has occurred. After this, coitus is permitted. If the patient is not sexually active, then vaginal dilatation may be necessary to maintain established patency. Alternatively, a silicone elastomer (Silastic) vaginal form can be inserted at night until the constrictive phase of healing is complete. A combination of a perineal (transvaginal) and

P.528

laparoscopic approach may also be useful. Laparoscopy can provide assistance with mobilization of the upper vagina, using dissection both anteriorly at the bladder and in the posterior cul-de-sac. This technique can decrease tension on the anastomosis of upper and lower vagina and minimize the risk of stricture.

FIGURE 25.12 Correction of an atretic vagina. **A:** A large portion of atretic vagina is palpated with two fingers. Once the vaginal space is developed, it may be necessary to open the abdomen via laparotomy and pass a probe through to the uterine fundus (**B**) to tent out the septum, which may then be safely excised. **C:** An acrylic resin (Lucite) form is then placed into the vagina and secured with rubber straps.

High Transverse Vaginal Septum

If the length of the obstructing transverse vaginal septum is such that reanastomosis of the upper and lower vagina is impossible, as is the case with a high transverse vaginal septum, in which a significant portion of the vagina is atretic, then a space is created between the rectum and bladder to permit identification of the obstructed vagina (**Fig. 25.12**). The mass that has resulted from accumulated menstrual blood must be distinguished from the bladder anteriorly and the rectum posteriorly, a process that is facilitated by the mass itself. When differentiation is impossible, however, exploratory laparotomy can be performed. During this procedure, a probe is passed through the fundus of the uterus to tent out the vaginal septum and enable the surgeon to excise it from below and resect it safely.

In most surgical procedures to remove the high transverse vaginal septum, the obstructing membrane can be readily identified (**Fig. 25.13**), after which the operator can probe the mass with an aspirating needle to identify old menstrual blood. The upper vagina is then opened and the septum excised. Because the distance between the septum and the upper vagina is too great to permit an anastomosis, an indwelling acrylic resin (Lucite) form, consisting of a bulbous end and a channel through which menstrual blood can drain, is placed into the vagina and anchored with a retaining harness. The bulbous end of the form, in most instances, is retained in the upper vagina and should be left in place for 4 to 6 months while epithelialization is accomplished. After its removal, vaginal dilatation should be practiced on a daily basis for 2 to 4 months to prevent contracture of the space. It is essential to the success of the operation that the new space not become constricted; to avoid constriction, the form must be worn for many months during the constrictive phase of healing. As an alternative to the Lucite form, the physician can consider using a split-thickness graft to bridge the gap. The graft is usually sutured in situ in the vagina rather than sutured to a form. An ingenious but rather complicated Z-plasty method of bridging the gap has been described by Garcia and by Musset. A simpler flap method was described by Brenner and associates.

A transverse vaginal septum diagnosed after the onset of puberty presents numerous problems. Often, a large segment of the vagina is absent, making anastomosis of the upper and lower segments difficult. Furthermore, postoperative vaginal dilatation is necessary to prevent stenosis at the anastomosis site. Poor compliance with dilatation in a poorly motivated pubertal patient is always a concern. However, rarely is the surgeon able to delay vaginoplasty until the patient is more mature because of increasingly severe cyclic abdominal pain caused by the hematocolpos. Thus, a difficult vaginoplasty can have less than optimal results.

Hurst and Rock have described an alternative approach to maximize surgical resection and anastomosis in women with a high transverse vaginal septum. Aspiration of the hematocolpos under ultrasound guidance was necessary to relieve the acute pain and delay surgery. Continuous oral contraceptives were used to delay recurrence of hematocolpos. Most important, vaginal dilatation was used to lengthen the lower vaginal segment to facilitate resection and reanastomosis (**Fig. 25.14**). In all three patients, the approach was successful.

FIGURE 25.13 A high transverse vaginal septum. **A:** The neovaginal space is dissected, revealing a high obstructing vaginal membrane. **B:** This can be palpated with the middle finger. **C:** A needle is then placed into the mass. **D:** The incision is made with a sharp knife, and considerable bleeding can occur. **E:** The septum is excised. **F:** The septum is removed. **G:** After the septum is removed, the wall of the septum is oversewn with interrupted sutures of 2-0 chromic catgut. **H:** Because the distance between the septum and the upper vagina is too great to allow anastomosis, an acrylic resin (Lucite) form is placed in the vagina so that epithelialization can occur over the form while vaginal patency is maintained. The form, in place, is fitted with a plastic retainer. Rubber straps can be placed through the retainer and attached to a waist belt to allow constant upper pressure so that the form is retained in the upper vagina. Modification of this method includes a small adapter to allow drainage through the acrylic resin (Lucite) form, preventing the accumulation of old blood and mucus in the upper vagina.

P.530

FIGURE 25.14 **A:** High transverse vaginal septum demonstrating a small hematocolpos and hematometra. Upper to lower vaginal anastomosis at this stage can result in stenosis at the anastomosed site. **B:** Vaginal depth is increased with passive dilatation using progressively larger dilators. **C:** A primary upper to lower vaginal anastomosis can be performed easily after dilatation.

Congenital Absence or Dysgenesis of the Cervix

Agenesis or atresia of the cervix (AFS class IIB) is a relatively infrequent müllerian anomaly. When this anomaly does occur, it is often in association with absence of a portion or all of the vagina. In many cases of cervical agenesis or atresia, retention of menstrual blood initiates symptoms of cyclic lower abdominal pain without menstrual flow, causing the patient to seek gynecologic evaluation and care. In past times, diagnosis was suspected on the basis of a history and physical findings but was not proved until the time of surgery. Today, diagnosis of cervical agenesis or atresia is still usually difficult before operation, but the possibility of making a correct diagnosis before surgery does exist, with the help of modern diagnostic tools. Early diagnosis offers significant advantages in patient care, the most important of which is effective presurgical planning and preparation.

Diagnosis of Cervical Dysgenesis

Patients with congenital absence of the cervix present a diagnostic challenge. Patients with cervical aplasia with a functioning midline uterine corpus have aplasia of the lower two thirds of the vagina with an upper vaginal pouch. Similarly, some patients have a considerable atretic segment of vagina and an upper vaginal pouch with a properly developed uterine cervix and corpus above. Differentiation of these two müllerian anomalies is essential. Ultrasonography may be helpful. Valdes and associates have reported the use of preoperative ultrasonography in the evaluation of two patients with atresia of the vagina and cervix. Magnetic resonance imaging has been found to be

P.531

helpful in confirming this diagnosis, as reported by Markham and associates. The lower uterine segment and cervical tissue can be carefully examined (Fig. 25.15). With cervical dysgenesis, there is no vaginal dilatation with the accumulation of blood, as seen with a high transverse vaginal septum. Both ultrasonography and MRI are most helpful when they are correlated with the findings of a careful pelvic examination under anesthesia.

FIGURE 25.15 Magnetic resonance T1-weighted image showing atretic segment of distal cervix. The tip of an atretic cervix is shown. No vagina is noted.

Anatomic Variations of Congenital Cervical Anomalies

Two basic categories of cervical anomalies have been observed in several configurations. Patients exhibiting the first type, cervical aplasia, lack a uterine cervix (Fig. 25.16A), and the lower uterine segment narrows to terminate in a peritoneal sleeve at a point well above the normal communication with the vaginal apex. Omurtag and colleagues' report of uterine torsion and acute pain in a 13-year-old with hematometra reminds the reconstructive gynecologic surgeon of the consideration of uterine torsion in the absence of a well-formed cervix. The uterus can be susceptible to rotation on its horizontal axis, particularly with the mass effect of hematometra. The second type, cervical dysgenesis, can be described in four subtypes:

1. Cervical body consisting of a fibrous band of variable length and diameter (endocervical glands may be noted on pathologic examination) (Fig. 25.16B)
2. Intact cervical body with obstruction of the cervical os (the cervix is usually well formed, but a portion of the endocervical lumen is obliterated) (Fig. 25.16C)
3. Stricture of the midportion of the cervix (which is hypoplastic with a bulbous tip and no identifiable cervical lumen) (Fig. 25.16D)
4. Fragmentation of the cervix (with portions that can be palpated below the fundus and that are not connected to the lower uterine segment) (Fig. 25.16E)

Associated anomalies of the urinary tract are rare, but they do occur. Variable portions of the vagina can be atretic. Cervical obstruction is most often associated with a vagina of normal length.

Treatment

When both the vagina and cervix are absent and a functioning uterine corpus is present, it is difficult to obtain a satisfactory fistulous tract through which menstruation can occur. Many methods have been tried, most of them involving creation of a passage through the dense fibrous tissue between the uterine cavity and the vagina and placement of a stent to keep the tract open. Occasional successes in maintaining an open passageway and normal cyclic menstruation have been reported, but endocervical glands do not develop, and there is no way to compensate for the absence of the cervical mucus, which plays an important role in sperm transport. Even though cyclic ovulatory periods can be achieved in a few patients, pregnancy is unlikely. Eventually, the uterovaginal tract closes from constriction by fibrous tissue. Endometriosis can develop along the tract. Endometriosis also can develop in ovaries and other pelvic sites because of retrograde menstruation. Recurrent and severe pelvic infection is a common problem and may require total hysterectomy and removal of both ovaries. As in vitro fertilization procedures began to offer the possibility for a host uterus to carry a pregnancy to term, procedures to establish a fistulous tract were abandoned. Nevertheless, Cukier and associates in 1986 reported treating a patient with congenital absence of the cervix by construction of a splint that extended into the neocervical canal such that a split-thickness skin graft could actually be placed within the endocervical canal. This patient has continued to menstruate without difficulty, although pregnancy has not been accomplished.

Many authors have recommended hysterectomy as an initial procedure for a patient with a functioning uterine corpus and congenital absence of the cervix and vagina. A hysterectomy eliminates much needless suffering from associated problems such as cryptomenorrhea, sepsis, endometriosis, and multiple operations. If the hysterectomy is performed soon enough, before the problems become great, it may be possible to conserve the ovaries and their useful functions. The reconstructive surgeon should be prepared to perform a vaginoplasty if hysterectomy is performed, particularly if there has been a vaginal dissection. If the neovaginal space is allowed to close and scar, then future operations to develop an adequate neovagina are associated with increased risks of graft failure and fistula formation.

Despite the overall poor results from reconstruction for congenital absence of both the cervix and the vagina, clinical experience suggests that cannulization procedures can be worthwhile in a few carefully selected cases with adequate stroma to allow a cervicovaginal anastomosis. If a long segment of cervix is fibrous cord, a cervical grafting technique may be required. If a fragmented cervix is noted, then hysterectomy is usually warranted. The few patients who have achieved a pregnancy after cervical reconstruction have had a well-formed cervical body. Anecdotal reports of resection of the dysgenetic cervix and reconstruction with uterovaginal anastomosis may be promising. The isthmus of the uterus is anastomosed directly to the vagina as in patients with cervical malignancy who undergo trachelectomy. Successful pregnancies have

been reported. More experience with this type of reconstruction is necessary to fully understand the unique challenges that may occur in this population compared to patients who experience disease in an otherwise normally developed cervix.

Anecdotal case reports occasionally appear in the literature confirming the necessity of palpable cervical tissue. Letterie described the development of a cervicovaginal tract in an adolescent patient with a core of cervical tissue. The tract remained patent for menstrual flow for 2 years; however, pregnancy had not yet been attempted. Data published by the

P.532

senior author regarding the long-term follow-up of 21 patients with abnormal cervical development support the success of cannulization in only selected patients with sufficient rudimentary cervical tissue. All of the patients with fragmentation of the cervix ($n = 4$) eventually underwent hysterectomy. Only those patients with a well-formed cervical body, with at least a palpable cord or only distal obstruction, achieved successful surgical outcomes (4/7 patients). Only one patient with distal obstruction treated with cannulization using a full-thickness skin graft achieved pregnancy.

FIGURE 25.16 Congenital cervical anomalies. **A:** The fundus of the uterus is noted without a cervix. **B:** The cervical body consists of a fibrous band of variable length and diameter that can contain endocervical glands. **C:** The cervical body is intact with obstruction of the cervical os. Variable portions of the cervical lumen are obliterated. **D:** Stricture of the midportion of the cervix, which is hypoplastic with a bulbous tip. No cervical lumen is identified. **E:** Cervical fragmentation in which portions of the cervix are noted with no connection to the uterine body. Hypoplasia of the uterine cavity can be associated with cervical cord fragmentation.

P.533

Others have reported the anastomosis of a well-developed distal vagina to a substantial midline uterine body. Creighton and colleagues described the use of the laparoscope for this procedure; however, Deffarges and associates examined the outcomes of 18 patients after open uterovaginal anastomosis. Twenty-two percent of patients required additional surgery. Eighty-three percent of the cases were associated with upper genital tract complications. Six spontaneous pregnancies also were reported in four of the patients. Despite the small potential for pregnancy, it is imperative to realize the potential for complications, including sepsis and even death as a result of ascending infection. Fedele and colleagues reported successful management of cervical atresia in twelve patients with vaginal aplasia with laparoscopy. All women experienced regular menstrual cycles. The mean vaginal length at 6-month follow-up was 6 cm. At the time of publication, none of the patients had attempted pregnancy. Kriplani and colleagues described 14 consecutive patients with congenital absence of the uterine cervix (Table 25.6). Laparoscopic-assisted uterovaginal anastomosis with placement of a silicone stent was performed. McIndoe vaginoplasty was performed concomitantly in patients with vaginal agenesis. Cervical dysgenesis was present in 5 (35.7%) and cervical agenesis in 9 (64.2%). Mean follow-up after surgery was 3.8 ± 1.2 years. Postoperatively, all but one patient experienced regular menses and relief of cyclic pain. One patient underwent hysterectomy because of genital infection and restenosis. The authors reported that five patients were sexually active and reported it to be satisfactory. Pregnancy occurred in 3/5 patients. Reoperation and subsequent hysterectomy have been reported in as much as half of patients undergoing cervical reconstruction as the primary procedure. Kriplani attributes the use of the silicone stent in the neocervix until the resolution of inflammation as one of the reasons the incidence of restenosis was decreased in their population. Only one patient (7.4%) required hysterectomy for recurrent infection and stenosis.

The surgical approach for the rare opportunity for cervical cannulation remains a challenge. Several additional factors may also influence the surgical outcome: the size of the created channel, the duration of stenting of the channel, the presence of rudimentary endocervical glands in the region of the created channel, the presence of a native vagina adjacent to the created channel, or the number of menses allowed to flow through the stented channel. Because the surgical approach for cervical cannulation is based only on several case reports, limited

P.534

data regarding safety and efficacy are available to share with patients and families. A frank discussion with both the patient and her family regarding the potential risks and morbidity is imperative. Even reportedly successful attempts have involved multiple surgical interventions, such as a reported cervicoplasty with bladder mucosa described by Bugamann and colleagues; the 12-year-old patient had to undergo at least one previously failed attempt at reconstruction before the reported successful procedure. Very young adolescents may be subjected to multiple surgical procedures without good evidence of success. These more aggressive, fertility-sparing procedures may be best suited for patients who have had good menstrual suppression and are more mature at the time of the discussion of risks and benefits and decision for surgery.

DISORDERS OF LATERAL FUSION

Failures of lateral fusion of the two müllerian ducts cause vaginal anomalies that are grouped as obstructed or unobstructed.

The Unobstructed Double Uterus (Bicornuate, Septate, or Didelphic Uterus)

Complete failure of medial fusion of the two müllerian ducts can result in complete duplication of the vagina, cervix, and uterus. Partial failure of fusion can result in a single vagina with a single or duplicate cervix and complete or partial duplication of the uterine corpus. A failure of absorption of the uterine septum between the two fused müllerian ducts causes the septum to persist inside the uterus to a variable extent while the external appearance remains that of a single uterus. The septum can be so complete that it divides both the uterine cavity and endocervical canal into two equal or unequal components. More often, incomplete disappearance of the septum leaves only the upper uterine cavities divided. Each of these and a variety of other forms of double uteri have their own individual features of clinical significance. When no obstruction is present, surgical reconstruction is performed primarily because of difficulties with reproduction.

Some aspects of lateral fusion disorders remain controversial because information is still inaccurate or incomplete. Many reports are based on small samples of selected patients, patients who have been diagnosed as having one anomaly or another based on incomplete data, and patients who have received unification operations without preliminary studies to rule out other causes of reproductive difficulty. A comparison of results from one series to the next is difficult because authors have used different classifications based on a variety of embryologic, anatomic, physiologic, functional, and radiologic considerations. Unknown numbers of uterine anomalies may have escaped detection because reproductive performance is generally acceptable and gynecologic difficulties do not necessarily occur.

The müllerian ducts undergo multiple steps in development, including caudal, medial growth followed by fusion and later resorption of the remaining septum. Apoptosis has been proposed as a mechanism by which the septum regresses. Bcl-2, a protein involved in regulating apoptosis, was found to be absent from the septa of several uteri. The absence of this critical protein may play a pivotal role in the persistence of the septum and lateral fusion disorders.

Historical Development of Surgical Procedures

Ruge, in 1882, first reported excision of a uterine septum in a woman who had suffered two pregnancy losses. The woman subsequently carried a pregnancy to term. Paul Strassmann of Berlin and later Erwin Strassmann, his son, were strong advocates of uterine unification operations. The studies of Jones and Jones have contributed greatly to modern understanding of the management of uterine anomalies. Their studies began with a report in 1953 of a series that was started in 1936. Updates have been published from time to time. Wheelless, Rock, Andrews, and others have joined in these reports.

Diagnosis of Uterine Anomalies

If a uterine anomaly is associated with obstruction of menstrual flow, then it causes symptoms that will come to the attention of the gynecologist shortly after menarche. Unobstructed uterine anomalies are diagnosed later in a variety of circumstances. Young girls may notice difficulty in using tampons or later difficulty with coitus if a longitudinal vaginal septum is present. This can lead to the diagnosis of an associated uterine anomaly. A patient with an anomalous upper urinary tract on intravenous pyelogram may be found to have a uterine anomaly on gynecologic evaluation. A uterine anomaly is occasionally found when a patient reports dysmenorrhea or menorrhagia or when a dilatation and curettage (D&C) is performed. A palpable mass may be a uterine anomaly but should be confirmed as such by ultrasonography, MRI, hystero-graphy, or laparoscopy. Woelfer and colleagues described the use of three-dimensional ultrasonography in screening for congenital uterine anomalies. During an investigation of the correlation of uterine anomalies with obstetric complications, the authors assessed the potential value of three-dimensional ultrasound for screening. More than 100 women with uterine anomalies were identified. Seventy-two arcuate uteri, twenty nine septate, and five bicornuate uteri were described. The authors emphasized how the threedimensional ultrasound may overcome the limitations of conventional two-dimensional ultrasonography in providing a coronal view of the uterus, thus differentiating between arcuate, bicornuate, and subseptate uteri. This technique remains investigational. Semmens has pointed out that the diagnosis of a uterine anomaly can also be made from astute observation of an abnormal uterine contour during pregnancy, either in the antepartum period or at the time of abdominal or vaginal delivery. The abnormal contour is caused by a combination of fetal malpresentation and an anomalous uterus. An anomalous uterus can also be diagnosed when a pregnancy occurs despite the presence of an intrauterine contraceptive device. Persistent postmenopausal bleeding despite recent D&C can lead to a diagnosis of an anomalous uterus. Sometimes the diagnosis is made as an incidental finding at laparotomy. Historically, most uterine

anomalies were diagnosed after hysterosalpingography to evaluate infertility or reproductive loss, usually from repeated spontaneous abortion, but increasingly, uterine anomalies are detected on MRI performed for other indications.

Uterine Anomalies and Reproductive History

Although some uterine anomalies can cause infertility, most patients with uterine anomalies are able to conceive without difficulty. There is no question that uterine anomalies can be associated with perfectly normal reproductive performance. Overall, however, the incidences of spontaneous abortion, premature birth, fetal loss, malpresentation, and cesarean section are clearly increased when a uterine anomaly is present. It is impossible to predict which patients with uterine anomalies will have these problems.

P.535

Etiology of Reproductive Failure

The etiology of reproductive failure in patients with uterine anomalies remains unclear. Mahgoub believes that the presence of a uterine septum can lead to spontaneous pregnancy loss because of diminished intrauterine space for fetal growth or because of implantation of the placenta on a poorly vascularized septum. Mizuno and associates have attached importance to the inadequacy of vascularization of the uterine septum. Associated cervical incompetence, luteal phase insufficiency, and distortion of the uterine milieu have all been implicated in the etiology of increased reproductive loss. However, it is as yet unexplained why some patients with a uterine anomaly have normal reproductive function, whereas others abort early in pregnancy. Interestingly, it has been reported that the chance for a liveborn child increases with each pregnancy loss. It is unknown whether this apparent "conditioning" of the uterus is due to better vascularization, better myometrial stretching and accommodation, or some other factor.

A medical history of three or more episodes of spontaneous abortion or premature labor merits evaluation of the uterine cavity to determine whether structural abnormalities of the uterus are present. An abnormality is found in approximately 10% of such cases. Among chronic early second-trimester aborters, the incidence may be higher. The etiology of spontaneous abortion is complex, and a complete workup should be done even when an anomalous uterus has been found. A careful history should include a detailed discussion of each previous pregnancy loss and inquiry into DES exposure or other drug or chemical toxicity, specific medical illnesses, and exposure to contagious diseases. A family history should emphasize reproductive failures among family members of both the patient and her partner. Specific medical diseases such as thyroid disease, diabetes mellitus, renal disease, and systemic lupus erythematosus should be ruled out. The possibility of infection by such agents as *Neisseria gonorrhoeae*, *Chlamydia*, *Mycoplasma*, *Toxoplasma*, and *Listeria* should be considered. Chromosome analyses should be done. Abnormalities in aborted tissue are found in more than 50% of spontaneous abortions, and abnormalities appear in up to one fourth of couples with a history of habitual abortion. Identifying such couples makes it possible to offer genetic counseling for subsequent pregnancies. Uterine leiomyomas, especially lower uterine segment and submucous leiomyomas, can cause spontaneous abortion. Basal body temperature charts, serum progesterone determinations, and endometrial biopsies timed in the luteal phase help determine the presence of luteal phase deficiency. The cervix should be studied for incompetence.

FIGURE 25.17 A: A hysterosalpingogram of a double uterus. A bicornuate uterus (B) and a septate uterus (C) are types of double uteri. Visualization of the fundus is required to determine the type of uterus.

Couples with multiple etiologies for reproductive loss should have all other problems corrected before metroplasty is considered. Indeed, correcting other factors first may correct the problem of reproductive loss without metroplasty. In 1977, Rock and Jones reported on seven patients who had anomalous uterine development and extrauterine factors in the etiology of their reproductive loss. These patients had already had 16 pregnancies, 5 (29%) of which resulted in a liveborn child. After therapy to correct the extrauterine factor, the success rate increased to 71%. Stoot and Mastboom reported an impressive increase in reproductive performance among uterine anomaly patients by simple improvement of abnormal carbohydrate metabolism.

Hystero-graphic Studies

Proper technique during the performance of hysterosalpingography to diagnose uterine anomalies is important. The hysterosalpingogram must be taken at right angles to the axis of the uterus for a true assessment of the deformity to be made. The study is best done under fluoroscopy. A septate uterus cannot be distinguished from a bicornuate uterus by hysterosalpingogram alone (Fig. 25.17). The external uterine configuration also cannot usually be determined by pelvic examination alone, but some idea of the configuration can be obtained by ultrasonography.

P.536

McDonough and Tho have suggested the use of double-contour pelvic pneumoperitoneum-hystero-graphic studies for precise identification of müllerian malformations. Of course, laparoscopy is even more certain. If the uterine corpus has not been previously visualized, the physician must be prepared to correct either anomaly (i.e., obstructed or unobstructed), depending on the findings at surgery.

Additional Testing

A complete investigation should also include an assessment of tubal patency and an MRI urogram or an intravenous pyelogram. A variety of upper urinary tract anomalies are seen, including absence of one kidney, horseshoe kidney, pelvic kidney, duplication of the collecting system, and ectopically located ureteral orifices. The lower urinary tract (bladder and urethra) is much less often anomalous.

The Double Uterus and Obstetric Outcome

The percentage of full-term pregnancies with various types of double uteri in an unselected series of women who have not been operated on is unknown. For all types combined, it is probably approximately 25%. In patients selected for operation, it probably increases from approximately 5% to 10% to approximately 80% to 90%. Because patients with uterine anomalies who have relatively normal obstetric histories cannot be identified, there is confusion in the literature about which anomalies are more often associated with obstetric difficulties and which are relatively benign in their effect. Special diagnostic procedures to detect uterine anomalies are not usually performed before reproductive performance is tested. A didelphic uterus is the exception. This anomaly can be diagnosed easily on routine pelvic examination by identification of two complete cervixes and perhaps also a longitudinal vaginal septum. A study by Heinonen in Finland of 182 women with uterine anomalies indicated that pregnancies in the septate uterus had a better fetal survival rate (86%) than they did in the complete bicornuate uterus (50%) or in the unicornuate uterus (40%). These findings differ from prevailing opinions that the septate uterus is associated with the highest reproductive loss, as proposed by Jones and Jones. A 2011 report by Woelfler and associates supports Jones and Jones's opinions by noting that women with a septate uterus had a significantly higher proportion of first-trimester loss than did women with a normal uterus.

In 1968, Capraro and colleagues reported on 85 patients with uterine anomalies seen between 1962 and 1966. One uterine anomaly was seen for every 645 admissions (0.145%). Metroplasty was considered necessary in only 14 (16%) of these 85 cases. According to Jones and Jones, only one third of patients with a double uterus have important reproductive problems. In most instances, the presence of a double uterus is not in itself an indication for metroplasty.

In 1980, Jewelewicz and coworkers estimated the spontaneous abortion rate to be 33.8% in women with a bicornuate uterus, 22.2% in those with a septate uterus, and 34.6% in those with a unicornuate uterus. More recently, Ludmir and associates reported that high-risk obstetric intervention did not significantly increase the fetal survival rate for uncorrected uterine anomalies. Capraro and associates found a preoperative fetal salvage rate of 33.3% for the septate uterus, 10% for the bicornuate uterus, and 0% for the didelphic uterus. Postoperatively, the fetal salvage rate was 100% for the bicornuate uterus, 80% for the septate uterus, and 66% for the didelphic uterus. The report gives the improved salvage figures, compared with several previous studies, after abdominal metroplasty.

Ravasia and colleagues described the incidence of uterine rupture in a cohort of women with müllerian duct anomalies who attempted vaginal birth after cesarean delivery (VBAC). Of the 1,813 patients who attempted VBAC between 1992 and 1997, only 25 patients with known müllerian duct anomalies attempted a trial of labor. This included 14 patients with a bicornuate uterus, five with a septate uterus, four with a unicornuate uterus, and two with uterine didelphys. Uterine rupture was diagnosed in two patients with müllerian anomalies. The authors proposed several mechanisms for the higher incidence of uterine rupture in this population: abnormal development of the lower uterine segment, previous scar similar to a vertical or classic incision, and the possibility of abnormal traction on the uterine scar during labor.

The Didelphic Uterus

A didelphic uterus with two hemicorpora is easily diagnosed because all patients have two hemicervices visible on speculum examination and most, if not all, have a longitudinal sagittal vaginal septum. In the series reported by Heinonen and associates, all 21 patients with a didelphic uterus had a vaginal septum. Conversely, a patient with a longitudinal vaginal septum usually has a didelphic uterus. The indication for uterine unification is related to the role of this anomaly as an etiologic factor in reproductive loss. Of all the uterine anomalies (except arcuate uterus), the didelphic uterus is associated with the best possibility of a successful pregnancy. However, there is still some increase in perinatal mortality, premature birth, breech presentation, and cesarean section for delivery. Heinonen and associates reported a fetal survival rate of 64% without metroplasty. Musich and Behrman stated that the didelphic uterus offers the best chance for a successful pregnancy (57%) and should not be considered an appropriate indication for metroplasty. However, W. S. Jones considered the didelphic uterus to give the worst obstetric outcome. In the opinion of the editors of this book, a unification operation for a didelphic uterus is not often indicated, and the results may be disappointing, especially when an attempt is made to unify the cervix. Not only is this procedure technically difficult in a complete didelphic anomaly, but it can also result in cervical incompetence or cervical stenosis.

The Septate Uterus

Most patients who are evaluated for repeated pregnancy loss and who are found to have a uterine anomaly have a septate uterus. A few have other anomalies, mostly the bicornuate uterus. Proctor and Haney's review of women with recurrent first-trimester pregnancy loss reinforces the role of the septate uterus in repeated pregnancy loss. Of 35 women reviewed with a divided uterine cavity on hysterosalpingogram, all women were found through diagnostic hysteroscopy and laparoscopy to have a septate uterus. In our experience, fetal survival rates are higher after septate uterus repair than after other repairs. In 1977, Rock and Jones reported on 43 patients with septate uteri selected for Jones metroplasty at the Johns Hopkins Hospital. Of these 43 patients, 95% became pregnant postoperatively, 73% carried to term, and 77% delivered a liveborn child. Similarly, hysteroscopic metroplasty for the septate uterus provides a substantial improvement in obstetric outcome. Data obtained from retrospective studies suggest that hysteroscopic metroplasty is associated with favorable outcomes, with a pregnancy rate of approximately 80% and a miscarriage rate of only approximately 15%. Recent prospective observational studies reported similar findings. Pabuccu and Gomel reported the reproductive outcome of 61 patients; however, the patients had unexplained infertility, and nearly 15% were also treated with cervical cerclage. Litta and colleagues also reported an 83.3%

P.537

term delivery rate in their population of women with a septate uterus who underwent hysteroscopic metroplasty. Patton and colleagues described 16 women with a complete uterine septum. The preoperative pregnancy loss rate was 81%. Eleven of the fourteen septa treated with a hysteroscopic approach were successfully removed. The remaining three unsuccessful hysteroscopic procedures and two additional patients were treated using the Tompkins metroplasty. Postoperatively, 9 women conceived after hysteroscopic surgery, and term live births occurred in 9 of 12 (75%) conceptions. The most controversial area remains the resection of the cervical portion of the septum. Parsanezhad and colleagues reported a multicenter, randomized controlled trial regarding the management of the cervical septum. Surgical issues, complications, and pregnancy outcomes were compared. Operating times, distending media deficits, and perioperative complications were all substantially better in the cervical septum resection group. The reproductive outcomes were similar; however, the cesarean section rate was higher in the group in which the cervical septum was spared. The histologic features of the septum in this abnormal uterus have been described. Dabirashrafi and colleagues noted less connective tissue in uterine septa. Poor decidualization and placentation were suggested as a cause.

Finally, the AFS class Va uterus (a double cervix and uterine cavity with a single fundus) can result from a rotation abnormality during the descent of the müllerian ducts. Among the reported cases of the septate uterus, the incidence of the complete septum involving the cervix varies from 4% to 29%. If the dextrorotating müllerian ducts overrotate, the senior author theorizes that the septum fails to absorb after fusion of the ducts (J. A. Rock, *personal observations*, 1991). In virtually every patient with a complete septate uterus, the left cervix is higher than the right. In one patient, one cervix has been noted above the other (**Fig. 25.18**). This rotation abnormality may be a factor associated with lack of absorption of the uterine septum in these patients.

Uterine Anomalies and Menstrual Difficulties

Dysmenorrhea and abnormal and heavy menstrual bleeding have been reported to occur more frequently with any form of double uterus and to be relieved after unification operations. Capraro and associates reported several cases in which dysmenorrhea was cured by metroplasty. Erwin Strassmann also believed that all cases of dysmenorrhea and menorrhagia associated with uterine anomalies were relieved by unification of the two uterine cavities. Generally, however, dysmenorrhea and menorrhagia are inappropriate indications for uterine unification, and the operation should not be performed solely for these reasons. Grynberg and colleagues reported on women who experienced infertility, pregnancy losses, dyspareunia, or dysmenorrhea. In their series, 22 patients underwent hysteroscopic resection of complete uterine septum and resection of longitudinal vaginal septum. The data suggested that hysteroscopic incision of the septum did not improve reproductive outcomes (miscarriage rate increased from 25% to 43%, cervical cerclage rate was not significantly changed). In their series, the advantage of surgery was limited because the miscarriage and the preterm delivery rates were not improved after metroplasty. This publication reminds reconstructive gynecologists that careful consideration of indications for surgery is imperative before surgery. Until more data are available, systematic surgical intervention for young women diagnosed with complete uterine septum without evidence of pregnancy loss should be discouraged.

FIGURE 25.18 A double uterus with two cervixes and a single fundus (class V). Note that the left cervix is positioned over the right cervix. This rotation abnormality may be a factor associated with a lack of absorption of the uterine septum.

Uterine Anomalies and Infertility

Opinions differ considerably in terms of whether infertility is a proper indication for metroplasty. Erwin Strassmann stated that primary infertility could be cured in 60% of patients with uterine anomaly if all other causes of infertility were excluded. Strassmann reported eight metroplasties for primary sterility that yielded nine pregnancies and seven liveborn children, although the number of patients who conceived was not given. Similar reports of small numbers of patients can be found throughout the literature. Heinonen and Pystynen indicated that uterine anomalies are rarely the reason for infertility. Nonuterine causes of infertility must be ruled out before metroplasty, as a last resort, is considered.

Certainly, a full infertility investigation to rule out other causes should be completed before the anomalous uterus is blamed. Even when no other cause for infertility is found, if the uterus is septate or bicornuate, then there may not be any proper indication for metroplasty. This question of when to perform metroplasty simply has not yet been answered. The decision is difficult and becomes even more difficult when the opportunity for metroplasty presents itself because a septate or bicornuate uterus requires laparotomy for some other reason, such as endometriosis or tubal occlusion.

Surgical Technique for Uterine Unification

Historically, the septate uterus has been unified with either the Jones or the Tompkins procedure. Clinical reports by Chervenak and Neuwirth; by Daly, Walters, and colleagues; by DeCherney and associates; and Israel and March have favorably compared hysteroscopic (resectoscopic incision of a uterine septum) with the more traditional transabdominal approach. Term pregnancy rates after these procedures have approached 80% to 85%. Several attempts may be necessary to incise a wide septum, although the septum usually can be incised completely at the first operation.

Transcervical Lysis of the Uterine Septum

Abdominal metroplasty for transfundal incision or for excision of the septum associated with the septate uterus generally has been abandoned. With hysteroscopic scissors, the procedure can be tedious, especially with a large, broad septum. Although

P.538

the hysteroscope and scissors are still used for cutting the septum, the resectoscope has been found to be comparable. The optics are excellent, and the septum can be electrosurgically incised with little difficulty. Laser-assisted procedures have also been described.

Before transcervical lysis of a uterine septum, a gonadotropin-releasing hormone agonist may be given for 2 months to reduce the amount of endometrium that can obscure the surgeon's view during the procedure. Many authors do not consider routine preoperative preparation of the endometrium essential and may only use medications in procedures involving exceptionally wide septa or complete septa that involve the lower one third of the uterine cavity or the cervical canal. If medical preparation is not used, surgical intervention should be scheduled during the early proliferative phase of the cycle to avoid bleeding and impaired visualization from a vascular endometrium associated with the secretory phase. Transcervical lysis is usually performed in conjunction with laparoscopy under general endotracheal anesthesia. The uterine cavity is distended with dextran 70 (Hyskon) by way of the resectoscope, which is inserted into the cervix. The septum is then electrosurgically incised by advancing the cutting loupe, using the trigger mechanism of the resectoscope. The uterine septum is incised until the tubal ostia are visualized and there is no appreciable evidence of the septum. The procedure is performed under simultaneous laparoscopy to limit the risks of uterine perforation. The laparoscopic light can be turned off so that the light from the hysteroscope can be clearly visualized through the fundus. Most patients can be discharged within 4 hours of the procedure. There is no role for placement of a postoperative intrauterine device. The benefit of routine procedure-related antibiotic therapy has not been well supported with evidence; however, it is recommended to administer antibiotics before the procedure and to continue for 5 days after surgery to limit the risks of infection. If excessive bleeding occurs after the procedure, a Foley catheter should be placed in the uterine cavity for tamponade and removed in 4 to 6 hours. Hormonal therapy is the most commonly used postoperative treatment regimen. The aim of the treatment is the promotion of rapid epithelialization. Dabirashrafi and colleagues reported that estrogen therapy did not appear to demonstrate a benefit. Further evidence is necessary before dismissing the current trend of postoperative estrogen therapy.

FIGURE 25.19 Resectoscopic metroplasty. **A:** A Foley catheter is placed in one cavity of a complete septate uterus (American Fertility Society class Va uterus). The resectoscope is inserted in the opposite cavity, and the septum is incised until the Foley is visualized. The septum can be easily incised with the resectoscope until both internal os are visible. **B:** A septate uterus with a single cervix. The septum can be incised with the straight loupe of the resectoscope.

Transcervical lysis also can be performed to repair a complete septate uterus (i.e., a single fundus with two cavities and two cervices). In this instance, a no. 8 Foley catheter is inserted into one cervix and indigo carmine is injected into the cavity. The other cavity is distended with dextran 70 (Hyskon) by way of the resectoscope. The septum is electrosurgically incised at a point above the internal cervical os until the Foley catheter is visualized. The septum is then incised in a superior direction until the tubal ostium is visualized and there is no appreciable septum (**Fig. 25.19**).

After transcervical lysis of a uterine septum, a 2-month delay before attempting pregnancy is suggested to allow complete resorption of the septum. Delivery may be vaginal. The Jones procedure is used to repair a septate uterus when a particularly broad septum cannot be easily incised with the resectoscope. The Strassmann procedure is used for unification of a bicornuate uterus. The safety and efficacy of hysteroscopic resection of the uterine septum in patients with a class Va septate uterus has been demonstrated by the senior author. Historically, case reports, such as that of Hundley and colleagues, were the only source of information about this interesting variant; however, one of the largest populations of patients with a complete septum was reported in 1999 by Rock, Roberts, and Hesla. The patients underwent hysteroscopic metroplasty with preservation of the cervical portion of the septum. With the exception of one case of pulmonary edema, no significant intraoperative or postoperative complications were reported. Postoperative hysteroscopy revealed only minor fundal septal remnants without clinical significance.

P.539

The Modified Jones Metroplasty

In the modified Jones unification operation (**Fig. 25.20**), the abdomen is generally opened through a transverse incision. If only the unification operation is planned, then a Pfannenstiel incision is permissible. The pelvic viscera are inspected. The septate uterus may demonstrate a median raphe across the fundus, but it is surprising how often the corpus looks normal. To facilitate manipulation, a traction suture of heavy silk is placed through the top of the septum. This suture is removed from the site when the septum is excised.

No attempt is made to stain the uterine cavity with methylene blue. Normal unstained endometrial tissue can be easily differentiated from the myometrium.

There are essentially two methods to control bleeding during this procedure. In the first, a tourniquet is applied at the junction of the lower uterine segment and cervix by inserting a 0.5-inch Penrose drain through an avascular space in the broad ligaments just lateral to the uterine vessels on each side. The tourniquet is placed around the lower uterine segment and is tied anterior to the uterus. Because the uterine corpus receives a significant blood supply through the ovarian arteries, tourniquets should also be tied around the infundibulopelvic ligaments on each side, using the same hole in the broad ligament. All tourniquets must be tied tightly enough to occlude both the arterial supply to and the venous drainage from the uterus. If only the venous drainage is occluded, then the corpus becomes engorged and congested, and bleeding is increased. If the arterial supply is occluded, then the uterus blanches, and the bleeding is minimal. A sterile Doptone can be used to establish disappearance of uterine artery pulsations. Hypotensive anesthetic techniques used in conjunction with the tourniquets allow a uterine unification operation to be accomplished with negligible blood loss.

FIGURE 25.20 The modified Jones metroplasty. See the text for a full description of the various steps in the operative repair of a septate uterus by excision of a wedge.

The alternative method for hemostasis uses up to 20 units of vasopressin that is diluted in 20 mL of saline and injected into the anterior and posterior walls of the uterus before the incision is made.

The uterine septum should be surgically excised as a wedge (**Fig. 25.20D**). The incisions begin at the fundus of the uterus. The approach to the endometrial cavity should be handled

P.540

carefully so that it is not transected (**Fig. 25.20E**). The original incisions at the top of the fundus are usually within 1 cm—and sometimes even less—of the insertion of the fallopian tubes. If the incision is directed toward the apex of the wedge, however, there seems to be little danger of transecting the tube across its interstitial transit in the myometrium.

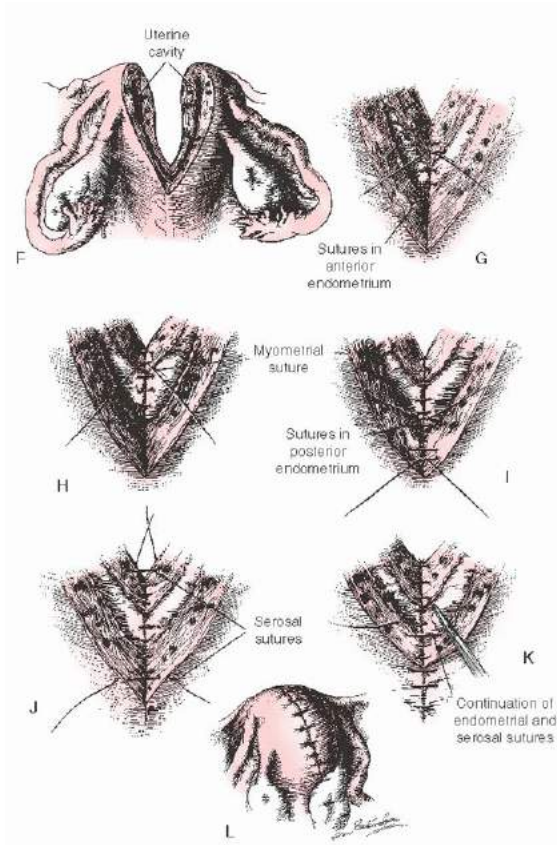

FIGURE 25.20 (Continued)

After the wedge has been removed, the uterus is closed in three layers with interrupted stitches; 2-0 nonreactive suture on an atraumatic tapered needle is convenient. Two sizes of

needles are needed: a half-inch needle for the inner and intermediate layers and a large needle (three fourths half round) for the outer muscular layer. The inner layer of stitches must include approximately one third of the thickness of the myometrium, because the endometrium alone is too delicate to hold a suture and will be cut through. The inner sutures should be placed through the endometrium and the myometrium in such a way that the knot is tied within the endometrial cavity (Fig. 25.20G, H). While the suture is being tied, the two lateral halves of the uterus should be pressed together both manually and with the guy sutures to relieve tension on the suture line and to reduce the possibility of cutting through. These sutures are placed alternately, first anterior and then posterior. After the first few stitches are placed and before the first layer is completed, the second layer can be started to reduce tension.

As the operation proceeds, the third layer of stitches is begun in the serosa both anteriorly and posteriorly (Fig. 25.20I-K). Finer, nonreactive suture material can be used to approximate the serosal edges of the uterus more precisely to prevent adhesion formation to the suture line (Fig. 25.20K, L). By the conclusion of the operation, the uterus appears near normal in configuration. The striking feature is usually the proximity of the insertions of the fallopian tubes. Special care must be exercised not to obstruct the interstitial portions of the fallopian tubes while placing the fundal myometrial and serosal sutures.

The final size of the uterine cavity seems to be relatively unimportant to reproductive capability; uterine symmetry appears to be a more important factor. Often, the constructed cavity is quite small compared with the normal uterus.

P.541

Whether the surgeon removes the septum with the Jones procedure or lyses the septum transcervically, postoperative hystrogram films often show small dog-ears that are leftover tags from the original bifid condition of the uterus. Such dog-ears do not seem to interfere with function, although a postoperative roentgenogram cannot be considered normal in the sense that it does not have the appearance of a normal endometrial cavity after such an operation. If a double cervix is present, the physician should not attempt to unify the cervix because an incompetent cervical os will result. To allow the uterine incision the best possible opportunity to heal, a delay of 4 to 6 months in attempting pregnancy is advised after abdominal metroplasty.

The Jones Metroplasty versus the Tompkins Procedure

The technique of modified Jones metroplasty is a compromise between the classic Jones metroplasty and the Tompkins metroplasty. In the Jones operation, the entire septum is removed. In the Tompkins operation, a single median incision divides the uterine corpus and septum in half. The incision is carried inferiorly until the endometrial cavity is reached. Each lateral septal half is then incised to within 1 cm of the tubes. No septal tissue is removed. The myometrium is reapproximated, taking care not to place sutures too close to the interstitial portion of the tubes. Proponents of the Tompkins technique suggest that it is simpler than the classic Jones procedure, that it conserves all myometrial tissue and leaves the uterotubal junction in a more normal and lateral position, and that it provides better results than the Jones metroplasty. Good results with the Tompkins technique have been reported by McShane and colleagues.

The Wedge Metroplasty versus Transcervical Lysis

There are obvious advantages to a transcervical incision of a uterine septum for patients with a septate uterus. Morbidity is decreased after the procedure, and delivery can be vaginal. Term pregnancy rates are comparable with those after abdominal metroplasty for repeated pregnancy wastage.

Most of the septa associated with a septate uterus can be cut through the cervix by way of the hysteroscope or the resectoscope. Nevertheless, cases of broad uterine septum can benefit from the wedge metroplasty, and reconstructive surgeons should be knowledgeable in its performance.

The Strassmann Metroplasty

The Strassmann procedure is not easily adapted to the septate uterus, but it is the procedure of choice for unification of the two endometrial cavities of an externally divided uterus, both bicornuate and didelphic (Fig. 25.21). A bicornuate uterus cannot be repaired through transcervical lysis because perforation will result. When there has been failure of fusion of the two müllerian ducts, inspection of the pelvic cavity often reveals a broad peritoneal band that lies in the middle between the two lateral hemicorpora. This rectovesical ligament is attached anteriorly to the bladder, folds over and is attached between the uterine cornua, continues posteriorly in the cul-de-sac, and ends with its attachment to the anterior wall of the sigmoid and rectum. It is not invariably present, but when it is, its potential significance in the etiology of the anomaly, possibly by preventing the two müllerian ducts from joining, must be considered. This rectovesical ligament must be removed before a unification procedure can be performed (Fig. 25.21A).

For hemostasis, tourniquets are used in a manner similar to that described for the modified Jones procedure. The two uterine cornua are incised on their median sides in their longitudinal axes, deeply enough to expose the uterine cavities (Fig. 25.21B). Superiorly, the incision must not be too close to the interstitial portion of the fallopian tubes. Inferiorly, the incision is carried far enough to join the two sides into a single endocervical canal. If it appears that a deeper incision will compromise the competence of the cervix, then a double cervical canal can be left. If the cervix is already duplex, then it should not be joined. As the incision in the myometrium releases the internal stresses in the walls of the hemicorpora, each one everts and is perfectly positioned for apposition, almost as if the original intention in embryologic development is finally to be realized. The suture technique for joining the two sides (Fig. 25.21C-E) is exactly the same as for the modified Jones procedure. The suture line in the uterine corpus should be observed for several minutes to determine the adequacy of hemostasis. Occasionally, it is necessary to place one or two extra sutures to control bleeding.

A uterine suspension can be performed as necessary. However, in the event of pregnancy, the shortened round ligaments can produce symptoms from an enlarging uterus. Presacral neurectomy in association with uterine unification should be considered only in patients with severe midline dysmenorrhea.

The cervix should be dilated to ensure proper drainage from the uterine cavity. This can be accomplished transvaginally after the abdominal procedure or from above by inserting a dilator through the cervical canal into the vagina to be removed later.

The operative technique should always be consistent with the goal of maintaining or enhancing fertility and possibly achieving a successful pregnancy. Tissue surfaces should be kept moist throughout the procedure, and instruments should be selected and used in such a way that tissue damage is minimized. Abdominal packs should be placed in plastic bags to avoid adhesions, or no-lint laparotomy pads can be used. Talc should be carefully washed from gloves, and meticulous aseptic technique should be used. The appendix should not be removed. Lactated Ringer solution containing heparin and corticosteroid can be used for peritoneal lavage throughout the procedure.

Cervical Incompetence Associated with a Double Uterus

When a patient with an anomalous uterus, with or without unification, becomes pregnant, she must be watched closely for evidence of cervical incompetence, especially if a history of previous reproductive loss suggests cervical incompetence. Heinonen and associates improved fetal survival rate from 57% to 92% by cervical cerclage. Cerclage was used mostly in patients with a partial bicornuate uterus. In these patients, the fetal salvage rate was improved from 53% before cerclage to 100% afterward. Prematurity also was decreased, from 53% to 3%. The authors stress that cervical incompetence, not the uterine anomaly, is the proper indication for cerclage in these patients. However, the frequency with which these problems are found together suggests the importance of doing a careful evaluation for both problems. Some reproductive losses from a uterine anomaly might be prevented by cerclage of an incompetent cervix during metroplasty. However, routine cerclage at the time of metroplasty is not recommended.

Attempts to unify a double cervix or a septate cervix also are not recommended because of the possibility of causing cervical incompetence. However, a double or septate cervix can adversely affect the outcome of delivery if vaginal delivery is attempted, and delivery should be by cesarean section if it appears that the cervix will cause dystocia.

P.542

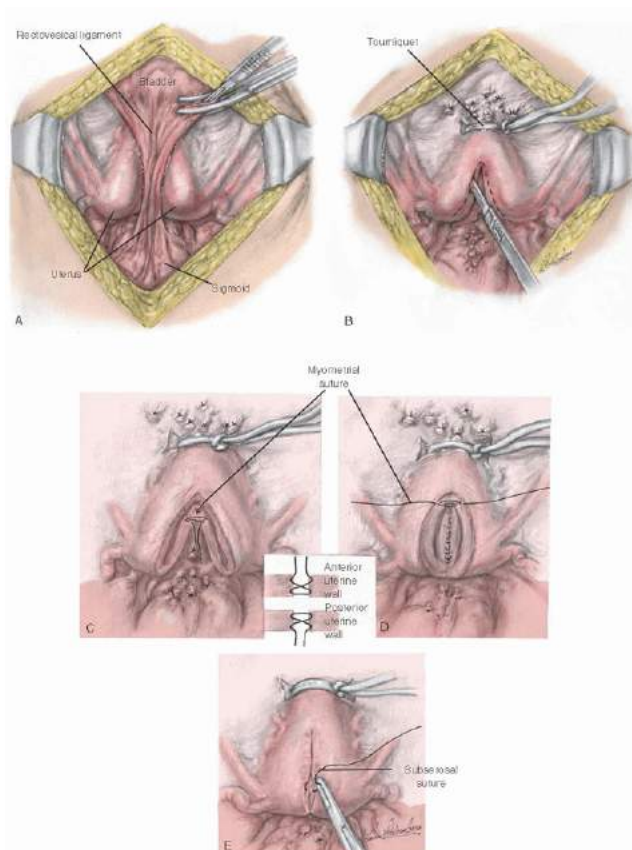

FIGURE 25.21 The Strassmann metroplasty with modification. **A:** If a rectovesical ligament is found, it should be removed. **B:** An incision is made on the medial side of each hemicorpus and carried deep enough to enter the uterine cavity. The edges of the myometrium will evert to face the opposite side. **C and D:** The myometrium is approximated by the use of interrupted vertical figure-of-eight 3-0 polyglycolic acid sutures. One should avoid placing sutures too close to the interstitial portion of the fallopian tubes. **E:** A continuous 5-0 polyglycolic acid subserosal suture is used as a final layer. Tourniquets are removed, and defects in the broad ligament are closed.

P.543

Mode of Delivery after Metroplasty

The scar formed in the myometrium after unification is as strong as, if not stronger than, the scar formed after cesarean section. The biologic conditions under which healing occurs are entirely different in these two situations. Endomyometritis is a common complication after cesarean section but is not a complication of uterine unification. Of 71 known pregnancies in Strassmann's collected series reported in 1952, 61 were delivered vaginally. There were no cases of uterine rupture during pregnancy or delivery. Lolis and colleagues reported the reproductive outcome of 22 women who underwent the Strassmann metroplasty for a bicornuate uterus; 88% achieved pregnancies that ended with the delivery of a viable infant. All were delivered by cesarean section without evidence of scar rupture. Despite evidence that the uterine scar heals securely after unification operations, our policy is to recommend delivery by elective cesarean section in all patients who have undergone abdominal metroplasty. Patients can deliver vaginally after a metroplasty by hysteroscope or resectoscope.

Diethylstilbestrol-Related Uterine Anomalies

Exposure of the female fetus to DES can cause significant anomalous development of the uterus, as reported by Kaufman and associates and by Haney and colleagues. The T-shaped uterus is the variant most commonly seen. It is associated with an increased rate of spontaneous abortions, preterm deliveries, and ectopic pregnancies.

Nagel and Malo determined the feasibility of correcting the uterine malformations seen in DES-exposed women by incising constriction rings and septa. Their goal was to incise the irregular uterine walls until the cavity assumed a smooth, straight line from the lower uterine cavity to the uterine tubal ostium. Their results suggested that metroplasty can decrease pregnancy loss but does not enhance fertility. The editors of this book suggest that the rare patient can benefit from a uterine reconstructive procedure, but that most will not. Surgeons may never develop a large series to document efficacy of surgical outcomes because patients with this anomaly are close to aging out of the natural reproductive years (last dispensed in 1971 in the United States). DES-exposed patients must be monitored closely for evidence of dilatation and effacement of the cervix early in pregnancy. Cervical cerclage may be indicated in some patients.

Unicornuate Uterus

A unicornuate uterus can be present alone or with a rudimentary horn or bulb on the opposite side. In a series reported by Heinonen and associates, 11 of 13 patients with a unicornuate uterus had a rudimentary horn, and two did not. The rudimentary anlagen (uterine muscle bundle or bulb) can communicate directly with the unicornuate uterus. In some instances, there is no cavity within the anlagen, or there is no rudimentary horn. Most rudimentary horns are noncommunicating (90% according to O'Leary and O'Leary). The two sides may be connected by a fibromuscular band, or there may be no connection and no communication between the two uterine cavities. Fedele and associates have found sonography useful in determining the presence of not only a rudimentary horn but also a cavity within.

Associated Anomalies

Urinary tract anomalies are often associated with a unicornuate uterus. On the side opposite the unicornuate uterus, there may be a horseshoe or a pelvic kidney, or the kidney may be hypoplastic or absent. This is especially true if there is associated müllerian duct obstruction. When all müllerian duct derivatives and the kidney are absent on one side, this implies failure of development of the entire urogenital ridge, including the genital ridge where the ovary forms. In addition, the ovary may be malpositioned (**Fig. 25.22**). Rock, Parmley, and associates reported a unilateral ovary located above the pelvic brim in four cases of uterine anomalies. The orifice of the müllerian duct develops at approximately the level of the fourth thoracic vertebra (T4) in the embryo. The tip subsequently migrates along the course of the müllerian duct into the pelvis. The orifice of the duct or the fimbriated end of the tube comes to lie in the pelvis as a result of differential growth of the fetus. The subsequent differential growth is retarded so that the portion of the urogenital ridge that gives rise to both the gonad and tube does not displace into the pelvis. Malpositions of the ovary and tube are the result.

Reproductive Performance

According to Heinonen and associates, the unicornuate uterus carries the poorest fetal survival rate (40%) of all uterine anomalies. In 1957, Jones reported similar findings. The

abnormal shape, the insufficient muscular mass of the uterus, and the reduced uterine volume and inability to expand may explain the poor obstetric outcome.

Moutos and colleagues compared the reproductive performance of the unicornuate uterus with that of the didelphic uterus. Twenty of the 29 women with a unicornuate uterus produced a total of 40 pregnancies, whereas 13 women with a didelphic uterus produced a total of 28 pregnancies. The percentages of pregnancies resulting in preterm delivery, term delivery, and living children were similar in both groups. The authors concluded that reproductive performance of the unicornuate uterus was not different from that of the didelphic uterus, that it is uncommon for either malformation to be a primary cause of infertility, and that there is insufficient information to support recommendation of placement of a cervical cerclage in the absence of cervical incompetence. Reichman, Laufer, and Robinson reviewed 20 published reviews on patients with a unicornuate uterus. They examined 290 total women who were reported in the literature; 175 patients conceived with 468 pregnancies reported. They reported 2.7% ectopic pregnancy, 24.3% first-trimester loss, 9.7% second-trimester abortion, 20.1% preterm delivery, and 10.5% intrauterine fetal demise. They reported a 49.9% livebirth rate. The authors also suggested that the current data available about the benefit of cervical cerclage (nonrandomized and lacking control subjects) seem inadequate to support a role for cervical incompetence for recurrent losses in patients with a unicornuate uterus.

Because most cases of unicornuate uterus have a noncommunicating rudimentary uterine horn on the opposite side, there is danger of pregnancy in the rudimentary horn from transperitoneal migration of sperm or ovum from the opposite side. According to Holden and Hart, approximately 350 cases of pregnancy in a rudimentary horn have been reported since the original case report by Mauriceau in 1669. O'Leary and O'Leary found the corpus luteum on the side contralateral to the rudimentary horn containing a pregnancy in 8% of cases. Signs and symptoms of an ectopic pregnancy develop with eventual rupture of the horn if the pregnancy is not detected early. Rupture through the wall of the vascular rudimentary horn is associated with sudden and severe intraperitoneal hemorrhage and shock. Death can occur in a few minutes. It is surprising that the current mortality rate has decreased to 5%.

Very little, if anything, can be done to improve the reproductive performance of patients with a unicornuate uterus. The physician should observe closely for signs and symptoms of preterm labor. Cervical incompetence is likely less common than previously suggested, yet if present, cerclage should be

P.544

considered as indicated. Andrews and Jones have suggested that removal of the rudimentary uterine horn may improve the chances of a successful pregnancy, eliminating the risk of ectopic pregnancy in the rudimentary horn as well as the risk of possible retrograde menstruation and the development of endometriosis. Typically, the procedure is a straightforward laparoscopic procedure with the potential for substantial benefit. Cases of asymmetric development of the unicornuate uterus with an opposing rudimentary uterine horn are not amenable to unification.

FIGURE 25.22 A unicornuate uterus associated with ovarian malposition on the left. Note that the ovary and the tube are slightly above the pelvic brim. In this instance, the ovary measured 6 inches long.

Longitudinal Vaginal Septum

Failure of fusion of the lower müllerian ducts that form the vagina can result in a vagina with a longitudinal septum. The septum can be partial or complete. Young patients have difficulty using tampons. In cases of didelphic uterus with a longitudinal vaginal septum, one uterine hemicorpus is usually better developed than the other. If intercourse consistently occurs on the vaginal side connected to the uterine hemicorpus that is less well developed, then infertility or repeated pregnancy loss could result. For these reasons, the septum should be removed (when the patient is not pregnant) unless there is a contraindication. This can usually be accomplished easily with reasonable precautions against injury to the urethra, bladder, and rectum.

Haddad and colleagues reported their experience over a 24-year period with management of the longitudinal vaginal septum. The retrospective review of 202 patient charts described a complete septum (extending from cervix to introitus) in 45.6% of patients, high partial in 36.1%, and a medium or low partial, involving only the distal vagina, in 18.3%. Uterine malformations were noted in 87.8% of cases. The frequency of uterine malformations was 99.4% in cases of complete or partial high septum and 30.3% in cases of partial medium or low septum. The most common malformation was class Va complete septate uterus in 59.5% of malformations, followed by class III uterus didelphys (24.3%), and class Vb partial septate uterus (15%). Section or resection was performed in 201 cases. Bladder injury in one patient was the only reported complication. As highlighted by the high prevalence of associated uterine malformations in this review, management should always include an assessment of uterine anatomy.

Asymmetric Obstruction of the Uterus or Vagina

Unicornuate Uterus and Noncommunicating Uterine Anlagen Containing Functional Endometrium

If one müllerian duct develops normally while the opposite müllerian duct fails to develop or develops incompletely, then a relatively normal unicornuate uterus is found on one side

and the cervix, musculature, uterine cavity, endometrium, fallopian tube, blood supply, and ligamentous attachments are absent or hypoplastic to a varying degree on the other side.

P.545

Obstruction to menstruation can also occur to varying degrees on the improperly developed side. For example, if a rudimentary uterine horn does not communicate externally but does have an endometrium-lined uterine cavity, then clear symptoms of obstructed menstruation may begin soon after menarche, and severe dysmenorrhea will be present. Cryptomenorrhea can be overlooked as the diagnosis because there is cyclic menstruation from the opposite side. It is important to make the diagnosis as soon as possible, because if the lumen of the tube communicates with the endometrial cavity of the rudimentary uterus, then retrograde menstruation and pelvic endometriosis will develop, and reproductive potential can be damaged. During the operation illustrated in [Figure 25.23](#), which was performed to remove an obstructed rudimentary uterine horn, the fallopian tube was obstructed, and retrograde menstruation was impossible. Occasionally, the fallopian tube connected

P.546

to the rudimentary uterine horn may not be patent because of incomplete development. Multiple case reports regarding the laparoscopic resection of obstructed uterine anlagen have supported the use of multiple techniques (stapling, bipolar or monopolar cautery, and the harmonic scalpel). Fedele and colleagues reported a series of 10 patients who have done well; however, the follow-up was only reported out to 6 months postprocedure. The authors strongly recommend the removal of the associated fallopian tube to minimize the risk of an ectopic pregnancy.

FIGURE 25.23 A: A noncommunicating rudimentary horn with functional endometrium that contains menstrual blood under pressure. Note the congenital abnormality of the fallopian tube, which prevented retrograde menstruation. **B:** The same patient after excision of the rudimentary horn.

Unilateral Obstruction of a Cavity of a Double Uterus

Another example of a rare obstructed lateral fusion problem is the complete septum between two uterine cavities illustrated in [Figure 25.24](#). One cavity communicated with a cervix, and the other did not. This could represent an example of unilateral failure of cervical development. The patient reported incapacitating dysmenorrhea that appeared shortly after the menarche and lasted 5 days. A tense, cystic mass was palpable in the right half of the pelvis. The operation, described originally by Jones in the second edition of this book, consisted of making an incision through the anterior wall of the cystic right portion of the uterus. It was found to contain old menstrual blood. The entire septum was excised, and the uterus was reconstructed by anastomosis of the two cavities. A continuous lockstitch was reinforced by interrupted myometrial sutures, and the plastic reconstruction of the uterus was completed by a third layer of interrupted sutures uniting myometrium and serosa. Steinkampf and colleagues reported a similar case in a 17-year-old girl with progressive pelvic pain. The authors described an accessory noncommunicating uterine cavity, which they treated by excision at laparotomy.

FIGURE 25.24 A: A double uterus seen at operation. Hematometra in the right uterine cavity (*inset*), which does not communicate with the other cavity or the cervical canal.

Sanders and colleagues described several cases in which the role of interventional radiology was crucial in the management of obstructive anomalies. The report described the drainage of a noncommunicating right uterine cavity distended with blood in a unicornuate uterus in a 14-year-old patient. Adequate access was established by using ultrasound-guided needle aspiration followed by a hysteroscopic excision. The assistance of interventional radiologic procedures, including percutaneous drainage and dilatation of small maldeveloped areas, may allow access to areas otherwise inaccessible by conventional mechanisms and assist in preserving reproductive function.

Double Uterus with Obstructed Hemivagina and Ipsilateral Renal Agenesis

The unique clinical syndrome consisting of a double uterus, obstruction of the vagina (unilateral, partial, or complete), and ipsilateral renal agenesis is rare. The renal agenesis (mesonephric involution) on the side of the obstructed vagina associated with a double uterus and double cervix is suggestive of an embryologic arrest at 8 weeks of pregnancy that simultaneously affects the müllerian and metanephric ducts. The exact cause is unknown.

P.547

FIGURE 25.24 (Continued) B: The septum of the double uterus has been excised, and anastomosis is performed to unite the two cavities. **C:** Anastomosis is completed. The small incision in the left uterine cavity was made before the septum was removed for the purpose of orientation.

Clinical symptoms vary depending on the uterovaginal relations in individual cases, but the syndrome can be described generally in three groups. Group 1 patients have complete unilateral vaginal obstruction without uterine communication, resulting in a paravaginal mass and symptoms of severe dysmenorrhea and lower abdominal pain. Menses are regular. Group 2 patients have an incomplete unilateral vaginal obstruction without uterine communication. The presenting symptoms are lower abdominal pain, severe dysmenorrhea, excessive foul mucopurulent discharge, and, in some instances, intermenstrual bleeding. Group 3 patients have complete vaginal obstruction with a laterally communicating double uterus. They have a paravaginal mass, lower abdominal pain, and dysmenorrhea. Menses are regular. A 10-year review of patients with this anomaly was published by Phupong and colleagues. Most patients presented with dysmenorrhea (73%) or a pelvic or paravaginal mass (71%). The right uterus and vagina were affected in 63.5% of patients.

Because menses in patients with this syndrome are rarely irregular, the possibility of this syndrome as a diagnosis can easily be overlooked. A careful pelvic examination is necessary to make the correct diagnosis. Magnetic resonance imaging can identify the obstructed vagina, double uterus, and absence of a kidney on the side of the obstruction (Fig. 25.25), but it may not be helpful if there is incomplete vaginal obstruction or a uterine communication. With the onset of more universal prenatal imaging, the diagnosis of unilateral renal agenesis in a female fetus should prompt the obstetric team to interact with pediatric providers about the possible association with müllerian anomalies, particularly obstructing hemivagina with double uterus. The obstructed vagina may even prolapse through the introitus in newborns with mucocolpos of the obstructed vagina. A postdelivery pelvic ultrasound, combined with renal/bladder

P.548

sonogram, can provide data on the uterovaginal anatomy as well as rule out hydronephrer and hydronephrosis.

FIGURE 25.25 A double uterus with unilateral complete vaginal obstruction and ipsilateral renal agenesis. Magnetic resonance imaging reveals the left hematocolpos, both uteri, and absence of the left kidney on the side of the vaginal obstruction.

Complete unilateral vaginal obstruction (Group 1) can go unrecognized for a number of years after the onset of menses unless the obstructed vagina is significantly smaller causing hematometra to develop more quickly. The vagina is quite distensible and can accommodate a large amount of accumulated blood in the obstructed side. There is sufficient absorption of menstrual blood between periods so that each subsequent flow can add to the increments of accumulated blood without pain. Nevertheless, once retrograde menstruation occurs, endometriosis invariably is the result.

Surgical Treatment

Careful excision of the vaginal septum is the treatment of choice for a unilateral vaginal obstruction. Prophylactic antibiotics should be administered before surgery. After opening the vaginal pouch, the surgeon should use suction and lavage to remove the pooled blood and mucus. Phupong and colleagues' review also confirms the successful use of this primary therapy in 84.3% of patients. Haddad and colleagues reported a similar experience in a report describing patient management over a 27-year period. Excision of the vaginal septum was successful in 88% of patients, with complete excision in one procedure in 92% of those patients. In cases of pyocolpos or hematocolpos, distention and stretching of the septal tissue may increase the risk of inadequate resection and possible postoperative stenosis; the authors found the use of a twostep graduated resection advantageous to ensure adequate resection. A limited resection (3 cm) was performed to allow adequate drainage, followed by a return to the operating room in approximately 1 month to remove any remaining septum.

Because the obstructing septum is usually thick, removal can be difficult. Cooper and Merritt proposed the novel use of a tracheobronchial stent to maintain patency after excision of the obstructing vaginal septum. The stent allows maintenance of patency while epithelialization of the vaginal walls occurs. This technique can be particularly useful in high obstructing septa or in very young patients when access for reapproximation of vaginal mucosa is virtually impossible. In most cases, clamps should be used to isolate a generous vaginal pedicle while the suture is being tied in place to prevent slippage of tissue. Such pedicles generally retract during healing, and formation of a vaginal stenosis is avoided. In most instances, surgery is restricted to excision of the septum. A handheld harmonic scalpel can be advantageous for negotiating an appropriate pedicle and providing excellent hemostasis. Abdominal exploration is usually unnecessary; however, in cases with a high vaginal obstruction, an abdominal approach may provide the best surgical access to unify the vaginas. Uterine reconstruction is not indicated for cases of lateral communication of the uterine horns. Some authors have reported the use of hemihysterectomy in patients with a high, thick-walled obstruction, massive ovarian involvement, endometriosis, or adenomyosis; however, this is generally not recommended in young patients.

Reproductive Performance

Reproductive performance for patients with this disorder is usually consistent with that of patients with a double uterus unless the delay in diagnosis and resection of the obstructing septum has been sufficient to destroy tubal function or to cause the development of endometriosis. Haddad and colleagues' review was notable for a predominance of pregnancies (80%) in the contralateral endometrial cavity.

UNUSUAL CONFIGURATIONS OF VERTICAL-LATERAL FUSION DEFECTS

Unusual configurations of both vertical and lateral fusion defects may occur simultaneously. Figure 25.26 depicts the radiographic evaluation (MRI) of a young woman in whom cryptomenorrhea developed above a transverse vaginal septum. The MRI study depicting the hematocolpos also suggests the longitudinal vaginal septum. Incision, drainage, and resection of the transverse vaginal septum allowed appropriate evaluation of the more proximal müllerian anatomy. The artist's depiction in Figure 25.26A demonstrates the unusual constellation of a uterus didelphys with an intrauterine communication of the cavities and a longitudinal vaginal septum. This type of atypical combination occurs frequently enough to emphasize the importance of proper delineation of individual anatomy preoperatively for proper surgical preparation.

P.549

FIGURE 25.26 An unusual combination of both vertical and lateral fusion defects. **A:** A uterus didelphys with an intrauterine communication and a longitudinal vaginal septum are present proximal to a transverse vaginal septum. **B:** The magnetic resonance image demonstrates the presence of both septa.

Müllerian duct anomalies can occur in association with a variety of other problems. For example, Stanton reported that in a series of 70 patients with bladder exstrophy, 30 (43%) had reproductive tract abnormalities. He suggested that the true figures were actually higher. Müllerian abnormalities included absence of the vagina; septate vagina; unicornuate, bicornuate, and didelphic uterus; and absent uterus. Fewer müllerian anomalies are seen with epispadias. Jones investigated anomalies of the external genitalia and vagina in 30 patients with bladder exstrophy seen at the Johns Hopkins Hospital and suggested operative techniques for correction of these anomalies. Techniques for the management of other gynecologic and obstetric problems (especially uterine prolapse) also have been discussed by Weed and McKee and by Blakeley and Mills. A number of other rare combinations of congenital malformations of the vagina and perineum have been found in association with uterine anomalies. Their surgical correction, especially in children, is reported by Hendren and Donahoe and by others. Several authors have considered the uterovaginal anomalies that occur in association with multiple other gastrointestinal and genitourinary abnormalities. Goh and colleagues described an infant girl with complete duplication of the bladder, urethra, uterus, and vagina associated with a urogenital sinus and an anterior ectopic anus. Gastol and colleagues and Magalhaes and associates also described children with complete duplication of the bladder, urethra, vagina, and uterus. These complex anomalies include significantly more defects than lateral fusion concerns in the müllerian ducts. These cases emphasize the variable anatomy in this rare group of anomalies and that a substantial effort should be placed on defining anatomy before surgical exploration and management. Sheldon and colleagues reviewed 13 consecutive cases of vaginal reconstruction in pediatric patients with multisystem anomalies. The review emphasized several important principles involved in the surgical management: (a) all anticipated perineal reconstruction should be performed in a single stage, (b) urethral catheterization has an important role, (c) urinary reconstruction is often intimately involved in the vaginal reconstruction, (d) avoidance of overlapping suture lines is essential for optimal healing, (e) maximum growth potential of the neovagina should be considered, and (f) meticulous follow-up of proper routine dilatation of the neovagina should be expected. Coordinated reconstruction of all organ systems is especially important in these complex cases.

Müllerian duct anomalies are seen with the McKusick-Kaufman syndrome, an autosomal recessive disorder. Other clinical findings reported with this syndrome include hydrometrocolpos, postaxial polydactyly, syndactyly, congenital heart disease, intravaginal displacement of the urethral meatus, and anorectal anomalies. In 1982, Jabs and colleagues added an unusual case to the few cases previously reported in the literature.

Müllerian duct anomalies may also affect the development of the fallopian tube. Although extremely rare, episodes of unilateral or bilateral absence of the fallopian tube have been reported. Of the less than 10 cases in the literature, Eustace reported two of the described cases. He hypothesized that compromise of the local blood supply to the caudal aspect of the müllerian duct was a more likely cause than a fusion disorder. This situation could affect fallopian tube development to a variable extent with even some effect on ovarian development.

BEST SURGICAL PRACTICES

- Vaginal dilatation should be the first line of treatment for creation of a neovagina in patients with müllerian agenesis.
- The gynecologic literature supports the historical role of the McIndoe vaginoplasty as a safe and effective procedure for surgical creation of a neovagina, when necessary. The surgical tenants of the McIndoe procedure are the basis for innovative techniques in surgical creation of the neovagina.
- Appropriate preoperative evaluation of reproductive and pelvic anatomy remains a critical step before a patient is taken to the operating room for treatment of any müllerian anomaly.
- In patients with müllerian agenesis, removal of uterine anlagen that contain endometrium and have the potential to cause obstruction and subsequent pelvic pain should be strongly considered.
- Hysteroscopic metroplasty is a successful, minimally invasive technique for removal of a uterine septum.
- Resection of a uterine septum has been shown to improve pregnancy success in patients with a history of recurrent pregnancy loss.
- Strassmann metroplasty should be considered in select women with a bicornuate uterus who have experienced recurrent pregnancy loss or preterm delivery.

Chapter 26

Normal and Abnormal Uterine Bleeding

Diana Broomfield

Alicia Armstrong

David Carnovale

William J. Butler

DEFINITIONS

Amenorrhea—The absence of menstrual bleeding for more than 6 months.

Breakthrough bleeding—Intermenstrual bleeding that occurs despite the use of exogenous hormones.

Dysmenorrhea—Painful menstruation.

Interval bleeding—Bleeding between menstrual cycles.

Menorrhagia—Prolonged menstrual bleeding that is excessive in amount, duration, or both that occurs at regular intervals.

Metrorrhagia—Bleeding between periods.

Oligomenorrhea—Bleeding that occurs less frequently than every 35 days.

Polymenorrhea—Bleeding that occurs more often than every 21 days.

Postmenopausal bleeding—Uterine bleeding occurring more than 12 months after the last menstrual period of a menopausal woman.

PALM-COEIN—Polyp; adenomyosis; leiomyoma; malignancy and hyperplasia; coagulopathy; ovulatory dysfunction; endometrial; iatrogenic; and not yet classified. The term *dysfunctional uterine bleeding (DUB)* is discouraged since the implementation of this classification system.

INTRODUCTION

Abnormal uterine bleeding (AUB) is an extremely common gynecologic complaint. It is estimated that 30% of women experience menorrhagia annually. This debilitating condition is clinically important; Mahoney and colleagues report it is the indication for two thirds of hysterectomies and nearly 25% of gynecologic operations. Thus, the impact of this condition on the public health and health care costs is significant. Because medical therapies for AUB have significant failure rates or side effects, surgical treatment by hysterectomy remains a major therapeutic option for chronically symptomatic women. This chapter reviews normal menstruation, the pathophysiology underlying AUB, the evaluation of AUB, and current treatment modalities.

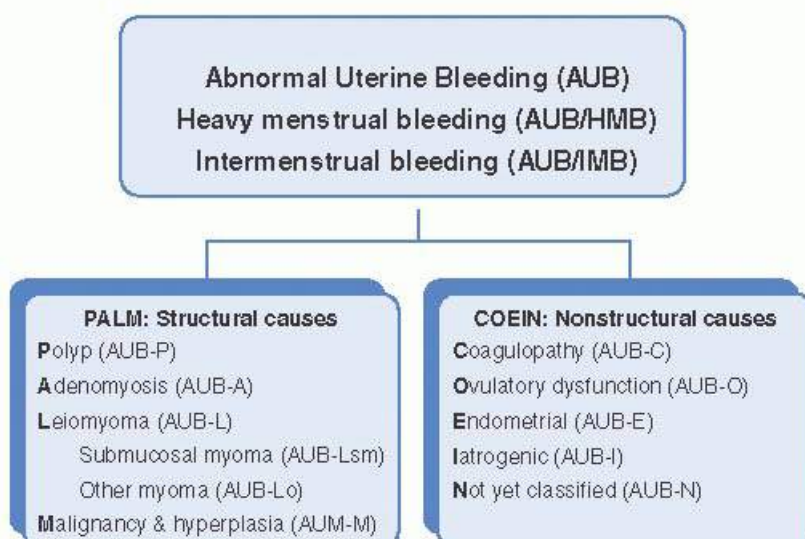

Reproductive capability in a young woman begins at the point of menarche, which is the beginning of cyclic uterine bleeding in the anatomically and physiologically normal female. Menarche marks the beginning of an important stage in a young woman's physical reproductive maturation and development. Attitudes toward menstruation, what is considered "normal," and the decision to seek medical evaluation are impacted by a variety of factors. In one cross-sectional US study of nearly 2,000 women, the authors concluded that Western cultures tend to "medicalize" menstruation, as evidenced by the media information that depicts menstruation as something that should be managed and remedied. This investigation also suggested that positive attitudes toward menstruation are

more prevalent among women with higher educational levels and higher incomes. Positive attitudes were more common among women who exercised frequently and older women who were approaching menopause. Race and ethnicity also played a role in attitudes toward menstruation with non-European Americans having a more positive attitude toward menstruation. Common wisdom would suggest, and studies support, the assumption that women who do not have an understanding of normal menstrual physiology are more likely to become alarmed about any disruption in what is perceived to be normal menstruation. As health care providers, it is our responsibility to educate our patients about what is normal and what symptoms would require medical evaluation. Current medical therapies are quite effective in the management of most of the disturbances of menstrual function that occur in the absence of infection, gestation, or uterine tumor. The success of these therapies depends on a complete understanding of normal menstrual physiology and of the effects of the various agents available for treatment. In addition, new surgical diagnostic and therapeutic technologies are becoming available to aid in the management of patients who fail to respond to conventional endocrine manipulation by medical therapies.

The normal interval between menstrual cycles is 21 to 35 days, and the normal duration is generally 5 days. Although heavy bleeding has been traditionally described as a blood loss exceeding 80 mL, a more practical approach is to rely upon the patient's perception. The term *menorrhagia* has been used to define heavy bleeding, while *metorrhagia* is used to define bleeding between periods. *Oligomenorrhea* is used to describe bleeding that occurs less frequently than every 35 days, and *polymenorrhea* is used to define bleeding that occurs more often than every 21 days.

In 2011, in an effort to standardize the nomenclature used to describe uterine bleeding abnormalities, a new classification system was introduced by the International Federation of Gynecology and Obstetrics (FIGO). The classification system known by the acronym **PALM-COEIN** (polyp; adenomyosis; leiomyoma; malignancy and hyperplasia; coagulopathy; ovulatory dysfunction; endometrial; iatrogenic; and not yet classified) is also supported by the American Congress of Obstetricians and Gynecologists.

The PALM-COEIN system differs from the previously used nomenclature in that it categorizes uterine bleeding by etiology as well as bleeding pattern. Under the new classification system, terms such as menorrhagia would be replaced by heavy menstrual bleeding. The PALM-COEIN system also uses letter qualifiers to identify the etiology (**Fig. 26.1**). Prior to the implementation of the PALM-COEIN classification system, the term dysfunctional uterine bleeding (DUB) was often used interchangeably with AUB; DUB was used to indicate AUB for which there was no systemic or structural etiology. The use of the term DUB is not part of the PALM-COEIN system, and its use is discouraged by the FIGO Working Group in 2011.

MENSTRUAL PHYSIOLOGY

Menstruation is the physiologic shedding of the endometrium associated with uterine bleeding that occurs at monthly intervals from menarche to menopause. In the years between these two physiologic landmarks, menstruation will occur 400 to 500 times in the average woman. According to the classical theory of the physiology of menstruation, it is the superficial functional layer of the endometrium that is shed during menstruation, and regeneration proceeds from the remaining intact basalis.

Recent work in humans has confirmed the presence of endometrial stem cells, which most likely are located in niches within the basalis layer. Additionally, it appears that these progenitor cells are hormonally independent. The proliferative potential of these cells is maintained in the noncycling state as demonstrated by their ability to regenerate endometrium in postmenopausal women given hormone replacement therapy.

The regenerating properties of the endometrium and its ability to support and nourish a fertilized ovum are an extremely complex system that appears to involve numerous endocrine, paracrine, and autocrine interactions. At the endometrial level, all three inhibin subunits are expressed in the human. It is believed that these dimeric glycoproteins may be involved in endometrial maturation, such as angiogenesis, decidualization, and tissue remodeling. Epidermal growth factors (EGFs) are extremely important in human embryogenesis, development, and proliferation differentiation. Human endometrial cells have been shown to express all four EGF receptors and two ligands amphiregulin and transforming growth factor alpha. Other substances with known angiogenic properties, such as leptin and erythropoietin, have also been shown to be expressed along with their receptors by human endometrium.

This process of monthly shedding and regeneration can occur as often as it does without producing permanent tissue damage possibly because most of the functional endometrium is conserved during menses and because the metamorphosis from proliferative to secretory endometria is controlled not only by processes of cell desquamation and re proliferation but also by dynamic and interactive processes of the endocrinologic and reproductive systems involving many organs. Any interruption of these normal but quite complex cyclic processes can lead to irregularities in endometrial breakdown and to AUB; the categorization of type of AUB is determined by the PALM-COEIN classification system ([Fig. 26.1](#)).

ENDOCRINOLOGY

The endometrium is an endocrine organ that responds to circulating blood levels of estrogen and progesterone. These two steroids alone are sufficient to induce growth and maturation of an endometrium that can support blastocyst implantation, as has been demonstrated by their sequential administration to patients with ovarian failure to prepare for the transfer of donated embryos. Estradiol (E_2) production by the developing follicle stimulates metabolic activity in the endometrium. E_2 has multiple effects that are mediated through binding to estrogen receptors. There are two estrogen receptors: alpha and beta. The estrogen receptors are members of a hormone receptor family that includes not only the other steroid receptors but

P.556

also receptors for vitamin D and thyroid hormone. All receptors in this family have three domains. The regulatory domain at the amino acid terminal binds regulatory protein factors. The hormone-binding domain on the carboxy terminal, with its contiguous hinge region, undergoes conformational changes when a steroid hormone binds to it, allowing DNA binding. The DNA-binding domain binds to the hormone-responsive elements in the target gene. The conformation of the DNA-binding domain consists of the highly conserved zinc finger structures that interact with complementary patterns in the DNA.

Steroid hormones have relatively low molecular weights and are rapidly transported into cells by passive diffusion. Binding of a steroid hormone to the intranuclear receptors transforms and activates the hormone receptor complex to allow DNA binding to specific hormone response elements and initiates subsequent transcription. Both estrogen and progesterone receptors bind to their response elements as dimers. After gene activation, the hormone receptor complex undergoes processing with dissociation and loss of activity.

Transcription of target genes with mRNA synthesis leads to translation with synthesis of proteins on ribosomes in the cytoplasm. The biologic effects of E₂ are mediated through this protein synthesis.

Estrogen and Progesterone Receptor Induction

One important function of estrogen is the induction of synthesis of its own and other steroid hormone receptors, called replenishment. Estrogen receptors reach a maximum concentration in the middle-to-late proliferative phase of the menstrual cycle. Progesterone receptors are also induced, and their concentration peaks in the late proliferative phase. Progesterone then blocks the estrogen replenishment mechanism, possibly by accelerating receptor turnover and inhibiting E₂-induced gene transcription. Enough progesterone receptors persist throughout the luteal phase, however, to maintain endometrial responsiveness and induction of decidualization.

Estrogen and Progesterone Target Genes

Target genes of the E₂ receptor complex code for the synthesis of numerous proteins, including structural proteins, enzymes, and growth factors. The relative roles played by the alpha and beta estrogen receptors in the endometrium have yet to be completely elucidated. The net effect of estrogenic stimulation is to induce DNA synthesis and mitotic activity with proliferation of the endometrial glands and stroma. The results are cessation of menstrual flow and an increase in the thickness of the endometrium.

Progesterone also has multiple biologic effects mediated through its receptors. It actively inhibits synthesis of both its own receptors and estrogen receptors, although sufficient progesterone receptors remain throughout the luteal phase of the cycle to mediate maturation and secretory differentiation of the endometrium. The net effect is to antagonize estrogenic metabolic activity with suppression of DNA synthesis in endometrial cells, which results in dynamic inhibition of cell mitosis. Progesterone is also responsible for the active induction of synthesis of various cytoplasmic enzymes, the secretion of proteins such as prolactin-dependent and progesterone-dependent endometrial peptide from decidualized stromal cells, and the stabilization of lysosomes, all of which may play an important role in the onset of menstruation.

Histology and Physiology

The postmenstrual endometrium that remains after collapse and partial shedding during menstruation consists of a thin but stable layer of basalis cells and the dense irregular remnants of the stromal cell-derived stratum spongiosum. The glands are narrow and lined by low cuboidal epithelial cells with few mitoses. The glandular stromal cells are small and spindle shaped with little cytoplasm or mitotic activity. Protein synthesis and secretory activity are minimal. It is on this substrate of basal and stromal cells that estrogen induces a proliferative response.

Early Proliferative Phase

Mitotic activity results in growth and pseudostratification of the glandular epithelial cells. With development and elongation of the glands, the epithelial cells assume a more columnar shape, with secretory granules in the cytoplasm, and glycogen begins to collect in the basal vacuoles. Arteriolar vessels grow up into the endometrium as part of the general proliferative response. The stromal cells also proliferate and expand from a dense compact state to an expanded matrix by transient edema. The combined effects of proliferation and expansion cause the endometrium to grow in this phase to a thickness of 3 to 5 mm.

The increased mitotic activity that results in proliferation is mediated by way of estrogen induction of various peptide growth factors. Epidermal growth factors and insulinlike growth factor I (IGF-I) are two potent mitogens with synthesis that is stimulated by estrogen in endometrial epithelial and stromal cells. Endothelin-1 is a vasoactive peptide with mitogenic activity; its synthesis is induced by both estrogen and growth factors, and its metabolism is enhanced by progesterone. Endothelin-1 may play a role in proliferation and in menstruation. The various peptides that are secreted from stromal and epithelial cells to form the extracellular matrix of the endometrium can be either induced or suppressed by both estrogen and progesterone. Fibronectin, for example, is suppressed by progesterone, whereas several integrin subtypes are stimulated by progesterone. These peptides may have a functional role in proliferation, differentiation, and embryo implantation.

Angiogenesis both allows repair of the endometrium after menstruation and supports cellular proliferation for regrowth during the follicular phase. It is supported and promoted by multiple growth factors. An important role is played by vascular endothelial growth factor (VEGF). Torry and Torry found VEGF mRNA expression is induced by E_2 and increases from the early proliferative phase through the secretory phase. Vascular endothelial growth factor is produced by the glandular epithelial cells, although some stromal expression is evident in the secretory phase. The increased expression throughout the cycle supports a possible role of VEGF in expansion and coiling of the spiral arterials. Kooy et al. detected changes in VEGF in women with AUB, supporting a possible role in the pathogenesis of menorrhagia.

E_2 induces several enzymes (alkaline phosphatase, 5α -reductase, and possibly phospholipase A_2).

Phospholipase A_2 , which releases arachidonic acid from phospholipid esters, controls the rate-limiting step in prostaglandin synthesis. E_2 also stimulates cyclooxygenase synthesis of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and prostaglandin E_2 (PGE_2), both of which have a role in menstrual function. $PGF_{2\alpha}$ has vasoconstrictive and muscle contraction effects. PGE_2 is generally a vasodilator but can also cause contractions in uterine smooth muscle. Alterations in the relative levels of $PGF_{2\alpha}$ and PGE_2 are known to change menstrual bleeding patterns.

Late Proliferative Phase

Ovulation with corpus luteum formation and significant progesterone secretion leads to secretory transformation in the

P.557

late proliferative phase endometrium. Progesterone inhibits both estrogen and progesterone receptor synthesis and inhibits DNA synthesis and mitosis. This inhibition process is accompanied by the development of RNA-filled channels between the nucleoli and nuclear membranes that are responsible for the progesterone-induced active synthesis of cytoplasmic enzymes during the secretory phase of the cycle.

The Secretory Phase

The cytoplasmic enzymes 17β - and 20α -hydroxysteroid dehydrogenase (HSD) are induced by progesterone and modulate steroid activity. The enzyme 17β -HSD catalyzes the conversion of E_2 to the relatively weaker estrogen estrone, which, when sulfated by estrogen sulfotransferase, can no longer bind to estrogen receptors. The enzyme 20α -HSD alters progesterone receptor binding and activity. Cytoplasmic lytic enzymes such as acid phosphatase are also induced by progesterone but are kept inactive within Golgi-derived lysosomes, the membranes of which are stabilized by progesterone. Insulin-like growth factor II is synthesized locally by middle-to-late secretory phase endometrium and appears to be involved in the differentiation response of the endometrium to progesterone. Insulinlike growth factor-binding protein I also appears at this time and is regulated by the IGFs and by relaxin. Other autocrine or paracrine agents secreted locally by decidual cells are relaxin, progesterone-dependent endometrial peptide, and prolactin.

Progesterone has also been shown to induce the activity of metalloendopeptidase, which degrades the endothelin-1 peptide. Withdrawal of progesterone can lead to increased endothelin-1 activity with vasospasm and initiation of menstrual bleeding. Several investigators have described increased levels of protease inhibitors, such as α_1 -antitrypsin and antithrombin III, in secretory phase uterine fluid, which may also be involved in the mechanism of menstrual bleeding.

The Luteal Phase

Morphologically, secretory transformation of the endometrium results in coiling of the spiral arterioles and endometrial glands. The endometrium reaches its maximum thickness of 5 to 6 mm and maintains this thickness throughout the luteal phase. The subnuclear intracytoplasmic glycogen vacuoles in the basal glandular cells transpose to the apex and are expelled into the glandular lumen. The stromal cells subsequently flatten into a low cuboidal form. Stromal cell differentiation from reticular spindle-shaped cells into plump predecidual cells and phagocytic granulated cells defines two layers in the functional endometrium known as the superficial compactum and the deeper spongiosum. The spongiosum has a loose edematous matrix that is the consequence of increased capillary permeability, mediated possibly by prostaglandins. The predecidual, late secretory phase stromal cells produce several metabolically active substances, as previously described, and are infiltrated by migratory leukocytes. The release of lysosomal enzymes from endometrial cells and possibly also from leukocytes may be involved in the initiation of menstruation.

Menstruation

Menstruation is controlled by many complex, interrelated, and incompletely understood factors. Normal menstruation results from progesterone withdrawal from the estrogen-primed endometrium. Changes that occur in the endometrium during menstruation were described by Markee by observation of endometrial tissue transplanted to the anterior chamber of the eyes of rhesus monkeys. Markee described cyclic changes in endometrial vascularity and the development of coiled vessels supplying the superficial two thirds of the endometrium. The estrogen-primed endometrium of the follicular phase is compact, with relatively underdeveloped vasculature. Progesterone converts this endometrium into a thick, edematous, secretory lining that is glycogen enriched and prepares the metabolically active stroma and glands with an increased vasculature to receive and nourish a fertilized ovum. If implantation does not occur, estrogen and progesterone levels fall, prostaglandin synthesis occurs, and lysosomal membranes rupture, causing constriction of the spiral arterioles, ischemic necrosis, and sloughing of the endometrium superficial to the basalis layer.

Lysosomal release and ischemic necrosis has been believed to be the main mechanism for normal menstrual bleeding for many years. However, the difficulty in detecting cell necrosis during menstruation and viability of menstrual fragments has raised a number of questions about this theory. Current data support the "metalloproteinase theory" as the mechanism leading to menstrual tissue breakdown and shedding. Matrix metalloproteinases (MMPs), lytic enzymes in conjunction with activated endometrial stromal granulocytes, macrophages, and mast cells together are now thought by most investigators to cause menstruation. It is believed that tissue inhibitors of metalloproteinases (TIMPs) remain constant throughout the menstrual cycle. Before menstruation, production and activation of MMPs increases in an environment of stable amounts of TIMPs, leading to an altered MMPs/TIMPS ratio, resulting in tissue breakdown. Estrogen and progesterone, along with cytokines, appear to play a significant role in the regulation and expressions of the MMPs. High levels of progesterone are believed to inhibit MMP production and activity. This would explain endometrial tissue breakdown that occurs coincident with decreasing progesterone levels from an involuting corpus luteum.

In the second part of the menstrual phase, mitotic activity resumes and epithelial regeneration begins. This process occurs even while menstrual bleeding continues. Horizontal growth from the stem cells of the glands present in niches within the basalis layer continues the regenerative process. New blood capillaries are formed

by the stimulating effect of VEGF and thymidine phosphorylase (TP) secreted by both epithelial and stromal cells. Continuous proliferation of stem cells is ensured by high telomerase activity.

This process begins in the premenstrual phase of the cycle with cessation of synthesis and inspissation of ground substance and supporting tissues by lytic enzymes released from lysosomes, which causes loss of fluids and compression of the endometrium, tonic contractions of spiral arterioles with reduction of blood flow to the tissues, loss of stromal edema, and kinking of the coiled spiral arterioles caused by the reduction in endometrial thickness.

A generalized state of ischemia develops in the superficial layers of endometrium, and bleeding into the stroma begins. Acid phosphatase and prostaglandin substances released from autolyzed cells, together with increased endothelin-1 activity, cause more intense vasoconstriction of spiral arterioles, and devitalized tissues finally slough as small hemorrhages in the stroma coalesce. According to Beller, coagulation factors are decreased in normal menstrual discharge. Fibrinogen is absent, plasminogen is converted to plasmin by released peptidases, and the amount of plasmin inhibitor is decreased. Menstrual blood generally does not clot, but it can form red blood cell aggregates with mucoid substances, mucoproteins, and glycogen as it collects in the vagina. These red cell aggregates may appear to be blood clots, but they contain no fibrin. In the presence of very heavy flow, however, clotting can occur.

P.558

According to classical theory, during menstruation the superficial compacta and the intermediate stratum spongiosum layers of the endometrium are shed, leaving only the basalis layer intact. New endometrium is regenerated from the basalis. Regeneration of new capillaries from the basalis has been observed by Markee, and restoration of the endometrial circulation has been correlated with the cessation of menstrual bleeding. Blood loss from the process of normal menstruation is limited by recovery of tone in the myometrium and endometrial vasculature, cessation of cellular autolysis, eventual clotting over the endometrial surface, and eventual active regeneration of glands, stroma, and vessels in the basalis layer in response to rising estrogen levels in the new cycle. The retained basalis endometrium is protected from destruction by lysosomal enzymes by a mucinous carbohydrate coat that covers the free surfaces of endometrial cells. This mechanism for retention of some endometrium during menstruation may explain the lack of permanent damage during the years of menstruation.

Endometrial regression during menstruation is described by classical theory as the result of four processes: autophagia, heterophagia, extrusion of secretory products, and elimination of fluids with some, but not complete, shedding of tissue. Autophagia and heterophagia are the kindred processes of intracellular lytic digestion of debris in vacuoles and of extracellular lytic digestion of debris taken up by phagosomes. Both processes eliminate damaged tissue to allow regeneration of normal endometrial cells. With fluid loss and secretion, the functionalis (the remaining functional basalis) regresses to a resting state, ready to regenerate in the next cycle. These two processes can only partially explain the observation that initial endometrial regeneration occurs in the absence of estrogen. This initial lack of estrogen dependence can also be secondary to the lesser proliferative response required after regression, compared with complete endometrial shedding. Much work remains to be done to define the complex processes involved in menstruation.

ABNORMALITIES OF THE MENSTRUAL CYCLE

STEPS IN THE PROCEDURE

Evaluation of Abnormal Uterine Bleeding

- Rule out pregnancy
- Document ovulation
- Screen for medical disorders
- Endometrial biopsy if at risk for hyperplasia
- Treat underlying medical disorders
- Correct anatomic abnormalities
- Medical therapy in anovulatory women

Given the complexities and varieties of possible alterations of the systems that control menstruation, it is not surprising that AUB should occur even in the absence of obvious disease. Prolonged estrogen stimulation can result in endometrium that outgrows its blood supply and has asynchronous development of endometrial glands, stroma, and blood vessels. Any failure of progesterone production can also profoundly affect endometrial glands, stroma, and blood vessels. Abnormal synthesis of acid mucopolysaccharides can result in the release of excessive amounts of hydrolytic enzymes into the stroma. Lysosome release from endometrial glands, influenced by plasma progesterone levels, can affect menstrual flow. The endometrium and myometrium of patients with menorrhagia produce altered types of prostaglandins. Smith and associates have shown that the amount of menstrual flow is influenced by a change in the endometrial conversion of prostaglandin endoperoxide from PGF_2 to PGE_2 and that women with menorrhagia synthesize mainly the vasodilator PGE_2 in the endometrium.

Menstruation has three clinical characteristics: the menstrual interval or cycle length, the duration of flow, and the amount of flow. The mean cycle length is 28 to 29 days, although a menstrual interval of 21 to 35 days can be considered normal. A menstrual interval shorter than 21 days and a menstrual interval longer than 35 days are considered abnormal. Amenorrhea is the absence of menses for 6 months or longer. The menstrual interval can vary from month to month by several days. Regularity of the menstrual cycle is more important than exact approximation to the 28-day mean menstrual interval. Variation in the length of the menstrual interval in regular ovulatory cycles usually occurs in the preovulatory (proliferative) phase of the cycle and is more frequent among postmenarchal teenagers and in women approaching menopause.

A duration of flow of 7 days or less is considered normal. A patient bleeding beyond 7 days enters the intermenstrual phase of the cycle, which was previously defined as metrorrhagia and is now categorized by the American Congress of Obstetricians and Gynecologists (ACOG) as intermenstrual AUB. Regardless of the length of the menstrual flow, 70% of the blood loss usually occurs by the 2nd day and 90% by the 3rd day. The mean menstrual blood loss for a normal period is approximately 40 mL. A total blood loss of 20 to 80 mL, representing 10- to 35-mg iron, has long been accepted as within the normal range. Menstrual blood loss of 80 mL or less was established as the upper limit of normal, as this is the 95th percentile in healthy women with normal iron stores measured in a population of Swedish women in the 1960s. The clinical utility of these measures is very limited. Additionally, it has recently been shown that the 80-mL value has neither the sensitivity nor specificity for disease, compromised iron status, or adverse impact of periods. The determination of the normalcy of menstrual bleeding amount is better addressed in a clinical context. Concerns about anemia in a particular patient should be investigated with appropriate laboratory tests for iron stores. A thorough menstrual history should establish the patient's perception of the heaviness of her flow, impact on her life, difficulty with containment of flow, and associated symptoms. Quantitation of menses is difficult, and a perfect measurement tool does not exist. There have been multiple survey questionnaires that have attempted to objectively measure menstrual bleeding. These measures include surveys such as the validated Menorrhagia Impact Questionnaire (MIQ) and menstrual calendars described by Bushnell and colleagues. Although the Uterine Fibroid Quality of Life questionnaire developed and validated by Spies et al. is designed for fibroid patients, there are a number of questions within the survey that assess bleeding.

We believe that development and routine use of a convenient, standardized, objective method for measuring menstrual blood loss would significantly improve the clinical practice of gynecology. Iron deficiency anemia is a late manifestation of excessive menstruation. Serum iron (ferritin) levels are more sensitive than hematocrit and hemoglobin levels for detection of iron depletion before anemia develops, as shown by Guillebaud and colleagues. The method of Hallberg and Nilsson for quantification of iron and blood loss is based on

P.559

the simultaneous use of tampons and pads for the collection of menstrual blood. Menstrual blood is extracted with 5% sodium hydroxide, which converts hemoglobin to alkaline hematin. The concentration is then determined spectrophotometrically. The method is simple and gives accurate results but is not widely used outside of clinical investigations.

Acute Abnormal Uterine Bleeding

STEPS IN THE PROCEDURE

Acute Abnormal Uterine Bleeding

- Determine patient acuity (hemodynamically unstable or hypovolemic patients require immediate intravenous access)
- Determine etiology using the PALM-COEIN classification system
- Select appropriate medical or surgical treatment

Patients who have an episode of bleeding that is sufficient to require immediate intervention should be approached in three stages. First, the patient should be rapidly assessed to determine acuity. Patients who are hemodynamically unstable should have one or two large-bore intravenous lines started in the event transfusion, or clotting factor replacements are necessary. Second, the etiology of the bleeding should be determined. The determination of etiology should be guided by the PALM-COEIN classification system, which separates causes into the two broad categories of “related to structural abnormalities” and “unrelated to structural abnormalities” (**Fig. 26.1**). Finally, an appropriate treatment should be chosen.

Similar to nonacute abnormal bleeding, described in the following sections, the treatment of acute bleeding is medical or surgical. Hormonal management using intravenous (IV) conjugated equine estrogens can stop bleeding within 8 hours in 72% of patients compared to placebo. Oral contraceptives or progestins can be used to manage bleeding chronically. Mechanical and surgical methods to manage acute bleeding include the use of intrauterine tamponade with a 26-F Foley catheter inflated with 30 mL of saline, dilatation and curettage, and in rare cases hysterectomy. Case reports have shown that both uterine artery embolization and endometrial ablation can successfully control acute AUB according to the American Congress of Obstetricians and Gynecologists Committee Opinion on the management of acute AUB.

Abnormal Uterine Bleeding Ovulatory Dysfunction

The state of chronic anovulation is the result of unopposed estrogen stimulation of the endometrium with consequent irregular breakdown and bleeding. Chronic anovulation syndrome is a “wastebasket” diagnosis for multiple endocrine etiologies. Hyperthyroidism and hypothyroidism, hyperprolactinemia, hormone-producing ovarian tumors, and Cushing disease are all endocrine syndromes that can induce anovulation, but the primary etiology of abnormal uterine bleeding ovulatory dysfunction (AUB-O) is chronic anovulation syndrome, often commonly described as the polycystic ovary or Stein-Leventhal syndrome. Any imbalance in hypothalamic

pulsatile release of gonadotropin-releasing hormone (GnRH), in pituitary synthesis or release of follicle-stimulating hormone (FSH) or luteinizing hormone (LH), or in ovarian follicular production of E₂, androgens, or progesterone can upset the delicate balances that induce cyclic ovulation and normal menstrual function. Exogenous androgen production in the adrenal glands and estrone production in adipose tissue produce identical clinical pictures.

Anovulation is also more common at the extremes of reproductive life. Perimenarchal and perimenopausal women require evaluations modified to include diagnoses that are less common in the mid reproductive years, such as coagulopathies in the perimenarchal patient and endometrial hyperplasia in the perimenopausal patient.

Menorrhagia has been described as an early symptom in patients with subclinical hypothyroidism before diagnosis of overt disease. Thyroid replacement in a normal physiologic dosage should resolve the abnormal bleeding. Because this is one of the less common causes of AUB, there is some controversy about whether thyroid testing should be part of the initial screening of patients with AUB.

Although anovulation is a frequent cause of AUB, histologic studies consistently show that 15% to 20% of AUB patients have secretory endometrium, indicative of at least intermittent, if not regular, ovulation. Livingstone and Fraser provide evidence to suggest that ovulatory AUB is more common than AUB that is associated with ovulatory dysfunction. The differential diagnosis of abnormal bleeding with ovulation differs from that of anovulation. Ovulatory patients with abnormal bleeding are more likely to have an underlying organic pathology and are not; therefore, true AUB-O patients by strict definition.

Aksel and Jones studied endometria of patients with AUB and found hyperplasia in 63% of cases; secretory endometrium was observed in 17%, and no secretory endometrium of the interval, postmenstrual, or atrophic type made up the remaining 20%. Thus, at least 17% of patients in this series had normal cyclic hormonal function and ovulation before the endometrium was examined, and it is possible that many patients with the postmenstrual type of endometria would have shown secretory changes if curettage had been performed somewhat later. In addition to histologic confirmation of ovulation by the presence of secretory endometrium, ovulation can be documented by basal body temperature charting, urinary LH surge detection, or prospective hormonal evaluation. In some cases, the prospective hormonal studies using daily serum estrogen and progesterone levels are more accurate for defining ovulatory status than are the historically accepted studies of endometrial histology, which can be misleading because of previous hormonal therapy. Although serum progesterone concentration exceeding 3 ng/mL in the luteal phase of the cycle indicates ovulation, a single measure will only identify the presence of ovulation in that cycle. Serial measures may be necessary to identify the patient that is anovulatory on an intermittent basis.

Abnormal Uterine Bleeding Coagulopathy

Proper evaluation of abnormal bleeding in the ovulatory patient demands assessment for other less common causes of bleeding. According to Claessens and Cowell, bleeding dyscrasias are particularly common in perimenarchal patients, up to 19% of whom have a primary coagulation disorder, such as idiopathic thrombocytopenic purpura or von Willebrand disease. An ad hoc consensus conference that met in May 2004 concluded that underlying hemostatic disorders were a more common cause of menorrhagia in adult women than has been currently recognized. The most common of

P.560

these coagulopathies is von Willebrand disease. The incidence of von Willebrand disease in the general population has been estimated at 0.8% to 1.3%. The consensus conference calculated, by review of the literature, an incidence of 13.2% (range 11.2% to 15.5%) in healthy women with menorrhagia. Conversely, women with von Willebrand disease report menorrhagia in 78% to 93% of patients. If von Willebrand disease is excluded, the inherited disorders of hemostasis are relatively rare. Disorders of platelet number and function

have variable effects on menstrual bleeding, depending on their severity. Treatment of AUB secondary to coagulopathy may involve medical management with tranexamic acid, desmopressin acetate (DDAVP), hormonal therapy, or a progestin-containing intrauterine device (IUD). Endometrial ablation is also appropriate in these patients.

Abnormal Uterine Bleeding Iatrogenic

Hemorrhagic diatheses can occur with leukemia, with chemotherapy treatment, or secondary to oral anticoagulant therapy or ingestion of foods or drugs that inhibit platelet aggregation. Women taking anticoagulants are at risk for iatrogenic AUB. Hormonal interventions such as oral contraceptives can also result in abnormal bleeding patterns rather than improvement of symptoms. The lowest doses of oral contraceptives are more likely to be associated with spotting than formulations containing 35 µg of ethinyl estradiol. Kaunitz et al. report a higher likelihood of unscheduled bleeding with continuous and extended-cycle regimens such as Seasonale, Seasonique, and Lybrel than with the traditional 28-day schedule.

Abnormal Uterine Bleeding Not yet Classified

Although infection is considered to be a cause of AUB, infection is not one of the categories identified under the PALMCOEIN classification system. This category would therefore be classified as not yet classified. Mobiluncus species identified in cases of abnormal bleeding respond to oral metronidazole therapy. Chlamydia has been implicated in abnormal bleeding, particularly with concurrent use of oral contraceptives.

Arteriovenous malformation is a very rare cause of ovulatory bleeding. In a report by Fleming and colleagues, only two cases were diagnosed before definitive surgery; the diagnosis was by pelvic angiography.

The reported association between tubal ligation and new onset of AUB should also be noted. Although numerous anecdotal reports exist, no underlying pathologic changes in anatomy or hormone production have ever been documented. Long-term follow-up studies do not confirm an increased incidence of abnormal bleeding in these patients, but do implicate biased patient perception. Patients who discontinue oral contraceptive use after tubal ligation have heavier and more painful bleeding, whereas patients who have intrauterine devices removed after sterilization have improved menstrual symptomatology.

Pathophysiology

As stated earlier, the most common etiology for AUB is estrogen withdrawal or estrogen breakthrough bleeding in an anovulatory patient. In the absence of progesterone exposure to cause inhibition of DNA synthesis and mitosis, the estrogenic proliferative response causes stromal cell growth to exceed the structural integrity of its stromal matrix, and the endometrium breaks down with irregular bleeding.

Unopposed estrogen results in vascular endometrial tissue with relatively scant stroma, giving glands a back-to-back appearance. The endometrium is fragile and undergoes repetitive spontaneous breakdown. In the absence of normal control mechanisms to limit menstrual blood loss, bleeding can be prolonged and excessive.

Other contributing factors are the lack of coordinated vasoconstriction and the release of lytic enzymes, which occurs in a normal progesterone-stimulated endometrium. The absence of progesterone stimulation of metalloendopeptidase increases endothelin-1 activity, which contributes to vasospasm. Lysosomal enzymes inappropriately released in the absence of progesterone stabilization of the lysosomal membrane further contribute to structural breakdown. The same lytic enzymes, MMPs, and their inhibitors involved in normal menstrual bleeding have been found to have aberrant locally restricted expression, activation, and uncontrolled activity in the endometrial tissue biopsy specimens from women with metrorrhagia.

Many questions still remain about the mechanisms responsible for all cases of AUB. Although the

mechanisms described above can explain some cases of AUB, it does not explain clinical scenarios such as bleeding unresponsive to hormonal manipulation after structural lesions have been ruled out. Hemostasis in a bleeding endometrium depends both on coagulation, with thrombus formation forming plugs in superficial blood vessels, and on vasoconstriction of spiral arterioles; generalized endometrial collapse with compression of bleeding vessels can also contribute. The lack of coordinated vasoconstriction and the irregular structural collapse lead to irregular and often heavy bleeding. The amount of bleeding correlates directly with the level of estrogen stimulation. The chronic high estrogen milieu seen in cases of obesity and chronic anovulation, and in perimenarchal and perimenopausal patients, cause the greatest amount of AUB blood loss.

Unopposed estrogen stimulation can, over time, induce a hyperplastic response in the proliferating endometrium (**Fig. 26.2**). Such hyperplasia can eventually develop the cytologic changes associated with neoplasia: atypical adenomatous hyperplasia or even low-grade adenocarcinoma. Such cellular transformation takes time, as much as 10 to 20 years; a young patient with AUB has a low risk of hyperplasia or neoplasia and generally does not require endometrial sampling. Patients with a long history of chronic anovulation are at greater risk of hyperplasia and undergo histologic evaluation earlier. The perimenopausal patient has a substantially higher risk, however, and sampling is mandated.

Diagnostic Imaging Techniques

Diagnostic vaginal ultrasound can be particularly useful in cases of ovulatory AUB. A nonrandomized study of 45 otherwise unselected patients with AUB demonstrated anatomic pathology in 31% by vaginal ultrasound compared with 9% by clinical examination. Pathologic findings included leiomyoma uteri, polyps, and abnormal endometrial architecture. If these data are confirmed by later studies, the implication is that true AUB in ovulatory patients may be even more rare than the currently accepted figure of 15% to 20%. Endovaginal ultrasound is also of particular value in cases of perimenopausal and postmenopausal abnormal bleeding, which will be discussed later (**Fig. 26.3**).

Saline infusion sonography (SIS) is a technique to improve visualization of the endometrial cavity during transvaginal ultrasonography. Dueholm and colleagues compared the accuracy of SIS with transvaginal sonography, hysteroscopy, and magnetic resonance imaging (MRI). In 108 patients with AUB, pain, endometriosis, or myomas, SIS had an overall sensitivity comparable to the gold standard of hysteroscopy and better than either MRI or transvaginal sonography. Magnetic resonance imaging had the highest sensitivity for submucous

P.561

P.562

myomas, but a relatively low sensitivity for other intrauterine pathology, such as polyps. As SIS is a less invasive procedure than a surgical technique, such as hysteroscopy, and is much less expensive than MRI, it should be the procedure of choice for imaging of the endometrial cavity in patients with AUB.

FIGURE 26.2 A: Endometrial hyperplasia before treatment showing hyperplastic cellular changes of glands. **B:** Hyperplastic endometrium after continuous progestin treatment.

FIGURE 26.3 A: Single-line endometrium consistent with postmenstruation, early proliferation, and postmenopause. **B:** Three-line endometrium from estrogen stimulation, late follicular phase. **C:** Endometrial polyp in hyperechoic thickened endometrium consistent with luteal phase or hyperplasia-neoplasia. **D:** Submucous myoma with distortion of endometrial cavity marked by single-line endometrium.

Differential Diagnosis of Abnormal Uterine Bleeding

Abnormal uterine bleeding occurs most frequently at the extremes of menstrual life, but it can develop at any intervening time. The characteristics of AUB are variable, from infrequent heavy flow (oligomenorrhea) to almost continuous spotting or bleeding. The age at onset and duration of irregularity can provide important clues to etiology. Anovulation is common in the perimenarchal girl. More than 50% of cycles are anovulatory in the first 2 years after menarche. Complications of pregnancy also are common in this age group and must be ruled out before initiation of treatment for AUB. New sensitive radioimmunoassays for the beta subunit of human chorionic gonadotropin are accurate for evaluating the possibility of pregnancy. Although relatively rare, endocrinologically active ovarian neoplasms do occur and should be particularly excluded in prepubertal vaginal bleeding. Other causes of irregular bleeding in the adolescent include genital trauma and coagulopathies such as idiopathic thrombocytopenic purpura and von Willebrand disease. As previously mentioned, the Claessens and Cowell review of children's hospital admissions for menorrhagia reports an overall 19% incidence of primary coagulation disorders and a 50% incidence in patients presenting at the time of menarche. Some more recent studies have disputed this high figure and cited a lower risk of 5%. Given the new data on von Willebrand disease in adult female menorrhagia, this newer figure is questionable, and coagulopathies should still be considered a significant cause of AUB in adolescents. The most common diagnosis is idiopathic thrombocytopenic purpura, but platelet disorders such as von Willebrand and Glanzmann diseases, thalassemia, and leukemia are also found.

The adult patient with AUB can have either an acute or a chronic history of menstrual irregularity. Onset at menarche and persistence into adulthood is a classic history for chronic anovulation syndrome, but nonclassical adrenal hyperplasia must be differentiated when there is coexistent androgen excess. The differential diagnosis can be made by obtaining a baseline 17α -hydroxyprogesterone level. A level less than 200 ng/dL rules out partial adrenal 21-hydroxylase enzyme deficiency. An elevated baseline 17α -hydroxyprogesterone requires a cosyntropin stimulation test to confirm the nonclassical adrenal hyperplasia diagnosis. A more acute history requires a differential diagnosis of other endocrinologic causes of anovulation, for example, thyroid and prolactin disorders, complications of pregnancy, neoplastic processes such as fibroids or hormoneproducing ovarian tumors, intrauterine lesions such as polyps and synechiae, and coagulopathies. Adult patients with menorrhagia are at higher risk than previously thought to have a bleeding diathesis. Dilley and colleagues identified coagulopathies in 10.7% of 121 patients in a case-control study. The majority of cases were von Willebrand disease. Women older than the age of 30 years with a history consistent with chronic anovulation should undergo endometrial sampling because of their greater risk of hyperplasia and neoplasia. Perimenopausal women with AUB have an even higher risk of hyperplasia and neoplasia and should always undergo endometrial sampling. Several years before menopause, menstrual cycles usually shorten secondary to a decreased proliferative phase, with resultant moderate elevation of FSH and subsequent frequent anovulatory cycles. This unopposed estrogen environment is conducive to the development of both AUB and hyperplasia. Appropriate evaluation of the premenopausal and postmenopausal patient will be discussed later in this chapter.

A diagnosis of AUB is often a diagnosis of exclusion. Problems of pregnancy such as incomplete or missed abortion, subinvolution of the placental site, placental polyp, trophoblastic disease, and extrauterine pregnancy must be ruled out. All gynecologic malignancies can cause abnormal bleeding. Common epithelial tumors of the ovary can produce estrogen and cause uterine bleeding. Submucous leiomyoma and endometrial polyps can be

present in older women but are not a problem in the differential diagnosis of adolescents. Excessive anovulatory bleeding is common with polycystic ovarian disease, with functional cysts of the ovary. The patient workup for AUB should include a complete history and physical examination. Pelvic examination may disclose an adnexal mass, evidence of genital trauma or laceration, or a fibroid uterus. Laboratory studies should include thyroid function tests and the evaluation of levels of human chorionic gonadotropin, FSH, LH, prolactin, and serum androgens, if indicated. A significant increase in dehydroepiandrosterone sulfate indicates a need to screen for nonclassical adrenal hyperplasia. A serum progesterone level measurement is useful for assessment of ovulatory status. A complete blood count with platelet and coagulation studies is appropriate, and in some cases, a bleeding time may be indicated to assess platelet function. As mentioned earlier, endovaginal ultrasound and SIS are valuable adjuncts to pelvic examination. They are particularly informative for assessment of intrauterine or extrauterine pregnancies and pelvic masses detected on examination. Occasionally, they also may reveal anatomic pathology not detected by other means (**Fig. 26.3**). Invasive tissue-sampling procedures include endometrial sampling and sampling at the time of hysteroscopy. Diagnostic hysteroscopy can be an office procedure and has replaced blind D&C as a diagnostic test. Diagnostic hysteroscopy, with its lower false-negative rate, is preferable in the perimenopausal or postmenopausal patient. An office endometrial biopsy or diagnostic hysteroscopy is not necessary in adolescents, as patients of this age are unlikely to have structural lesions such as fibroids and polyps or endometrial hyperplasia. Hysterosalpingography and hysteroscopy will be reviewed later in this chapter.

Treatment

Because most patients with AUB have an underlying etiology of chronic anovulation with unopposed estrogen stimulation of the endometrium, medical treatment with progestational compounds is the mainstay of therapy. Precise amounts can differ depending on the patient's age, but adequate progestin stimulation will decrease DNA synthesis and cell proliferation, deplete estrogen receptors, and increase the conversion of E_2 to the less potent estrone sulfate. These effects will induce maturation of the endometrium, healing of superficial breaks, and enhancement of the stromal matrix with increased structural stability and cessation of bleeding. Withdrawal of the progestin after adequate exposure results in orderly and uniform shedding of the endometrium with a finite self-limited bleed. The progestin dosage and duration of therapy must induce a complete secretory transformation; otherwise, complete inhibition of all estrogenic effects will fail, and islands of proliferative endometrium will remain.

Although postmenopausal estrogen replacement doses are low, progesterone is needed to prevent hyperplasia. Whitehead and Frazier have shown that postmenopausal estrogen

P.563

replacement mimics the unopposed estrogen environment of chronic anovulation and that 4% of patients develop endometrial hyperplasia with only 7 days of progestin exposure, 2% with 10 days of exposure, and 0% with 12 days of exposure. They recommend 12 days of progestin every month to counteract the estrogen proliferative effects. Medroxyprogesterone acetate 10 mg, or norethindrone acetate 5 mg per day, may be prescribed. After initial control of the dysfunctional bleeding, the 12-day course can be repeated at monthly intervals to prevent the development of hyperplasia. It is convenient to start each new course on the 1st day of each month. A regular withdrawal can be expected to start either during the last 2 days of progestin or within several days of the last dose. Failure to withdraw could signify pregnancy, development of a hypoestrogenic state, or, rarely, induction of ovulation by progestin stimulation of the estrogen-primed patient. In such a case of endogenous progesterone production, the menses can be delayed 2 weeks. A word of caution: This regimen is not contraceptive. It should also be noted that the numbers of women using hormonal therapy (HT) have markedly decreased since the Women's Health Initiative (WHI). In one study by MacLennan and colleagues, 64% of women using HT prior to the WHI study discontinued treatment.

An alternative method for delivery of a progestin to control dysfunctional bleeding and menorrhagia is local administration with a progestin-impregnated IUD. Numerous studies have demonstrated significant reductions in menstrual blood loss in patients using the progestin-impregnated IUD. Xiao and colleagues showed reductions of more than 80% at up to 36 months. Irvine and associates performed a randomized trial of 44 women with menorrhagia, comparing a levonorgestrel IUD with cyclic progestin therapy. The IUD group had blood loss reduced by 90%, along with higher patient satisfaction, compliance, and continuation. In a comparison of endometrial resection with the levonorgestrel IUD, Rauramo et al. showed highly significant decreases in menstrual blood loss with both treatment arms. The incidence of complications was similar in both groups, and 3-year follow-up rates were similar. Seventeen percent of the resection group required follow-up surgery. Other studies have shown a significant cost benefit to the use of the levonorgestrel IUD compared with surgical management of AUB, including hysterectomy. As noted earlier, the levonorgestrel IUD has also shown to be effective in controlling menorrhagia in patients with hemostatic disorders such as von Willebrand disease.

New research from the Los Angeles Biomedical Research Institute (LA BioMed) found a progestogen-only treatment halted bleeding in women suffering from severe menorrhagia. In a group of 48 women, Ammerman and Nelson found that injection of depo-medroxyprogesterone acetate 150 mg intramuscularly combined with 3 days of oral medroxyprogesterone acetate 20 mg every 8 hours for 9 doses had a mean time to bleeding cessation of 2.6 days, with high patient satisfaction.

Chronic unopposed estrogen can produce a very lush endometrium that can bleed heavily during progestin withdrawal. Speroff and colleagues recommend treatment using combination oral contraceptives in a step-down regimen. Two to four pills are given daily, one every 6 to 12 hours, for 5 to 7 days for acute control of bleeding. This will usually control acute bleeding within 24 to 48 hours, allowing time to complete the diagnostic evaluation. Withdrawal of medication will result in a heavy bleed. On the 5th day of this bleed, a low-dose cyclic oral contraceptive is started and repeated for three cycles to allow orderly regression of the excessive proliferative endometrium. Alternatively, the dosage of combination pills can be tapered (four times a day, then three times a day, then two times a day) over 3 to 6 days and then continued at one pill every day. Combination oral contraceptives induce atrophy of the endometrium because the chronic estrogen-progestin exposure suppresses pituitary gonadotropins and inhibits endogenous steroidogenesis. They are useful for long-term management of AUB in patients without contraindications and have the added benefit of pregnancy prevention. Particularly in perimenarchal patients, heavy prolonged bleeding can denude the basal endometrium and make it unresponsive to progestins. Curettage for control of hemorrhage is contraindicated because of a high risk of development of intrauterine synechiae (Asherman syndrome) if the basalis is curetted. High-dose intravenous estrogen (conjugated estrogens 25 mg every 4 hours until bleeding abates) will give acute control by proliferative repair of the endometrium and by direct effects on coagulation, including increased fibrinogen and platelet aggregation. Megestrol 20 mg twice daily is also an excellent method for obtaining acute control of AUB without the side effects of intravenous estrogen treatment. It will be effective in any situation other than one in which the entire endometrium has sloughed, leaving only basalis. A progestin alone or oral conjugated estrogens in combination with a progestin can then be used to induce orderly withdrawal bleeding.

Although tranexamic acid has been available for a number of years, it has come into more widespread use. In a doubleblind placebo-controlled study by Lukes et al., women who received tranexamic acid ($n = 115$) had significantly greater reduction in menstrual blood loss of -69.6 mL (40.4%) compared with -12.6 mL (8.2%) in the 72 women who received placebo ($P < 0.001$). They also had a reduction of menstrual blood loss that exceeded the prespecified amount of 50 mL. Finally, they had a reduction of menstrual blood loss that was considered meaningful to women. Compared with women receiving placebo, women treated with tranexamic acid experienced significant improvements in limitations in social or leisure and physical

activities, work inside and outside the home, and self-perceived menstrual blood loss ($P < 0.01$).

Selective progesterone receptor modulators, such as ulipristal acetate (UPA), have been shown by Nieman et al. to be efficacious in the treatment of leiomyoma, and have been noted to cause amenorrhea in the vast majority of patients. Treated patients developed anovulatory amenorrhea without becoming hypoestrogenic, suggesting that decreased bleeding is mediated by a direct endometrial effect as well as inhibition of ovulation. Ulipristal acetate is currently only available as emergency contraception in the United States and for the treatment of leiomyoma in Europe, but may have potential use as a treatment of AUB.

Hysteroscopy of patients who fail to respond to hormonal therapy may reveal previously missed pathology, such as a submucous myoma or polyp. These diagnoses are particularly common in patients with ovulatory dysfunctional bleeding. If a diagnostic curettage has not been previously performed, one can be performed in conjunction with the hysteroscopy, both for diagnosis and for temporary therapy. The ACOG no longer considers D&C long-term therapy. If atypical hyperplasia has been identified and preservation of fertility is desired, more aggressive progestin therapy is recommended. Medroxyprogesterone acetate, 30 mg, or megestrol 20 to 40 mg daily for 3 months, should be prescribed, and the patient should be monitored by repeat endometrial sampling to assess the efficiency of the medical treatment (**Fig. 26.2B**). If atypical hyperplasia persists, very high-dose progestin protocols can be tried, but hysterectomy must be considered. Menorrhagia can be reduced when PGE_2 and prostacyclin synthesis are decreased by nonsteroidal anti-inflammatory

P.564

medications. These drugs inhibit the cyclooxygenase enzyme necessary for endometrial production of prostaglandin under estrogen stimulation and thus alter the relative production of the proaggregation vasoconstrictor thromboxane A_2 and the antiaggregation vasodilator prostacyclin. Pathology studies have confirmed that this improves both platelet aggregation and vasoconstriction. Fraser and colleagues demonstrated these compounds to be most effective when given in therapeutic dosages for 7 to 10 days before the expected onset of the next menstrual period in ovulatory AUB patients, but they are commonly started with the onset of menses and continued throughout the bleeding episode with good success.

For coagulation disorders, 1-desamino-8-D-arginine vasopressin (also known as desmopressin or simply DDAVP) increases coagulation factor VIII with a therapeutic effect lasting approximately 6 hours. It is best administered intravenously, 0.3 $\mu\text{g/kg}$ in 50 mL saline over 15 to 30 minutes, but can be used intranasally. Antifibrinolytic agents such as ϵ -aminocaproic acid and tranexamic acid can decrease blood loss up to 50%, but their significant central nervous system and gastrointestinal side effects and the purported risk of intracranial arterial thrombosis have traditionally limited their applicability. New data do not support a significant thrombotic risk, and tranexamic acid is widely available in Europe for use in menorrhagia. Ergot derivatives are ineffective for treatment of menorrhagia. Local delivery of progestational agents by way of an intrauterine device has been demonstrated by Milsom and colleagues to be extremely effective, with more than a 90% reduction in bleeding in some patients. This has the potential to provide long-term therapy for patients with chronic bleeding unresponsive to other therapies.

Long-acting derivatives of GnRH agonists down-regulate pituitary synthesis of FSH and LH and induce a "medical menopause." Withdrawal of endogenous steroid stimulation will result in endometrial atrophy. Various delivery options are available, including intranasal delivery, daily subcutaneous delivery, monthly intramuscular depot, and subcutaneously implanted pellet analogue. Gonadotropin-releasing hormone agonists are not effective in acute control of abnormal bleeding. At least 2 to 4 weeks are required for adequate suppression of gonadotropin production and inhibition of steroidogenesis. Long-term therapy can effectively control blood loss with chronic AUB secondary to chronic systemic illness, thrombocytopenia, or other coagulopathies. Because of the profoundly hypoestrogenic state induced by these drugs, there is

accelerated bone resorption and the risk of development of significant osteoporosis. Therefore, long-term therapy requires “add-back” treatment with an estrogen-progestin combination to prevent bone loss. Gonadotropin-releasing hormone agonists can also be used as adjuncts for endometrial preparation before endometrial ablation.

Ablation or destruction of the endometrium has been advocated for treatment of chronic abnormal bleeding unresponsive to medical management in the presence of a normal endometrial cavity and the absence of submucous leiomyomata, endometrial hyperplasia, or neoplasia. Although there has been significant disagreement regarding the appropriate indications for this procedure, it has been widely applied with varying success. The original methods included use of hysteroscopy with electrosurgical roller-ball cauterization or endomyometrial resection using a loop electrode. These hysteroscopic surgical techniques require special training. More recently, new techniques have been described to ablate the endometrial cavity without the requirement for hysteroscopy. These include thermal balloon ablation, direct instillation of heated saline, cryoablation with a cryoprobe, microwave endometrial ablation, and use of radiofrequency electromagnetic energy. Success rates reported with the various techniques have ranged from 60% to 95% of patients achieving either hypomenorrhea or amenorrhea. Brooks and Donnez et al. report pretreatment with danazol, GnRH analogues, or suction curettage to thin the endometrium appears to improve long-term success rates. Seeras and Gilliland reported resumption of menstruation in 44% of women after ablation if they had not received preoperative endometrial suppression.

A number of comparison studies have looked at success rates of the various techniques to determine relative efficacy, complication rates, and relative cost. Meyer and colleagues compared roller-ball ablation with thermal balloon ablation in a prospective, randomized trial. A greater percentage of women in the roller-ball group (27.2%) were amenorrheic at their 12-month follow-up than were women in the uterine balloon group (15.2%). The rates of hypomenorrhea plus amenorrhea were not significantly different (balloon, 80.2%; roller ball, 84.3%). Overall patient satisfaction was equivalent. The complication rate was 3.2% in the hysteroscopic roller-ball group with no significant intraoperative complications in the thermal balloon group. A comparison of thermal balloon ablation with the progestin-containing IUD showed similar results as far as overall satisfaction; however, bleeding scores were lower and amenorrhea rates higher in the IUD group (Busfield et al.). Corson, with follow-up by Goldrath, performed a prospective randomized trial of endometrial ablation using the Hydro ThermAblator (HTA; Boston Scientific Corporation, Natick, MA, USA) versus roller ball (Figs. 26.2 and 26.4). This system uses heated saline flowing free under low pressure to ablate the endometrium under hysteroscopic guidance. Success rates for both groups were comparable at 3 years with amenorrhea rates of 53% for HTA and 46% for roller ball and overall satisfaction rates of 98% and 97%, respectively. There were no significant differences in complication rates or repeat surgical procedures.

The NovaSure system (Cytac Corporation, Palo Alto, CA, USA) uses radiofrequency current through a mesh electrode that conforms to the endometrial cavity to ablate the endometrium. Tissue desiccation is rapid compared with thermal devices and requires no pretreatment of the endometrium. The overall success rate of 88.3% and amenorrhea rate of 41% for NovaSure-treated patients were higher than 81.7% and 35% rates, respectively, for endometrial resection in a randomized

P.565

trial by Cooper et al. A randomized trial versus hydrothermablation (Fig. 26.5) also demonstrated higher amenorrhea rates. Microwave energy can also be used to ablate endometrium. The MEA (Microsulis Americas, Pampano Beach, FL, USA) device was tested in a prospective randomized trial by Cooper et al., comparing it with roller-ball ablation. Success rates were 87% and 83.2%, respectively, for MEA and roller ball. Amenorrhea rates were 61.3% for MEA and 51% for the roller-ball group. This trial also included patients with up to 3-cm submucous myomas. Subgroup analysis did not show any difference in the

success rate in this group.

FIGURE 26.4 Hydro ThermAblator. (HTA; Boston Scientific Corporation, Natick, MA, USA.)

FIGURE 26.5 Endometrial cavity before and after endometrial ablation using Hydro ThermAblator.

Endomyometrial resection has been reported by Kooy et al. to have higher amenorrhea rates compared with rates for other techniques. Vercellini and colleagues compared myometrial resection with endometrial ablation using a vaporizing electrode similar to a roller ball. Amenorrhea rates were 48% for the endomyometrial resection group and 36% for the ablation group, although overall patient satisfaction rates were equivalent. Difficulty of surgery and mean fluid deficit were both described as greater in the resection group. In a comparison of endometrial ablation with laser versus endomyometrial resection, Battacharya et al. showed equivalent amenorrhea rates of approximately 45%, with overall patient satisfaction rates of 90%.

Operative hysteroscopic techniques require specialized training, and complications, although relatively infrequent, can be significant. A multihospital survey by Jansen et al. in the Netherlands revealed an overall complication rate for hysteroscopy of 0.28%. Diagnostic hysteroscopy had a significantly lower complication rate than that of operative hysteroscopy (0.13% vs. 0.95%). The most frequent surgical complication was

uterine perforation (0.76%). Reported complication rates for hysteroscopic ablation procedures are significantly higher. O'Connor and Magos followed 525 women for up to 5 years after endometrial resection. They reported a 6% incidence of intraoperative complications and a 3% incidence of postoperative complications. They also reported a 15% complication rate in patients who required a repeat ablative procedure. The "Mistletoe" survey led by Overton et al. from the Royal College of Obstetricians and Gynaecologists recorded endomyometrial resection complication rates of 7.2% but only 4% for roller-ball and laser ablations. A prospective trial by Meyer et al. of thermal balloon versus roller-ball ablation reported intraoperative complications in 3.2% of the roller-ball patients but no significant intraoperative complications in the thermal balloon patients. Reported complications include uterine perforation with hemorrhage, laser or electrosurgical damage to the bowel, excessive absorption of distending medium with fluid overload, hyponatremia and pulmonary edema, and persistence of bleeding requiring repeat ablation or hysterectomy. The complication rates reported by Summitt et al. compare favorably with reported morbidity rates for women undergoing hysterectomy, which range from 7% to 15%.

There is concern regarding the potential outcome of pregnancies conceived after endometrial ablation. A literature review by Cook and Seman reports a miscarriage rate of 21.7%, a preterm rate of 26.1%, and a perinatal mortality rate of 11.8%. Of those pregnancies that continued beyond 20 weeks, 35.3% were described as having abnormal placental adherence, including placenta accreta and increta. The hysterectomy rate for this series of patients was 8.9%. These outcomes were attributed to the possible presence of intrauterine synechiae, although in most cases, no direct endometrial cavity assessment was performed.

Another concern has been possible obliteration of warning signs heralding the development of endometrial carcinoma, with subsequent delay in diagnosis. Endometrial ablation procedures usually result in a narrowed tubular uterine cavity without the obliteration seen in Asherman syndrome, but are rarely expected to result in total ablation of all endometrial tissue. Several cases of postablation endometrial carcinoma have been reported by Brooks-Carter et al. and Copperman et al. The cost of endometrial ablation does compare favorably with that of hysterectomy, with hysterectomy reported by Vilos et al. as 58% more expensive when all costs, including lost work time, are considered.

Dilatation and curettage is most useful as a diagnostic technique when it is combined with hysteroscopy. Although D&C will acutely address AUB, it is not a long-term treatment of AUB. Removal of the structurally fragile bleeding endometrium allows restoration of normal hemostatic events, with regeneration of the integrity of the endometrium and restoration of the normal proliferative response. If the patient fails to respond to medical therapy, repeated curettage, or even endometrial ablation, then more definitive therapy, such as hysterectomy, should be considered, taking into account the age of the patient and her desire for future childbearing. It

P.566

has been estimated that 2 million women in the United States are seen annually with reports of excessive uterine bleeding, and approximately 150,000 undergo hysterectomy, which accounts for 20% to 30% of all hysterectomies performed.

In general, the ovulatory type of bleeding has the poorest response to replacement hormonal therapy and the highest incidence of recurrence. Although a hysterectomy can be considered an admission of therapeutic defeat, it is frequently an expeditious method of resolving this refractory and recurrent type of AUB. When bleeding persists after repeated curettage and cyclic hormonal therapy, hysterectomy may be required. If other conditions are present that should be corrected surgically, such as a relaxed vaginal outlet, rectocele, cystocele, or uterine descensus, we recommend vaginal hysterectomy with support of the vaginal vault and repair of the vaginal wall relaxation. When hysterectomy is indicated in premenopausal women younger than 50 years of age, normal ovarian tissue is conserved. In a patient younger than 30

years of age, radical surgical treatment should be strongly avoided; one can almost always control uterine bleeding by repeated curettage or by increasing amounts of cyclic hormone therapy. Today, the availability and use of estrogen and progesterone have changed the need for hysterectomy to treat AUB. Hysterectomy is not indicated in young women but may be indicated in older women when hormonal therapy and curettage have failed. Although curettage may acutely improve bleeding, it is not a long-term therapy.

Blood transfusions are seldom required when AUB is associated with anemia, but they may be given if the anemia is so severe that symptoms are present. Oral iron therapy should be started at the first sign of heavy menstruation to prevent depletion of iron stores, and it should be given for 3 to 6 months after normal hemoglobin and hematocrit levels have been restored in patients with iron deficiency anemia.

PERIMENOPAUSAL AND POSTMENOPAUSAL BLEEDING

When uterine bleeding occurs more than 12 months after the last regular menstrual period, it is defined as postmenopausal bleeding. For a period varying from months to years before menopause, the individual patient may experience irregular patterns of bleeding. Often, the first sign is a shortening of the menstrual interval secondary to premature elevation in FSH, followed by intermittent periods of amenorrhea alternating with heavy bleeding consistent with oligoovulation or anovulation. With this clinical picture, special consideration must be given to ruling out a neoplastic process as the source of the bleeding. The first diagnostic consideration is to ensure that the bleeding originates from the uterus. In elderly women especially, bleeding from the urethra or rectum may be reported as vaginal bleeding. Vaginal or cervical lesions causing the bleeding should be diagnosed readily with careful inspection or biopsy. Cancers of the vagina or cervix or cervical polyps can also be readily diagnosed and appropriate treatment rendered.

When the source of the bleeding is determined to be the uterine cavity, sampling of the endometrium for pathology examination is usually considered to be mandatory. Although D&C at the time of hysteroscopy continues to be a commonly performed procedure for both its diagnostic and short-term therapeutic benefits, office endometrial biopsy can often expedite appropriate evaluation and therapy. Many instruments have been devised for the sampling of endometrial tissue and evaluation of the endometrial cavity. The standard instrument used for many years had been the Novak curette because of the discomfort associated with passage of the Novak curette; newer Silastic curettes have been developed. These have a smaller diameter (3 mm), are flexible, and are often better tolerated by patients. They can be difficult to pass through a truly stenotic cervix because of their pliability. Often, there is an accompanying syringe that attaches and develops effective vacuum pressure to improve the size of the sample obtained. A four-quadrant endometrial biopsy with passes along the anterior and posterior and both lateral walls of the endometrial cavity is recommended for diagnosis of abnormal bleeding. Another potentially useful device not requiring a syringe to develop negative pressure is a disposable plastic tube with a 3.1-mm outer diameter, an aspiration port, and solid plastic obturator at its tip. The obturator fits so closely that its slow withdrawal from the uterine cavity causes sufficient suction to obtain an adequate endometrial specimen in most cases. However, the endometrial surface area sampled is small (5%) and can easily miss polyps, submucous myomas, and endometrial carcinoma that occupies only a small portion of the endometrial cavity. Because of the small aperture of this device and its almost total reliance on suction to obtain a specimen, the architecture of the obtained biopsy may be somewhat distorted.

Vacuum suction curettage has gained some popularity as an office procedure for endometrial sampling that does not require general anesthesia. A small metal or plastic cannula with an outside diameter of 3 mm that has a slightly curved tip and an opening on the concave surface for easier insertion through a small endocervical canal is connected to a plastic collection chamber, which, in newer models, is a large syringe rather than the old pumps or faucets. Several studies have compared the results of suction curettage with those of regular curettage under anesthesia in the same patient. Cohen and colleagues studied 98 patients; in 93, they found identical

histologic patterns with both methods. In five patients, there was no correlation between the results of the two techniques, and none of these had cancer. At the Medical University of South Carolina, Lutz and colleagues found suction curettage to be 98% accurate in evaluating high-risk women with abnormal bleeding for endometrial malignant disease. Recent evidence from Kazandi et al. suggests that although Pipelle biopsies have equivalent diagnostic accuracy with widespread endometrial lesions they provide limited diagnostic accuracy in cases with focal pathologies.

The principal value of an endometrial biopsy is that a formal D&C under anesthesia has been avoided if the removed tissue contains adenocarcinoma. If the cause of postmenopausal bleeding is not identified in a screening endometrial biopsy and the endometrial stripe is greater than 5 mm, a hysteroscopic-directed endometrial sampling is obligatory. In office biopsies of the endometria of more than 20,000 patients of all ages, Hofmeister detected 273 cases of endometrial carcinoma, 32 of which (14.28%) were totally asymptomatic. The endometrial carcinoma detection rate was 1.76% of the total group of 23,202 patients. Hofmeister's routine office endometrial biopsies using a modification of the Novak and Randall curette provide one of the largest clinical experiences of this instrument to date. Unfortunately, only patients who had continued uterine bleeding or who demonstrated an atypical pattern in the office biopsy were subjected to a complete curettage. Therefore, the true-negative and false-negative rate for the Novak type of curette in the detection of endometrial cancer has not been determined accurately. In other studies, summarized by Cohen and colleagues, the accuracy of detection of endometrial cancer by endometrial curettage varied from 76% to 92%. However, a thorough endometrial curettage under

P.567

anesthesia is also not infallible in the detection of endometrial cancer. Bettocchi and colleagues evaluated the diagnostic accuracy of endometrial curettage in 397 patients; D&C failed to detect intrauterine pathology in 62.5% of patients, including four cases of complex hyperplasia, five cases of endometrial adenocarcinoma, and many endometrial polyps and submucous myomas. The use of hysteroscopic-directed sampling may decrease that number.

Vaginal ultrasound has been investigated as a screening tool in patients with postmenopausal bleeding. The average thickness of the postmenopausal endometrial stripe has been reported as 2.3 ± 1.8 mm, with a range of 0 to 10 mm, in a series of 300 asymptomatic women. Twenty-two had endometrial stripes of 5 mm or larger, and all had benign pathology. In a series of 51 cases of postmenopausal bleeding, Nasri and colleagues reported that if the endometrial thickness was less than 5 mm, the pathology would show either inactive or no endometrial tissue. Karlsson and associates reported on 1,168 women with postmenopausal bleeding. Patients with an endometrial echo of less than 4 mm had a sensitivity of 96% and a specificity of 68% for detecting endometrial pathology. If a 5-mm cutoff was used, two endometrial carcinomas would have been missed. In another study by Gull and colleagues, 198 women screened for postmenopausal bleeding had an endometrial thickness of 5 mm or greater. Endometrial sampling diagnosed 36 primary endometrial cancers, one metastatic breast cancer, and three cases of atypical endometrial hyperplasia. Of 163 women with an endometrial stripe of 4 mm or less, only one was found to have endometrial cancer. Other series have shown that an endometrial thickness of greater than 8 mm is an indication for endometrial sampling, regardless of whether there is a report of bleeding. This will detect most, if not all, endometrial cancers. A meta-analysis by Smith-Bindman et al. reviewing the accuracy of transvaginal sonography reported that 96% of women with endometrial cancer and 92% of women with other endometrial diseases had an endometrial echo of greater than 5 mm. The false-positive rate was dependent on the use of hormone replacement therapy, with nonusers having a false-positive risk of 8%, whereas those on hormones had a 23% false-positive rate. Saline infusion sonography can be used to further evaluate patients with thickened endometrial stripes to detect structural problems such as polyps as an adjunct to endometrial sampling. Although the exact indications for patient screening and parameters for follow-up need to be more precisely defined, vaginal ultrasound appears to have promise as a noninvasive method for evaluating the

postmenopausal patient.

Office hysteroscopy using new smaller-diameter flexible or rigid hysteroscopes is growing in popularity because it enables selective biopsy of the areas of visualized endometrium that appear most likely to contain a neoplastic process. A blind endometrial biopsy that reveals benign endometrial histology does not absolutely preclude the presence of a malignant process elsewhere within the endometrium. A neoplastic transformation in the endometrium is often a focal abnormality. Another major advantage of hysteroscopy is the diagnosis of endometrial polyps, submucous myomas, or other sources of bleeding that may not always be identified by endometrial biopsy or conventional curettage. In a series of 110 cases of postmenopausal bleeding, the causes of 95 were identified as endometrial polyps or submucous myomas. Only two cases of early adenocarcinoma were identified. Operative hysteroscopy, endometrial ablation, or both successfully controlled bleeding in most cases of benign disease. In cases of postmenopausal uterine bleeding, the recommended diagnostic procedures may or may not produce a tissue sample of endometrium. If the endometrium is not atrophic, a wide range of histology can be observed. Occasionally, simple proliferative endometrium is found. The endometrium can exhibit simple hyperplasia, more marked adenomatous hyperplasia, or hyperplasia with atypical cells, resulting in a diagnosis of atypical endometrial hyperplasia. Later in the menopausal years, it is not uncommon for the endometrium to have the characteristics of cystic hyperplasia, often referred to in the older literature as "Swiss cheese hyperplasia."

Hormone-induced postmenopausal uterine bleeding can be the result of endogenous or exogenous hormonal effects. The proliferation of endometrium in a patient who is not receiving exogenous hormonal therapy is generally attributed to endogenous production of estrone. Estrone is the peripheral conversion product of the weak androgenic precursor androstenedione (85% from adrenal and 15% from ovary), and its synthesis occurs primarily in adipose tissue. In the absence of exogenous hormonal therapy, one must also exclude the possibility of an estrogen-producing ovarian tumor (granulosa cell tumor).

Management of perimenopausal bleeding in the absence of significant hyperplasia or neoplasia is essentially the same as for AUB in a younger patient. One recently accepted method that in the past was proscribed is the use of low-dose oral contraceptives. The Food and Drug Administration has approved them for patients older than 40 years of age in the absence of specific contraindications, such as hypertension, hyperlipidemia, and smoking. They provide excellent cycle control with a monthly withdrawal bleed and suppression of the endometrium. Oral contraceptives can be continued until an FSH level greater than 40 IU/L during the week of placebo pills confirms ovarian failure. Standard postmenopausal hormone replacement can then be used. A sequential program of 12 days of progestin, 5- to 10-mg medroxyprogesterone acetate, or 5-mg norethindrone acetate on a monthly basis is an alternative and is continued until failure of withdrawal bleeding occurs, indicating the need for estrogen replacement. Endometrial hyperplasia requires a more aggressive progestational regimen. Atypical adenomatous endometrial hyperplasia is considered by most to be the equivalent of an intraepithelial malignancy, and hysterectomy is often advised. Management of several types of endometrial hyperplasia other than atypical adenomatous hyperplasia can generally be accomplished by monthly administration of a progestin such as medroxyprogesterone acetate, 10 mg per day for 12 days, or norethindrone acetate, 5 mg per day for 12 days. Another endometrial biopsy should be obtained within 3 to 6 months to assess for resolution of the hyperplasia. A more aggressive hormonal regimen uses continuous high-dose progestin for 3 to 6 months (i.e., megestrol 20 to 160 mg per day).

Any of the regimens currently in use for postmenopausal hormonal replacement therapy can cause uterine bleeding. Since the WHI, the number of women using postmenopausal HT has markedly decreased, but there is still a role for this therapy in symptomatic women. A summary of the guidelines published by several major medical societies can be found in a recent publication by Dr. Pines. Unopposed estrogen is no longer recommended for postmenopausal hormone replacement in the case of an intact uterus because hyperplasia

develops in 18% to 32% of cases and because unopposed estrogen has an up to sevenfold increased risk of endometrial carcinoma. Cyclic estrogen-progestin regimens significantly decrease this risk to less than 1% with 12 days of progestin. There are numerous dosage regimens for the use of conjugated estrogens 0.625 to 1.25 mg; micronized E₂ 1 to 2 mg; esterified estrogens 0.625 to 1.25 mg; and E₂ patches. Although estrogen

P.568

replacement therapy performs well if used for only 21 to 25 days of the month, there is no clinical reason for its discontinuance, and recent recommendations are to continue it throughout the entire cycle. The progestin regimens are those that have already been outlined. The bleeding that accompanies these commonly used continuous-estrogen and cyclic progestin regimens should occur predictably, at the conclusion of the progestin phase of the cyclic administration. Most investigators of the subject now agree that the predictable and appropriately timed withdrawal bleeding that occurs with these regimens does not require sampling for endometrial histology. As a general rule, just as intermenstrual bleeding during the regular menstruating years dictates investigation and management, so do patterns of postmenopausal bleeding not following an anticipated schedule require investigation and management.

The most important point about the significance of postmenopausal bleeding is its frequent association with gynecologic malignancy, particularly endometrial carcinoma. Although the incidence of malignancy to explain postmenopausal bleeding has decreased in recent decades, diagnostic efforts must carefully consider and rule out possible malignancy by use of appropriate diagnostic procedures, especially careful pelvic examination and uterine curettage. An endometrial biopsy is helpful for the diagnosis of suspected endometrial carcinoma only if the biopsy is positive. The definitive method for obtaining adequate histology for diagnosis is hysteroscopy and D&C.

CURETTAGE OF THE UTERUS

Indications and Contraindications

STEPS IN THE PROCEDURE

Dilatation and Curettage

- Lithotomy position, empty bladder, and sterilely drape perineum
- Thorough exam under anesthesia to evaluate uterine size and position
- Adequate exposure of the cervix with open-sided or weighted speculum
- Assess depth of uterine cavity using a uterine sound
- Curettage of the endocervix using a small box curette
- Dilatation of cervix using Hegar or Hank dilators
- Measure endometrial cavity depth using a sound
- Curettage of anterior, lateral, and posterior walls using a small or medium malleable, bluntly serrated curette

It is important that D&C be performed for the proper indications, be performed correctly to obtain the most useful information, and be performed safely. A curettage performed properly and with aseptic technique involves little risk, but if precautions are disregarded, complications and even death can result.

The chief purpose of curettage of the uterus is the removal of endometrial or endocervical tissue for histologic study of cases of AUB. Although classical curettage of the uterus continues to be a useful procedure, new

practices and instrumentation permit the procurement of endometrium as a screening diagnostic test under many circumstances. Appropriate use of such procedures can reduce significantly the need for operating room curettage. Careful pelvic examination under relaxation anesthesia has been an important adjunctive diagnostic aid to conventional D&C, but the precision and availability of ultrasound and other imaging techniques have brought them to the forefront of importance in diagnosis.

Outpatient Curettage

Over the years, there have been efforts to lower the cost of D&C by making it an outpatient procedure. Today, D&C is often performed satisfactorily on an outpatient basis or in an ambulatory surgery center. Reports by Sandmire and Austin and by Martin and Rust are among many that record favorable experiences with this procedure.

As mentioned earlier, endometrial sampling today is often performed by biopsy, suction, or D&C as an office procedure. Only if they show frank adenocarcinoma can the outpatient biopsy results be considered definitive. If the histology of the office procedures is negative, a more serious condition has not been ruled out. A further note of caution is that none of the office endometrial sampling methods can ensure the removal of an endometrial polyp. Therefore, endometrial carcinoma in a polyp could be missed, as could a polyp that is a source of benign bleeding. Office sampling techniques are used only as screening procedures; if the results are negative, a more thorough evaluation using hysteroscopy is indicated. Office hysteroscopy can sometimes identify missed pathologies, such as a polyp or a submucous myoma, or to allow directed biopsy of a suspicious endometrium.

Indications for obtaining endometrial histology by one or more of the aforementioned methods include the following:

- Abnormal bleeding at any premenopausal age, especially when not corrected promptly by medical management; in women older than 35 years of age; or if a submucous myoma is suspected (include hysteroscopy or hysterosalpingography),
- Postmenopausal bleeding of any amount, regardless of a finding of atrophic vaginitis, polyp, or urethral caruncle,
- Prehysterectomy in the postmenopausal woman at risk for endocervical or endometrial carcinoma, and
- Postmenopausal vaginal surgery without hysterectomy in women at risk for endometrial pathology.

When office procedures fail to establish the diagnosis, hysteroscopy is the preferred diagnostic method. Unlike blind D&C, it allows for visualization of the uterine cavity and direct biopsies. Hysteroscopy performed under general anesthesia allows for more extensive operative procedures if indicated. Occasionally, new and important pelvic findings will be discovered. In a study of 2,666 women requiring curettage, McElin and colleagues found unanticipated adnexal masses in 30 women during pelvic examination under anesthesia before D&C. Twenty-eight masses were benign, and two were malignant. Even in women who have medical contraindications to anesthesia, office hysteroscopy can be performed with minimal anesthesia. A single curettage will not remove all of the surface endometrium completely from the uterine cavity. Repeated studies have demonstrated the inability of a thorough curettage to remove more than 50% to 60% of the endometrium when the procedure has been performed by experienced gynecologists immediately before a planned hysterectomy. Stock and Kanbour, from McGee Hospital in Pittsburgh, observed that in 60% of hysterectomy specimens studied, less than 50% of the endometrial surface had been removed by a prehysterectomy curettage. They also found 26 cases of endometrial carcinoma that had been classified as clinically normal-appearing tissue

on prehysterectomy curettage; six of these carcinomas were reported as benign on frozen section. These facts and other similar experiences indicate that it is difficult to be certain of the histology of the endometrium by gross

examination of the curetting. If the symptoms warrant curettage, then the endometrium deserves a full histologic diagnosis under hysteroscopic visualization.

Curettage is also performed for bleeding from a cervical stump and is frequently performed as part of a cervical conization to rule out extension of cervical carcinoma into the endometrium. Helmkamp and associates found no evidence of endometrial abnormality in any of 114 curettage specimens removed at the time of 114 cervical conizations. These investigators recommend that curettage at the time of cervical conization should not be performed routinely but should be performed selectively in postmenopausal and perimenopausal patients when the cytology smear shows abnormal glandular cells or when an intrauterine abnormality is suspected.

The chief contraindication to curettage is infection. Acute endometritis and salpingitis are conditions under which curettage should be avoided. If curettage is necessary for removal of infected placental tissue, it should be preceded by a period of parenteral antibiotic therapy adequate to achieve therapeutic tissue levels. Endometritis associated with retained products of conception will remain unresolved until the infected necrotic material is removed. Curettage is also contraindicated when pyometra is present.

Technique of Curettage of the Uterus

After the patient is anesthetized and placed in the lithotomy position, the bladder is emptied with a catheter. The pelvic organs are examined thoroughly before the patient is prepped and draped. The procedure includes a bimanual rectovaginal-abdominal examination. The examination under anesthesia is one of the most informative features of this operation because it can provide anatomic details of the reproductive tract that are unrecognizable without anesthesia. The vagina and perineum are cleaned with the usual technique.

Fractional curettage is an attempt to remove tissue samples from the endocervical canal apart from tissue removed from the endometrial cavity. The cervical canal should be curetted before dilatation of the cervical canal and curettage of the endometrial cavity. The special shape of the small Gusberg curette makes it particularly useful for curetting the endocervix. Differential curettage of the endocervix, separate from the endometrium, is important for diagnosis of endometrial carcinoma that may have extended to the endocervix. All cases of perimenopausal bleeding should be fractionally curetted; this procedure is too often neglected. If the endocervical curettage is not performed, a second fractional curettage is required to determine the anatomic boundaries of endometrial carcinoma. The value of fractional curettage has been questioned, but Chen and Lee and others have emphasized the importance of cervical stromal invasion, rather than the finding of tumor tissue, as the crucial criterion in endocervical curetting affecting staging and prognosis.

The uterine cavity is then sounded to determine its size and to confirm the position determined from examination under anesthesia. The cervical canal is dilated with the Hegar or Hank-Bradley ([Fig. 26.6](#)) dilator. A dilatation to 8 or 9 mm by a Hegar dilator ([Fig. 26.7](#)) is sufficient for the usual diagnostic curettage. A gauze is placed in the posterior vaginal fornix along the posterior retractor so that the blood and the endometrium removed from the uterus can fall on it. Before the curettage is performed, the uterine cavity is explored for endometrial polyps by use of a narrow stone forceps. This forceps can be opened and closed as the tip of the forceps is moved systematically across the dome of the uterus and the anterior and posterior walls. An endometrial polyp can be easily missed with an ordinary curette, and unnecessary hysterectomies have been performed because of supposed persistent

P.570

or recurrent dysfunctional bleeding after curettage ([Fig. 26.8](#)). If polyp forceps are routinely used, such operations can be avoided. It is easier to identify and remove an endometrial polyp if the uterine cavity is explored with the stone forceps before the uterus is curetted. In a 28-month period during which forceps were used routinely at the Johns Hopkins Hospital, Josey found that endometrial polyp was diagnosed 130 times. In 83 of these cases, the polyp was removed by forceps. Although the sessile form of a submucous myoma is

diagnosed easily by noting an irregularity of the uterine wall with the curette, the pedunculated variety, like the endometrial polyp, can escape detection because of its narrow stalk. Removal of pedunculated leiomyoma can sometimes be accomplished with the polyp forceps. A uterine septum can also sometimes be detected with the forceps, but imaging modalities such as saline sonohysterogram and hysterosalpingogram are more accurate diagnostic tests. The procedure is most likely to be diagnostic and therapeutic when it is combined with direct visualization of the uterine cavity through hysteroscopy. A small-sized or medium-sized, malleable, bluntly serrated curette (**Fig. 26.9**) is then introduced into the uterus, and the entire uterine cavity is systematically curetted. The anterior, lateral, and posterior walls should be sampled (**Fig. 26.10**). The handle of the curette should be held gently, as one would hold a pencil. The instrument is held loosely as it is inserted for the full distance. Pressure is then exerted against the uterine wall as the curette is drawn in an outward direction. Because the instrument is malleable, its curvature can be changed to conform to the contour of the uterine cavity. A uterine “cry,” vibrations felt in the hand holding the curette, is often used as a sign that adequate tissue has been removed. It should be remembered, however, that overly aggressive curettage can lead to scarring of the endometrial cavity.

FIGURE 26.6 Hank-Bradley dilators in graduated sizes. Note central canal that extends through length of dilator.

FIGURE 26.7 Graduated Hegar dilators and “half-size” Hegar dilators.

FIGURE 26.8 Opened uterus, showing two separate endometrial polyps.

FIGURE 26.9 Small serrated curette for routine curettage.

The unclotted blood is absorbed quickly by the gauze sponge, leaving the relatively clean endometrium to be placed in a prepared container with appropriate fixative. Again, the curettings should be removed carefully from the sponge with a pair of smooth-tipped forceps and placed immediately in the fixative. The curettings should be examined carefully at this time for fatty tissue or other unusual tissue.

When curettage is performed as a curative measure for removal of placental tissue, a large, blunt, smooth curette is used to lessen the possibilities of perforation and endometrial sclerosis. The larger and softer the uterus, the larger the curette should be and the more care one should exercise to avoid these complications. When large masses of placental tissue are present, ovum forceps are most useful when used in conjunction with the curette. High-vacuum suction is now used almost routinely for placental tissue removal.

Routine blind biopsy of the cervix is usually unrewarding if a negative cytologic smear has been obtained and there is no suspicious cervical lesion. A blind biopsy of the cervix at the time of curettage should not be performed unless an abnormal lesion is present. If a gross lesion is seen, directed biopsy of the lesion is indicated.

Complications of Cervical Dilatation and Uterine Curettage

If the position and the consistency of the uterus are carefully observed on bimanual examination under anesthesia before curettage is begun, perforation will rarely occur. Special care should be exercised with a

retroflexed (**Figs. 26.11** and **26.12**). With cervical stenosis, pregnancy, or intrauterine malignancy, perforation is more likely. The postmenopausal atrophic uterus can be perforated with only slight force applied to the uterine sound or the curette. Perforation is discovered when the sound or the curette fails to encounter resistance where it normally should, as judged by the palpated size of the uterus and initially measurement of the endometrial cavity by uterine sound. Abdominal ultrasound visualization of the uterus, cervix, and endocervical canal, which may require a distended bladder, can be useful in guiding the passage of either a dilator or a curette through the endocervical canal into the endometrial cavity in difficult cases. Ghosh and Chaudhuri found misoprostol in a dose of 400 µg twelve hours prior to the procedure can facilitate cervical dilation.

FIGURE 26.10 Method of curetting the uterine cavity systematically. **A:** The anterior, posterior, and lateral walls of the cavity are curetted systematically. **B:** The top of the cavity is then curetted thoroughly.

Perforation by the uterine sound or cervical dilator causes less damage than perforation by the sharp curette or suction cannula. Sharp curettage for legally induced abortion has a major complication rate that is two to three times higher than that for suction curettage, according to Grimes and Cates. The two principal dangers of uterine perforation are bleeding and trauma to the abdominal viscera. Lateral perforation through the uterine vessels is especially dangerous from the standpoint of intraperitoneal hemorrhage and broad ligament hematoma formation. Damage can occur to the bowel, omentum, mesentery, ureter, and fallopian tube. Perforation of the anterior or posterior wall of the uterus by a small curette in performing a diagnostic curettage is usually not a serious accident. However, it is usually necessary to discontinue curettage. One must

watch carefully for signs of hemorrhage or infection. If signs of hemorrhage develop, the abdomen should be opened and the uterine wound sutured. If signs of infection occur, broad-spectrum antibiotics should be given. If a pelvic abscess develops, the abscess should be drained if possible. As described by Chappel and colleagues, this can sometimes be accomplished under radiographic guidance. Serious hemorrhage or infection occurs only rarely. When serious damage from perforation is suspected, laparoscopy can be performed to assess the extent of the damage and the needed repair. According to MacKenzie and Bibby, complications occurred in 1.7% of cases of D&C. McElin and colleagues reported that 0.5% of cases had postoperative febrile morbidity after D&C. Uterine perforation occurred in 0.63% of cases.

FIGURE 26.11 Perforation of the acutely anteverted uterus. The uterus was thought to be in retroversion, and the Hegar dilator was erroneously directed posteriorly.

FIGURE 26.12 Perforation of the retroverted uterus. The uterus was thought to be in anteversion, and the Hegar dilator was erroneously directed anteriorly.

One should be absolutely certain that the endometrial cavity has been entered when D&C is performed for postmenopausal bleeding. A relatively stenotic internal cervical os and a fear of uterine perforation can prevent

entry into the uterine cavity above the internal cervical os, resulting in failure to curette the uterine cavity and consequent failure to diagnose the cause of the bleeding. Again, ultrasound can be a valuable tool for confirming placement of the curette tip in the endometrial cavity. Many office hysteroscopes are small enough in diameter that they can be safely used in patients with cervical stenosis. It is also possible to use laminaria or misoprostol to facilitate cervical dilatation.

Perforation of a pregnant uterus is a more serious complication than is perforation of the nonpregnant uterus. First, there is the requirement that all remaining pregnancy tissue be completely removed to prevent sepsis. To accomplish this blindly when there is a defect in the uterine wall is unsafe. Second, the pregnant uterus is a much more vascular organ than is the nonpregnant uterus, and intraperitoneal bleeding can be profuse without significant external bleeding. Third, it often is difficult to be certain when the perforation occurred. If a highvacuum suction Vacurect has passed through the myometrium and the vacuum has been activated, major bowel injury can be present. These considerations have led to the following protocol for D&C of the pregnant uterus:

1. Never activate the vacuum suction if there is any question about the safe location of the Vacurect within the uterine cavity.
2. Laparoscope any pregnant uterus that is possibly perforated. With the laparoscope in place, a second operator can evacuate remaining placental tissue while the laparoscopist monitors safety. Many perforations in which no other visceral damage has occurred are fundal. If laparoscopic observation confirms that bleeding is minimal, the perforation can be managed conservatively with antibiotics and serial hematocrit determination for 24 to 48 hours. If there is no evidence of continued bleeding or developing infection, the patient can be discharged.
3. During laparoscopy, if there is any evidence of intestinal injury or any suspicion of such injury, or if bleeding is significant, then laparotomy is mandatory. Unfortunately, bowel injury by high-vacuum suction may require bowel resection and anastomosis.

Figure 26.13 shows a uterus removed immediately after a perforation because of intraperitoneal bleeding. Word analyzed 70 accidental uterine perforations. Among these, an unplanned hysterectomy was performed on seven unprepared patients. In none of these cases did the intraperitoneal findings indicate the need for hysterectomy. In fact, hysterectomy compounded the surgical error. Fifty-five patients were treated conservatively, and only one developed a complication, in the form of a pelvic abscess that was drained by colpotomy. Forty-one of the 70 perforations occurred in postmenopausal women.

When a large, boggy, postabortion or puerperal uterus is perforated by a large curette or placental forceps in removing placental tissue, there is more danger of hemorrhage, infection, or injury to bowel. The treatment protocols and the procedures for these serious complications are discussed elsewhere in this textbook.

Asherman syndrome is a pathologic condition of intrauterine adhesions that can cause secondary amenorrhea, other menstrual irregularities, infertility, or recurrent abortion. Numerous investigators have shown a strong association between puerperal D&C and the formation of synechiae that can partially or completely obliterate the endometrial cavity. No incidence figures are available because no prospective studies have been performed, but factors other than pregnancy that increase the risk of endometrial sclerosis after D&C are infection, scant endometrium that exposes the basalis to trauma, and a hypoestrogenic state. Rarely, significant synechiae are seen in the absence of an antecedent

curettage. Cases have been reported after severe endometritis, tuberculosis, myomectomy, and cesarean section. Diagnosis is made by clinical history, hysterosalpingography, or hysteroscopy. Therapy requires lysis of adhesions by repeat curettage or, preferably, by hysteroscopic scissors.

FIGURE 26.13 Result of uterine perforation. Specimen removed directly after perforation.

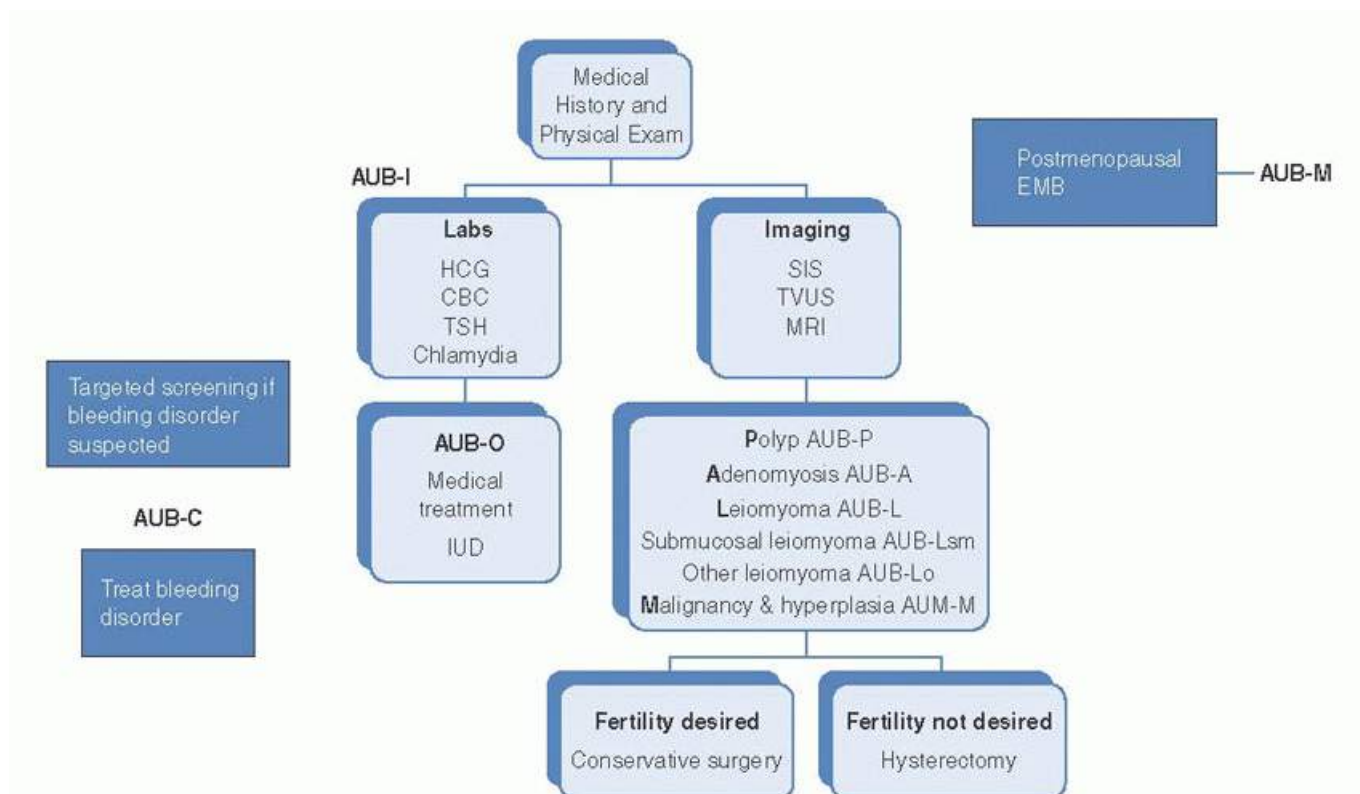

FIGURE 26.14 Diagnostic evaluation and treatment of AUB.

Patency of the uterine cavity is maintained with an intrauterine device or balloon catheter, and endometrial regeneration is stimulated by oral estrogen therapy. Women with synechiae are significantly more likely to have placental abruption (2.1% vs. 0.6%), premature rupture of membranes (5.5% vs. 2.3%), and cesarean delivery for malpresentation (5.1% vs. 3.0%). In a recent review of 296 pregnancies with uterine synechiae and over 65,000 pregnancies without synechiae, Tuuli and colleagues did not find a significant increase in placenta previa, fetal growth restriction, stillbirth, and preterm delivery.

This chapter has reviewed normal menstruation, the pathophysiology underlying AUB, the evaluation of AUB, and current treatment modalities. It concludes with a detailed description of the technique of dilatation and

curettage and management of complications of this procedure. Despite emerging medical and surgical therapies, AUB remains a common medical problem among women. An organized approach to the diagnosis and treatment of this problem is critical to the successful management of AUB. **Figure 26.14** provides an algorithm for the diagnosis and evaluation of AUB.

BEST SURGICAL PRACTICES

- Although hysteroscopy is the gold standard for evaluating endometrial cavity pathology, SIS has comparable sensitivity and is less invasive and less expensive.
- Historic data showed higher amenorrhea rates with endometrial ablation using endomyometrial resection. However, newer techniques of hydrothermablation, radiofrequency current, and microwaves have comparable amenorrhea rates. Hydrothermablation has the advantage of visualization of the endometrial cavity, radiofrequency ablation does not require endometrial pretreatment, and microwave endometrial ablation has been reported to be successful in the presence of small submucous myomas.
- Endometrial sampling can be done by Pipelle, four-quadrant endometrial biopsy, or formal dilatation and curettage (D&C). All of these techniques can miss significant lesions, and the concurrent use of vaginal ultrasonography or SIS will improve sensitivity.
- Hysteroscopy is a valuable adjunct to D&C, particularly in the patient at higher risk for focal endometrial pathology that might be missed on endometrial sampling.
- Abdominal ultrasound guidance may reduce the risk of complications (e.g., perforation during difficult cervical D&C, such as in the stenotic postmenopausal patient or in the case of a large uterus).

Chapter 27

Tubal Sterilization

Herbert B. Peterson

Jeffrey S. Warshaw

Amy E. Pollack

Barbara S. Levy

DEFINITIONS

Bipolar coagulation—Method of tubal occlusion usually performed via laparoscopy that causes electrocoagulation of the tube when current is applied by grasping forceps; one jaw of the forceps is an active electrode, and the other is a return electrode. There is less chance for unintended thermal injuries than with unipolar coagulation, and the chance of unintended thermal injury by capacitive coupling is virtually eliminated. However, less widespread thermal destruction of the tube increases the chance for sterilization failure relative to unipolar coagulation unless the surgeon uses techniques that maximize the likelihood of adequate tubal coagulation.

Capacitive coupling—Unintended consequence of laparoscopic use of unipolar coagulation, which under certain conditions can result in a charge being transferred to the operative laparoscope or conductive laparoscopic sheath. Subsequent occult transference of this charge to intestines can lead to thermal injury and subsequent perforation with infectious morbidity or mortality.

Cumulative failure rates—Contrary to previous beliefs, tubal sterilization failures are not isolated to a narrow window of time after the procedure but rather increase cumulatively with each passing year following sterilization. Younger women, who are more fecund at sterilization and for years after, have higher failure rates initially and over time.

Gas embolism—Potential complication of laparoscopic abdominal insufflation with the Veress needle, associated with “vapor lock” of the right ventricle, which occludes blood flow and results in cardiovascular collapse. A “cogwheel” murmur can sometimes be heard.

Hysteroscopic sterilization—Surgical approach in which an endoscope is introduced transcervically into the uterine cavity for the purpose of placing the Essure microinsert into the fallopian tubes across the uterotubal junction. It has the advantage of requiring no abdominal incision and only minimal analgesia. It can be performed in an outpatient or office surgery setting.

Irving method—Method of partial salpingectomy that buries the end of the proximal tubal stump in the myometrium of the uterus, in an attempt to reduce the rate of tuboperitoneal fistula.

Luteal phase pregnancy—Refers to pregnancies that occurred before sterilization but were detected after sterilization. Such pregnancies may be erroneously attributed to sterilization “failure.”

Open laparoscopy—Laparoscopic procedure begun without prior insufflation by directly visualizing, elevating, and incising the layers of the abdominal wall near the umbilicus. Has the benefit of reducing vascular injuries and, potentially, bowel injuries associated with blind direct Veress needle and trocar insertion.

Parkland method—Method of partial salpingectomy that involves ligation of the tube in two places, followed by excision of the intervening segment of tube. Achieves immediate separation of severed tubal ends.

Pomeroy method—Method of partial salpingectomy that involves ligation, followed by excision, of a loop of tube. No attempt to bury the severed ends of the tube.

Poststerilization regret—Regret after the decision to undergo surgical sterilization can be related to several factors, including preexisting patient characteristics, subsequent changes in the patient's situation or attitudes, and dissatisfaction resulting from adverse side effects caused or perceived to be caused by the procedure. Studies have identified young age at tubal sterilization as a risk factor for later regret.

Posttubal ligation syndrome—Refers to the historic perception that menstrual disturbances could result from tubal sterilization. This term is outdated, as substantial evidence against such a syndrome now exists. Women who undergo sterilization are no more likely than are their nonsterilized counterparts to experience a syndrome of menstrual abnormalities.

Silicone rubber banding—Method of tubal occlusion usually performed via laparoscopy in which a silicone rubber band is applied to the isthmic portion of the tube. The technique is most effective when the tube has normal anatomy and the operator is experienced with the technique of application. The possibility of tubal transection, and resultant hemorrhage, appears to be highest with this technique.

Sterilization timing—Sterilization can be performed in relation to pregnancy (following vaginal delivery, cesarean section, or abortion) or remote from pregnancy (interval sterilization).

Tubal clips—Method of tubal occlusion usually performed via laparoscopy in which a Filshie or Hulka clip is applied to the isthmic portion of the tube. The technique is most effective when the tube has normal anatomy and the operator is experienced with the technique of application. These methods inflict the narrowest zone of tubal damage (3 to 5 mm), affording a greater chance of sterilization reversal when compared with other methods.

Tuboperitoneal fistula—Poststerilization communication of the proximal tubal stump with the peritoneal cavity, which can result in sterilization failure, including ectopic gestation. Theoretically, may be reduced by leaving a proximal tubal stump of 2 cm and by minimizing ligature-induced necrosis at the site of tubal interruption.

Uchida method—Method of partial salpingectomy that buries the end of the proximal tubal stump within the leaves of the mesosalpinx in an attempt to reduce the rate of tuboperitoneal fistula.

Unipolar coagulation—Method of tubal occlusion usually performed via laparoscopy that causes electrocoagulation of the tube when current is applied by grasping forceps; both jaws of the forceps serve as an active electrode. The high effectiveness rates observed with this method are a property of the wide zone of thermal destruction of the tube that results, but this same property increases the potential for morbidity from unintended thermal injuries. The surgeon must be vigilant regarding possibility of capacitive coupling.

In proposing the concept of tubal sterilization in 1842, James Blundell suggested the following:

... the operator ... ought to remove a portion, say one line, of the Fallopian tube, right and left, so as to intercept its caliber—the larger blood vessels being avoided. Mere divisions of the tube might be sufficient to produce sterility, but the further removal of a portion of the tube appears to be surer practice. I recommend this precaution, therefore, as an improvement of the operation.

Samuel Smith Lungren of Toledo, Ohio, is credited with having performed the first tubal sterilization in 1880, after having performed a cesarean section for a woman whose previous child was also born by cesarean section because of a contracted pelvis. During the second cesarean section, Lungren intended to remove

the woman's ovaries to prevent future pregnancy, but instead decided that "the risk would be lessened and the same result would be accomplished by tying both Fallopian tubes with strong silk ligatures a one inch from the uterus." At the time of Lungren's successful tubal sterilization, laparotomy was a life-threatening procedure; thus, the performance of tubal sterilization at the time of cesarean section to prevent future pregnancy was potentially lifesaving. In 1919, Madlener reported on 85 tubal sterilizations performed at the time of laparotomy for other reasons, including cesarean section; 3 of the 85 women died postoperatively from infection. Because of the extreme risks, performing a laparotomy for the sole purpose of tubal sterilization remained an unpopular idea until the mid-20th century. Indeed, when three deaths occurred from 1936 to 1950 among 1,022 women who had postpartum Pomeroy sterilization, investigators Prystowsky and Eastman concluded that the risk for sterilization was comparable to that for multiparity and that "sterilization because of great multiparity alone cannot be justified on medical grounds."

In addition to concerns about safety, the early history of tubal sterilization included debate about the appropriateness of tubal sterilization for fertility control. At the 21st Annual Meeting of the American Gynecological Society in 1886, participants debated a woman's right to undergo surgical sterilization. During this debate, Edward P. Davis said, "I hold it [sterilization] to be the right of a woman who is in a condition to which natural delivery is impossible...." H. J. Garrigues objected by saying,

We must leave that to Nature or to God. ... I do not think that the woman has a right of that kind. ... The mere fact that she does not want to have more children should not decide the question. (Speert)

The availability and acceptability of tubal sterilization as a method of fertility control remained limited until the mid-20th century, and, accordingly, tubal sterilization remained uncommon in the United States and around the world until the 1960s. In the 1970s, the worldwide popularity of tubal sterilization increased dramatically. Between 1970 and 1980, the estimated number of tubal sterilizations increased markedly in Europe, China, India, other parts of Asia, and Latin America. In the United States, the number of tubal sterilizations increased nearly fourfold—from approximately 200,000 in 1970 to approximately 700,000 in 1977. Among the factors affecting this increase were the availability and acceptability of two new surgical approaches—minilaparotomy and laparoscopy. In contrast to laparotomy for sterilization, these approaches were safer, allowed for surgery without hospitalization, reduced recovery time, and gave a better cosmetic result. Minilaparotomy has been used in many developing countries, and laparoscopy has been used in many developed countries, including in the United States.

Minilaparotomy for interval sterilization (i.e., sterilization at a time unrelated to pregnancy) requires a 2.5- to 3.0-cm suprapubic incision. The technique was first described by Uchida and colleagues in Japan in 1961. It was used in the early 1970s in Thailand by Vitoon and associates and then rapidly gained acceptance worldwide. Laparoscopy for tubal sterilization was first proposed by Anderson in 1937 and later described by Power and Barnes in 1941. The use of laparoscopy in Europe was encouraged by the work of Palmer (France), Steptoe (Britain), and Frangenheim (Germany), and use of the technique rapidly gained popularity in the 1970s, particularly in Europe and the United States.

In the United States, the increased use of tubal sterilization in the 1970s occurred concurrently with the widespread availability and acceptability of laparoscopy. In 1970, less than 1% of sterilizations were performed with a laparoscope, but by 1975, more than one third of the 550,000 women who had tubal sterilization had the procedure performed laparoscopically. This transition was associated with a marked reduction in length of hospital stay for tubal sterilization—from 6.5 nights in 1970 to 4 nights in the years 1975 to 1978. By 1987, one third of tubal sterilizations in the United States required no overnight hospital stay, and 79% of these were performed by way of laparoscopy. In 2002, the FDA approved a new even less

invasive hysteroscopic approach for sterilization (Essure) that can be performed successfully in the office setting.

Sterilization is now the method of contraception most commonly used in the world. In 2009, about 251 million couples used sterilization (of themselves or their spouses) for contraception; 223 million were women using tubal sterilization and 28 million were men using vasectomy. Most of these sterilizations were performed in the developing world—229 million versus 22 million in the developed world.

In the United States, sterilization is also the most commonly used method of contraception. According to data from the National Center for Health Statistics, among women aged 15 to 44 in 2006-2010, about 14 million (22.7%) reported using either tubal sterilization (about 10 million) or vasectomy (about 4 million) for contraception. Among currently married women using contraception in 2006-2010, 47.3% were using either tubal sterilization (30.2%) or vasectomy (17.1%) for contraception. These percentages were very similar to those for 1995 (31.2% and 17.3%, respectively).

In 2006, of an estimated 643,000 tubal sterilizations, 351,000 (55%) were inpatient procedures and 292,000 (45%) were performed in an ambulatory setting. Nearly all of the former were postpartum procedures (either after vaginal delivery or concurrent with cesarean section). An increasing proportion of ambulatory procedures is being performed by hysteroscopy using the Essure device, but it is too early to determine the impact of such procedures on sterilization trends.

TIMING OF STERILIZATION

Tubal sterilization can be performed at the time of cesarean section, shortly after delivery or induced abortion, or at a time unrelated to pregnancy. About one half of tubal sterilizations in the United States are performed at a time unrelated to pregnancy. The timing of tubal sterilization can influence the choice of anesthetic, surgical approach, and method of tubal occlusion. For example, most sterilizations performed concurrently with cesarean section require no separate anesthesia and involve partial salpingectomy as the method of tubal occlusion. Most tubal sterilizations performed after vaginal delivery are done by minilaparotomy with subumbilical incisions and partial salpingectomy. Tubal sterilization not associated with birth usually is performed by laparoscopy (with use of coagulation, silicone rubber band application, or clip application), hysteroscopy (with use of Essure device), or minilaparotomy (with use of partial salpingectomy).

PREOPERATIVE EVALUATION

The candidate for sterilization should be extensively counseled. The intended permanence of the procedure, alternatives to sterilization, and risks of surgery should be discussed.

P.579

For couples desiring sterilization, no such discussion is complete without consideration of vasectomy as an alternative. Women also should be made aware that sterilization failure can occur and that the relative likelihood of ectopic pregnancy is increased when sterilization failure does occur.

The workup of women who are to undergo tubal sterilization includes a history and physical examination and a laboratory evaluation, as indicated. Consideration should be given to whether the woman might be pregnant at the time of sterilization, and pregnancy testing should be ordered as necessary.

A careful gynecologic history and examination also are necessary before sterilization. Women with gynecologic disease or symptoms may require additional diagnostic or therapeutic measures. Some ultimately may be better served by other surgical procedures, either instead of or in addition to sterilization. For example, some women with enlarged and symptomatic uterine leiomyomata, women with severe dysmenorrhea, and those with symptomatic pelvic relaxation may benefit more from hysterectomy than from tubal sterilization. Others, such as

women with abnormal cervical cytology, need careful evaluation before a decision can be made about preventing or treating invasive cervical cancer.

ANESTHESIA

Complications of general anesthesia are the leading cause of death attributed to sterilization in the United States. The risks inherent in general anesthesia are exacerbated by its use postpartum and during laparoscopy. The special requirements of general anesthesia for laparoscopy have been well described.

Except for the use of conduction anesthesia postpartum, general anesthesia is the technique most often used for female sterilization by laparoscopy and minilaparotomy in the United States. A 1988 survey of members of the American Association of Gynecologic Laparoscopists revealed that the number of providers of tubal sterilization who used local anesthesia for laparoscopic sterilization had increased from 4% (in the 1982 survey) to 8%. Worldwide, more than 75% of tubal sterilization procedures are performed under local anesthesia. A discussion of the technology and regimen for administering general or conduction anesthesia is beyond the scope of this chapter. Instead, we focus on local anesthesia because of its increasing use in outpatient settings for many types of surgery.

Sterilization by laparoscopy, hysteroscopy, or minilaparotomy can be performed safely under local anesthesia, and hysteroscopic sterilization with the Essure device can be performed with minimal analgesia alone. The patient avoids the risks associated with general anesthesia, spends less time sedated or anesthetized, and has a more rapid recovery. Nausea and vomiting are less likely to occur, and the patient is awake to report symptoms that can indicate the occurrence of a complication. Furthermore, the overall expense often is reduced compared with procedures done under general anesthesia.

In the United States, the overall morbidity rate for female sterilization is so low that it is difficult to obtain a sample large enough to demonstrate a comparative safety advantage for local versus general anesthesia. One US study randomly assigned 100 women to either local or general anesthesia for laparoscopic sterilization. Serious or life-threatening events did not occur in either group. However, women who had general anesthesia were more likely to have intraoperative hypotension, hypertension, or tachycardia, which suggests that these women were hemodynamically less stable and may have been at increased risk for cardiovascular complications. In another study, 125 women were randomly allocated to the use of local or general anesthesia for laparoscopic sterilization. Women who had general anesthesia were more likely to develop hypotension; hypertension was more common in the local anesthesia group. No women in either group had tachycardia.

Operating under local anesthesia incurs several possible disadvantages. The patient's anxiety may be increased; therefore, the surgeon must use a decisive and gentle surgical technique while talking with the patient. The patient may feel discomfort; thus, the physician must have a thorough understanding of the use of sedative and analgesic drugs. Although obesity can complicate the use of local anesthesia, several studies indicate that local anesthesia can be used successfully for obese women. Women with a history of multiple abdominal or pelvic surgical procedures or peritonitis may need additional anesthesia if the procedure is difficult or prolonged. Additional anesthesia also may be required during minilaparotomy if the abdominal incision needs to be extended. The hysteroscopic approach may be ideal for both obese women and those with multiple previous abdominal procedures as it avoids the necessity to access the tubes through the abdominal wall.

One US-based retrospective study reviewed 2,827 outpatient laparoscopic sterilizations performed under local anesthesia and mild sedation from 1980 to 1988. The mean operating time was 10.0 (± 5.1) minutes, and the mean anesthesia time was 23.3 (± 6.9) minutes. The hospital cost to the patient was reduced 65% to 85%. Another US study reported on 358 minilaparotomies for interval sterilization performed under local anesthesia. The average operating time was 21 minutes, and no complications were reported. In both series, the local anesthetic was 0.5% bupivacaine hydrochloride used alone or in combination with lidocaine. In one series,

midazolam hydrochloride and fentanyl citrate were used for mild intravenous sedation; in the other series, meperidine hydrochloride and diazepam were used.

For local infiltration and paracervical block, agents of intermediate intrinsic potency (defined as the minimum concentration required to produce a block within 5 to 10 minutes), such as lidocaine or mepivacaine, have been found suitable. Both are amides with good stability and low toxicity. Onset of analgesic effects is rapid, even when a low concentration of medication is used, and the duration of the effect is sufficient for the procedure but not prolonged (about 1.5 hours when the medication is given in plain solution). Bupivacaine, a more potent and a longer-acting amide, is frequently used in the United States. However, the short duration of action provided by lidocaine or mepivacaine is preferred by some because it allows for awareness of any abnormal degree of persistent pain and early diagnosis of complications, such as hematoma formation.

SURGICAL APPROACH

Minilaparotomy

The minilaparotomy approach to tubal occlusion can be used in the interval or postpartum period. Although interval sterilization by minilaparotomy is the sterilization procedure most frequently performed in many countries, it is not a common procedure in the United States. Minilaparotomy in the United States often is used preferentially among women considered to be at increased risk for laparoscopy.

Interval minilaparotomy is performed with the use of a 2- to 3-cm midline vertical or transverse suprapubic incision. In patients with an enlarged uterus resulting from uterine leiomyomata or other benign conditions, the minilaparotomy incision should be made at the level of the uterine fundus to ensure access to the fallopian tubes. A uterine manipulator is placed through the cervix just before surgery and is used to bring the uterus toward the incision. Placement of a paracervical block before insertion of the uterine manipulator reduces

P.580

discomfort for patients having surgery under local anesthesia. The abdomen is then entered with the approach that is used for laparotomy; small handheld retractors and the Trendelenburg position are used to enhance exposure. Once the uterus is identified, a tubal hook or a finger is placed posteriorly at the top of the fundus and moved along the uterus. The fallopian tube is identified first by the fimbriated end, and then the midportion of the fallopian tube is grasped with a small Babcock clamp and elevated through the abdominal incision. Tubal occlusion most often is performed by use of the modified Pomeroy or Parkland technique. However, clips or rings can be applied through the minilaparotomy incision with modified instruments originally developed for use through the operating laparoscope.

Postpartum minilaparotomy is performed in a manner similar to that of interval minilaparotomy. It is ideally performed before the onset of postpartum uterine involution while the uterine fundus is high in the abdomen (within 48 hours of delivery). A 2- to 3-cm subumbilical vertical or semicircular incision is made in the midline where the abdominal wall is thin. Because of the proximity of the enlarged uterus to the incision, access to the fallopian tubes is easier than it is with an interval approach. A uterine manipulator is unnecessary when minilaparotomy is performed in the postpartum period.

Laparoscopy

The magic is in the magician, not in the wand. ... Entering the abdomen is the most dangerous part of the laparoscopic procedure. (Hulka and Reich)

The laparoscopic instrumentation, including laparoscope, light cables and light source, insufflator and tubing, and video camera and television, if used, should be set up and tested for proper functioning before any incisions

are made. If a Veress needle is to be used, it is good practice to attach it to the insufflation tubing and test that gas flows freely through it. High line pressures (3 mm Hg or higher) during low-flow insufflation (1 L/min) through a Veress needle that has yet to be inserted into the abdominal cavity suggest that the needle has some occlusion. Checking for occlusion before inserting the needle can avoid the multiple attempts at needle placement that might occur in the belief that incorrect placement, rather than needle occlusion, is the cause of resistance to flow. It is convenient, while waiting for surgery, to have the end of the laparoscope bathing in warm sterile fluid to prevent it from fogging when it is inserted into the abdominal cavity.

A no. 11 scalpel blade is used to make a single vertical incision in the lower rim of the umbilicus. This must be done carefully because the aorta can lie just a few centimeters beneath the abdominal wall, particularly in a thin patient. The abdominal wall is lifted away from the aorta by pinching the skin beneath the umbilicus between thumb and index finger. The umbilicus is elevated with one hand or towel clips while the surgeon's other hand makes the controlled incision.

The Veress needle is disconnected from the insufflation tubing before insertion. The stopcock on the needle then is placed in the open position, and the spring action of the needle is tested for smooth operation. Elevating the abdominal wall and using the Veress needle with the stopcock open allows air to rush into the previously gas-free abdominal cavity when the end of the needle penetrates the peritoneal layer. The intruding air, if heard, is one of the first indicators that successful abdominal entry has occurred. Outflow of blood likewise can serve as an immediate indicator of vessel injury. Allowing air to rush in also can cause the bowel to fall away from the abdominal wall.

The terminal aorta is palpated, even in a moderately obese patient, through the abdominal wall in the midline, just above or at the umbilicus. The pulsations of the aorta are lost in the midline just beneath the umbilicus, corresponding to the sacral hollow. The aorta bifurcates at the level of L4, which corresponds to the summits of the iliac crests. This is a more reliable landmark for bifurcation of the aorta than the umbilicus. The Veress needle is placed through the umbilical incision and is directed at an angle toward the sacral hollow or uterine fundus (to avoid the aorta) and in the midline (to avoid the iliac vessels). Elevating the abdominal wall during this placement increases the distance between the Veress needle and major vessels. While placing the Veress needle, the surgeon should hold the needle like a dart, being careful not to impede the action of the spring mechanism. Resistance at the tip of the needle causes the blunt cannula inside the needle to be pushed back, and the spring mechanism at the hub of the needle extends. When resistance at the tip of the advancing needle is lost, as occurs with successful penetration of the peritoneal cavity, the blunt cannula inside the needle advances back out to the tip, and the spring mechanism at the hub of the needle snaps back in. Observing the spring mechanism for this snap can serve as a sign to test for successful placement. Often, there are two snaps—the first when the fascia is penetrated and the second with peritoneal penetration. Continuing to advance the needle tip much beyond the point of penetration of the parietal peritoneum risks placing the needle tip between loops of bowel or under the omental apron, both of which can cause resistance to flow and can result in reinsertion of the needle. Continued advancement of the Veress needle also risks vascular injury. The needle tip should not be moved laterally once the tip is inserted in the abdomen; any simple vascular or intestinal puncture could be transformed into a major laceration if the needle tip is moved from side to side. Once abdominal penetration is made with the Veress needle, the needle should be stabilized carefully until the safety checks have been completed. The needle should not be moved, and a laparotomy should be performed immediately if major vascular injury is suspected.

The distance between skin and fascia can increase with increasing patient obesity. A given angle of entry of the Veress needle that successfully penetrates the peritoneal cavity in a thin patient might fall far short of the peritoneum in an obese patient. To bring the peritoneal cavity within the physical length of the Veress needle, it is often necessary to pursue entry with a trajectory closer to the vertical. However, this also directs the Veress

needle toward the aorta and therefore should be attempted only by experienced surgeons, and with extreme care. Alternatively, open laparoscopy can be performed.

Several safety checks for correct intraabdominal placement can be performed while the Veress needle is held steady. The instillation of 5 to 10 mL of sterile saline through the needle, followed immediately by aspiration, can be helpful. The fluid should meet little resistance, and, more important, scant fluid should return on reaspiration. Reaspiration of fluid suggests that the needle tip is in a small enclosed space that does not allow immediate dispersion of the instilled fluid. Reaspiration of feculent fluid or bloody fluid suggests bowel or vascular penetration, respectively. Simple penetration of the bowel with a Veress needle does not mandate immediate exploratory laparotomy. Depending on the setting and the skill level of the surgeon, reinsertion of the needle or open laparoscopy, followed by laparoscopic visualization of the intestine, can be pursued.

A second safety check consists of attaching a filled 10-mL syringe to the hub of the Veress needle and then removing

P.581

the plunger. Elevation of the abdominal wall at this point should cause an increased negative intraperitoneal pressure, which allows the fluid in the syringe to drain passively into the abdominal cavity through an open stopcock. Alternatively, a drop of saline (drip test) can be placed on the hub of the Veress needle, and, with the stopcock open, elevation of the abdominal wall should result in the drop flowing downward freely.

Once these safety checks are performed, insufflation is begun at 1 L/min or less. Initial insufflation pressures often are 5 mm Hg or less in thin patients and, even with correct needle placement, can be 10 mm Hg or more in obese patients. An intraabdominal pressure greater than 15 mm Hg during insufflation generally is avoided to prevent respiratory compromise and decreased venous return secondary to vena caval compression. Abdominal distention increases the distance between the abdominal wall and major pelvic vessels, and this increases the safety buffer when the trocar is inserted. However, the abdomen should not be distended so taut that it is difficult to manually elevate it for trocar insertion.

During insufflation, a shift from dullness to tympany with percussion over the liver is indicative of pneumoperitoneum formation. It also is prudent for the surgeon to pay attention to the electrocardiogram rhythm during insufflation, because the sudden appearance of premature ventricular contractions can be an indicator of intravascular insufflation. Sudden vascular collapse during insufflation can be caused by a gas embolism into the right side of the heart and, at times, this life-threatening event can be signaled by a new “cogwheel” or “mill wheel” murmur. Rapidly tilting the patient into Trendelenburg position and onto her left side and advancing a Swan-Ganz catheter into the right heart for aspiration can be lifesaving.

Once insufflation is complete, the Veress needle is removed, and the umbilical incision is widened to accommodate the trocar and sleeve. An incision that is too large can result in leakage of gas around the sleeve. An incision that is too small can restrict access. The trocar should be checked before insertion to ensure that it is sharp; a dull trocar potentially is dangerous because it requires increased force for abdominal entry.

The trocar is grasped as shown in [Figure 27.1](#). If the surgeon’s hand is large enough, the middle finger can serve as a stopper, preventing the forward momentum following fascial puncture from carrying the trocar deep into the pelvis. The precautions for insertion of the Veress needle pertain even more to insertion of the trocar; the abdominal wall is elevated, the trocar is directed toward the hollow of the sacrum or the uterine fundus, and a midline trajectory is followed. Slow, steady pressure with a sharp trocar will permit immediate recognition when the gas-filled cavity is penetrated.

Open laparoscopy is performed without previous creation of a pneumoperitoneum. The skin beneath the umbilicus is incised sufficiently with a scalpel in either a vertical or transverse direction to adequately visualize the underlying fascia. Small S retractors are most helpful in visualization—especially in obese patients. The skin

is released, and the fascia is grasped and elevated. The fascia is then incised in the midline, and the opening is stretched with a hemostat or incised to a length just sufficient to visualize the underlying peritoneum, which in turn is elevated and incised. Keeping the incision in the central portion of the umbilicus where the peritoneum and fascia are fused is the easiest method for entry in obese patients. Each angle of the fascial incision is sutured with a no. 0 absorbable stitch but not tied. The Hasson blunt cannula and sleeve are then placed through the opening of the peritoneum. The blunt cannula then is removed, and the abdomen is insufflated through the port found on the sleeve.

FIGURE 27.1 Trocar entry. When inserting the trocar through the abdominal wall, the trocar is “palmed” in the surgeon’s dominant hand, with the extended middle finger serving as a stopper to prevent deep abdominal penetration. If the surgeon’s hand is too small to accomplish this, open laparoscopy should be considered.

METHOD OF TUBAL OCCLUSION

All tubal sterilization methods rely on correct identification of the fallopian tube for success. With any of the transabdominal methods, the tube should be followed out to its fimbriated end to confirm that the correct structure has been identified.

Theoretically, the risk of tuboperitoneal fistula formation can be reduced by preserving a proximal tubal segment 1 to 2 cm in length. It is possible that the proximal tubal stump serves as a distensible reservoir for the small amount of uterine fluid that is normally forced through the interstitial portion of the tube by uterine contractions. This distensibility capacitance of the proximal stump might serve to dissipate the fluid pressure emanating from the uterus. Otherwise, this direct fluid pressure on the cut end of the tube might prevent complete closure of the tubal lumen during the healing process.

Irving Procedure

In 1924, and later in 1950, Irving reported on his method of achieving tubal sterilization. He attempted to reduce

the risk of tuboperitoneal fistulae by extensively dissecting the ligated ends of the tubes and burying the proximal tubal segment. Although the extra dissection in this technique likely enhances effectiveness, it also carries the potential for greater blood loss, as well as increases the difficulty of performing the technique through a minilaparotomy incision. The procedure also takes slightly longer to perform than simpler methods.

The Irving technique is accomplished by first using a hemostat or scissors to create a window in the mesosalpinx just beneath

P.582

the tube, about 4 cm from the uterotubal junction (**Fig. 27.2A**). Then, the tube is twice ligated (no. 1 chromic) and divided between the ties at this location. The free ends of the proximal stump ligature are held long. A 1-cm incision is made in the serosa of the posterior uterine wall near the uterotubal junction. A hemostat, or similar pointed instrument, is then used to bluntly deepen the incision, creating a pocket in the uterine musculature about 1 to 2 cm deep (**Fig. 27.2B**). The two free ends of the proximal stump ligature, previously held long, are then individually threaded onto a curved needle and brought deep into the myometrial tunnel and out through the uterine serosa (**Fig. 27.2C**). Traction on the sutures then draws the ligated proximal stump deep into the myometrial tunnel, and tying the free sutures fixes the tube in this buried location (**Fig. 27.2D**). Often, this can be accomplished without incising the mesosalpinx, but if extra mobilization of the proximal stump is needed, or if the proximal stump mesosalpinx appears in danger of being torn when traction is applied, then the mesosalpinx under the proximal tubal segment can be incised partly back toward the uterus. The serosal opening of the myometrial tunnel is then plicated closed around the tube with the use of a fine absorbable suture, but great care should be exercised to avoid compromising the tube as it enters the tunnel. Strangulation or damage to the tube with this stitch could cause necrosis and fistula formation in the extramyometrial portion of the proximal tube. No treatment of the distal tubal stump is necessary, but some surgeons choose to bury that segment in the mesosalpinx.

Modified Pomeroy Procedure

Bishop and Nelms, colleagues of Pomeroy, reported on the Pomeroy technique for tubal occlusion in 1930. They were careful to point out the importance of using absorbable suture as opposed to permanent suture.

In this method, the tube is grasped in its midportion, usually with a small atraumatic clamp such as the Babcock, and a loop of tube is elevated (**Fig. 27.3A**). The base of the loop is ligated with no. 1 plain catgut, leaving a 2-cm proximal stump of isthmus, and the sutures are held long. A 2- to 3-cm portion of tube in the ligated loop is transected and removed with scissors (**Fig. 27.3B**). Bishop and Nelms, in the original report on this method, pointed out that ligation was performed with a double strand of absorbable chromic catgut suture to allow the cut tubal ends to quickly separate after surgery. It was their belief that this would allow the ends to naturally fibrose and peritonealize without fistulization or communication. This also is the rationale for the common modification of the Pomeroy technique, in which the original chromic suture is replaced by plain catgut because of the more rapid degradation of the latter. Surgeons have a tendency to strenuously tighten the catgut ligature around the tube (as though the tighter the ligature, the better the occlusion), but this appears to go against the very principles of the procedure. This tightening can result in greater strangulation and necrosis of the adjoining tubal segments, potentially increasing the risk of fistula formation

P.583

and failure. Taking time to identify the muscular tube, which is often seen pouting from each of the severed limbs of the ligated tube, is a good habit to develop, as is checking the tubal stumps for hemostasis. Resection of a limited amount of tube, restricted to the isthmus section, is ideal should unexpected future reanastomosis be requested. Making the knuckle of tube in the loop too small, however, can result in only a shave excision of the side of the tube, with incomplete transection of the lumen. To avoid incomplete resection, the mesosalpinx within the ligated loop should be perforated with scissors before the tubal limb on each side of this window is

individually cut. It is important not to cut the loop so close to the suture that only short distal segments of tube remain beyond the tie. These short limbs can easily slip out of the ligature and cause delayed bleeding.

FIGURE 27.2 Irving method. **A:** A fenestration is made beneath the tube about 4 cm from the uterotubal junction using scissors or a hemostat. **B:** The tube is then twice ligated and a portion resected. A deep pocket is created in the myometrium on the posterior uterus. The *dashed line* shows the line of incision if added mobilization of the proximal tube is necessary to bury the end of the tube in the myometrium. **C:** The tagged ends of the tube are sutured deep into the myometrial tunnel and out through the uterine serosa. **D:** Tying these sutures secures the cut end of the proximal tube deep in the myometrial pocket.

FIGURE 27.3 Pomeroy method. **A:** A loop of the isthmic portion of the tube is elevated and ligated at its base with one or two ties of no. 1 plain catgut suture. If performed through a minilaparotomy incision, these ties should be held long to prevent premature retraction of the tubal stumps into the abdomen when the loop of tube is

transected. **B:** A fenestration is bluntly created through the mesentery within the tubal loop, and each limb of the tube on either side of this fenestration is individually cut. The cut ends of the tube are inspected for hemostasis and allowed to retract into the abdomen.

The Pomeroy method minimizes bleeding by compressing and sealing the vascular mesosalpinx before tubal transection. It is not unusual when performing tubal sterilization at the time of cesarean section to find the mesosalpinx greatly engorged with distended veins. Elevation of the uterus through the abdominal incision often facilitates tubal occlusion by allowing the vessels to drain and decompress. It is important when replacing the uterus into the peritoneal cavity to lead with one adnexa at a time while protecting the tubal ligation site on that side. Otherwise, when the uterus is replaced, a tight fit can cause the adnexa to be squeezed against the incision, with resultant avulsion of the ligature and postoperative bleeding. When a Pomeroy ligation is performed through a minilaparotomy incision, the ligation sutures are held while the tube is cut. This prevents retraction of the cut tubal stumps into the peritoneal cavity before they can be adequately examined and before hemostasis can be ensured. After examination is complete, the sutures are cut, and the tubal stumps are allowed to retract into the abdomen.

It is also possible to perform a modified Pomeroy tubal ligation as a laparoscopic interval procedure. In this technique, a laparoscope with an operating channel is placed through the umbilical port, and a 5-mm midline suprapubic cannula is introduced under direct vision. A plain gut Roeder loop (endoscopic slip knot) is introduced through the 5-mm port. A grasper is introduced through the operative channel of the laparoscope, advanced through the suture loop, and the appropriate portion of tube is grasped and retracted back through the loop. The slip knot of the loop is then tightened, ligating a knuckle of the tube. Scissors are then introduced through the operative scope, and the suture is cut. With the use of a grasper through the 5-mm port, the loop of tube is held on tension while the scissors are used through the operative channel to transect the tube above the ligature. When the procedure is complete and the tubal segment has been resected, the grasper is used through the operative channel to hold the specimen while the operative scope and grasper are removed together through the umbilical sleeve. In contrast to most other methods of laparoscopic sterilization, this technique has the advantage of producing a surgical specimen for evaluation.

Uchida Method

Originally reported on in 1961, and reported on in revised form in 1975, the Uchida method, like the Irving procedure before it, recognized the role of fistula formation in tubal sterilization failures and included steps to prevent this complication.

This method begins by having the surgeon grasp the tube in its midportion, about 6 to 7 cm from the uterotubal junction. A 1:1,000 epinephrine in saline solution is injected subserosally, creating a bleb over the tube that is then incised (**Fig. 27.4A**). The muscular tube, which often can be seen springing up through the serosal incision, then is divided between two hemostats. The serosa over the proximal tubal segment is dissected bluntly toward the uterus, exposing about 5 cm of the proximal tubal segment (**Fig. 27.4B**). The tube then is ligated with no. 0 chromic suture near the uterotubal junction, and this 5-cm segment of exposed tube is resected. The shortened proximal stump is allowed to retract into the mesosalpinx (**Fig. 27.4C**). The serosa around the opening in the mesosalpinx is sutured in a purse-string fashion with a fine absorbable

stitch. Simultaneous ligation of the distal tube and gathering of the mesosalpinx around the distal stump are accomplished when the purse-string suture is tied (**Fig. 27.4D**). This step also fixes the distal stump in a position open to the peritoneal cavity while burying the proximal stump within the leaves of the mesosalpinx.

FIGURE 27.4 Uchida method. **A:** An injection of vasoconstricting solution is given beneath the serosa of the tube about 6 cm from the uterotubal junction. The serosa is then incised (*dashed line*). **B:** The antimesenteric edge of the mesosalpinx is pulled back toward the uterus, exposing about 5 cm of the tube. **C:** The tube is ligated proximally and cut, and the tied stump is allowed to retract into the mesosalpinx. The hemostat on the distal stump remains attached to facilitate exteriorization of this portion of the tube. **D:** The mesosalpinx is closed. A purse-string stitch of the mesosalpinx around the exteriorized tubal stump secures it in a position open to the abdomen, whereas the ligated proximal stump is buried within the mesosalpinx. Once the purse-string suture is tied, the hemostat can be removed.

Uchida added fimbriectomy to the procedure in 1975 to enhance effectiveness. Some surgeons omit this step, and in addition excise only 1 to 2 cm of tube (rather than the recommended 5 cm) to permit future tubal anastomosis.

Parkland Method

In this method, made popular during the 1960s at Parkland Memorial Hospital, the tube is grasped in its midportion with a Babcock clamp, and a hemostat or scissors is used to create a window in an avascular area of the mesosalpinx just beneath the isthmic portion of the tube (**Fig. 27.5A**). The window is stretched to about 2.5 cm in length by opening the hemostat. Two ligatures of no. 0 chromic material are passed through the window, and the tube is ligated proximally and distally, leaving a 2-cm proximal stump of isthmic tube (**Fig. 27.5B**). The intervening segment of tube between the ties then is resected (**Fig. 27.5C**). In contrast to the Pomeroy method,

in which the resected portions of the tubes are ligated together and later separate when the suture weakens, immediate separation of the tubal ends is accomplished with the Parkland method. Care should be taken to avoid undue traction on the ligatures while resecting the tubal segments, because this could result in tearing of the mesosalpinx and excessive bleeding.

Unipolar Coagulation

Unipolar coagulation was the first method of laparoscopic tubal occlusion to achieve widespread use. However, reports of electrical complications, particularly thermal bowel injury, resulted in a significant decline in this method's popularity as soon as alternative methods of laparoscopic tubal occlusion became available in the mid-1970s. In unipolar coagulation, a specially designed insulated grasping forceps is introduced through the operating channel of the laparoscope or independently through a 5-mm second-puncture port. As a safety precaution, attachment of the

P.585

electric cable to the grasping forceps should be delayed until the surgeon is ready to coagulate the fallopian tube.

FIGURE 27.5 Parkland method. **A:** A 2- to 3-cm fenestration is made beneath the isthmus portion of tube either

with scissors or bluntly with a hemostat. **B:** Ligation of the tube. Pulling up on the suture during ligation or during transection of the tube can shear the tube off the underlying mesentery, resulting in troublesome bleeding. **C:** Portion of tube removed.

With unipolar coagulation, as much as 3 to 5 cm of tube can be destroyed with a single burn, with occult damage occurring beyond the visual zone of desiccation. For this reason, the isthmus-ampullary portion of the tube should be carefully identified and grasped about 5 cm from the uterus to preserve some length of proximal tube. The jaws of the grasping forceps should completely encircle the fallopian tube and include a portion of the mesosalpinx as well. The tube should be elevated away from adjacent structures, such as bowel and bladder, before current is applied for about 5 seconds. If a second burn is required, it should be applied to the proximal rather than the distal portion of the tube. The current should be turned off before the tube is released and the grasping forceps are retracted into the laparoscope. Both jaws of the grasping forceps serve as active electrodes and will cause electrosurgical injury to any structure they touch while current is applied.

The thermal injuries to abdominal viscera that are seen with unipolar coagulation are, in some cases, likely attributable to the phenomenon of capacitive coupling. The current flowing down the unipolar probe creates an electromagnetic field that can transfer an electric charge to any conductor surrounding the probe. The greater the voltage being used with the probe, the greater this capacitive effect. In the case of laparoscopic unipolar coagulation for sterilization, the conductor surrounding the insulated unipolar probe is the operative laparoscope itself. As long as the operative laparoscope is safely grounded (usually by contact with a metal trocar sleeve that, in turn, is in contact with the abdominal wall over a large surface area), then the capacitive charge on the laparoscope can be harmlessly dissipated. If, however, the laparoscope is prevented from safely grounding into the abdominal wall by a nonconducting trocar sleeve or by a nonconducting barrier around the trocar sleeve (e.g., a plastic collar with threads), then the capacitive charge that builds up on the scope discharges when and wherever any portion of that instrument touches the patient's tissues. Depending on the surface area of contact, the discharging current from the scope into the patient's tissues has either a high current density (small contact surface) or a low current density (large contact surface), resulting in either a large thermal effect or a minimal thermal effect, respectively. In the case of contact with bowel, this thermal effect easily can result in delayed necrosis and peritonitis. If the unipolar probe is brought into the abdomen by way of a second puncture trocar sheath, then it is the sheath itself that is capacitively charged (if it is made of a conducting material). If the charge on the conducting trocar sleeve is prevented from grounding through the abdominal wall (as could occur if a plastic collar with threads is being used around the trocar sleeve), then any bowel or other grounded tissue touching the trocar sleeve again has capacitive current flowing into it. The use of unmodulated cutting current minimizes the voltage required to create the desired tissue effect. Coagulation or modulated current relies on short bursts of much higher

P.586

voltage and should be avoided in order to reduce the risk of capacitive coupling and unseen or unrecognized injury.

If thermal injury to the intestine is noticed during the laparoscopic procedure, then it is important to recognize that the injury can extend well beyond the visibly damaged area. Small burns of the bowel serosa may not require repair, but close observation for 5 to 7 days is recommended so the patient can be monitored for delayed peritonitis. A laparotomy is required if peritonitis occurs. A large area of superficial thermal bowel injury, or one that is thought to extend beyond the serosa, requires resection of that portion of intestine with a 5-cm margin on either side of the lesion. Oversewing the damaged area can result in stitches being placed in bowel that appears healthy visually but in reality is destined to necrose from occult thermal or electrical injury.

Bipolar Coagulation

The use of bipolar coagulation for tubal sterilization was reported by Rioux and Cloutier in 1974. With bipolar coagulation, current flows from one jaw of the grasper to the other, requiring only the intervening tissue of the patient within the jaws of the instrument to complete the circuit. This eliminates the need for a distant return electrode. Compared with unipolar coagulation, which uses the patient's body to complete the circuit, bipolar coagulation applies current in a more discrete manner (a 1.5- to 3-cm zone of thermal injury) and with a potentially increased element of safety. Capacitive coupling does not occur with bipolar forceps because the field effects from the equal but opposite currents that flow in both directions along the shaft of the instrument cancel out one another.

Once the fallopian tube is carefully identified, it is grasped in the distal isthmic section with the bipolar forceps in such a way that the tube is completely encircled, including a portion of the mesosalpinx (**Fig. 27.6**). The tube then is elevated away from any adjacent structures, and current is applied. Two additional contiguous areas similarly are coagulated to ensure at least a 3-cm area of desiccation. As with unipolar coagulation, an effort should be made to leave the proximal 2 cm of tube undisturbed to reduce the risk of tuboperitoneal fistula formation.

The visual end points of tubal blanching and swelling noted with bipolar coagulation cannot be used to ensure destruction of the endosalpinx. Desiccation of the outer one third of the fallopian tube can occur without desiccation of the inner one third. The use of an optical flowmeter has been recommended to evaluate cessation of current flow through the tube as an end point. Presumably, when complete desiccation occurs, there will be no further electrolytes in solution to carry current through the dehydrated tissue. Soderstrom and coworkers have demonstrated that complete desiccation of the fallopian tube with bipolar systems is more likely when a cutting waveform, as opposed to a coagulation or blended waveform, is used and when the power output is at least 25 W against a 100-V load.

Silicone Rubber Bands

Complications associated with the use of unipolar coagulation led to the pursuit of safer, nonthermal methods that could be applied laparoscopically. The first of these methods to gain popularity was the silicone rubber band, developed by Yoon and coworkers in the early 1970s.

The band is introduced with a specially designed endoscopic applicator that can be delivered through either the operating channel of a laparoscope or a separate second puncture port. The band is first stretched over the distal end of the applicator barrel (immediately before use to avoid extended deformation of the band). A transcervical uterine manipulator can be used to help achieve proper exposure. After the device is introduced into the abdominal cavity, grasping tongs are extended from within the applicator barrel. One of the tongs is used to gently hook and elevate the isthmic portion of the tube about 3 cm from the uterus. The tongs then are retracted into the applicator, which closes both arms of the tongs around the grasped tube while pulling the loop of tube up into the barrel (**Fig. 27.7**). The surgeon must take care in ensuring that the tube is completely encircled by the tongs as they are retracted into the applicator. Failure to do this can result in a band that is only tangentially applied to the tube (failing to occlude its lumen) or applied only to the mesosalpinx.

It is important to avoid excessive traction on the tube during retraction of the tongs. The surgeon should slowly advance the entire applicator toward the tube while gradually retracting

the tongs and tube up into the applicator. Failure to do this can result in mesosalpingeal hemorrhage and tubal laceration. Once the loop is fully retracted into the device, the band is slid off the applicator barrel and onto the base of the loop.

FIGURE 27.6 Bipolar method. A 3-cm minimum zone of isthmic tube is desiccated with bipolar forceps. The paddles of the forceps extend across the tube onto the mesosalpinx.

FIGURE 27.7 Silicone band method. The isthmic portion of the tube is retracted into the applicator barrel using grasping tongs, which should completely surround the tube. The applicator barrel is advanced toward the tube during this retraction process to avoid excessive traction on the tube and its mesentery.

Approximately 1.5 to 2 cm of tube is contained in the constricted loop. After devascularization, this portion of tube becomes anoxic and resorbs over time. Eventually, the band no longer encircles any tube; later it is often found in the mesosalpinx. Apart from the 2-cm loop of encircled tube, very little destruction is caused by the band, and 2 mm lateral to the area of constriction of the tube is relatively undisturbed.

It is difficult to apply a band to edematous or thickened fallopian tubes successfully. Tubal adhesions can reduce the mobility of the tube and preclude pulling an adequate loop of tube into the applicator. Additional rings can be applied to the cut edges if transection of the mesosalpinx or tube with accompanying hemorrhage occurs. Bipolar or unipolar coagulation can be used if this is unsuccessful.

Spring Clip

The use of a spring clip for tubal sterilization was reported by Hulka and colleagues in 1973. The introducer for the clip can be delivered into the abdomen through the operative channel of the laparoscope or a second puncture cannula (**Fig. 27.8**). Because the clip must be applied exactly perpendicular to the long axis of the fallopian tube, it is helpful at times to use the two-puncture method—placing the tube on stretch by use of a transcervical uterine manipulator and a grasping forceps inserted through the operating channel of the laparoscope and introducing the applicator through the second puncture port.

The clip is held in a cradle by the applicator and can be closed and opened on the tube multiple times until an acceptable application is achieved. At this point, further pressure on the thumb device of the applicator drives the spring mechanism over the jaws of the clip, locking it closed. If improper application is determined at this point, the clip cannot be removed, and another clip has to be placed. To be effective, the clip must be applied to the isthmic portion of the tube, approximately 2 cm from the uterus and exactly at right angles to the long axis of the tube. It must be applied fully advanced over the tube, with the hinge of the clip pressing against the tube and with the tips of the jaws of the clip extending beyond the tube onto the mesosalpinx, creating a characteristic fold in the mesosalpinx when the clip is closed. The tube is not elevated when applying the clip, in contrast to the techniques used in coagulation and band application.

The clip, like the silicone rubber band, is most likely to be successful when applied to a normal tube. Tubal distortion, thickening, and adhesions make correct application difficult and often impossible.

A considerable advantage to the clip method of sterilization is that only 3 mm of tube is compressed by the clip, and minimal collateral damage occurs in the adjacent tissue. As a result, anastomosis procedures after clip sterilization often are highly successful.

Filshie Clip

The Filshie clip was first introduced in Europe in 1975, and the hinged Mark VI model was approved for use in the United States by the U.S. Food and Drug Administration (FDA) in 1996. The device has titanium jaws lined with silicone rubber and is used with specially designed applicators that are available in both single- and double-puncture versions for use with laparoscopy or minilaparotomy. The Filshie clip has a hinge on one end and a small curve on the other and is designed to be placed on the isthmic portion of the fallopian tube approximately 1 to 2 cm from the cornua (**Fig. 27.9**).

To be effective, the jaws of this clip, as with the spring clip, must include the entire circumference of the tube. Only one properly applied clip needs to be applied to each fallopian tube. Once the tube is occluded, both the tube and the silicone

P.588

rubber lining of the clip are compressed. Over time, approximately 3 to 5 mm of the compressed tissue undergoes avascular necrosis, and the compressed silicone rubber expands. Eventually, plical attenuation and fibrosis of the adjacent tubal segments occurs, and the clips are peritonealized.

FIGURE 27.8 Spring clip method. The clip is applied to the midisthmus (approximately 2 cm from the cornua) at a 90-degree angle to the long axis of the tube. The hinge of the clip should be pressed against the tube, and the tips of the clip should extend onto the mesosalpinx.

FIGURE 27.9 Filshie clip method. The clip is applied to the midisthmus (approximately 1 to 2 cm from the cornua) with the lower jaw of the clip being visible in the mesosalpinx to assure that the entire circumference of the tube is included.

The clip is placed into the applicator, and the applicator and clip then are introduced through the cannula with the jaws of the clip in a partially closed position so that the instrument with the clip in place can be used to manipulate the fallopian tube into proper position. The clip may close prematurely if too much pressure is placed on the handle of the applicator. The lower jaw of the clip, with its small curve at the tip, should be seen through the mesosalpinx to assure that the clip includes the entire circumference of the isthmic portion of the tube before the clip is applied. Because of the clip's hinge and the silicone lining of the jaws, the tubes can be manipulated and released several times for better positioning of the clip. Gentle pressure is placed on the applicator handle once desired placement is obtained, which causes the upper jaw of the clip to flatten and lock under the curved tip of the lower jaw. The clip should be closed slowly to avoid transection of the fallopian tube, which is more likely with edematous tubes. A clip can be placed on each transected end if transection occurs. Many surgeons recommend the use of a double-puncture technique to assure proper placement.

Essure

The Essure microinsert was approved by the FDA for use as an interval tubal sterilization device in 2002. In 2007, the FDA approved the ESS 305 model, which was developed to improve bilateral placement rates. The device is inserted transcervically via hysteroscopy and thus avoids both entry into the abdominal cavity and the need for general or regional anesthesia. It is available as part of a disposable system that includes the microinsert, a delivery system, and a split introducer. The microinsert is comprised of a stainless steel inner coil, a nickel titanium alloy outer coil, and a layer of polyethylene terephthalate (PET) fibers around the inner coil. The microinsert is 4 cm in length and 0.8 mm in diameter before release from the insertion catheter; following release, it expands to 1.5 to 2.0 mm in diameter as the coils open up to anchor into the fallopian tube across the uterotubal junction (Fig. 27.10).

FIGURE 27.10 Essure method. The Essure microinsert is designed to be placed in the fallopian tube across the uterotubal junction where the tube exits the uterine wall but with 5 to 10 mm (the equivalent of three to eight coils) still trailing into the uterus.

The Essure microinsert can be placed in an outpatient or office surgery setting with oral analgesia alone or using a paracervical block with or without intravenous sedation. Using a sterile standard 5-mm hysteroscope with a minimum 5-French operating channel and a 12- to 30-degree angled lens, the uterine cavity is distended adequately with 2 to 3 L of warmed physiologic saline to allow accurate identification of both tubal ostia. The procedure should be terminated if both tubal ostia are not visible, accessible, and considered likely to be patent. The manufacturer's package insert recommends that the risk of hypervolemia be reduced by immediately

terminating the procedure if the fluid deficit of the physiologic saline distention medium exceeds 1,500 mL and by limiting the time of the hysteroscopic procedure to a maximum of 20 minutes.

The Essure microinsert is designed to be placed in the fallopian tube across the uterotubal junction where the tube exits the uterine wall but with 5 to 10 mm (the equivalent of three to eight coils) still trailing into the uterus. This is achieved by inserting the delivery catheter with the microinsert into the proximal tubal lumen to the level indicated by the black position marker on the catheter. When the device is correctly placed, the delivery catheter is withdrawn, and the delivery wire is separated from the microinsert. The trailing end of the coils aids in anchoring the device to decrease the risk of expulsion. The device is also anchored as it expands in the tube at placement, but occlusion is not considered adequate without tissue ingrowth from the tubal wall into the coils that occurs as a result of an inflammatory and fibrotic response to the PET fibers in the inner coil. A hysterosalpingogram (HSG) must be performed 3 months postinsertion to assure complete bilateral tubal occlusion. Transvaginal ultrasonography has also been used for microinsert localization but is not approved by the FDA as an alternative to HSG for this purpose. Alternate contraception should be used until occlusion is documented.

In early studies, 14% of microinsert attempts failed with the first attempt on one or both sides, using the original braided catheter. Although the rate of failed attempts was reduced as training improved, the insertion failure rate remained considerable at 10%. In a postapproval trial by Levie et al. of the ESS 305 model reported in 2011, the successful bilateral placement rate was 97.2%, but these encouraging findings require confirmation in the general population.

The Essure microinsert is indicated, as for other methods of sterilization, only for women who are certain about their desire to terminate future fertility. The effects of the microinserts on a desired subsequent pregnancy are unknown, but they are not removable once the fibrotic ingrowth is complete, and several coils may potentially project into the uterine cavity, making in vitro fertilization potentially less feasible than following sterilization by laparoscopy or minilaparotomy.

P.589

STEPS IN THE PROCEDURE

General Considerations

- Patient counseled on alternative options, permanence, risks, and failure rate of intended procedure
- Pregnancy test obtained preoperatively as indicated
- Procedure performed in follicular phase of cycle
- Sterilization procedures are performed on the area of tube, appropriate for the specific procedure approximately 2 cm from cornu

Minilaparotomy (Postpartum) Sterilization Pomeroy Technique

- Incision at umbilicus, with patient in Trendelenburg position
- Sweep tube up to incision using finger behind adnexa, Babcock clamp, and table tilt
- Elevate 2- to 3-cm knuckle of mid-isthmic portion of tube with Babcock clamp
- Ligate a 2- to 3-cm knuckle of tube with no. 1 plain catgut suture
- Bluntly create window in mesosalpinx of looped tube
- Excise the knuckle of the tube, cutting the tube to one side of window and then the other

Laparoscopic (Interval) Methods

Bipolar Coagulation

- Three contiguous burns (approximately 3 cm length) of fallopian tube using bipolar forceps, beginning 2 cm from cornu and progressing distally
- Bipolar at least 25 watts cutting current, and forceps grasp entire width of tube to include portion of underlying mesosalpinx
- Ammeter demonstrating cessation of current flow can help determine end point of desiccation

Clips

- Hulka or Filshie clips applied with device at right angle to the isthmic portion of tube, approximately 2 cm from cornu
- Clips should traverse entire width of tube and extend onto a portion of the mesosalpinx

Ring (Bands)

- One tong of the applicator gently hooks and elevates tube, approximately 3 cm from the cornu
- Ensure tongs completely encircle the tube as they are retracted into the applicator
- To avoid excessive traction that can sever tube, applicator should be advanced toward tube as tongs are retracted

Hysteroscopic Method

- Essure
- Gently introduce an operative hysteroscope through the cervix
- With adequate uterine distention using warmed normal saline, visualize both fallopian tube orifices
- Place the delivery catheter through the operating port of the scope and into the tubal orifice up to the level of the black marker
- Deploy the microinsert and separate it from the delivery catheter
- Remove the first catheter and repeat the procedure on the opposite side
- Visualize both tubal ostia and record the number of trailing coils visible on each side

Women with a known hypersensitivity to nickel should not have the Essure devices inserted because the outer coil is made of nickel-titanium alloy.

IMMEDIATE COMPLICATIONS

Mortality

In an international study of 41,834 sterilizations performed from 1971 to 1979 in 28 countries, the estimated case fatality rate was 13.4 per 100,000 interval tubal sterilization procedures, 53.3 per 100,000 postabortion sterilization procedures, and 43.4 per 100,000 sterilizations after vaginal delivery. At least some of the differences in case fatality rates between interval tubal sterilization and sterilization associated with pregnancy were likely attributable to complications of pregnancy termination or delivery rather than tubal sterilization per se.

The potential health impact of tubal sterilization in countries that have a high rate of maternal mortality can be

assessed by analyzing sterilization-attributable deaths in Bangladesh. In the first of two epidemiologic investigations, 28 deaths were attributed to tubal sterilization in two geographic areas; the case fatality rate was 19 deaths per 100,000 tubal sterilizations. In the second investigation, 19 deaths were identified nationwide, for a case fatality rate of 12.4 deaths per 100,000 procedures. Anesthesia overdosage, tetanus, and hemorrhage were the leading causes of death in both investigations. On the basis of an estimated maternal mortality rate of 570 per 100,000 live births, more than 1,000 maternal deaths for each 100,000 tubal sterilizations performed would have been averted during the reproductive years of the cohort.

In the United States, deaths attributable to tubal sterilization are rare. Based on an assessment of tubal sterilizations performed in US hospitals in 1979 and 1980, the estimated case fatality rate for tubal sterilization is 1 to 2 per 100,000 procedures. Complications of general anesthesia are the leading cause of sterilization-attributable death. In a survey of deaths attributable to tubal sterilization in the United States from 1977 to 1981, 29 deaths were identified: Eleven followed complications of general anesthesia, seven were caused by sepsis, four were caused by hemorrhage, three were caused by myocardial infarction, and four were related to other causes.

At least some of these deaths are preventable. Safer use of general anesthesia or use of local anesthesia, particularly for interval laparoscopic and minilaparotomy procedures, should reduce the risk of death from anesthesia. Of the seven identified deaths caused by sepsis from 1977 to 1981, three were associated with the use of unipolar electrocoagulation. Safer use of unipolar coagulation or alternative methods of tubal occlusion reduces the risk of thermal bowel injury. Three of the four deaths attributable to hemorrhage occurred after major vessel laceration during abdominal entry for laparoscopy. Safer insertion of the Veress needle and trocar or use of alternative techniques, such as open laparoscopy or minilaparotomy, should reduce the risk of such major vessel injuries.

Morbidity

Morbidity attributable to tubal sterilization is uncommon but not rare. The risks for and types of morbidity vary somewhat by surgical approach and method of tubal occlusion. Direct comparisons of minilaparotomy and laparoscopy for tubal sterilization are limited, but studies suggest several differences. In a nonrandomized study in 23 countries, 7,053 women who had silicone rubber band application by way of laparoscopy were compared with 3,033 women who had silicone rubber band application by minilaparotomy and 5,081 women who

P.590

had modified Pomeroy ligation by minilaparotomy. The surgical complication rates were 2.04%, 1.45%, and 0.79% for the three groups, respectively. In a smaller but randomized study in eight centers, 791 women who had modified Pomeroy occlusion by minilaparotomy were compared with 819 women who had occlusion from electrocoagulation (technique not specified) by way of laparoscopy. Major complications occurred in 1.5% of the women in the minilaparotomy group and 0.9% of the women in the laparoscopy group. Minor complications, which are more common, occurred in 11.6% of women in the former group and 6.0% in the latter group.

In a US multicenter, collaborative study, major complications were more common among women who had minilaparotomy (3.5%) than among those who had interval laparoscopic sterilization (1.6%). However, women in the study were not randomly assigned to groups, and the sterilization procedures were performed in institutions where most interval tubal sterilizations were done by way of laparoscopy. Thus, minilaparotomy sterilizations may have been performed selectively for women at increased risk for complications.

Although the overall complication rates are similar for minilaparotomy and laparoscopy, the types of complications appear to vary. Complications of minilaparotomy usually are not serious and typically include minor wound infection, longer operating time, slightly longer postoperative convalescence, and greater postoperative pain. Laparoscopic complications are more likely to include rare but life-threatening hemorrhage and viscus

perforations during abdominal entry and thermal bowel injury during electrocoagulation. A study of 100,000 laparoscopies in France suggests that major vessel laceration occurs in three of 10,000 procedures. In a study conducted in the United Kingdom, major vessel laceration occurred in nine of 10,000 laparoscopies.

Some of the most serious complications of both interval minilaparotomy and laparoscopy occur during abdominal entry. Bladder laceration during suprapubic minilaparotomy can occur, but usually, it is recognized during surgery and is repaired easily. Major vessel and bowel laceration during needle or trocar insertion for laparoscopy are more difficult to recognize or repair, and delayed treatment of these injuries can be fatal. Meticulousness is required to reduce the risks of abdominal entry. Comparative studies of open versus conventional laparoscopy are limited and have insufficient power to assess the risk of life-threatening complications, but use of open laparoscopy should markedly reduce the risk of major vessel laceration and should reduce, to a lesser extent, the risk of bowel laceration. The use of open laparoscopy can be particularly advantageous for women known or strongly suspected to have multiple abdominal or pelvic adhesions. However, even open laparoscopy can result in bowel injury if the bowel is adherent to the anterior abdominal wall.

The method of tubal occlusion chosen influences the risk for and type of complications during laparoscopy. Thermal bowel injury is more common with unipolar than bipolar coagulation, but it can occur during the latter if the bowel is grasped and coagulated. Transection of the fallopian tube can occur with any technique, particularly when an attempt is made to mobilize the fallopian tube in the presence of thick peritubal adhesions. Tubal transection is most likely to occur when silicone rubber bands are used, but any resultant bleeding usually can be managed by the application of a second ring or by the use of coagulation.

Complications associated with insertion of the Essure device are generally related to the risks inherent in hysteroscopy, including hypovolemia, uterine perforation, and vasovagal syncope. Tubal spasm may occur precluding delivery of the microinserts beyond the tubal orifice. Patience while reducing intrauterine pressure and gentle pressure with the delivery catheter tip at the tubal orifice will usually result in relaxation of the spasm and successful microinsert placement. Intravascular delivery of local anesthetic solutions can occur. This may create the potential for seizures and cardiopulmonary arrest. Care should be taken when performing paracervical block anesthesia to infiltrate tissues superficially. Tubal perforation may also occur with placement of the microinserts across the uterotubal junction. This is typically unrecognized until the 3-month HSG confirmation test demonstrates poor positioning of the devices. Very rarely, patients may develop unrelenting crampy pain after insertion, which may necessitate removal of the devices if relief cannot be obtained with 7 to 10 days of medical management.

DELAYED COMPLICATIONS

Pregnancy

Tubal sterilization is highly effective in preventing pregnancy. A frequently cited failure rate is four pregnancies per 1,000 sterilization procedures. However, a range of failure rates is more likely to portray the risk of pregnancy after sterilization. The determinants of that range are likely to include the method of tubal occlusion, surgical technique, and the age of the woman at sterilization. In the US Collaborative Review of Sterilization, a multicenter, prospective, cohort study, 10,685 women undergoing tubal sterilization in medical centers in nine US cities from 1978 to 1987 were followed for up to 14 years. A total of 143 sterilization failures were identified with the 10-year cumulative probability of failure ranging from 7.5 per 1,000 procedures (for unipolar coagulating procedures and postpartum partial salpingectomy procedures) to 36.5 per 1,000 (for spring clip application procedures). The failure rates for most methods of tubal occlusion were higher for women aged 18 to 27 years at sterilization (as high as 54.3 and 52.1 per 1,000 bipolar coagulation and spring clip applications, respectively) than for women aged 34 to 44 years at sterilization (as low as 1.8 and 3.8 per 1,000 unipolar coagulation and postpartum partial salpingectomy procedures, respectively).

This large US multicenter study and two smaller studies in Thailand and Belgium have dispelled the widely held belief that nearly all pregnancies after sterilization occur in the first year or two after the procedure. In the Thai study, 418 women were followed for 6 to 10 years after sterilization, and only one of four pregnancies identified occurred within 2 years of the procedure. In the Belgian study, of 17 pregnancies after 1,437 sterilizations by bipolar coagulation, none occurred within 12 months of electrocoagulation, and eight occurred more than 24 months after the procedure. In the US study, the 10-year cumulative probability of pregnancy after bipolar coagulation (24.8 per 1,000 procedures) was approximately 10 times the probability (2.3 per 1,000) at 1 year. Further, pregnancies occurred in the 10th year after all four methods of laparoscopic sterilization studied (bipolar and unipolar coagulation, silicone rubber band application, and spring clip application).

The fact that the risk of pregnancy after sterilization only can be determined after long-term follow-up creates a dilemma in interpreting published failure rates. For example, the failure rates in the US Collaborative Review of Sterilization for six methods of tubal occlusion were based on procedures performed in the late 1970s and 1980s when laparoscopic sterilization was fairly new. Whether failure rates for procedures performed in the past reflect the risk for current procedures

P.591

is unclear. In an analysis of bipolar coagulation procedures in the US Collaborative Review of Sterilization, the 5-year cumulative probability of pregnancy for women sterilized in 1978 to 1982 (19.5 per 1,000 procedures) was significantly greater than that for women sterilized in 1985 to 1987 (6.3 per 1,000 procedures). Further, most of the procedures evaluated in that study were performed in teaching institutions; it is unclear whether procedures performed in teaching institutions can be generalized outside such settings.

Luteal phase pregnancy, or pregnancy diagnosed after sterilization but conceived before sterilization, is estimated to occur in 2 to 3 per 1,000 sterilization procedures. The most effective strategy for reducing the risk for luteal phase pregnancy is to time the sterilization procedure to occur during the follicular phase of the menstrual cycle. Reliance on dilatation and curettage at the time of sterilization is substantially less effective. The likelihood of luteal phase pregnancy occurring also depends on the method of contraception used before tubal sterilization. Women who use steroid hormonal contraceptives or intrauterine devices are at substantially lower risk for luteal phase pregnancy than are women who use barrier methods or no method of contraception. Testing for pregnancy by using an enzyme-linked immunosorbent assay pregnancy test as indicated before sterilization also reduces the risk for luteal phase pregnancy.

The likelihood of ectopic pregnancy occurring is increased when pregnancy occurs after sterilization. In the US Collaborative Review of Sterilization, the highest proportion of ectopic pregnancies among all pregnancies after sterilization was among women who underwent bipolar coagulation (65%), followed by interval partial salpingectomy (43%), silicone rubber band application (29%), postpartum partial salpingectomy (20%), unipolar coagulation (17%), and spring clip application (15%). The proportion of pregnancies that were ectopic increased over time; for all methods combined, the proportion of ectopic pregnancies was three times greater in the 4th through 10th years after sterilization (61%) than in the first 3 years (20%). All pregnancies that occurred in the 10th year after unipolar and bipolar coagulation, silicone rubber band application, and spring clip application were ectopic. All but one (an ovarian pregnancy after bipolar coagulation) of the 47 ectopic pregnancies identified in the study were tubal pregnancies. The index of suspicion for ectopic pregnancy should be high when pregnancy is suspected after tubal sterilization. Pregnancy should be confirmed by use of a highly sensitive pregnancy test as soon as feasible.

A woman's individual risk for ectopic pregnancy can be considered in both absolute and relative terms. Her absolute risk is determined by the likelihood that the sterilization procedure can fail to prevent pregnancy and the likelihood that a resulting pregnancy will be ectopic. This risk is also relative to the risk for ectopic pregnancy that a woman had before tubal sterilization. Depending on the method of contraception used before sterilization,

some women may be at greater risk for ectopic pregnancy after tubal sterilization. In a report from a case-control study in Seattle, both postpartum sterilization and interval sterilization were associated with a lower risk of ectopic pregnancy than was use of no contraception. However, women who had interval tubal sterilization had a higher risk of ectopic pregnancy than did women who were using oral contraceptives or barrier methods of contraception. In contrast, the risk for ectopic pregnancy was similar between women who had postpartum tubal sterilization and those who used oral contraceptives or barrier contraception.

Careful attention to surgical technique is required to maximize sterilization effectiveness. To reduce the risk of pregnancy after bipolar coagulation, Soderstrom and colleagues identified determinants of complete electrocoagulation. In the US Collaborative Review of Sterilization, women undergoing bipolar coagulation later in the study who had three or more sites of coagulation had a 5-year cumulative probability of failure of 3.2 per 1,000 procedures. This is similar to the 5-year probability for unipolar coagulation (2.3 per 1,000) and substantially lower than that for women undergoing bipolar coagulation with fewer than three sites of coagulation (12.9 per 1,000). Stovall and coworkers reported on the use of silicone rubber bands and spring clips in a residency training program; all of 20 sterilization failures were associated with improper application of the occlusive device on gross and microscopic evaluation after subsequent bilateral salpingectomy. In the US Collaborative Review of Sterilization, the risks of pregnancy were significantly increased among women who had a silicone rubber band applied solely to the distal one third of at least one fallopian tube and among women who had a spring clip applied to a site other than the proximal one third of at least one tube.

The likelihood of sterilization failure depends not only on the sterilization technique but also on patient and physician factors. For example, proper application of silicone rubber bands and spring clips generally is difficult in the presence of thickened tubes or dense pelvic adhesions; under such circumstances, alternative techniques usually are preferred. As noted, failure rates generally are higher for women sterilized at younger ages, not only because they are more fecund at the time of sterilization than older women but also because they have a longer period after sterilization during which it would be feasible for pregnancy to occur. The latter consideration, which is an issue because it is now clear that pregnancy can occur for many years after sterilization, also applies to any temporary method of contraception that a woman chooses to use. For example, based on data from the US Collaborative Review of Sterilization, a woman sterilized at 28 to 33 years old has a 10-year chance of pregnancy of less than 1% to approximately 3%, depending on the method of tubal occlusion. The comparable risk for 10 years of use of the Copper T 380 intrauterine device is approximately 2%, but the typical failure rate for oral contraceptive use is approximately 6% to 8% in just the first 12 months of use. Data regarding the long-term failure rates of the Filshie clip and the Essure microinsert are less complete than those for the other commonly used techniques. However, based on data to date, both appear highly effective with proper placement.

In a 2012 systematic review that included 22 studies, 102 pregnancies were identified after Essure placement, but most of these pregnancies occurred when FDA's instructions for use were not followed. Especially noteworthy findings were not placing the microinserts during days 7 to 14 of the menstrual cycle, not having an imaging study at 3 months postinsertion to document successful placement, and not using effective contraception until tubal occlusion had been documented. Only 15 pregnancies occurred among women who had imaging confirmation of correct placement or tubal occlusion, highlighting not only the very low risk of pregnancy after successful bilateral tubal occlusion but also the importance of adequate follow-up imaging. Given the fundamentally different mechanism of tubal obstruction (fibrotic endosalpingeal ingrowth) with the hysteroscopic technique, the risk of ectopic pregnancy in sterilization failures may be quite different than with the laparoscopic or minilaparotomy approaches. Long-term careful follow-up studies will be needed to establish the long-term failure and ectopic risks with Essure.

Menstrual Changes

After nearly a half century of debate, questions regarding the existence of a posttubal ligation syndrome of menstrual abnormalities appear to be largely resolved. Questions arose initially when Williams and colleagues reported in 1951 that sterilized women had a higher-than-expected occurrence of menorrhagia and metrorrhagia. Studies in the 1970s appeared to support the existence of a poststerilization syndrome, but most of those studies had major methodologic shortcomings, including failure to account for factors other than sterilization per se that might have influenced poststerilization menstrual changes. One such factor was the use of oral contraceptives; in the United States, as many as 30% of women may use oral contraceptives immediately before tubal sterilization, and many of these women have menstrual changes after sterilization attributable solely to cessation of oral contraceptive use. Although one well-controlled study by Shain et al. in the 1980s identified poststerilization menstrual changes, nearly all other studies reported in the 1980s that controlled for factors such as cessation of oral contraceptive use found little or no evidence of a poststerilization syndrome at 1 to 2 years after sterilization.

Until the 1990s, questions remained about whether menstrual changes attributable to sterilization may occur several years after the procedure. Two US multicenter, prospective, cohort studies argue strongly against such an occurrence. In the first, reported in 1993, 500 women were evaluated at 6 to 10 months and 3 to 4.5 years after sterilization. When women who were taking oral contraceptives were excluded, no significant differences in seven menstrual parameters were found between sterilized women and two groups of nonsterilized women.

In the second, reported in 2000, 9,514 sterilized women enrolled in the US Collaborative Review of Sterilization were compared with 573 women whose husbands underwent vasectomy. All women were asked the same questions about six menstrual parameters before tubal sterilization or the husband's vasectomy and again at annual follow-up interviews for up to 5 years. The sterilized women were no more likely than the nonsterilized women to report changes in intermenstrual bleeding or cycle length. The sterilized women were more likely than the nonsterilized women to have decreases in the number of days of bleeding and the amount of bleeding and menstrual pain; they were also more likely to have an increase in cycle irregularity. When the risk of menstrual abnormalities was evaluated by method of tubal occlusion, there were no significant differences between the women sterilized by any of six methods and the women whose husbands underwent vasectomy in amount or duration of menstrual bleeding, intermenstrual bleeding, or menstrual pain. Women undergoing one of three methods of sterilization (silicone rubber band application, interval partial salpingectomy, and thermocoagulation) were more likely than nonsterilized women to have an increase in cycle irregularity, whereas women undergoing either of two other methods (unipolar and bipolar coagulation) were more likely to have decreases in cycle irregularity. This latter observation suggests strongly that the differences between sterilized and nonsterilized women in the likelihood of cycle irregularity and other menstrual features were attributable to chance or unmeasured differences between the study groups. Finally, sterilized women were compared with nonsterilized women for risk of a syndrome consisting of persistent increases in amount of bleeding, days of bleeding, or intermenstrual bleeding; no significant differences were identified.

Although sterilization procedures have been hypothesized to adversely affect ovarian function, laboratory studies have identified no consistent abnormalities that reflect ovarian dysfunction. Further, the biologic plausibility of such an occurrence is uncertain. The tubal branch of the uterine artery, which often is occluded during sterilization, connects with the ovarian branch of the uterine artery; thus, interrupting the tubal branch could affect the blood supply to the ovary. However, blood also is supplied to the ovary by the ovarian artery, which branches directly off the aorta and is remote from the site of tubal occlusion. The possibility has been raised that tubal occlusion could damage the ovary by acutely increasing pressure in the uteroovarian arterial loop. However, as noted, neither laboratory nor epidemiologic studies find changes consistent with acute injury to the ovary, and there is now strong evidence against the occurrence of sterilization-attributable menstrual abnormalities within 5 years of the procedure.

Some women who have no menstrual abnormalities before sterilization have them later, and for other women, menstrual abnormalities before sterilization resolve. To consider the former group as having a syndrome is inappropriate unless the latter group is considered to have an opposing syndrome. Although menstrual abnormalities are common among sterilized women, they also are common among nonsterilized women of similar ages. The balance of the evidence to date suggests strongly that sterilized women are no more likely than comparable nonsterilized women to have menstrual abnormalities.

Hysterectomy

Tubal sterilization and hysterectomy are common procedures in the United States, and any relation between the two has important consequences. Tubal sterilization could increase the risk for hysterectomy by increasing either the reality or the perception that a poststerilization syndrome occurs. As noted, the evidence against such a syndrome is now strong; thus, it should not be an indication for hysterectomy. Alternatively, the fact that a woman has had tubal sterilization could affect decision making about further surgery. At least three studies suggest that this effect can occur. Cohen studied 4,374 women 25 to 44 years old who had tubal sterilization in 1974 while enrolled in a universal health insurance plan in Canada. Women 25 to 29 years old at the time of sterilization were 1.6 times more likely than nonsterilized women to have a hysterectomy at a later time. However, women 30 years or older at the time of sterilization were no more likely than nonsterilized women to have a hysterectomy subsequently. Goldhaber and colleagues, who studied 39,502 women sterilized during 1971 to 1984, found that women sterilized at 20 to 24 years old were 2.4 times more likely than nonsterilized women to have a hysterectomy subsequently. For other sterilized women, the risk for hysterectomy steadily decreased with increasing age; women sterilized at 40 to 49 years old had no increased risk. Stergachis and associates studied 7,414 women sterilized during 1968 to 1983 and found that women sterilized at 20 to 29 years old were 3.4 times more likely than nonsterilized women to subsequently have a hysterectomy. Women sterilized at 30 years old or older had no increased risk for hysterectomy.

The fact that the increased risk for hysterectomy was concentrated among women sterilized at a young age in the noted studies suggests that any increased risk for hysterectomy after tubal sterilization is not biologic in etiology but attributable to other factors, such as removal of fertility preservation as a factor in decision making. In the US Collaborative Review of Sterilization, women sterilized at 34 years old and younger were four to five times more likely to undergo hysterectomy than women the same age whose husbands underwent vasectomy. However, women sterilized at 35 years old and older were also four to five times more likely to undergo hysterectomy than women

P.593

whose husbands underwent vasectomy, suggesting that fertility preservation does not explain all differences in decision making between sterilized and nonsterilized women.

In the US Collaborative Review of Sterilization, the cumulative probability of undergoing hysterectomy within 14 years after sterilization was 17%. Although women with gynecologic disorders at the time of sterilization were at greater risk of hysterectomy, most women who reported gynecologic disorders at sterilization did not undergo hysterectomy within the followup period. For example, women who reported having a history of endometriosis at sterilization were more likely to undergo hysterectomy than women without a history of endometriosis; the probability of women reporting endometriosis undergoing hysterectomy within 14 years was 35% versus 15% for women without endometriosis. Similarly, women who reported having a history of uterine leiomyomata at sterilization were more likely to undergo hysterectomy than women without a history of leiomyomata; the 14-year cumulative probability of hysterectomy among women reporting leiomyomata was 27% versus 14% for women without leiomyomata.

Regret

The decision to undergo sterilization is serious to both men and women because the intent is to permanently terminate fertility. Although microsurgical methods of reversal are available, these methods require special skill, the procedures are complicated and lengthy, the costs are high, and none of the methods guarantees success.

Findings from studies of poststerilization regret provide useful information for presterilization counseling. Sterilization regret is a complex condition that is often causally linked to unpredictable life events. The risk factors for regret described here should not be used as reasons for restricting access to sterilization. Instead, they should be used to identify persons who may need extensive counseling. Presterilization counseling has been shown to correlate with poststerilization satisfaction.

Poststerilization regret can arise from several factors, including preexisting patient characteristics, subsequent changes in the patient's social situation or attitudes, and dissatisfaction resulting from adverse side effects caused or perceived to be caused by the procedure. Estimates of the prevalence of sterilization regret vary widely by measure of indication of regret and geographic region. During the last two decades, US-based studies have reported rates of poststerilization regret ranging from 0.9% to 26.0%. The wide range reflects, in part, differences in study design and questions asked of respondents. In general, the likelihood of a woman expressing regret after sterilization appears to increase over time. In the US Collaborative Review of Sterilization, the cumulative probability of regret increased from 4% at 3 years after sterilization to 8% at 7 years and 13% at 14 years. The 5-year cumulative probability of regret after tubal sterilization (7%) was similar to that for women whose husbands underwent vasectomy (6%).

In the 1982 National Survey of Family Growth, approximately 10% of women who had been sterilized reported that they would have the sterilization reversed if it were safe to do so. In the US Collaborative Review of Sterilization, 14% of sterilized women reported that they had sought information about tubal reanastomosis at least once within 14 years of sterilization; only 1% actually obtained a reversal.

At least five studies have identified young age at sterilization as the strongest predictor of later regret of sterilization. In the US Collaborative Review of Sterilization, young age at sterilization also was a strong predictor of regret, regardless of parity or marital status. After adjusting for other risk factors, women 30 years of age or younger at sterilization were about twice as likely as older women to express regret within 14 years of sterilization. Similarly, the cumulative probability of expressing regret within 14 years was 20% for women 30 years old or younger versus 6% for women older than 30 years at sterilization. Likewise, the 14-year cumulative probability of requesting information about reversal was 40% among women sterilized at 18 to 24 years of age, and, after adjustment for other risk factors, women 18 to 24 years old were almost four times as likely as women 30 years old or older to request information about reversal. Although low parity has been identified as a risk factor for regret in some studies, it was not an independent risk factor in other studies after control for factors such as young age at the time of sterilization. The US Collaborative Review of Sterilization also found that women identifying substantial conflict with their husbands or partners before sterilization were more than three times as likely to regret their decision and more than five times as likely to request sterilization reversal.

Timing of the procedure in relation to pregnancy has been reported as a risk factor for regret. Several studies found that women who had tubal sterilization concurrent with cesarean section or following vaginal delivery or abortion were more likely to regret sterilization, but studies have been inconsistent in this regard. In the US Collaborative Review of Sterilization, the 14-year cumulative probability of regret was nearly identical for women whose sterilizations were concurrent with cesarean section (16%), after vaginal delivery (18%), and within 1 year of pregnancy (18%). The probability of regret decreased with time since the birth of the youngest child; women with 8 or more years since the birth of the youngest child had a probability of only 5%, a rate similar to that for women with no previous births (6%).

In summary, indicators of regret can vary significantly by cultural and individual circumstances. Most studies

have found that age younger than 30 years is an independent risk factor for regret. The presterilization counseling for women in this age group should place special emphasis on the risk for regret. Other risk factors, such as time in relation to an obstetric event, ambivalence, or unstable life circumstances, should be assessed with each patient on an individual basis.

Sexual Function

In the US Collaborative Review of Sterilization, approximately 80% of women undergoing interval sterilization reported no consistent change in either sexual interest or pleasure in the first 2 years after the procedure. Of women reporting a consistent change, women were 10 and 15 times more likely to report positive changes in sexual interest or pleasure than negative ones.

Cancer

Although there is no evidence that tubal sterilization increases the risk for cancer at any site, studies are inconsistent regarding a possible reduction in risk of breast cancer after sterilization. One large prospective study by the American Cancer Society found that tubal sterilization reduced the risk of breast cancer mortality but only among women sterilized before 1975. It is unclear whether women who were sterilized had rates of screening mammography similar to those of nonsterilized women; thus, women who underwent tubal sterilization may have had greater access to screening services. A retrospective cohort study using data from the Ontario Cancer Registry found a reduced risk of breast cancer incidence among sterilized women, but that study was unable to control for potentially confounding variables. Two population-based case-control studies supported by NIH that did control for

P.594

confounding found no effect of sterilization on breast cancer risk. Thus, at this point, it is unclear whether there is any biologic relationship between tubal sterilization and reduction in risk of subsequent breast cancer.

Several studies have identified a reduced risk of ovarian cancer after tubal sterilization. Hankinson and colleagues reported on the first large prospective cohort study of this relation; the risk of ovarian cancer for women who had tubal sterilization was one third that of nonsterilized women. In a pooled analysis of case-control studies, Whittemore and coworkers found a reduced risk of ovarian cancer after tubal sterilization. Whether the observed reduction in risk of ovarian cancer is a real protective effect or is attributable to some other factor remains unclear. However, there is reason for optimism that reduction in risk of ovarian cancer may be an important noncontraceptive health benefit of tubal sterilization.

VASECTOMY AS A SURGICAL ALTERNATIVE

Some couples who have chosen surgical sterilization for permanent contraception have difficulty in deciding whether vasectomy or tubal sterilization is most appropriate. Although numerous individual- or couple-related concerns can influence the decision, many couples include considerations about safety and effectiveness in their decision making. To assist such couples, we provide a brief overview of the health effects of vasectomy.

In regard to immediate surgical complications, vasectomy is a remarkably safe procedure. Serious morbidity and death are extremely rare. Fairly minor complications, such as scrotal swelling, ecchymosis, and pain, occur in up to 50% of men who have a vasectomy, but these symptoms usually resolve spontaneously within 1 to 2 weeks. Vasectomy generally has been performed through two incisions in the scrotum, one overlying each vas. Hematoma formation occurs in approximately 2% of such procedures; infections occur in less than 2%. In 1985, a new vasectomy technique was introduced, referred to as no-scalpel vasectomy. It reduced the already low rate of minor complications. In most reports, pregnancy rates after vasectomy are less than 1%. Unlike tubal sterilization, vasectomy is not immediately effective. Three months are required to flush the vasa of viable sperm. This should be confirmed by a postvasectomy semen analysis at 3 months or more after the procedure.

In 1978, questions about the long-term health effects of vasectomy were raised when an increased risk for atherosclerosis was found among monkeys that had had a vasectomy. At least nine subsequent epidemiologic studies in men found no such increased risk, and later findings in monkeys did not support an increased risk. Thus, vasectomy does not affect the risk for subsequent cardiovascular disease. These studies also provided strong evidence that vasectomy does not increase overall mortality. More recently, questions were raised about the risk of prostate cancer after vasectomy. A 1998 metaanalysis of 14 observational studies concluded that the evidence for an association between vasectomy and prostate cancer was of low quality because of biases that overestimate the effect of vasectomy and that any association is likely not a causal one. Subsequently, a large population-based study in New Zealand found no relation between vasectomy and risk of prostate cancer. Thus, the evidence to date argues strongly against any causal relationship.

Questions remain regarding a potential syndrome of postvasectomy pain. The purported syndrome has been varyingly defined as chronic testicular, epididymal, or scrotal pain, and the proposed causes include epididymal congestion, nerve entrapment, and sperm granulomas. Although a few small, uncontrolled surveys found rates of such pain as high as 2% to 15%, the largest and best study found the incidence of epididymitis-orchitis more than 12 months after vasectomy to be 24.7 per 10,000 person-years versus 13.6 per 10,000 person-years among men who did not undergo vasectomy. Although uncertainties remain, it is likely that a small percentage of men will indeed experience chronic pain after vasectomy. It appears, based on limited information, that many such men will respond to conservative measures and that surgical management, including vasectomy reversal, may help others.

BEST SURGICAL PRACTICES

- Preprocedure assessment and counseling are essential elements in a successful sterilization procedure. Counseling regarding failure rates, risks, and risk factors for later regret should be performed. Preprocedure cytologic screening and day-of-surgery pregnancy testing are encouraged if indicated.
- General anesthesia is the leading cause of death from tubal sterilizations in the United States. Although tubal sterilizations can usually be performed safely under local anesthesia, general anesthesia is used more often in the United States. One of the reasons that vasectomy is safer than tubal sterilization is that general anesthesia is rarely required.
- A major portion of morbidity and mortality associated with laparoscopic methods of sterilization is related to entry into the abdominal cavity. Open laparoscopy can reduce the incidence of major vascular injury at entry. In closed laparoscopy technique, meticulous attention to details of entry can help reduce injury. Hysteroscopic sterilization eliminates both the need for general anesthesia and the risk of abdominal entry.
- With all the techniques of tubal sterilization, success is dependent on correct identification of the tube; hasty tubal identification, without taking the time to follow the tubes out to their fimbriated ends (if not distorted by adhesions), can result in procedural failure.
- Nearly all the techniques of tubal sterilization involve the isthmic portion of the fallopian tube, which is the narrowest and most uniform caliber portion of the extramural tube. However, it is suggested that 2 cm of the isthmic portion of the tube be left at the cornu, proximal to the site of tubal interruption, to theoretically reduce the incidence of tuboperitoneal fistula. Aggressive overtightening of ligatures, just as avoided in surgical technique elsewhere in the body, should likewise be avoided at the time of tubal interruption, as strangulation and necrosis of the tube can lead to fistulization and failure rather than success. Ligatures applied during partial salpingectomy methods of sterilization (e.g., Pomeroy, Parkland) at the time of cesarean delivery are at risk of dislodgement by shearing forces when the uterus is repositioned into the abdominal cavity at the end of the procedure. Care should be exerted to protect the ligated areas as one and then the other adnexum is replaced into the abdomen.

- Laparoscopic unipolar coagulation of the fallopian tube is one of the most successful methods of sterilization, likely attributed to the approximately 5-cm zone of thermal destruction that results. However, the risk for thermal injuries is also highest with this method, unless the safe application of unipolar energy at laparoscopy and the concept of capacitive coupling are understood by the surgeon. Greater tubal destruction and sterilization success with this method go hand in hand with least likelihood that reversal could ever be achieved.

P.595

- Laparoscopic bipolar coagulation creates a smaller zone of thermal injury (approximately 3 cm) than unipolar and is also not likely to result in indirect thermal injury by capacitive coupling. Three contiguous burns over a 3-cm length of tube, beginning approximately 3 cm from the cornu and moving toward the fimbriated end, are recommended. Also recommended are the use of the cutting waveform, delivering at least 25 W of bipolar energy (continuous waveform by default), and the use of an optical flowmeter to estimate when coagulation (and flow of current) is complete.
- Silastic band application requires familiarity with the applicator and the tendency of its grasping tongs to transect the fallopian tube when trying to retract a knuckle of tube into the hollow applicator cannula. Tethered or thickened tubes are at greatest risk of transection, and an alternative method should be considered. A complete encirclement of the tube by the grasping tongs is necessary if a partial or tangential application of the ligating band is to be avoided.
- Hulka and Filshie clips are reliable methods of tubal interruption but require strict adherence to surgical technique to be successful. Application at right angles to the tube, 2 cm from the uterus, without excessive tubal elevation, and with the tips of the clips advanced onto the mesosalpinx are the key points of the application. Clips are associated with minimal tubal destruction (3 mm) and are therefore the most amenable to tubal reversal.
- Essure microinserts are placed transcervically via hysteroscopy. Care should be taken to create sufficient distention to identify both tubal ostia clearly and to insert the device into the proximal lumen to the level marked on the catheter. Hypervolemia should be avoided, and a confirmation HSG must be performed at 3 months postinsertion. Alternate contraception should be used until occlusion is documented.

Chapter 28

Surgery for Benign Disease of the Ovary

Joseph S. Sanfilippo

John A. Rock

DEFINITIONS

Accessory ovary—An additional ovarian mass close to the normally placed ovary and connected to it by the utero-ovarian or infundibulopelvic ligament.

Fertility preservation prior to cancer therapy—Affording the patient prior to provision of chemoradiation therapy a host of options that provide for ovarian tissue, embryo, or oocyte cryopreservation as well as surgical procedures designed to protect the ovaries from radiation therapy.

Fimbria ovarica—The structure attaching the infundibulum of the fallopian tube to the distal pole of the ovary. It is vitally important to the fimbrial ovum capture mechanism.

Malpositioned ovary—An ovary located above the pelvic brim because of a lack of normal descent into the pelvis. It may be elongated, but it remains attached to the uterus by the utero-ovarian ligament and to the fallopian tube by the fimbria ovarica.

Ovarian cortex—The outer layer of the ovary consisting of an outer zone, which is mainly collagenous (tunica albuginea), and an inner zone, which is less fibrous and more cellular and contains the germ cells (primordial follicles).

Ovarian medulla—The inner region surrounding the hilum of the ovary. It contains no follicles, only blood vessels and the remnants of the tubular structures that are homologous to the male testis (rete testis).

Ovarian remnant—Persistent ovarian tissue unintentionally left behind following oophorectomy.

Prophylactic oophorectomy—In genetic mutation carriers, that is, BRCA1 or BRCA2, removal of both ovaries upon completion of childbearing in an effort to minimize chance of ovarian cancer.

Residual ovary—Symptomatic ovarian tissue following removal of the ovary.

Supernumerary ovary—An additional ovary that has no direct or ligamentous connection with a normally placed ovary. It is located at a distance from the normally placed ovaries.

Tumor markers—Substances identified in higher than normal amounts in blood, urine, or body tissues of patients with specific malignancies. They are produced directly by the tumor or as a response to the presence of cancer, that is, indirect marker.

Tunica albuginea—Condensed ovarian stroma that forms a fibrous capsule.

Evaluation and management of benign disease of the ovary continues to unfold with new and challenging clinical alternatives. Progress has occurred with regard to understanding the genetics of ovarian function, new surgical approaches to ovarian disease, and a host of knowledge that clinicians should be aware of. The population is living longer, and cancer survivors are increasing exponentially. All of this leads us to focus on enhancing our understanding of preservation of ovarian function; expanding the potential for conception, which includes determining treatment related to decreased postoperative adhesion formation; and addressing an array of other aspects related to ovarian activity.

It has been established that the ovaries and fallopian tubes are sensitive to ischemia from surgical trauma; adhesions may develop as a result; the normal anatomic relationship between fallopian tubes, ovaries, and uterus may be altered. Knowledge regarding anatomy and embryology of the ovaries and other reproductive organs complemented by mastery of the principles of microsurgery that can be applied to virtually any surgical procedure are the prerequisites for excellent results following ovarian reconstructive surgery. Embryology and anatomy are addressed in this chapter with emphasis on the importance of the anatomic relationship of the ovary to other pelvic organs in the section on the evaluation and management of an adnexal mass. State-of-the-art surgical procedures—both via minimally invasive, robotic-assisted and laparotomic approaches and techniques devised for the reconstruction of the ovary—for restoration of normal pelvic anatomy are presented in the context of specific pathology or other abnormal conditions that require surgical intervention. This chapter also focuses on pediatric and adolescent gynecologic surgical procedures that are performed when ovarian

EMBRYOLOGY

The reproductive system is derived from mesoderm. The primordium of the urogenital ridge is divided into two segments. One is the nephrogenic ridge, that is, metanephros derivatives, the renal system; the other is the gonadal ridge for development of the reproductive tract. Gonads are a reflection of three origins: mesothelium, mesenchyme, and primordial germ cells. The paramesonephros gives rise to the fallopian tubes and the uterus. Two gonadal ridges arise early in gestation (4 to 5 weeks) in the

P.598

developing embryo as thickening on the medial aspect of the coelomic cavity adjacent to the mesonephros. These gonadal outgrowths are composed of coelomic epithelium and underlying mesenchyme projecting into the future peritoneal cavity. The epithelial and mesenchymal cells of the gonadal primordia are of mesodermal origin (large, spherical ovoid germ cells that originate extragonadally in the wall of the yolk sac and migrate to the developing gonads). Until the 6th week of gestation, the gonads of the two sexes remain morphologically indistinguishable. The presumptive ovaries remain undifferentiated until the onset of meiosis at the end of the first trimester. The ovarian cortex is a single germinal epithelium. The tunica albuginea lies beneath the cortex and is composed of connective tissue. The stroma is composed of fibroblasts, smooth muscle, endothelium, and interstitial cells, including undifferentiated theca cells and corpora albicans.

Sexual differentiation requires initiation by various genes, along with a single gene determinant on the Y chromosome (testis-determining factor), which is necessary for testicular differentiation. In XX individuals (in the absence of a Y chromosome), the bipotential gonad develops into an ovary.

The mechanisms responsible for gonadal sex differentiation are largely unknown. Investigators have theorized the presence of a testis-determining factor (H-Y cell-surface antigen on the short arm of the Y chromosome) that is elaborated by a specific gene. Meiosis-inducing and meiosis-preventing substances, both of which are produced by cells derived from mesonephric structures adjacent to the gonad, are the agents of regulation of ovarian and testicular germ-cell differentiation. The balance between these two substances varies between the two sexes and at different stages of development. The meiosis-inducing substance predominates in the fetal ovary. Maternal ovarian hormone production is not required for differentiation of the germ cells or, apparently, for later development of the fetal reproductive tract. Various ultrastructural studies have shown no specific changes in fetal granulosa cells that can be definitely associated with steroid hormone secretion such as is identified in the fetal Leydig cells. Thecal cells play an essential role in steroid synthesis in the adult ovary, but they do not appear until later in gestation and even then retain a relatively undifferentiated appearance. Fetal pituitary gonadotropin production begins as early as 10 weeks gestation and reaches peak levels at midgestation. Gonadotropins have a major influence on follicular development in the adult ovary, but evidence for a similar function in the fetus is lacking.

GENE EXPRESSION

Understanding of the genetics of the ovary continues to evolve. With the advent of polymerase chain reaction (PCR), real-time PCR, fluorescence in situ hybridization, single nucleotide polymorphism, and a host of other genetic advances, understanding of ovarian function has reached a new level (**Fig. 28.1**). **Table 28.1** provides information regarding genes and associated phenotype.

Genes often are associated with specific clinical problems, for example, Kallmann syndrome, a genetic condition that results in the failure of pubertal development. Hypogonadism associated with a total lack of sense of smell (anosmia) or a heavily reduced sense of smell (hyposmia) characterizes the syndrome. Premature ovarian insufficiency (POI) is characterized by hypergonadotropic hypogonadism, which equates with the loss of ovarian function before age 40. The problem of POI overall is associated with a host of gene defects, all of which set the stage for genetic testing in patients in the reproductive age group with amenorrhea in association with hypergonadotropic state. Genes are also involved with cumulus expansion (GDF9 and BMP15) and endometriosis, and most recently serve as predictors of oocyte quality and successful embryo implantation and development. Specific follicular cell receptors bind growth factors, which are locally synthesized with the ultimate effect of intracellular signaling and protein kinase activation. This activity affects transcription of targeted genes. Gene expression is involved in follicle development, ovulation,

P.599

and corpus luteum and corpus albicans formation. Transcription factors include protooncogenes, c-Myc, and

CCAAT/enhancer binding protein.

TABLE 28.1 Gene Mutations and Ovarian Activity

Bone morphogenetic protein receptor 1 beta (BMPR 1Beta)	Ovarian dysfunction
Fibroblast growth factor beta (FGFBeta)	Kallmann syndrome (KAL2)
Fragile X mental retardation 1 (FMR1)	Premature ovarian insufficiency
Kallmann syndrome 1 (KAL1)	Hypogonadotropic hypogonadism and insomnia X-linked Kallmann syndrome
Premature ovarian failure 1 beta (POF1Beta)	Hypergonadotropic, primary amenorrhea (POF2Beta)
Prokineticin receptor 2 (PROKR2)	Kallmann syndrome (KAL3)

FEMALE FETAL DEVELOPMENT

The ovarian surface cortex, during the early prefollicular stage, is characterized by germ cells and granulosa cells organized in cords and sheets, but the cortex lacks specific conformation. The final distinctive change to occur in the fetal ovary is the onset of meiosis at the 11th or 12th week of gestation. Meiosis is preceded by differentiation of primitive germ cells into actively dividing mitotic cells called *oogonia*. The mitotic divisions of the oogonia are associated with complete separation at telophase, leaving the daughter cells connected by intracellular bridges. After a series of mitotic divisions, there is progressive entry of cells into meiosis, beginning in the innermost cortex and gradually extending to the periphery. These cells passing through the various stages of the first meiotic prophase are then designated *oocytes*. By late gestation, all surviving oocytes have advanced to the diplotene stage. Further differentiation of the oocytes is arrested at this stage and does not resume until ovulation begins at menarche, approximately 12 years later.

Follicular formation begins at 18 to 20 weeks gestation and continues throughout the remaining weeks of fetal development.

All the surviving oocytes are surrounded by adjacent granulosa cells; oocyte and follicular growth are well established by the late fetal and early neonatal period. The constant degeneration and loss of oocytes before their incorporation into the follicles reduces their numbers to only 1 to 2 million (follicles) in the newborn ovary.

ANATOMY

The dimensions of the adult ovary vary from individual to individual but average 3 to 5 cm in length, 2 to 3 cm in width, and 1 to 2 cm in diameter, with a weight of 3 to 8 g. The ovarian capsule is smooth in childhood, but its surface becomes pitted from follicular maturation and atresia.

The size, shape, and position of the ovary in the pelvis are somewhat variable, and both the consistency and the follicular changes taking place within the ovary vary with stage of the menstrual cycle. The ovary typically is anchored to the sidewall of the pelvis in the shallow peritoneal fossa of Waldeyer formed between the angles of proximity of the ovary to the ureter. This knowledge is important before dissecting the ovary off the pelvic sidewall.

The ovary is connected to the uterus by the utero-ovarian ligament, to the posterior aspect of the broad ligament by the mesovarium ligament, and to the lateral pelvic sidewall by the infundibulopelvic ligament (**Fig. 28.2**). The

P.600

mesovarium ligament attaches to the mesentery of the ovary. The other two ligaments are attached at the hilum of the ovary.

FIGURE 28.2 Normal anatomy of the ovary. **A:** Anatomic relations of the uterus, tube, and ovary. **B:** The infundibulum of the oviduct extends onto the ovary and is attached at its most distal pole (ovarian fimbria). The mesovarian suspends the ovary. Each ovary is attached at the hilum.

The ovary migrates downward from high in the abdomen during embryonic life. The infundibulum of the fallopian tube extends onto the ovary and is attached to it at its most distal pole by the fimbria ovarica. The relation of the ovary to the fimbria ovarica and to the utero-ovarian ligament is crucial, and they should be carefully maintained during ovarian reconstruction.

During embryogenesis, the ovary may assume an unusual appearance (i.e., it may be septate) or assume an unusual position (**Fig. 28.3**). An accessory ovary (**Fig. 28.3A**) usually is close to or is connected to a normally placed ovary. An accessory ovary also may be attached to the broad, utero-ovarian, or infundibulopelvic ligaments. Unlike the accessory ovary, a supernumerary ovary (**Fig. 28.3B**) must have an independent embryologic origin. It may develop from a primordium such as arrested migrating gonadocytes. A supernumerary ovary consists of typical ovarian tissue but has no direct or ligamentous

connection with a normally placed ovary. A supernumerary ovary is thus a true third ovary that has independent function and is located at a point that is distant to a normally placed ovary. Ovarian malposition (Fig. 28.3C) also may occur when the ovary fails to descend into the pelvis to assume its normal location. In ovarian malposition, the ovary is attached as it should be to the uterus by the utero-ovarian ligament and to the fallopian tube by the fimbria ovarica, but it may lie adjacent to the liver or spleen. The ovary is elongated and may measure up to 15 cm in length. The fallopian tube attaching to such a malpositioned ovary may be 20 to 26 cm in length, almost twice its normal length.

The normal ovary has a surface covering composed of a single layer of flattened, germinal epithelial cells. This layer is contiguous at the ovarian hilum, with the peritoneal epithelium of the posterior leaf of the broad ligament. Beneath the germinal epithelium is a second layer of condensed ovarian stroma that forms a fibrous capsule, the tunica albuginea. The area through which the vessels and nerves enter and exit is the hilum of the ovary. Immediately around the hilum and extending into the substance of the ovary is an area known as the medulla, which is covered by the cortex. The medulla is composed of fibrous tissue unlike the condensed stroma of the ovarian cortex. The medulla contains no follicles; it has only blood vessels and the remnants of the tubular structure that would have developed into a testis (i.e., the rete ovarii) had the fetus been male.

The ovarian artery arises from the renal arteries. The artery descends from the aorta and crosses the ureter obliquely to enter the infundibulopelvic ligament on its course to the ovary. When it reaches the broad ligament, the ovarian artery branches to supply the fallopian tube and ovary before it finally anastomoses directly with the uterine artery to form a continuous arcade in the broad ligament. The ovarian veins are situated mainly in the mesosalpinx, where they give rise to the pampiniform plexus. At the outer end of the broad ligament, this plexus coalesces to form a single, large ovarian vein. The ovarian vein runs adjacent to ovarian artery to terminate in the inferior vena cava on the right and the renal vein on the left.

The lymphatic vessels of the ovary drain in three directions. The main group accompanies the ovarian vessels in the infundibulopelvic ligament and eventually reaches the periaortic nodes in the vicinity of the kidney. Other lymphatic channels communicate with channels of the opposite ovary by crossing the fundus of the uterus through the ovarian ligament. Some channels drain through the ovarian and round ligaments into the superficial inguinal lymph nodes in the groin. The ovary is supplied by both motor and sensory parasympathetic and sympathetic nerves,

P.601

which accompany the ovarian vessels from the abdomen as they pass into the infundibulopelvic ligament to reach the hilum of the ovary. The segmented nerves supply the ovary from T10 and T11.

FIGURE 28.3 Ovarian anomalies. **A:** Accessory. **B:** Supernumerary. **C:** Malpositioned.

ADNEXAL MASS

The uterine adnexa (gynecologic origin) consist of the ovaries, the fallopian tubes, and the uterine ligaments. Although adnexal pathology often involves one of these structures, contiguous tissue of nongynecologic origin also may be involved. Adjunctive diagnostic techniques such as sonography, magnetic resonance imaging (MRI), and computed tomography (CT) may help delineate the nature of adnexal enlargement. Pelvic ultrasonography, especially three dimensional, is an accurate means of determining the location, size, extent, and consistency of pelvic masses and is also useful for detecting obstructive uropathy, ascites, and metastasis. Other more specialized diagnostic procedures also may be necessary for the evaluation of an adnexal mass ([Table 28.1](#)).

Computed tomography scanning has been particularly useful in gynecologic oncology because it helps define the extent of paracervical and parametrial involvement and allows a reasonable determination of the resectability of malignant neoplasms. Magnetic resonance imaging has surpassed CT in the precision of measurement of adnexal masses. Magnetic resonance imaging also allows a clear definition of the relationship of adjacent organs.

In a study conducted by Timmerman and coworkers, assessment was made of the use of both ultrasound and circulating levels of CA-125 antigen. Multivariate logistic regression analysis algorithms were used to distinguish benign adnexal masses from a malignant process. Transvaginal ultrasonography with color Doppler imaging was recorded in the 191 patients evaluated, aged 18 to 93 years. Of interest, 26.7% of the cohort of patients studied had malignant tumors. The authors believed that regression analysis could be used to accurately discriminate malignant from benign adnexal masses preoperatively.

An intriguing aspect of ultrasound assessment is the prediction of malignancy in adnexal masses using an artificial neural network. Taylor and colleagues reported generating a neural network algorithm that enabled computing of a probability of malignancy score for preoperative discrimination between malignant and benign adnexal masses. A retrospective analysis that included training in artificial neural network assessing transvaginal B-mode ultrasonography and color Doppler imaging was determined. The variables that were put into the artificial neural network included age, menopausal status, maximum diameter of the neoplasm, tumor volume, and papillary projections. The results identified four primary variables that were most effective in distinguishing benign versus malignant processes. These variables included age, time-averaged maximum velocity, papillary projection score, and maximum tumor diameter. The authors concluded that artificial neural networks are a useful clinical parameter to distinguish benign from malignant ovarian masses.

Surgical intervention ultimately may be necessary to determine the nature of the adnexal mass. Minimally invasive surgery is useful to exclude benign ovarian or nonovarian neoplasms. Indications for visualization and as indicated to obtain a tissue diagnosis of an adnexal mass with laparoscopy or exploratory laparotomy include the following:

- Ovarian mass greater than 6 cm in diameter
- Adnexal mass greater than 10 cm in diameter
- Any solid mass first developing after menopause
- Failure to discover the nature of the mass (e.g., leiomyoma) with radiologic or sonographic imaging techniques

One of the major goals of evaluation of the adnexal mass is to rule out malignancy. There is an age-dependent risk for a malignant adnexal mass. The incidence of malignant neoplasm increases significantly after age 50 years. Increased size of the adnexal mass is associated with an increased risk of malignancy.

Granberg and colleagues found that less than 1% of masses smaller than 5 cm were malignant, less than 11% of masses 5 to 10 cm were malignant, and 72% of masses larger than 10 cm were malignant. Sassone and associates, in an evaluation of women of all ages (mean age 41 years) by transvaginal sonography, found that 3% of masses smaller than 5 cm and 7% of masses 5 to 10 cm were malignant; the incidence of malignancy for masses larger than 10 cm was 13%.

Endometriosis is a common cause of an adnexal mass. An endometrial cyst of the ovary may develop into an endometrioma. Leakage of blood from the cyst may cause peritoneal irritation, pelvic adhesions, and pelvic organ fixation.

Tubo-ovarian inflammatory complex usually is the result of incompletely treated or unresolved subacute, chronic pelvic inflammatory disease (PID) in the walled-off area surrounding the pelvic structure.

Uterine leiomyomata cause nodularity and consequent irregular conformation of the uterus. The uterus may become enlarged

and may present as an abdominal mass. The inability to distinguish a leiomyoma from an ovarian tumor on pelvic examination is an indication for further diagnostic evaluation.

Adnexal enlargement may be the result of carcinoma of the rectum, appendix, or bladder. Patients present with a variety of symptoms according to the organ involved. A complete and thorough evaluation is necessary to delineate the etiology of a neoplasm.

An adnexal mass may be noted in cases of acute abdomen. The differential diagnosis should include adnexal torsion, ruptured hemorrhagic cyst, degenerating leiomyomata, ectopic pregnancy, unruptured tubo-ovarian abscess, acute appendicitis with or without abscess formation, and diverticular disease of the sigmoid colon. A careful history, pelvic examination, and appropriate imaging studies often allow a prompt diagnosis.

Although every adnexal mass requires individual evaluation and management, it is possible to make a number of useful general recommendations. Expectant management is justified only when an asymptomatic physiologic cyst is suspected. Most cysts greater than 6 cm in diameter require a thorough evaluation. Imaging techniques are invaluable for characterizing the nature of the adnexal enlargement, but these procedures do not replace a careful medical history and thorough physical and pelvic examination.

ADNEXAL MASS DURING PREGNANCY

The incidence of adnexal mass in pregnancy requiring surgical intervention has been reported to occur at 1 in 81 to 2,500 pregnancies. When an adnexal mass is noted incidentally on ultrasound during pregnancy, the majority of small, simple cysts do not pose a risk to the pregnancy. Furthermore, most large or sonographically complex masses spontaneously resolve, as reported by Bernhard and colleagues; this study evaluated 18,391 ultrasound studies done in an obstetric population for which 432 women were identified with an adnexal mass. The incidence of adnexal masses was 2.3% in the pregnant population evaluated. In addition, the rate of torsion of the adnexal mass was 1%, and the rate of malignancy was also reported as 1%.

The majority of patients in one other study involving 320 pregnant patients with an adnexal mass were noted to have a simple cyst less than 5 cm, specifically 76%; the cysts were

P.602

more commonly asymptomatic. The remaining patients were noted to have complex cysts greater than 5 cm; of interest, of the complex cysts, 69% resolved spontaneously. The concern always remains regarding the potential for malignancy. Masses with increased blood flow or decreased resistance index and greater than 10 cm or a growth rate greater than 3.5 cm per week were noted to have a higher risk for malignancy.

Hoover and Jenkins addressed the incidence and differential diagnosis, benign cystic teratoma (7% to 37%), serous cystadenoma (5% to 28%), mucinous cystadenoma (3% to 24%), endometrioma (0.8% to 27%), paraovarian cyst (<5%), and leiomyoma (91% to 25%). Ovarian malignancy accounted for 1% to 8%, most of which were low malignant potential (LMP).

Other risks related to adnexal mass in pregnancy include rupture and obstruction regarding labor. Randomized prospective data focused are lacking with regard to pregnant patients with adnexal masses addressed surgically versus expectant management. Complications that include preterm labor and spontaneous abortion must be included in the overall assessment and management. Evaluation of oncofetal antigens includes alpha-fetoprotein, human chorionic gonadotropin (hCG), lactate dehydrogenase, estradiol, and testosterone.

Before operative intervention, a complete assessment of the fetus—including ultrasound to rule out a lethal anomaly and to document cardiac activity—is in order. The optimal time for elective surgery is during the second trimester. The patient should be informed of the increased risk of preterm labor and delivery. The patient should be placed in the left lateral tilt position to avoid inferior vena cava compression and associated uteroplacental insufficiency. Postoperatively, the fetus should be placed on continuous fetal heart rate monitoring.

The most effective approach in the management of adnexal masses during pregnancy remains a point of controversy (i.e., laparoscopy vs. laparotomy). In a series of 88 pregnant women who underwent 93 surgical procedures for suspected adnexal pathology, laparoscopy was performed during the first trimester in 39 patients. The remaining 54 patients underwent laparotomy, 25 during the first trimester and 29 during the second trimester. Neither intraoperative nor postoperative internal complications were reported in the series. Five of thirty-nine women undergoing the first-trimester surgery had a spontaneous abortion. During the first trimester, a Veress needle was used for insufflation, and the procedure was in essence conducted in a manner virtually identical to that in the nonpregnant state (i.e., closed laparoscopy). It was concluded that laparoscopic

gynecologic surgery is safe during pregnancy when conducted in the first trimester.

ULTRASOUND

Ultrasound is useful in predicting malignancy ([Table 28.2](#)). Characteristic features of benign versus malignant neoplasms have been reported. Collated data from studies of ultrasound accuracy in the prediction of malignancy have an average positive predictive value of 74% and an average sensitivity of 88% ([Tables 28.3](#) and [28.4](#)).

Weiner and coworkers have used transvaginal color flow imaging before exploratory surgery to study the impedance to blood flow in women with an adnexal mass. Intramural blood vessels consistently demonstrated low impedance to flow with a pulsatility index less than 1:16 in women with malignant tumors. The sensitivity and specificity of the preoperative pulsatility index in detecting malignant ovarian tumors were 94% and 97%, respectively. Kurjak and colleagues found that vessels with a low resistance index near the center of the mass or within papules or septa were highly correlated with malignancy. Therefore, transvaginal color flow imaging may be a useful clinical tool in the preoperative evaluation of ovarian masses.

Doppler resistance index has been used as a “vascular” scoring system. Color Doppler ultrasonography appears to be a reliable method in presurgically evaluating ovarian neoplasms.

Transvaginal color Doppler sonography has identified the following parameters as useful in determining malignant versus benign ovarian masses: number of vessels detected in each tumor, tumor vessel location (central vs. peripheral), peak systolic velocity, lowest resistance index, mean resistance index,

lower pulsatility index, and mean pulsatility index. Color Doppler signals were detected in 100% of malignant masses and 75% of benign masses, with the difference being statistically significant as reported by Alcazar and associates. Tumor vessel

location appears to be central in virtually all malignant masses. Overall, the receiver operating characteristic curves generated can be used to predict malignant processes. The lowest resistance index was associated with the majority of malignant tumors.

TABLE 28.3 Ultrasound Characteristics of the Ovary

Benign pattern
Simple cyst without internal echoes
Simple cyst with scattered echoes
Polycystic echoes
Polycystic echoes with thick septum
Sessile or polypoid smooth mural echoes
Central dense round echoes
Thin or thick multiple linear echoes
Thin or thick multiple linear echoes with dense part
Malignant pattern
Cystic echoes with papillary or indented mural part
Polycystic echoes with irregular thick septum and solid part
Solid pattern (50%) heterogeneous component with irregular cystic part
Completely solid with homogeneous component
Low impedance to flow (color Doppler)

Three-dimensional ultrasonographic technology has been used to evaluate adnexal masses. Images are dissected in XYZ planes and can be focused especially on areas suggestive of malignancy. Three-dimensional ultrasonography facilitates real-time analysis of acquired image data and allows reassessment of the findings at the time of the original ultrasound. Three-dimensional transvaginal ultrasonographic technology appears to enhance and facilitate morphologic assessment of benign as well as malignant ovarian masses.

The appearance on ultrasound provides clinically useful information. Up to 95% of endometriomas exhibit diffuse homogenous low-level internal echoes. They can vary in appearance to include large cystic and solid components; thus, hemorrhagic cysts must be included in the differential. Teratomas on ultrasound demonstrate hyperechoic nodules with distal acoustic shadowing, often termed a “dermal plug.” Hair and sebaceous contents are visualized as hyperechoic lines and dots, termed a “dermoid mesh.” With regard to cystadenomas, serous are more common than mucinous and the former are noted to have thin septations; occasionally, papillary projections may be noted. Mucinous cysts are multilocular with varying amounts of fluid content; low-level internal echoes with multiple thin septa are commonly noted. Cystadenocarcinoma is characterized by thicker septations, papillary projections greater than 3 mm, and irregular walls. Tumors of LMP demonstrate an “ovarian crescent sign,” equated with a rim of normal-appearing ovarian tissue adjacent to the tumor mass. Vascular mural nodules and papillary projection may be present. Paraovarian masses include paraovarian cysts and hydrosalpinx. Ovarian torsion is associated with a “ground-glass” appearance on ultrasound; a characteristic “whirlpool sign” is consistent with the appearance of vessels coiling in a twisted vascular pedicle on color Doppler studies. The latter may demonstrate arterial or venous flow, only arterial flow, or no flow at all to the torsed ovary.

In addition to the role of Doppler ultrasonography with regard to identifying a malignancy, it is also useful in following the progression or regression of the adnexal mass.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging is a “second-line imaging modality.” It is important that patients fast 4 hours before the planned MRI examination as this limits artifact from bowel peristalsis. Scanning in left lateral decubitus position may be necessary during pregnancy. A body array coil is frequently used over the pelvis in pregnant women undergoing MRI. Gadolinium-based contrast is a pregnancy category C drug.

TUMOR MARKERS

Tumor markers are substances that are identified in higher than normal amounts in blood, urine, or body tissues of patients with specific malignancies. Tumor markers are not unique to malignant processes and can be elevated with benign conditions. Tumor markers are not elevated in every patient with malignancy, especially in the early stages of the disease. Many tumor markers are not specific for a particular type of cancer; therefore, there are limitations to the use of tumor markers.

CA-125 is a tumor-associated antigen to an antibody expressed by approximately 80% of patients with epithelial ovarian cancer. It can be increased by nongynecologic malignancies with involvement of the pleura or peritoneum and by benign conditions that result in ascites. Because of the many medical diagnoses that give false-positive CA-125 results, CA-125 cannot be used for general population screening for ovarian cancer in either premenopausal or postmenopausal women. However, in menopausal women who present with a pelvic mass, CA-125 can help differentiate benign from malignant masses.

Because menopausal women have fewer gynecologic diseases that give false elevation of CA-125, the test is more sensitive and specific in this age group. Several authors have

demonstrated that a panel of assays can improve both sensitivity and specificity in the detection of ovarian malignancies. For example, Soper and associates demonstrated 100% specificity and predictive value for CA-125 with TAG 72 or CA-15-3. **Table 28.5** provides specific markers and their clinical application.

TABLE 28.5 Tumor Markers: Adnexal Masses	
MARKER	COMMENTS
CA-125	80% nonmucinous ovarian carcinomas have elevation of CA-125. Decreasing levels generally indicate response to therapy. Used to identify recurrences.
CEA	Primary use is to monitor recurrence of colon cancer. Oncofetal antigen-Ag complex glycoprotein, 20,000 d associated with plasma membrane of tumor cells. Increased with ovarian cancer and with melanoma, breast, pancreatic, stomach, cervical, bladder, kidney, thyroid, and liver cancer. Inflammatory bowel disease and smoking elevate CEA.
c-Myc	Amplified in 30%-50% of ovarian tumors. The protein is simultaneously overexpressed.
c-MycRA	Associated with aneuploidy in ovarian malignant cell progression.
BRCA1	Associated with mutations of breast tumor-related antigen. BRCA1 tumor suppressor gene has been identified; 63% risk of developing ovarian cancer with positive BRCA1 gene.

TABLE 28.6 Classification of the Adnexal Mass	
GYNECOLOGIC ORIGIN	NONGYNECOLOGIC ORIGIN
Nonneoplastic	Nonneoplastic
Ovarian	Appendiceal abscess
Physiologic cysts	Diverticulosis
Follicular	Adhesions of bowel and omentum
Corpus luteum	
Theca lutein cyst	Peritoneal cyst
Luteoma of pregnancy	Feces in rectosigmoid
Polycystic ovaries	Urine in bladder
Inflammatory cysts	Pelvic kidney
Urachal cyst	Anterior sacral meningocele
Nonovarian	Neoplastic

Ectopic pregnancy	Carcinoma
Congenital anomalies	Sigmoid
Embryologic remnants	Cecum
Tubal	Appendix
Pyosalpinx	Retroperitoneal neoplasm
Hydrosalpinx	Presacral teratoma
Bladder	
Neoplastic

TABLE 28.7 Clinical Findings Suggesting Benign or Malignant Adnexal Mass

BENIGN	MALIGNANT
Unilateral	Bilateral
Cystic	Solid
Mobile	Fixed
Smooth	Irregular
No ascites	Ascites
Slow growth	Rapid growth
Younger patient	Older patient

The clinical findings listed in [Tables 28.5 28.6](#) and [28.7](#) are often helpful in differentiating a malignant from a benign neoplasm. All ovarian neoplasms larger than 6 cm in diameter with a solid component should undergo investigation. The postmenopausal ovary is usually small and nonpalpable. Enlargement of the postmenopausal ovary requires appropriate investigation. Symptoms of ovarian neoplasms usually depend on their size, rate of growth, and position in the pelvis or abdomen. Symptoms may include vague lower abdominal fullness or pressure discomfort. Larger masses rise out of the true pelvis and may cause abdominal enlargement with varicosities and edema of the lower extremities. Most ovarian neoplasms are asymptomatic until they enlarge or affect adjacent organs and structures.

MINIMALLY INVASIVE APPROACH TO AN ADNEXAL MASS

P.605

STEPS IN THE PROCEDURE

Laparoscopic Excision of Adnexal Mass

- Preoperative assessment: Imaging studies and tumor markers as appropriate
- Intraoperative management:
 - Lithotomy position, Foley catheter in the bladder, drape perineum into sterile field
 - Laparoscopic placement of secondary trocar ports
 - Evaluation of the upper abdomen and pelvis
 - Identification of adnexal mass
 - Determine the most appropriate procedure
 - Obtain pelvic washings if appropriate
 - Restore normal anatomy
 - Identify ureter(s) in pelvis
 - If cystectomy, plan resection to preserve normal ovarian tissue
 - If adnexectomy, elevate adnexa; identify, isolate, and secure infundibulopelvic vasculature
 - Divide uterine tube at isthmus
 - Secure hemostasis along mesosalpinx/mesovarium
 - Extirpate adnexa
 - Reduce insufflation, and check for hemostasis
 - Remove adnexa using Endo Catch bag or other techniques for removal

The pelvic (adnexal) mass may be of gynecologic or nongynecologic origin ([Table 28.6](#)). Specific clinical findings are helpful to differentiate a malignant from a benign neoplasm ([Table 28.7](#)). It is important to establish whether the mass is of ovarian origin and to understand that a solid mass causing an ovary to enlarge to greater than 6 cm in diameter should be considered potentially malignant until proven otherwise. The most common ovarian mass is the physiologic ovarian cyst, which is caused by failure of a follicle to rupture or to regress. Physiologic ovarian cysts normally are less than 6 cm in diameter, smooth, mobile, and may be slightly tender to palpation. They usually contain straw-colored fluid and may be associated with menstrual irregularity. Physiologic ovarian cysts smaller than 6 cm usually regress by absorption of the fluid or spontaneous rupture. The premenopausal patient may be managed conservatively over two menstrual cycles. If regression fails to occur over two periods of observation or if enlargement is noted, reassessment is indicated.

Oral contraceptives have been suggested as an alternative treatment for functional cysts. The combination-type oral contraceptives send negative feedback to the pituitary gland to decrease gonadotropin stimulation of the ovary, which causes regression of the cyst. Steinkampf and colleagues noted that the rate of disappearance of functional ovarian cysts was not affected by estrogen-progestin treatment; nevertheless, a patient taking oral contraceptives with an adnexal mass should be thoroughly investigated.

Failure of the corpus luteum to regress (in the nonpregnant patient) may cause development of a corpus luteum cyst. The size of the corpus luteum cyst varies according to the amount of blood contained within the cyst. A large corpus luteum may rupture and cause intraperitoneal hemorrhage. Amenorrhea or irregular uterine bleeding may accompany the development of a corpus luteum cyst. A sensitive pregnancy test, ultrasonography, and laparoscopy can be used to differentiate an ectopic pregnancy from a persistent corpus luteum.

A theca lutein cyst, which may be associated with gestational trophoblastic disease or pregnancy, is the result of luteinization of the ovary by hCG. Many of these cysts are bilateral and multicystic. A reduction in hCG levels usually leads to their spontaneous regression.

Polycystic ovarian (PCO) disease is associated with bilaterally enlarged ovaries with a smooth surface. The ovaries contain multiple follicular cysts; many patients are obese and hirsute and have accompanying anovulation (see below).

Congenital anomalies of the müllerian system and vestigial remnants of the wolffian system are of gynecologic, if not strictly ovarian, origin. Müllerian anomalies should be considered in the differential diagnosis of an adnexal mass. Uterine anomalies with outflow tract obstruction oftentimes are associated with cyclic pain from development of hematometra, whereas an enlarged paraovarian cyst may be asymptomatic.

OVARIAN REMNANT SYNDROME

The ovarian remnant occurs in patients who have had previous oophorectomy with or without hysterectomy. The patient may present with symptoms with or without a palpable mass or with a palpable pelvic mass but no symptoms. Pathologic investigation confirms the presence of ovarian tissue when there should be none.

The ovarian remnant syndrome differs from the residual ovarian syndrome in that with the latter, the ovary is purposely saved, and a pathologic process subsequently develops in the ovary. The ovarian remnant syndrome follows attempted oophorectomy.

Minke and associates demonstrated that devascularization of ovarian tissue can occur with reimplanting on intact or abraded peritoneal surfaces, where it may resume endocrine function. Thus, the authors suggest that great care should be exercised to remove all ovarian tissue, particularly when oophorectomy is performed through the laparoscope.

Ultrasonography remains a valuable tool in establishing the diagnosis of ovarian remnant syndrome. The use of both transabdominal sonography and transvaginal sonography with use of color Doppler identification of the mass acquires information with respect to both arterial and venous flow. This facilitates identification of ovarian tissue.

Symmonds and Petit identified three major factors that may complicate the initial surgery and make it difficult or impossible for the surgeon to ascertain whether all ovarian tissue has been removed: increased pelvic vascularity, which renders hemostasis difficult; adhesions, which distort the anatomy and make dissection difficult; and neoplasms, which also distort the anatomy. The most common preexisting disease is endometriosis, followed in frequency by PID. Patients with ovarian remnant syndrome often present with both pelvic pain and a mass. The quality of the pain varies, often cyclically, and ranges from a sensation of pressure or dull aching to a severe stabbing pain.

The clinical diagnosis of ovarian remnant syndrome can be difficult. A finding of premenopausal levels of follicle-stimulating hormone (FSH) may facilitate the diagnosis. Sonography (especially vaginal) may be of value, and a CT scan or MRI may be useful for defining the physical relation of the ovarian remnant to surrounding structures.

The treatment of choice is adequate excision of the ovarian remnant with removal of contiguous adherent tissue such as pelvic peritoneum, bowel serosa, the underlying involved ligament, and alveolar and vascular tissues ([Fig. 28.4A, B](#)). Excision of ovarian tissue may require a retroperitoneal dissection to define the relation of the ureter to the bowel and ovary.

Magtibay and colleagues addressed the surgical management of patients with ovarian remnant syndrome at the Mayo Clinic. All operations for residual ovary syndrome were performed by laparotomy. Of 186 patients who underwent a wide dissection and removal of the remnant, a moderate risk of bowel, bladder, or ureteral injury was noted; however, 90% of patients had complete resolution or marked improvement of symptoms after surgery.

Laparoscopic excision of ovarian remnant ovaries is feasible. A retroperitoneal approach that allows dissection of the course of the ureters with coagulation and dissection of the infundibulopelvic ligament and the uterine vessels can be accomplished. There is potential for ureteral injury as well as cystotomy and bowel injury.

RESIDUAL OVARY

Based on the clinical circumstance, the gynecologic surgeon should consider the value of ovarian conservation at the time of hysterectomy for benign disease. Some authors have noted the incidence of malignant neoplasm in retained ovaries as a reason for prophylactic oophorectomy, and others have noted

P.606

the presence of “residual ovary syndrome,” characterized by either recurrent pelvic pain or a persistent pelvic mass (sonogram image) ([Fig. 28.5](#)). However, Funt followed 992 patients after conservation of one or both ovaries at the time of hysterectomy and reported that none developed ovarian malignancy, and only 1.4% required subsequent surgical intervention for adnexal pathology. The benefits of preserved ovarian function thus appear to substantially outweigh the risk of subsequent ovarian pathology requiring further surgery. Before surgery, the gynecologic surgeon should discuss the various risks and benefits of bilateral oophorectomy and should encourage the patient to participate in any decision concerning the fate of her ovaries.

FIGURE 28.4 A: Not infrequently, the ovarian remnant may adhere to the bowel and the pelvic sidewall peritoneum. **B:** The ureter must be visualized and its relation to the bowel and ovarian remnant established. This may require development of the pararectal and rectovaginal spaces.

Gonadotropin-releasing hormone (GnRH) agonists have been used to assess response of residual ovaries with chronic pelvic pain followed by surgical intervention to remove the residual ovarian tissue. Resolution of pelvic pain in six treated patients occurred with the analogize GnRH agonist and persisted with surgical extirpation of the ovarian tissue. Suppression of ovarian function by GnRH agonists allows differentiation of pelvic pain caused by residual ovary from other sources and thus should be a prerequisite to surgical intervention.

In a retrospective report of 20 years of experience with residual ovary syndrome in which 2,561 hysterectomies were performed, the incidence of residual ovary syndrome was 2.85%. Thus, 1 in 35 women who undergo hysterectomy with ovarian preservation become symptomatic—that is, they experience pelvic pain often with the presence of a benign cyst. Patients should be counseled preoperatively with respect to the potential for residual ovary syndrome when the initial surgical intervention is anticipated. In addition to chronic pelvic pain, a pelvic mass and dyspareunia include the “cluster of symptoms” that can occur in patients who have undergone previous hysterectomy.

FIGURE 28.5 Abdominal sonogram showing a residual ovary with presumed follicular activity.

P.607

ADNEXAL TORSION

Torsion of the adnexa is an infrequent cause of pain in the lower abdomen. However, torsion is a common gynecologic surgical emergency, with a prevalence of 2.7%. Treatment of adnexal torsion is considered an emergency because peritonitis and death can result. Any portion of the adnexa (tube or ovary) may undergo torsion. It may occur in neoplastic ovaries or as a consequence of hyperstimulation.

The clinical findings of torsion are nonspecific. For this reason, delay in diagnosis and surgical intervention is common. The classic presentation is the acute onset of abdominal pain with clinical evidence of peritonitis and an adnexal mass. However, according to Bayer and Wiskind, the presenting findings in most patients are nonspecific and unimpressive. Torsion is more likely to occur during ovulation or as a premenstrual event associated with increased pelvic congestion; the authors found no correlation between the phase of the cycle and the onset of the symptoms.

Historically, the adnexa usually were removed because some authors suggested that untwisting the adnexa could increase the risk of thromboembolism. This has not been well substantiated. There is growing evidence that unwinding the involved adnexa to observe for tissue reperfusion and viability is safe. Nevertheless, a significant delay in surgical intervention may result in irreversible necrosis, requiring removal of the tube, ovary, or both.

The minimally invasive surgical management of adnexal torsion has been increasing in efficacy. Mage and colleagues found that untwisting the adnexa was possible in most patients in their series, and no further intervention was required. Likewise, Shalev and Peleg demonstrated that laparoscopic detorsion of the adnexa is safe and reliable as a primary treatment of this condition. Thus, the weight of evidence warrants conservation of the adnexa if there is evidence of reperfusion and if significant delay has not resulted in irreversible tissue necrosis. In most instances, detorsion may be accomplished through the laparoscope.

SURGERY OF THE OVARIAN SURFACE

Surgery to remove adhesions or endometriosis from the ovarian surface is not unusual and primarily accomplished via minimally invasive surgery. De novo adhesions or adhesions between the medial surface of the ovary and the broad ligament may be filmy and vascular (**Fig. 28.6A**) and may be excised by fine electrocautery or vaporized with the use of a laser (**Fig. 28.6B**). More extensive adhesions that completely cover the ovarian surface may be thick and avascular (**Fig. 28.6C, D**). The plane of dissection between the broad ligament or pelvic sidewall and the adherent ovarian surface must be developed with care so as not to remove or damage the peritoneum while excising the adhesion (**Fig. 28.6D**). Multiple, small adhesions distributed over the ovarian surface, once coagulated, can be gently removed from the ovary without trauma to the ovarian cortex.

If the lateral aspect of the ovary is densely adherent to the broad ligament, it may be necessary to dissect the ovary free.

Some cases require that a large area of the sidewall or the broad ligament be denuded; reperitonealization can be accomplished with nonreactive absorbable suture material.

Small endometrial implants can be fulgurated or vaporized. The resulting small ovarian defect usually does not require closure. Care should be taken to ensure that the endometriosis is superficial and that the implant is not actually the tip of a large endometrioma within the substance of the ovary.

RECONSTRUCTION OF THE OVARY

Before ovarian reconstruction is begun, it is important that proper mobilization of the ovary be accomplished for reestablishment of normal anatomy. Once complete excision of the involved ovarian pathology has been accomplished, the main objectives of ovarian reconstruction are atraumatic closure of the stroma and cortex and prevention of adhesion formation. The principles for accomplishing this goal include gentle tissue handling, hemostasis, the use of fine (and ideally minimally reactive) suture material, and an effort to “bury knots” for the prevention of adhesions.

The restoration of normal-appearing anatomy is the most logical approach for creating maximal ovarian surface, which facilitates ovum pickup by the fallopian tube. Controversy continues as to whether it is more appropriate to completely excise or lyse paraovarian and peritubal adhesions.

The most important aspect of ovarian reconstruction whether done via laparotomy or with a minimally invasive, including robotic surgical, approach is excellent reapproximation of the cortex with the use of atraumatic techniques, including fine absorbable suture material and minimizing suture exposure on the cortex. On completion of the procedure, intraabdominal lavage should be used, ideally with a physiologic substance such as lactated Ringer solution. Every effort should be made to remove all blood from the peritoneal cavity, preferably with the patient taken out of the Trendelenburg position.

The approach to resection of an ovarian cyst should be planned so as to minimize adhesion formation. The incidence of de novo adhesion formation appears to be decreased when the initial approach is through laparoscopy. The Operative Laparoscopy Study Group assessed the issue of frequency and severity of adhesion reformation and of de novo adhesions after operative laparoscopy. In a multicenter collaborative approach that included early second-look intervention, 68 patients underwent operative laparoscopic procedures, including adhesiolysis as well as ovarian cystectomy. The scoring of adhesions noted during the second-look laparoscopy occurred at nine sites (each ovary, each fallopian tube, omentum, culde-sac, pelvic sidewall, and large and small bowel). The study concluded that adhesion reformation is a frequent occurrence and that de novo adhesion formation occurred less frequently after initial operative laparoscopy.

A number of agents have been advocated for preventing adhesions, including oxidized regenerated cellulose (Interceed [TC7], Johnson & Johnson Medical, Arlington, TX), which is an absorbable barrier that promotes reepithelialization of the affected area. Pagidas and Tulandi compared Interceed with lactated Ringer solution for adhesion prevention. Lactated Ringer solution was as effective as Interceed in decreasing adhesion formation. Haney and colleagues compared oxidized regenerated cellulose with expanded polytetrafluoroethylene (Gore-Tex surgical membrane). The results indicated that expanded polytetrafluoroethylene was associated with fewer postsurgical adhesions. Other agents include sodium hyaluronate carboxymethyl cellulose (Seprafilm). A number of adhesion barriers are currently being evaluated and include Hyalobarrier, SprayShield, Prevadh, and INTERCOAT. Further research may well provide clinicians with an extended armamentarium for adhesion prevention.

Functional Ovarian Cysts

Physiologic cyst enlargement of the ovary may occur as a sequela of failure of either follicular rupture or corpus luteum regression. The latter is termed Halban syndrome. The former has been associated with luteinized unruptured follicle syndrome, in which “intraovarian ovulation” is thought to occur; this is a diagnosis usually established with ultrasound. In general, functional ovarian cysts regress spontaneously; however, they may persist and become symptomatic, reaching dimensions as large as 10 cm in diameter. The obvious and most feasible approach is observation, because most such cysts are

self-limited. The cyst, however, may prove to be a source of continued pelvic pain or may adhere to the posterior broad ligament, producing persistent symptoms. The potential for adnexal torsion always exists with an ovarian cyst.

FIGURE 28.6 Ovarian adhesions. **A:** Filmy adhesions between the medial aspect of the ovary and the pelvic sidewall. **B:** These may be removed with laser or fine electrocautery with use of a quartz or glass rod, respectively, as a backstop. **C:** The ovary may be enveloped by adhesions. **D:** Care should be taken to tent up the adhesions so that the peritoneum is not damaged or incised.

RESECTION OF BENIGN CYSTS

Surgical intervention often is initiated with a laparoscopic approach, which permits completion of fenestration of the nonneoplastic ovarian cyst. The cyst lining is stripped from the remaining “normal ovary,” and ovarian reconstruction takes place. In several series of laparoscopic management of ovarian cysts, a simple follicular or luteal cyst was identified in most patients evaluated for pelvic pain. In a series by Kleppinger, 31 of 64 ovarian cysts were noted to fall into this category.

Surgical Techniques

Laparotomy

An elliptic incision is made through the thin ovarian cortex of a benign cyst (**Fig. 28.7**). The end of the knife handle is then inserted and a plane developed over the cyst wall. Alternatively, fine-needle electrocautery can be used to develop a plane, and microsurgical scissors can be used to separate the cyst wall from the ovarian cortex. Low-power magnification (i.e., surgical loupes) often assists the surgeon in identifying the correct plane between the cyst wall and the ovarian parenchyma. After the cyst wall has been completely separated from its adherent attachments to the thin ovarian cortex, it can be shelled out without rupture. However, even with the gentlest technique, rupture can occur because of the friability of the cyst wall. Before the cyst is shelled out, it is important to pack the culde-sac with moist, lint-free pads so that, if rupture does occur, spillage does not contaminate the pelvic cavity. After the cyst has been removed, the dead space can be obliterated with a purse-string suture of fine-gauge nonreactive material. Alternatively, nonreactive vertical mattress sutures or figure-of-eight, or both, can be placed to approximate the lateral walls of the ovary. The ovarian surface is then neatly reapproximated with a subcortical running suture of fine-gauge nonreactive material (**Fig. 28.7A**). If the cortex is quite friable, it may be necessary to place interrupted fine-gauge sutures to achieve adequate approximation. Some authors advocate leaving the ovary open after cystectomy. To date, there have been no controlled trials evaluating postoperative adhesion formation when the incised

ovarian surface is or is not reapproximated.

In some instances, there is excessive redundant thin cortex, which may present a special problem in ovarian reconstruction. The amount of cortex removed depends on the position of the cyst as well as its overall size. Careful assessment of the ovary is necessary before the initial incision is made. The incision in the ovarian cortex facilitates symmetric reconstruction. The redundant cortex can be removed and the dead space obliterated with an internal closure, with care taken to prevent suture material from penetrating the ovarian cortex. This prevents ischemia and adhesion formation. The infolding technique recommended by Kistner and Patton may result in anatomic distortion and puckering of the ovarian cortex. The

P.609

“baseball” closure allows careful approximation of cortical edges when redundancy is noted ([Fig. 28.8](#)).

FIGURE 28.7 Resection of benign cyst. **A:** Thin-walled ovarian cyst. **B:** An incision is made through the cortex. **C:** A plane is developed by the use of blunt dissection. The inner ovarian stroma may be approximated with a purse-string suture of 5-0 nonreactive material. **D:** The ovarian cortex is approximated with 7-0 nonreactive suture material.

Concern over ovarian surgery via laparotomy has been reported. In an older reference of 36 young women operated on for an ovarian cyst, 45% were noted subsequently to be infertile. The author, Van der Watt, conveyed the importance of not interfering with functional cysts in “normal ovaries,” because resulting adhesion formation could compromise fertility. It was advocated that benign ovarian cysts should not be removed at the time of surgery for other indications unless they are sufficiently large to interfere with tubal function or cause discomfort to the patient.

Minimally Invasive and Robotic-Assisted Surgery Overview

Specific skill levels reflecting both the degree of operator expertise and appropriate instrumentation provide clinicians with four

levels of training. Level I stands for equipment needs and potential surgical procedures for basic operative laparoscopy, including such entities as diagnostic laparoscopy, tubal sterilization, lysis of filmy adhesions, and biopsy. Level II reflects the clinician's ability to perform linear salpingostomy for ectopic pregnancy, salpingectomy, lysis of vascular adhesions, and elimination of endometriotic implants. Level III includes the ability to perform salpingo-oophorectomy, lysis of extensive adhesions (including bowel adhesions), ovarian cystectomy, appendectomy, myomectomy, laparoscopic-assisted hysterectomy, and neosalpingostomy,

P.610

as well as the ability to treat tubo-ovarian abscess and uterine suspension. Level IV includes bowel resection, anastomosis, pelvic lymphadenectomy, presacral neurectomy, tubal reanastomosis, and excision of deep, infiltrating vaginal, paravaginal, and rectal endometriosis.

FIGURE 28.8 Closure of the ovary with a baseball stitch.

A number of principles should be followed as surgeons proceed with the correction of pelvic abnormalities that are amenable to a laparoscopic approach. The first is to restore normal anatomy. Once the ovary is stabilized, ideally with an atraumatic forceps, an appropriately planned ovarian incision can be made to correct the pathology encountered. Every effort should be made not to spill the contents.

Large amounts of irrigation solution should be used. In some instances, the cyst wall can be stripped, electrocoagulated, or vaporized. The ovarian incision can then be either left open to heal by primary intention or reapproximated with sutures with either extracorporeal or intracorporeal suture-tying techniques. When this procedure is completed, the pelvis is irrigated with large amounts of irrigation solution (Ringer lactate), and the patient is taken out of the Trendelenburg position to facilitate removal of any blood products that remain in the peritoneal cavity.

One alternative to suturing is to reapproximate incised segments of ovarian cortex with the use of bipolar coagulation to provide coaptation of the incised segment of the ovary. There is continued debate regarding the use of adhesion prevention materials.

A number of potential pitfalls continue to be of concern in the laparoscopic approach to ovarian lesions. These have been addressed by Seltzer and colleagues and include the following:

- The potential for disruption of an ovarian malignancy
- Whether observation-recommended surgical intervention would be the most feasible alternative
- Potential for increased duration of the surgical procedure if done endoscopically

- Total cost
- Potential for incomplete resection of an ovarian lesion laparoscopically

One can view laparoscopic approach to the adnexal mass based on age. Specifically, in the pediatric patient, problems such as torsion, hemorrhagic cysts, benign neoplasm (e.g., teratoma), as well as oophorectomy have been reportedly addressed via the laparoscope. One advantage over laparotomy is the ability to better visualize the entire lower abdomen and pelvis, including the opposite ovary. In the adult, depending on the clinical circumstance, cyst aspiration, cystectomy, or oophorectomy can be accomplished laparoscopically.

Predictors of clinical outcomes in the laparoscopic management of adnexal mass have been addressed by Havrilesky and coauthors. The authors noted that adnexal mass thought to be benign preoperatively were successfully managed laparoscopically in three fourths of the patients. Adverse events were attributable to concurrent hysterectomy rather than removal of the adnexal mass. Malignancy occurred in 2%, and laparoscopic management was not associated with adverse outcomes.

Concern is expressed for an ovarian neoplasm subsequently noted to be malignant. In a countrywide survey in Austria, Wenzl and colleagues reported on 54,198 laparoscopies; 16,601 were performed for adnexal masses, and 108 cases of ovarian tumors were subsequently found to be malignant. Of the 108 cases, 20 were managed laparoscopically, 22 by immediate laparotomy, and the rest by delayed laparotomy (3 to 1,415 days). The authors concluded that laparoscopic surgery with the finding of an ovarian malignancy is rare: 0.65% of all endoscopic surgical procedures.

The extent of damage to ovarian reserve associated with laparoscopic excision of endometriomas was studied by Ragni and coauthors. A reduced number of dominant follicles, oocytes, embryos, and high-quality embryos were observed in the operated gonad. Fertilization rate and rate of good-quality embryos were similar in operated and control groups. Laparoscopic excision of endometriomas is associated with a quantitative but not a qualitative damage to ovarian reserve.

Robotic-assisted intervention brings a 3D perspective to surgical procedures. Wrist movement of the surgeon at the console provides seven degrees of freedom (movement) and can provide an added dimension to pelvic surgical procedures. Nezhat and coworkers assessed robotic surgical intervention in 15 patients undergoing gynecologic surgery. These clinicians concluded that robotic-assisted laparoscopic surgical intervention had advantages in providing a 3-dimensional visualization of the operative field, decreasing operator fatigue and tension tremor, and added wrist motion for improved dexterity and greater surgical precision. The disadvantages include additional expense and added operating time for assembly (docking) and disassembly (undocking) and the bulkiness of the equipment.

MANAGEMENT OF POLYCYSTIC OVARIAN DISEASE

Signs and symptoms of PCO syndrome (PCOS) begin at puberty. Polycystic ovary is a sign, not a diagnosis. In a consensus meeting held in Rotterdam, the American Society for Reproductive Medicine (ASRM) and the European Society of Human Reproduction and Embryology (ESHRE) agreed that two of the following criteria must be met once other endocrinopathies have been ruled out (i.e., Cushing, adrenal hyperplasia):

- Oligomenorrhea
- Clinical and/or biochemical evidence for hyperandrogenemia
- Polycystic-appearing ovaries on ultrasound

The polycystic ovary may result from a virilizing ovarian or adrenal neoplasm or from congenital adrenal hyperplasia, or it may result from suboptimal hypothalamic-pituitary function at puberty. The exact mechanism for the development of ovulatory failure has been attributed to androgen overproduction and its effect on the hypothalamic-pituitary-ovarian axis.

Stein and Leventhal, during the period 1902 to 1935, noted that a group of women had evidence for what is currently called polycystic ovaries at the time of laparotomy. Specifically, in 1935, Stein and Leventhal reported seven patients with the hallmarks of PCO.

The histologic findings in a polycystic ovary cover a broad spectrum, ranging from the originally described typical "Stein-Leventhal" type of polycystic ovary with a large number of follicular cysts and few atretic cysts in which there is marked stromal hyperplasia and hyperthecosis to a smaller ovary with a few follicular cysts and atretic follicles. The polycystic ovary may exhibit microscopic islands of luteinized thecal cells, that is, hyperthecosis, scattered in the stroma, but usually, there is a

thickened, fibrosed tunica with a large number of cystic follicles beneath this thickened capsule.

Methods of management of ovulation induction include use of clomiphene citrate, controlled ovarian hyperstimulation with gonadotropins-follicle-stimulating hormone, and the option of assisted reproductive technology (ART). With select indications use of metformin, in off-label indication, as management of associated insulin resistance-hyperinsulinemia. Ovarian drilling remains one additional option for management of PCOS in select patients. There are several hypotheses regarding the mechanism by which ovarian drilling (wedge

P.611

resection) of the polycystic ovary resolves ovulatory failure. The theory stating that the fibrous capsule acts as a mechanical barrier to the ovulatory follicle has been refuted. Evidence against this theory consists of the observation that if one ovary is removed, ovulation occurs from the remaining ovary. In addition, the use of clomiphene citrate or letrozole results in ovulation through an intact capsule. Some have stated that neonatal androgens may cause an abnormal hypothalamic-pituitary axis, resulting in abnormal gonadal patterns. This theory is not widely accepted. Neonatal androgen treatment in rats is associated with masculinization of the hypothalamus and with ovulatory failure with polycystic ovaries.

The most popular theory explaining how ovarian drilling results in the resumption of ovulatory cycles notes that the removal of androgen-secreting stroma and theca reduces the amount of abnormal steroid production in the ovary. After wedge resection, there is usually a decrease in the mean level of 17α -hydroxyprogesterone, dehydroepiandrosterone, androstenedione, and testosterone, as well as a transitory decrease in estradiol. This reduction in the steroidogenesis of androgens, allowing normalization of the luteinizing hormone (LH) to follicle-stimulating hormone (LH:FSH) ratio, results in the resumption of ovulatory cycles. Ovarian renin-angiotensin activity is enhanced with PCO. This system—renin-angiotensin—remains unaltered following ovarian electrocautery (i.e., ovarian drilling), even though serum levels of LH, testosterone, and androstenedione decline.

Sex hormone-binding globulin (SHBG) concentrations following electrocautery with PCO have been evaluated. Whereas there were significant decreases in serum androgens and gonadotropins, the concentration of SHBG increased in the serum. Gjonnaess has reported that there is no change with respect to dehydroepiandrosterone sulfate with ovarian drilling. This is indicative of neural alteration in the pituitary-adrenal axis in comparison to the pituitary-ovarian axis.

A consensus (2007) regarding PCOS focused on treatment. The results noted better pregnancy rates with use of clomiphene citrate or clomiphene citrate plus the insulin sensitizer metformin in comparison to metformin alone. They also felt that there is a role for ovarian drilling.

There is some debate as to the amount of ovarian mass that should be removed at the time of wedge resection. Halbe and coworkers attempted to clarify this question by removing different amounts of ovarian cortex and medulla from a random selection of patients with PCO disease. Thirty-eight of sixty-two patients were interested in conception. The 38 patients were divided into three groups, the first of which underwent removal of not more than one fifth of the original ovarian size. The second group had one third of the ovarian mass removed, and the third group had one half to three fourths of the original ovarian size reduced. The resumption of ovulatory cycles was recorded at 53%, 71%, and 91%, respectively. The authors concluded that the best ovulatory rate and the best pregnancy rate resulted after removal of at least half of the ovarian medulla.

The introduction of clomiphene citrate and the oral antihyperglycemic drug and insulin sensitizer metformin has changed the management of PCO syndrome in patients who desire pregnancy. Depending on the clinical circumstance, the conception rate with clomiphene citrate has been reported at 50% to 60%. The incidence of post-clomiphene citrate birth defects (3.1%) is not increased over commonly quoted rates for populations at large. Some patients may not want to accept the risks of multiple births or hyperstimulation with administration of pure FSH or FSH and LH ovulation induction.

Antidiabetic agents have been advocated to reduce insulin resistance with PCO. Metformin has been shown to decrease insulin levels with resultant diminishing of circulating androgens. Hirsutism often improves. Metformin may enhance the efficacy of clomiphene and gonadotropin therapy with PCO. Metformin may also promote weight loss. Baseline and periodic liver function tests are recommended. Metformin is contraindicated with renal or hepatic disease. Patients have shown a response at dosages of 500 mg three times per day.

Surgical Technique of Laparoscopic Treatment of Polycystic Ovaries

Polycystic Ovaries-Minimally Invasive Surgical Approach-Ovarian Drilling

- Lithotomy position, Foley catheter in the bladder, prepped, and draped
 - Laparoscope and secondary ports placed
 - Inspection of upper and lower abdomen
 - With monopolar 20 to 30 W cutting current (or analogous setting for bipolar), vaporize all visible subcapsular follicles
 - Place 2 to 4 mm depth punctures over capsule, caution must be addressed at stroma
 - Place 5 to 10 punctures in each ovary
-

The laparoscopic approach incorporates the use of monopolar cautery with a needlepoint applicator or bipolar cautery to drill holes several millimeters apart through the ovarian cortex (**Fig. 28.9**). Care should be exercised to avoid the hilum because bleeding could result if it is penetrated. It is important to achieve hemostasis over the drilled areas.

The ovarian drilling technique includes a 5-mm second puncture placed suprapubically, through which suction irrigation or grasping of tissues can be performed. All visible subcapsular follicles are vaporized, and a 2- to 4-mm-diameter crater is made randomly in the ovarian stroma. Hemostasis is accomplished with bipolar forceps.

Ovarian coagulation can be accomplished with unipolar electrode. The power setting is 20 to 30 W in a cutting mode. The cortex is usually penetrated at 10 to 15 sites for a depth of 3 to 5 mm. No study has correlated the number of drilling sites and incidence of ovulation or pregnancy. Different studies have recommended 5, 10, or 15 perforations per ovary. In general, 5 to 10 punctures are made in each ovary at a 40-W power setting for each puncture over a 2- to 3-second time frame. Caution is exercised to minimize thermal damage. Smaller ovaries may require fewer cauterization sites.

As noted above, the PCOS Consensus Workshop Group provided support for ovarian drilling in patient's refractory to medical methods of ovulation induction. The procedure has also been termed multiperforation as well as laparoscopic ovarian diathermy. Monopolar and laser techniques have been described.

Overall, ovarian drilling is a second-line treatment for PCOS patients who desire fertility. Benefits of ovarian drilling include low probability of multiple births and avoidance of ovarian hyperstimulation syndrome as is more common with gonadotropin ovulation induction. Preoperatively, patients should be apprised of the potential consequences of ovarian drilling, which include adhesion formation and damage to

ovarian reserve. Incidence of ovulation with ovarian drilling is reported at 70% and pregnancy rates as high as 40% after three monitored cycles.

FIGURE 28.9 Removal of a small ovarian endometrial cyst through the laparoscope. **A:** After incision of the ovarian cortex, the contents of the endometrioma are removed with suction and irrigation. **B:** The plane between the ovary and the cyst wall is developed by using traction and twisting the forceps clockwise. **C:** The endometrial cyst wall is grasped with forceps. **D:** The cyst wall separates from the ovarian tissue by use of a twisting motion. The ovarian defect may be left open to heal by secondary intention or may be closed with vertical mattress sutures. **E:** The cyst wall is removed.

There are no randomized controlled studies addressing the efficacy of the laparoscopic approach to ovarian drilling. Twenty-seven studies were evaluated by Donesky and Adashi and involved a total of 729 patients. The ovulation rate was 84.2%, and the pregnancy rate was 55.7%. These authors emphasized that well-designed studies are needed in this area, which would encompass the PCO population proposed for laparoscopic drilling. This cohort of patients would require a well-documented clinical and biochemical finding of PCO, documented long-standing infertility (2 years or more), evidence for failure of clomiphene citrate, absence or correction of other infertility factors, randomization into a treatment group, and standardized documented follow-up, with particular attention to postovulatory patterns.

As noted above with regard to complications, the major concern is that of adhesion formation after either wedge resection or laparoscopic drilling. Toaff and associates noted extensive peritubular and periovarian adhesions in a small series (seven) of patients who did not conceive after bilateral wedge resection. One other concern is that of bilateral ovarian atrophy as a reflection of aggressive ovarian resection. This is a rare complication of the procedure. Thus, iatrogenic consequences of the surgical approaches must be discussed with the patient preoperatively ([Fig. 28.10](#)).

INCIDENTALOMA

Incidental adnexal masses (incidentaloma) are more common in postmenopausal women with a prevalence of 3% to 18% among asymptomatic women. More commonly, these present as unilocular, benign-appearing ovarian cysts noted on ultrasonographic studies. Overall, 80% resolve spontaneously over several months. Persistent adnexal masses should be assessed which evaluation specific to the clinical circumstance, patient's age, sonographic findings, Doppler studies, etc. Masses greater than 10 cm should have a histopathologic diagnosis.

There does not appear to be consensus regarding methods of ovarian screening among major medical societies; ongoing studies continue to address this question from a cost-effective perspective. This includes use of CA-125 and pelvic sonography.

FIGURE 28.10 Laser drilling of ovary for surgical treatment of PCO disease.

P.613

PARADOXICAL OOPHORECTOMY

Paradoxical oophorectomy is the removal of severely pathologic adnexa to improve fertility in patients with strictly unilateral tubal disease. Consideration of removal of the contralateral ovary when there is single tubal patency (i.e., paradoxical oophorectomy) has perhaps taken on a new perspective with the advent of ART. From a historical point of view, it has been advocated that a patient with one functional tube would benefit from paradoxical oophorectomy, thus ensuring that ovulation would occur repeatedly on the appropriate side. Scott and coworkers reported a series of 24 patients with unilateral tubal patency diagnosed by retrograde injection at laparotomy. Contralateral oophorectomy or salpingo-oophorectomy was performed on all patients, and 16 women subsequently had 21 pregnancies, for a pregnancy rate of 67%. The authors suggested that the frequency with which transperitoneal migration occurs may be a factor. Hallet noted that one in five tubal ectopic pregnancies has a corpus luteum on the contralateral side; Jansen noted an intrauterine pregnancy rate of 18.7% ($n = 91$), contrasted with bilateral salpingostomy for hydrosalpinges in the presence of only one ovary wherein the pregnancy rate was 43.8% ($n = 16$). With unilateral salpingostomy or bilateral division of adhesions, pregnancy rates were comparable to those after bilateral salpingolysis. The mean surgery-pregnancy interval was longer after unilateral salpingostomy (104 weeks) than after bilateral salpingolysis (45 weeks). The author suggested that salpingooophorectomy may be preferable to salpingoneostomy for unilateral hydrosalpinx. With the provision of ART/in vitro fertilization (IVF), the management of tubal obstruction, especially in the absence of a hydrosalpinx, has led to a more conservative surgical approach.

Perhaps the major concern is for the patient who presents with tubal ectopic gestation in which the opposite (i.e., normal-appearing) adnexa appears to be unaffected. The paradoxical salpingo-oophorectomy approach has been advocated with this circumstance by Scott and coworkers. It has been advocated to wait at least 2 years after diagnostic laparoscopy reveals extensive unilateral disease before proceeding with paradoxical oophorectomy. From the other perspective, if the patient plans to proceed with IVF, the presence of two functional ovaries usually results in more oocytes recovered.

Randomized, carefully controlled clinical trials are necessary to further evaluate the efficacy of paradoxical oophorectomy. The risks and benefits must be carefully considered both preoperatively and intraoperatively, especially if the patient is a candidate for ART. There is clear evidence that increased numbers of ova can be recovered when both ovaries are in situ. Increased pregnancy success after superovulation is a reflection of the number of ovaries (one vs. two)—the total number of follicles available for stimulation.

Minimally Invasive Oophorectomy

The general principles of laparoscopic oophorectomy include placing the patient in the Trendelenburg position, with appropriate planning of ports for the proposed procedure and planning for removal of the affected adnexa. Pelvic washings

and use of frozen section may be germane to the task at hand. After restoration of normal anatomy and adhesiolysis as indicated, the adnexa are gently placed on stretch. They are approached from either the infundibulopelvic ligament or the insertion of the round ligament. Regardless of the approach chosen, identification of the ureter is of paramount importance. The infundibulopelvic ligament is identified and coagulated. The broad ligament is incised, beginning at the round ligament, and further dissection is performed into the retroperitoneal space. Every effort must be made to completely remove all ovarian tissue to prevent ovarian remnant syndrome.

With regard to tissue removal, once the adnexa have been completely freed, if benign disease is extremely likely, desiccation of the tissue and thus segmental removal are appropriate. However, if there is concern for the pathology, use of an endoscopic pouch is appropriate. In this circumstance, every effort is made to remove the ovary intact. Careful inspection of the operative site and a check for any bleeding are recommended. In addition, the end-point pressure of CO₂ insufflation should be reduced with suctioning of some of the CO₂ to check for any tamponade effect. As with all laparoscopic procedures, the patient should be monitored after surgery for any signs of intraperitoneal bleeding.

FERTILITY PRESERVATION WITH CANCER

As responses to both medical and surgical therapies continue to result in increasing numbers of cancer survivors, gynecologic surgeons must be kept abreast of current thinking in this field. Cryopreservation of ovarian tissue—nonfertilized, immature germ cells—is receiving increased attention including in prepubertal girls. Medical agents, including letrozole and tamoxifen, have been used prior to cryopreservation in women with breast cancer. Tamoxifen resulted in two to five times higher embryo yield than natural cycle IVF. The best prognosis for fertility appears to preserve gametes before initiation of chemotherapy for cancer. Ovarian transplantation with subsequent embryo generation has been reported after restoration of ovarian function by heterotopic transplantation. Ovarian transplantation remains an experimental technique at this point in time. Ovarian cortical tissue strip retrieval is amenable to a laparoscopic approach. Autologous, orthotopic transplantation after cryopreservation has been successfully used to restore fertility. Ovarian tissue banking and autografting of ovarian cortex are promising therapies for patients with ovarian failure. Kim and coauthors have verified the correlation between ischemic tissue damage and the duration of ischemia. The authors noted the ovarian cortex could tolerate ischemia for at least 3 hours. Thus, it appears that the future of ovarian transplantation depends on the postgrafting ischemia time by effective revascularization techniques.

Specific chemotherapeutic agents are proven to be toxic to the ovary. Resultant amenorrhea and infertility are the consequences. Patient age, drug dose, and dose and extent of disease are contributing factors (Table 28.8).

Fertility-sparing surgery includes oophoropexy-ovarian transposition (Table 28.9 and Fig. 28.11). This procedure temporarily relocates the ovaries as when pelvic radiation is planned. Cancers of the spine and colon and gynecologic cancers may require pelvic irradiation. The procedure of ovarian transposition (Fig. 28.11) can be done via a minimally invasive surgical approach. In general, such procedures reduce the ovarian exposure to radiation by 90% to 95%. On occasion, ovaries have been reported to migrate back to the pelvis.

Ovarian function remains intact in 60% to 89% of patients who undergo radiation therapy, while in the reproductive age, scattering of radiotherapy may account for the failures. Spontaneous pregnancies have been reported following oophoropexy. In addition, access for IVF has been successful in providing pregnancies following ovarian transposition. Complications include pelvic pain secondary to the ovarian relocation.

Tumors of LMP diagnosed in the reproductive age group can be managed, depending on the clinical circumstance, with unilateral salpingo-oophorectomy to preserve fertility (Table 28.9).

TABLE 28.8 Chemotherapy and Medical Diagnosis

AGENT	CANCERS IN THIS CATEGORY
High risk	
Cyclophosphamide	Leukemia lymphoma

Busulfan	
Intermediate risk	
Cisplatin	Breast cancer
Carboplatin	Ovarian endometrial
	Cervical
Low risk	
Doxorubicin	Hodgkin lymphoma
Bleomycin	Lymphoma
Vinblastine	Acute myelogenous leukemia
Dacarbazine	Breast cancer
Anthracycline	Multiple myeloma
Cytarabine	GI tract cancers
Methotrexate	
Dactinomycin	
Mercaptopurine	

Simultaneous administration of gonadotropin-releasing hormone agonists (GnRHa) with chemotherapy has been advocated in women in the reproductive age group but remains an area of controversy, the theory being to prevent or decrease the rate of ovarian damage. This may be more effective in the category of low-risk chemotherapeutic agents; however, there is a paucity of prospective studies assessing the efficacy of simultaneous GnRHa therapy with chemotherapy and ultimate effect on pregnancy rate. Detailed discussion of each option and specific indication is beyond the objective of this chapter. Suffice to say, it is important that patients be apprised of options prior to proceeding with chemo- and/or radiation therapy.

OVARIAN TRANSPOSITION BEFORE RADIOTHERAPY

Lemevel and coworkers reported laparoscopic transposition in a patient being treated for Hodgkin disease before receiving radiotherapy. The ovaries were laparoscopically suspended out of the field of radiation. Iatrogenic menopause did not occur in the four patients for which this was reported. Other authors have reported similar recommendations. Bisharah and Tulandi have recommended transection of the ovarian ligament and transposition of the ovaries without affecting the fallopian tubes. This is associated with positioning of the ovaries laterally and anteriorly at the level of the anterosuperior iliac spines.

Gonads are sensitive to irradiation. Whole-body, abdominal, or pelvic irradiation can cause ovarian damage and adversely affect uterine function. It is estimated that the sensitivity of oocytes to radiation is an LD50 (the lethal dose required to eliminate 50% of the oocytes) of 2 Gy.

FIGURE 28.11 Laparoscopic ovarian transposition. Ovarian ligament (a) and mesovarium (b) are divided. If mobility is inadequate, relaxing incision on peritoneum inferior to ovary (c) may be needed. Final location of ovary is shown (d). (Reprinted from Bisharah M, Tulandi T. Laparoscopic preservation of ovarian function: an underused procedure. *Am J Obstet Gynecol* 2003;188:367. Copyright © 2003, with permission from Elsevier.)

As noted in [Table 28.8](#), cytotoxic drugs are classified as follows:

High risk: Cyclophosphamide, ifosfamide, chlormethine, busulfan, melphalan, procarbazine, and chlorambucil

Intermediate risk: Cisplatin and carboplatin

Low risk: Vincristine, methotrexate, dactinomycin, bleomycin, mercaptopurine, and vinblastine

Attempts have been made to assess ovarian function and “ovarian reserve.” This has included evaluation of ovarian volume, serum inhibin B secreted by antral developing follicles, and antimüllerian hormone, a glycoprotein expressed in fetal tissue and preantral and small antral follicles, but in the adult, when levels are lowered (i.e., in cancer survivors), the ovarian reserve is decreased.

One alternative to oophoropexy is oocyte retrieval, fertilization, and cryopreservation—that is, ART/IVF. Preserving unfertilized oocytes remains an area of increasing success, as technology advances in cryopreservation continues to unfold.

Fertility outcome following ovarian transposition and pelvic irradiation for pelvic cancer has been addressed in a total of 37 consecutive cases by Morice and colleagues. Patients were treated for clear cell adenocarcinoma of the vagina or cervix, ovarian dysgerminoma, and sarcoma. The pregnancy rate was 15% (4/27) in patients attempting pregnancy with clear cell adenocarcinoma of the vagina or cervix. In the dysgerminoma and sarcoma group, 80% pregnancy occurred (8/10). Thus, the prognosis for future fertility following ovarian transposition and irradiation should be considered for discussion in selected patients before radiotherapy. The subject of fertility preservation in cancer survivors has been addressed by the Ethics Committee of the American Society for Reproductive Medicine, the main

focus of which is that physicians should inform cancer patients before treatment of their alternatives and include them in pretherapy discussion of alternatives before initiation of treatment.

PROPHYLACTIC OOPHOECTOMY IN ASSOCIATION WITH INCREASED CANCER RISK

Patients with a personal or family history that leads to assessment of genetic defects that include BRCA1 and BRCA2 mutation carrier status may benefit from prophylactic bilateral salpingo-oophorectomy (BSO), especially if childbearing is completed. No effective ovarian cancer screening exists. Tumor markers that include CA-125 and pelvic imaging done on a screening basis, as noted above, lack sensitivity and specificity. Overall, they are inefficient as a screening tool. Retrospective data support prophylactic BSO and lower occurrence of breast cancer in BRCA1 carriers (OR = 0.44, 95% CI: 0.28 to 1.15). Average interval between BSO and diagnosis of breast cancer was 7.2 years in those affected. The problem of primary peritoneal cancer remains a concern despite BSO. Thus, BSO does not completely eliminate the possibility of ovarian cancer. Primary peritoneal origin is associated with diffuse involvement of tumor on peritoneal surfaces and resembling papillary serous carcinoma of the ovary. This can occur with BRCA1 and BRCA2 mutations after BSO has occurred. Occult either ovarian or fallopian tube carcinoma has been noted at time of prophylactic BSO in 2% to 10% of patients with BRCA1 and BRCA2 mutations. Of note, use of hormone therapy following prophylactic BSO did not alter the reduction in breast cancer risk in BRCA1 and BRCA2 mutation carriers.

OVARIAN CYSTS IN NEONATE AND PREPUBERTAL CHILD

In a retrospective study of 65 fetal ovarian cysts noted by ultrasound, 57% were located on the left, 36% were on the right, and 7% were bilateral. In 17 patients, intervention was required after delivery because of persistence and/or enlargement. The histologic results included follicular cysts in 12 cases, a lymphangioma, and one teratoma; the remaining were amenable to aspiration. The authors, Mittermayer and colleagues, conclude that lack of regression requires intervention in the neonatal period. Ovarian cysts in the neonate greater than 5 cm in diameter have an increased chance of torsion.

Ovarian surgery in the premenarchal girl has been evaluated in a study from the University of Michigan in 52 patients, 50% of whom were less than 1 year old and 31% between 1 and 8 years of age. The most common presentation was abdominal/pelvic mass ($n = 24$), and the postoperative diagnoses included torsion in 18 and malignancy in 5 patients. Histopathologic evaluation included hemorrhagic infarction, dysgenetic gonads, simple cysts, teratoma, theca lutein cyst, fibroma, neuroblastoma, germ-cell tumor, gonadoblastoma, and metastatic Wilms tumor.

A general statement is that pathologic cysts in a newborn are equated with greater than 2 cm. There is no exact guideline for monitoring or management of neonatal ovarian cysts. Torsion of the intrauterine ovary can occur. Other problems to be considered included intracystic hemorrhage, rupture, and dystocia. A complex cyst is equated with increased chance of ovarian vascular dysgenesis or of a neoplasm. In general, neonatal ovarian cysts are predominately benign and self-limiting. There is a frequency of up to 5% of all abdominal masses in the 1st month of life. Overall, the earliest identification of neonatal ovarian cyst formation is 19 weeks of gestation and more often noted at 32 to 26 weeks gestational age.

Aspiration of a neonatal ovarian cyst can be considered if the concern for interference with spontaneous delivery exists. Postnatal percutaneous aspiration of a large ovarian cyst may reduce the rate of torsion and other sequela. Separation of fetal-neonatal cysts into simple versus complex allows the clinician options for management, the former being of less concern. In general, cysts less than 5 cm may be observed especially if they have a simple cyst appearance. Laparoscopic approach and, when feasible, an ovarian cortex-preserving approach are advised, especially when it is thought to be a benign process. Expectant management over a 4- to 6-month period is acceptable especially if the cyst appears to be "simple." Malignancy of the neonatal ovary is rare. In childhood during the second decade, ovarian malignancy becomes of higher probability than in the neonate. In a series from Children's Hospital of Philadelphia reported by Brown and associates, one malignancy in 34 adnexal masses in children less than 8 years of age was noted (2.9%) in comparison to a 33% incidence in children greater than 8 years of age (18 of 58). Treatment options in large part depend on the clinical circumstance, whether the mass is simple, complex, symptomatic, etc. Surgical intervention should include the possibility of minimally invasive approach if feasible.

LAPAROSCOPIC OVARIAN SURGERY IN THE PEDIATRIC OR ADOLESCENT PATIENT

STEPS IN THE PROCEDURE

- In pediatric patient, Crede bladder, prep, and drape abdomen
- Place Veress needle, and introduce 2- to 3-mm laparoscope and secondary ports
- CO₂ is introduced at 0.5 L/min with an end-point pressure of 6 to 8 mm Hg depending on age/size of patient
- In the adolescent, the pressure setting is 10 to 12 mm Hg; depending on age/size of patient, closed or open technique for abdominal insufflation and laparoscope placement is appropriate
- Port closure in the pediatric patient may require use of Steri-Strips
- In the adolescent, skin approximation at secondary ports can be accomplished with sutures

As noted above, a number of gynecologic problems from the neonatal period through adolescence can be addressed laparoscopically. Entities such as ovarian torsion, acute PID (diagnosis and treatment complementing antimicrobial therapy), torsion, and benign neoplasms must be considered in the latter age group. In addition, gonadectomy for problems such as male pseudohermaphroditism is amenable to a laparoscopic approach.

Follicular cysts appear to be of particular concern in both the pediatric and adolescent patient because they present with abdominal pain. An abdominal or pelvic mass can be identified on physical examination. The clinician must always keep in mind

P.616

the importance of appropriate preoperative assessment (with the use of ultrasound and other clinical parameters) in deciding which patients are candidates for operative intervention. Depending on the clinical circumstance, a conservative approach in this age group is advocated; concern must be given (especially in the pediatric patient) to the potential for malignancy with ovarian masses, particularly if a solid component is identified.

The literature attests to operative intervention of ovarian cysts that appear to be nonfunctional. One of these was reported in a 1.5-month-old infant in whom ultrasound showed evidence of an ovarian mass. At laparotomy, the mass proved to be consistent with right ovarian torsion and necrosis, and it required adnexectomy. In one other reported case, a follicular-appearing cyst seen on ultrasound was associated with rapidly progressive virilization and a markedly elevated plasma testosterone level (289 ng/dL); histologic evaluation identified a granulosa cell tumor with mild luteinization.

The feasibility of aspirating an ovarian cyst continues to be controversial. In two case reports, laparoscopic puncture and aspiration of a malignant ovarian cyst were performed. Preoperative ultrasound indicated that the involved adnexal mass had a benign nature. Cytologically negative fluid was obtained from the aspirate. Eight weeks after operation, extensive disseminated ovarian carcinoma was noted at laparotomy.

Endoscopic surgery continues to broaden its horizon with expansion into laparoscopic surgical care beginning with the neonate. The use of 2-mm laparoscopes with the addition of 2- to 3-mm instrumentation has facilitated the diagnostic and therapeutic aspects of laparoscopy in this age group. Miniaturized video camera systems are necessary when one uses the 2-mm laparoscope telescope. When a decision is made to proceed with laparoscopy in a neonate or infant, general endotracheal anesthesia is used. Ideally, prophylactic antibiotics are administered preoperatively. The stomach is emptied with a suction catheter when the patient is asleep, and the bladder is emptied by use of the Crede maneuver. The abdominal wall is thinner and more elastic in the child than in the adolescent or adult. One must take this into consideration when introducing instrumentation, because it may be easier to insufflate in the subcutaneous space of the child than in the subcutaneous space of an adult. A Veress needle can be used with insufflation of carbon dioxide at 0.5 L/min. In infants, the end point of peritoneal-distending pressure should be set at 6 to 8 mm Hg; in the pediatric patient, 8 to 10 mm Hg; and in the older child or adolescent, 10 to 12 mm Hg.

After surgery, the trocar sites can be sutured in children, whereas in neonates and infants, the use of Steri-Strips (3 M, St. Paul, MN) or other wound closure bandages is usually adequate for reapproximation of the incised skin edges. Waldschmidt and Schier reported a series of 136 laparoscopic surgical procedures in neonates and infants. The most frequent indications were lysis of adhesions, abdominal cysts and neoplasms, gonadectomy, appendectomy, and cholecystectomy. A 1,400-g preterm infant was the only one in the series who suffered a complication (hernia at the incision site). Thus, adnexal pathology in this age group appears to be amenable to a laparoscopic approach.

Procedures such as transposition of an ovary before radiotherapy, bilateral gonadal excision in a male pseudohermaphrodite

(i.e., Y-bearing chromosomal analysis), adnexal torsion, suspected salpingitis, and endometriosis all have been identified in this age group. The authors concluded that because the morbidity is low, a laparoscopic approach should be considered.

Although certain procedures in the child do not differ significantly from those in the adult, the early diagnosis of ovarian pathology (e.g., adnexal torsion) can result in a significant advantage in terms of managing the patient and preserving ovarian tissue.

BEST SURGICAL PRACTICES

- Minimally invasive surgery can be used to evaluate and manage ovarian masses ≥ 6 cm and adnexal masses ≥ 10 cm.
- Before operative intervention in a pregnant patient with a symptomatic adnexal mass, complete assessment of the fetus—including ultrasound to rule out any fetal anomalies—is recommended. The optimal time for elective intervention is during the second trimester. The patient should be informed regarding preterm labor and delivery. The surgical procedure ideally is performed in the left lateral decubitus position.
- Transvaginal color Doppler sonographic assessment of ovarian malignant masses includes vessels detected, location of tumor vessels (central vs. peripheral), determination of peak systolic velocity, low resistance index, mean resistance index, and lower pulsatility index.
- The major goal of the evaluation of a pelvic mass is to rule out malignancy. All ovarian neoplasms greater than 6 cm with a solid component should undergo a thorough evaluation to rule out cancer.
- In management of ovarian remnant syndrome, treatment of choice is adequate excision of the remnant ovarian tissue and contiguous adherent tissues: pelvic peritoneum, bowel serosa, and underlying involved alveolar and/or vascular tissues. Retroperitoneal dissection may be required.
- Prior to cancer therapy, whether it be chemo- or radiation therapy, patients should be counseled regarding option for fertility preservation.

Chapter 29

Persistent or Chronic Pelvic Pain

Matthew T. Siedhoff

DEFINITIONS

Allodynia—Pain resulting from a nonnoxious stimulus.

Hyperalgesia—Painful sensation of abnormal severity following noxious stimulation.

Neuropathic pain—Pain persisting after healing of disease or trauma-induced tissue damage.

Neuroplasticity—The malleability of central pain perception mechanisms in response to chronic pain states.

Nociceptor—A nerve receptor for pain.

There is not universal agreement on a single definition of chronic pelvic pain (CPP), but most practitioners accept the proposal of the American Congress of Obstetricians and Gynecologists: noncyclic pain of 6 or more months' duration that localizes to the anatomic pelvis, anterior abdominal wall at or below the umbilicus, or the lumbosacral back or the buttocks and is of sufficient severity to cause functional disability or lead to medical care. We are in need of deeper and updated investigation into the epidemiology of pelvic pain, but likely, at least 15% of women are affected by pelvic pain, most commonly during reproductive-age years. When last tabulated in 1996, it was estimated nearly \$3 billion was spent annually in physician costs and out-of-pocket expenses. CPP accounts for at least 10% of outpatient visits to a gynecologist and is the indication for 40% of gynecologic laparoscopies.

Endometriosis and adhesions are some of the most common conditions assigned as an etiology of pelvic pain, but the connection between these problems and pain symptoms is actually more tenuous than has been traditionally taught. More and more data confirming the coexistence of multiple chronic pain disorders in patients—conditions such as interstitial cystitis (IC), painful bladder syndrome, irritable bowel syndrome (IBS), temporomandibular joint disorder, migraine headaches, vulvodynia, and fibromyalgia—suggest that perhaps we ought to be treating pelvic pain under an updated paradigm where the disease is pain itself rather than pain a manifestation of a specific etiology. In this chapter, we will apply the concept of central sensitization to CPP and point out common peripheral pain generators—nociceptive stimuli—than can be modulated by gynecologic interventions. We will review important elements in evaluation and describe the criteria for a chronic pain syndrome (CPS), offering a theoretical model to explain the evolution of chronic pain over.

HISTORY

Over the past 60 years, the study of CPP has gone through significant changes in approach. Investigations undertaken before the development of laparoscopy focused on correlations between pelvic pain and psychological distress. In the absence of palpable pathology, the gynecologist of the 1950s and 1960s was understandably reluctant to subject a patient to laparotomy to investigate pain. During this era, the prevailing cartesian theory of pain perception suggested that pain should be somewhat proportional to the degree of tissue damage found. Hence, if the pathology was not big enough to palpate, it was seldom operated on. Although this model was sufficient to address most causes of acute pain, it fails to elucidate the majority of chronic pain disorders, in gynecology as well as other areas of medicine. The gate control theory, promulgated by Melzack

and Wall in 1965, allowed integration of physical and psychological parameters and explained how chronic pain can be quite different from acute pain. The model also suggests that information flows in two directions regarding pain: (a) nociceptive signals from peripheral tissue ascend through the spinal cord to higher centers, and (b) central centers can modulate, via descending signals altering spinal cord neurotransmitter and interneuron activity, the transmission of these nociceptive signals from the periphery. Deterioration of these regulatory processes was thought to potentially account for development of chronic pain states by allowing too many peripheral signals to pass through the spinal cord “gates.” Variation in patients’ relative degree of gate opening could thus explain why similar amounts of physical tissue damage result in different degrees of pain perception. The concept is similar to the way we view differences in depth of sleep—for some, the brain can easily filter out stimuli; for others, it takes very little exposure (e.g., light, sound) to overcome unconsciousness and bring about wakefulness.

TABLE 29.1 Contributors to Pelvic Pain in Laparoscopy-Negative Patients

Gastrointestinal
Constipation
Irritable bowel syndrome
Inflammatory bowel disease
Diverticulitis
Urinary
Urethral syndrome
Interstitial cystitis/painful bladder syndrome
Musculoskeletal or neurologic
Pelvic floor tension myalgia
Piriformis syndrome
Nerve entrapment
Ventral hernia
Rectus tendon strain
Myofascial pain

Gynecologic

Pelvic vascular congestion

Cervical stenosis

Reprinted from Steege JF, Stout AL, Somkuti SG. Chronic pelvic pain: toward an integrative model. *Obstet Gynecol Surv* 1993;48:95, with permission. Copyright © 1993 Wolters Kluwer Health.

While these theory changes were stimulating the field of pain research, gynecologists were busy developing laparoscopy. Previously cherished myths soon fell by the wayside: for example, the incorrect assumption that endometriosis is seldom found in adolescents or women of African descent. With these observations came the hope that laparoscopic and medical treatment of encountered pathology would fix CPP. Reports of CPP from that era focused on “laparoscopy-negative” patients; indeed, some pelvic pain clinics required a negative laparoscopy as an entry criterion, implying that if some pathology were found, it must be a “real” cause for pain. Subsequent experience has shown that even though treatment

P.620

of laparoscopically diagnosed pathology is often helpful, the clinical reality is more complex:

1. In many instances, the organic pathology found at laparoscopy may be incidental and not related to the pain.
2. In those with pathology that does contribute to nociception, the pain experienced by the patient may differ from another patient with anatomically similar pathology.
3. Pain from a laparoscopic finding may be the sum of that contribution plus signals from some or all of the disorders listed in [Table 29.1](#).

Consider the research of the 1980s that documented a distressingly high prevalence of physical and sexual abuse. Epidemiologic surveys of community samples revealed that as many as 25% to 30% of adult women reported having experienced sexual abuse during childhood. Studies of women attending pelvic pain clinics, especially those based in psychiatric settings, showed that up to 60% of these women had been abused. These observations led to the speculation that the experience of abuse may make a person more vulnerable to the development of CPP or perhaps be a specific cause for pain. Studies using positron emission tomography and functional magnetic resonance imaging suggest that the experience of abuse may indeed leave its neurophysiologic footprints: stressful stimuli produce different central response patterns in abused versus nonabused subjects. In relation to pain, abuse, particularly that which occurs in formative years, may serve to alter response to nociception and central pain processing. That said, not all abused patients go on to have chronic pain nor do all patients with pain have a history of abuse, so it might be the response to trauma that plays a key role in development of chronic pain. Health care providers need to take into account the presence of abuse in a patient’s history when detected, but be careful to avoid necessarily concluding a causal relationship in that patient’s pain.

Melzack neuromatrix theory is an expansion of his original work that includes the notion of neuroplasticity, among other elements. The concept of neuroplasticity suggests that experience can change the neurophysiologic behavior of the central nervous system in a manner that influences the subsequent processing of nociceptive stimuli. It may explain the apparent development of pain responses to stimuli usually thought of as nonpainful (allodynia), as well as exaggerated responses to painful stimuli (hyperalgesia). Every practicing gynecologist has

seen patients whose pain responses seem out of proportion to the pathology found. This may reflect the emotional meaning of the problem for the patient, as well as past or present trauma, but it may also be the result of nociceptive mechanisms not yet fully understood (e.g., the exact mechanism of pain from endometriosis) or the result of sensitization of spinal cord interneurons that have become pain amplifiers as a result of being on the receiving end of peripheral nociceptive stimuli for prolonged periods. When nociception has been emanating from one organ system for a period of time, adjacent organs may join the chorus. This concept may help explain the common finding of coexistent somatosensory disorders in the same patient, an observation that has led some investigators to pursue potential genetic variations in central neurotransmitter networks that might predispose to the development of multiple such disorders. The above is the negative side of neuroplasticity. The positive side of the neuroplasticity concept is that, perhaps, given enough time and the right treatment, even seemingly intractable chronic pain problems may ameliorate to the point of allowing substantially improved function.

The concept of central sensitization adds another layer to theoretical understanding of chronic pain. This idea emphasizes the ramping up of pain signaling with repeated stimuli over time. The centralized pain hypersensitivity helps us understand how multiple organ systems can be recruited into the syndrome, incorporating genetic and social factors in pain amplification.

CONTRIBUTIONS OF PERIPHERAL PAIN GENERATORS

This section deserves an important caveat. Though we believe that types of tissue damage or other nociceptive input can generate pain, they cannot be viewed in isolation of the patient's individual central pain processing. Management strategies will be discussed in more detail, but, in general, the goal of the treating provider involves trying to dampen overall pain signaling sensitivity—"turning down the master volume"—and looking for areas in the periphery that can be "tuned up" toward better functioning. The following peripheral generators represent areas where we can intervene but should not be described to patients with CPP as *the* cause of their pain. These conditions can be completely asymptomatic in many patients, and thus the host where the disease manifests is much more important than the disease itself.

Endometriosis

A review summarized laparoscopic findings from 2,615 patients in 15 studies (nine retrospective, six prospective). Endometriosis was found in 2% to 51% of patients, suggesting that referral biases lead to very skewed samples. Clearly, not every woman with pain has endometriosis, nor does every woman with endometriosis have pain, although women with the disease had pain more often than those without it. A number of previous studies of CPP described only either patients without visible laparoscopic findings or stratified patients according to the presence or absence of such findings. The description of atypical (nonpigmented) endometriosis by Jansen and Russell in 1986 calls these classifications into question. Laparoscopy studies published before that time reported that 11% of women with CPP had endometriosis, whereas three similarly conducted studies published since 1986 reported a 41% prevalence of endometriosis in women undergoing laparoscopy for CPP. The pre-1986 literature on pelvic pain must be reevaluated with this information in mind. Many studies may have included women with endometriosis in the anatomically normal group, thus generating erroneous conclusions about the entirely psychogenic nature of their pain.

There are a variety of proposed mechanisms explaining pain associated with endometriosis, including inflammatory, nociceptive, and neuropathic. There is no pathognomonic symptom associated with endometriosis. Laparoscopic treatment of endometriosis improves pain symptoms more than diagnostic surgery alone, but many of the symptoms often assigned to the disease (e.g., dyspareunia, dysmenorrhea, abnormal bowel or bladder function) are commonly found in functional disorders such as IBS, making it difficult to understand the relevant contribution of endometriosis to CPP. The severity of the pain correlates poorly with the amount of superficial peritoneal disease, and such implants do not localize to the site of patients' symptoms. Deeply infiltrating

endometriosis (DIE)—fibrotic, vascular, desmoplastic tissue destruction—is an exception to this rule. Nodular disease of the colon is associated with dyschezia and hematochezia; urologic tract disease with hematuria, dysuria, and obstruction; and cul-de-sac disease (uterosacral ligaments, rectovaginal septum, ovarian endometriomas) with deep dyspareunia. Fear of worsened pain, impaired fertility, or recurrent disease after treatment may increase pain levels. Of the women for whom we repeat laparoscopy for recurrent pain following complete hysterectomy and adnexectomy for endometriosis, only a small minority (3% to 5%) prove to

P.621

have recurrent disease. Most cases of continued postoperative pain are interpreted in the context of the patient's overall sensitivity to pain and other peripheral stimuli functioning under that same sensitivity, such as pelvic floor tension myalgia, painful bladder, or functional gastrointestinal disease.

Those experienced in treating the disease can often detect DIE with clinical exam and imaging. When endometriosis is strongly suspected otherwise, and initial treatment with oral contraceptives (OCs) has failed, diagnostic laparoscopy should be the next step. One widely discussed study by Ling et al. concluded that a careful clinical history and physical examination can predict the presence of endometriosis in approximately 80% of cases. However, this was done in the setting of a strict research protocol; the diagnostic sensitivity of this approach in general clinical practice is likely much lower. Unfortunately, the study is often misinterpreted as implying that pain relief following gonadotropin-releasing hormone (GnRH) agonist treatment is not only a sensitive detector of endometriosis but is also *specific*—that is, it makes the diagnosis of endometriosis. Careful reading of the data reveals that this is not the case: the frequency of relief following GnRH treatment was the same in women with and without endometriosis. In addition, pain sensitivity is known to increase perimenstrually even in women without CPP. This may mean that nociception from pain disorders outside the reproductive tract may also improve when menstrual cyclicity is eliminated. For example, IBS symptoms also decline in women taking GnRH agonists. Hence, although *failure* to relieve pain with a GnRH agonist supports the notion that the reproductive organs are not involved, relief of pain with these medications does not prove that they are to blame.

Pelvic Adhesions

Early reviews supported the role of adhesions as a significant peripheral pain generator in CPP. In one, 6% to 55% of the 2,615 patients who underwent laparoscopy for pelvic pain had pelvic adhesions. In more recent investigation, Latthe et al. demonstrated a relatively weak correlation between adhesions and CPP, much less than factors such as psychosomatic symptoms and substance abuse. Correlation, of course, does not imply causality, and few, if any, well-designed studies demonstrate effective treatment of CPP with adhesiolysis. Unfortunately, in an effort to provide some explanation for complex pain disorders, providers often still posit adhesions as an etiology, even when a patient's surgical history includes only laparoscopy with findings of minimal or no endometriosis, pelvic inflammatory disease, or other conditions associated with meaningful adhesions. This explanation can happen even when the patient's pain escalation is remote from the last surgery. Adhesions may play some role in pain conditions in some women, but the relative contribution is probably small. Also, the putative treatment—repeat surgical intervention—can add new contributions to pain syndromes, such as the impact of surgical trauma, disappointment from lack of pain relief, feeding the psychological need of being “ill” with more surgery, and, in the worst case, generating a complication such as enterotomy.

Pelvic Support

Most women in pain clinics are in their third or fourth decade of life, while pelvic organ prolapse affects significantly older women, suggesting a very minimal role for support problems in CPP.

Pelvic relaxation usually leads to reports of heaviness, pressure, dropping sensations, or aching. In attempting to hold in prolapsing organs, the patient may tense the levator plate, leading to tenderness during daily activities and intercourse. Fear of (or actual) loss of urinary control during coitus can add to the discomfort by impairing

physiologic sexual response.

Uterine retroversion is another potential etiology for CPP, particularly in the form of deep dyspareunia. Clearly for many women, retroversion is an innocent anatomic variant, but for those with pain, uncontrolled clinical series of uterine suspension procedures suggest changing the position of the uterus to an axial or anteverted position can improve dyspareunia by elevating a tender fundus out of the posterior cul-de-sac and allowing for better vaginal expansion as a natural part of the sexual response cycle.

Pelvic Congestion

Overfilling (congestion) of the pelvic venous system has been implicated as a cause of dull chronic aching pain that usually is unilateral and worse at the end of the day after prolonged standing, premenstrually, and postcoitally. Some studies suggest the condition is present in nearly one third of women with CPP, but there is no agreed-upon reference standard for diagnosis, despite individual technical regimens involving venography, MRI, and ultrasonography. Hormonal suppression, percutaneous embolotherapy, and surgery (vein ligation, hysterectomy, and salpingo-oophorectomy) represent available treatments, but study protocols involving these interventions are diverse, and few have been investigated in controlled trials.

Residual Ovary

When the uterus has been removed, with or without removal of one ovary, the remaining ovary or ovaries become symptomatic in 1% to 4% of women. Pain from the ovary can be increased by confinement within postoperative adhesions, rupture or leakage of a cyst prompting additional adhesion formation, or attachment of the ovary to the sigmoid colon or vaginal apex by postoperative adhesions. In the case of attachment to the vaginal apex, deep dyspareunia can result when the area is struck.

Ovarian Remnant

A more difficult situation can develop if a small fragment of ovarian tissue is left behind during attempted oophorectomy. In most instances, this happens when challenging dissection is required, such as cases of extensive pelvic adhesions and/or DIE. Within 1 to 3 years of the attempted oophorectomy, continued folliclestimulating hormone (FSH) stimulation will result in growth of the ovarian fragment, often producing an intermittently symptomatic pelvic mass located along the course of the ovarian vascular supply. A postulated mechanism for pain generation includes the cystic enlargement of the mass confined within fibrotic adhesions. If the remnant developed because endometriosis is made for difficult oophorectomy, that disease is often found in the remnant and probably also serves as a pain generator. Ovarian remnants are uncommon, but not rare, as implied by early case series. Classic symptoms include absence of vasomotor symptoms when bilateral oophorectomy was intended and presence of cyclic unilateral pain. As in the case of the residual ovary, the remnant can produce dyspareunia if it is located close to the vaginal apex. When performing oophorectomy, it is best to open the pararectal space and completely skeletonize the infundibulopelvic (IP) ligament, not only to avoid complications such as ureteral injury but also to prevent ovarian remnant syndrome. In difficult cases, dividing the IP at or above the pelvic brim, as in risk reduction prophylactic oophorectomy, is prudent.

Vaginal Apex Pain

Following hysterectomy, pain may persist or recur because of intrinsic sensitivity of the vaginal apex. Although the cuff may appear to have healed perfectly well, gentle examination with a cotton-tipped applicator may reveal focal sensitivity of

moderate-to-severe degree, many times located in one lateral fornix or the other and often replicating the reported pain of dyspareunia. When this is not done, the unaware examiner may then, noting pain upon traditional bimanual examination, mistakenly conclude that the source of nociception lies cephalad, for example,

in a remaining ovary, pelvic scarring, or bowel adhesions.

The diagnosis may be confirmed by noting elimination of the pain following injection of local anesthetic. The condition is generally considered neuropathic, by virtue of the character of the pain (burning, stinging, sharp), and that neuropathic treatments (overnight application of lidocaine, oral medications such as nortriptyline, amitriptyline, gabapentin, etc.) seem to benefit some patients. Laparoscopic revision of the vaginal cuff may give good initial relief in approximately two thirds of patients, but pain tends to recur to a degree over the subsequent 2 to 3 years.

Musculoskeletal Problems

Musculoskeletal changes can become involved with CPP, either as the primary problem or as a secondary reaction to the pelvic pain. Dysmenorrhea can be referred to the midline of the low back, especially when the uterus is retroverted. Pain can also be referred to the midline of the low back in the presence of cul-desac endometriosis. An ovary fixed to the pelvic sidewall can refer pain to the ipsilateral low back, lower quadrant, and upper thigh.

The muscular problem that most often produces pelvic pain is pelvic floor tension myalgia. Intermittent or constant painful contraction of the levator plate can be present as a primary psychophysiologic problem, but contraction is more often a reaction to some other source of pain. Even when the primary source of pain is successfully treated, the reactive muscle contraction can persist as a learned response, in much the same way that vaginal introital muscle spasm (vaginismus) can persist after transient but repeated painful vaginal events. Pelvic floor tension myalgia is often found in the setting of generalized somatic hypersensitivity, a condition whose worst case includes fibromyalgia.

Lumbar musculature can become tender as a primary problem or in reaction to subtle changes in posture and motion. Trigger points can be present in the low back and gluteal areas in the muscles best inspected by pelvic examination (e.g., levator plate, piriformis, obturator internus).

The piriformis and obturator muscles warrant additional mention because they are seldom appreciated as possible sources of pain. These muscles are external rotators of the leg, and rotation against resistance can allow detection of tender spasm of the muscles during the pelvic examination. The sciatic nerve can traverse the belly of the piriformis as a normal anatomic variant, producing symptoms similar to sciatica when the muscle is in spasm.

Myofascial Pain

Focal lower quadrant abdominal wall pain can be produced by entrapment of the genitofemoral and ilioinguinal nerves, as described by Applegate. Such entrapment appears most often after Pfannenstiel abdominal incisions. Reiter and Gambone reported that 14% of 122 laparoscopy-negative women had myofascial pain probably related to a previous surgical incision. Myofascial trigger points—palpable taut bands of tender skeletal muscle—may be a primary problem or a later reaction to the long duration of pain from some other source.

Medical Comorbidity

Peripheral pain generation in CPP often involves nongynecologic systems ([Table 29.1](#)). A careful history and close physical examination of gastrointestinal, urologic, musculoskeletal, and neurologic systems are needed to evaluate these additional contributions to CPP. Most of the available literature examines these problems of other systems independently of each other and without reference to their relevance to CPP or to the overall prevalence of these disorders in CPP.

The gastrointestinal system is perhaps the most common nongynecologic contributor to CPP. Constipation and IBS occur most frequently, although inflammatory bowel disease and diverticulitis can at times present with pain

alone. Women are proportionately more affected by IBS, and some have hypothesized increased relaxin levels produced by a dysfunctional corpus luteum as one of many possible contributing factors. As previously mentioned, treatment with a GnRH agonist may reduce symptoms of IBS.

Urologic problems, which are less easily confused with gynecologic disorders, are perhaps second in terms of prevalence. The urethral syndrome (frequency, urgency, and dysuria in the absence of bacteriuria), IC, and bladder spasms are all accompanied by significant anxiety and depression symptoms. The symptoms of these three disorders are very similar to those in a population of gynecologic CPP patients. Structured questionnaires (e.g., the Pelvic Pain and Urgency/Frequency [PUF] scale) help detect symptoms possibly emanating from the bladder. In some patients, however, a “positive” score can be achieved on the basis of other components of pelvic pain alone—without specific bladder symptoms—making the measure perhaps too *sensitive* and hence insufficiently *specific*. A history (whether pain occurs during micturition, daily activities, or coitus) does not always reveal the involved system, but careful pelvic examination with stepwise gentle palpation of the urethra, bladder base, and bladder may help the physician identify the site of the pain the patient is experiencing.

Many patients do not experience the problems described here in pure form, but rather in varying degrees of intensity, with varying contributions to an individual’s total discomfort. Indeed, we suspect that shared innervation of pelvic organs may often lead to subsyndromal symptoms in an organ system that neighbors one with different pathology. Such patients have a multifaceted somatosensory disorder, as opposed to being the unfortunate victim of multiple unrelated organ-specific disease processes. Close attention to such nuances of detail is warranted both in clinical management and in published reports.

PSYCHOLOGICAL FACTORS

Personality

The links between chronic pain and individual psychology and personality style have been sought after and discussed in the psychiatric literature for many years. Some early reports implied that women who reported CPP had a high prevalence of feminine identity problems related to conflicts about adult sexuality, psychiatric disturbance characterized by mixed character disorder with predominant schizoid features, high neuroticism, and unsatisfactory relationships. Although these initial studies were an important beginning, the high prevalence of psychopathology in some reported samples did not seem applicable to significant numbers of CPP patients seen in practice. The findings are difficult to interpret, partly because there is a lack of clarity concerning the operational definition of CPP that was used. Biases in patient selection and interviewer information, inadequate control groups, and the absence of diagnostic laparoscopy also contribute to the confusion. Despite these shortcomings, it seems apparent that disorders of personality, especially borderline personality, are overrepresented both in the general population of severe chronic pain patients and in the population of those with CPP.

P.623

In primary care, such patients usually are seen less often. In any case, a label of personality disorder should not be applied indiscriminately to every angry patient by her frustrated physician. People who have difficulties maintaining satisfactory relationships and function in life, even when these difficulties are caused in part by subsyndromal personality problems, can be more vulnerable to nociceptive signals from tissue damaged by endometriosis, infection, or surgery. Unmet dependency needs may lead them to seek external solutions such as medications and further surgery, rather than to rely on their own impaired coping skills.

Depression

Focusing specifically on a CPP sample that had been evaluated by diagnostic laparoscopy, Walker and associates found that women with CPP (with and without positive laparoscopic findings) met criteria for lifetime

major depression, current major depression, lifetime substance abuse, adult sexual dysfunction, and somatization more often than did control subjects. Stout and Steege found that 59% of 294 women seeking evaluation at a pelvic pain clinic scored in the depressed range (>16) on the Center for Epidemiologic Studies Depression Scale at the time of their initial visit. Slocumb and colleagues reported that patients with an abdominal pelvic pain syndrome scored higher on scales of anxiety, depression, anger-hostility, and somatization on the Hopkins Symptom Checklist.

Because no study of CPP has assessed its association with depression over time, no statement can be made as to whether depressive symptoms are a predisposing factor leading to, or a reaction to, the pain condition. There seem to be two distinct groups of CPP patients: one in which pain and depression are common final presentations reached by a number of pathways and another in which depression develops in reaction to pain, as is the case with many other acute and chronic medical diseases.

History of Sexual Abuse

Women seeking treatment for CPP have a high prevalence of sexual trauma in their personal histories. In Reiter's study of 106 women with CPP, 48% had a history of major psychosexual trauma (molestation, incest, or rape) compared with 6.5% of 92 pain-free control subjects presenting for annual routine gynecologic examination ($P < 0.001$). The high prevalence of reports of psychosexual trauma elicited from CPP patients supports the hypothesis that pelvic pain is specifically and psychodynamically related to sexual abuse. However, Rapkin and colleagues did not find a higher prevalence of childhood or adult sexual abuse in a group of women with CPP compared with women with chronic pain in other locations. These findings argue against a unique relation between sexual abuse and CPP and suggest that abusive experiences promote the chronicity of many different painful conditions.

When such a history is noted, the clinician and patient together must judge whether the feelings surrounding these events are intense enough to intrude upon the present. If so, psychotherapeutic help may be indicated. If not, although the memories may be painful, further emotional work on this area may not be beneficial. The literature on the sequelae of abuse and subsequent treatment is disappointing, especially when the abuse occurred in the distant past. In any case, it is difficult to judge whether these events are directly relevant to present pain and hence demand attention or whether they contribute to a psychologically vulnerable substrate influenced by subsequent physical and emotional events. In these circumstances, it may be worthwhile to suggest further mental health evaluation as an exploratory measure, being careful not to imply that the patient is being referred because the physician is certain that the abuse is related to the development of the pain.

Sexual Dysfunction

In clinical practice, women presenting with CPP often report a high incidence of marital distress and sexual dysfunction, particularly dyspareunia. Stout and Steege found that 56% of 220 married women scored in the maritally distressed range (<100) on the Locke-Wallace Marital Adjustment Scale at the time of initial visit. A high level of marital distress has also been reported in other chronic pain patients and their spouses. Although some women report satisfactory sexual functioning before the onset of pain symptoms, others appear to have longstanding impairments in sexual response. In our experience, sexual difficulties are often the problem that makes a person seek (or is encouraged by her partner to seek) help for her pain.

DIAGNOSTIC STRATEGIES

Recognizing a Chronic Pain Syndrome

Many women can experience pain for longer than 6 months without becoming debilitated; although their pain is chronic, such women are not described as having a CPS. The following are the common clinical hallmarks of true CPS:

1. Duration of 6 months or longer
2. Incomplete relief by most previous treatments
3. Significantly impaired physical function at home or at work
4. Signs of depression (sleep disturbance, weight loss, loss of appetite)
5. Hypersensitive response to nociceptive stimuli
3. Altered family roles

Of the signs of depression, sleep disturbance is usually the first to appear. Careful questioning is needed to distinguish awakening caused by pain from awakening that just happens. In the true vegetative sign, the person usually cannot get back to sleep even if pain is relieved (by medication or other means).

The alteration of family roles is perhaps the most important of those mentioned. This includes changed responsibilities for household, children, finances, and so forth. Initially intended as helpful, such changes may eventually diminish the patient's self-esteem and progressively reduce her family's interactions with her to little more than checking on her pain. Over time, this covertly reinforces the symptom of pain and imparts to it unintended value as a major means of maintaining communication within the family.

Simultaneous Medical and Psychosocial Evaluation

When the aforementioned markers of CPS are present, one should surrender the need to immediately discover how much of the pain problem is physical and how much is psychological. Rather than guess, it is useful to ask two separate questions: Is there physical disease that requires medical or surgical treatment? Is there emotional or psychological distress that requires treatment?

It is useful to directly state that the precise connection between these two cannot be measured; this can help diminish the patient's fear that she will be told "it's all in her head." In one sense, that statement is true: Pain is, by definition, a product of the brain, spinal cord, and peripheral nervous system, but few patients nefariously endorse nonexistent symptoms for secondary gain. A provider telling a patient he or she believes her pain symptoms are real—they might be modified

P.624

by a host of psychological, experiential, or genetic factors that influence the interpretation of peripheral stimuli, but they are real—can establish an important therapeutic bond. The patient may then be more open to sharing her personal and emotional concerns. If this statement is made early in the evaluation, before all physical evaluations have been carried out, the patient is likely to be less defensive. In this framework, a mental health consultant has a better chance of developing rapport with the patient and will be a more helpful collaborator when needed.

History Taking

The site, duration, pattern during activities, relation to position changes, and association with bodily functions are all important elements of pain. For example, pain that is absent in the morning but worsens progressively during the day may be associated with pelvic floor muscle dysfunction, while a tender "spot" of dyspareunia might be related to nodular cul-de-sac endometriosis.

The chronology of a patient's pain is critical. As CPS develops, pain can be present over a progressively larger area despite stable visible pathology. Interpreting this as the breakdown or wearing out of physiologic systems that deal with pain signals has some biologic validity and may make sense to the patient. The clinician may need to counter the idea patients sometimes have that endometriosis "flares" like rheumatoid disease or spreads like a malignancy.

From a cognitive perspective, it is invaluable to discern the patient's and her family's ideas about the causes of and future for her pain. Fears of cancer can be discovered even if this diagnosis was never even remotely considered by the clinician. Less dramatic but equally powerful attributions of cause can emerge, such as pelvic infection that is due to sexual acts remote in time, arguments with a spouse, divine retribution, and so forth.

Physical Examination

It can be helpful to begin the exam with the back, evaluating for tenderness of the spine, paraspinous muscles, and sacroiliac joints. This may identify pain generators and sites for therapeutic intervention, but it also allows for touch to begin in a very nonthreatening way. Gynecologic assessment is uncomfortable to some degree for almost all women, but the patient with CPP is particularly vulnerable. Moving from back to abdomen to pelvis can establish trust and reduce fear. The abdominal wall is examined with and without flexed rectus muscles. A positive Carnett sign (increased tenderness when palpation is done in the presence of abdominal wall flexion) implies at least a contribution to the pain from abdominal wall myofascial sources. Decreased pain during this maneuver implies a higher contribution from visceral sources. On occasion, gentle fingertip palpation of the abdominal wall can detect such trigger points in the musculature. Rarely, a subcutaneous abdominal wall endometrioma is discovered, a diagnosis supported by a history of predictable, cyclic focal tenderness.

Pelvic exam then begins with external review of the vulva and vestibule. Gentle palpation with a cotton swab can detect areas of sensitivity consistent with vestibulitis in the introitus or trigger points higher in the vagina.

Guiding a patient through contraction-relaxation sequences of the abdominal, thigh, and vaginal introital muscles can reduce the discomfort of the examination and can indicate the patient's degree of control over muscle tension. Single-digit palpation of the levator plate, piriformis, and obturator muscles can elicit the tenderness of pelvic floor tension myalgia. This condition can present as a sequel to some other pelvic pain or a problem in itself. Discomfort is usually felt as pelvic pressure and radiation pain to the sacrum, near the insertions of the levator plate muscles.

Single-digit palpation should also be used to discover areas of tenderness in the cervix, uterus, and adnexa as well. Premature addition of the abdominal hand to the exam adds in nociceptive signals from abdominal wall myofascial components that may lead the examiner to overattribute pain to the viscera. Finally, the abdominal hand is added to assess size, shape, and mobility of pelvic structures. Adnexal thickening and mobility, pelvic relaxation, coccygeal tenderness, and foci of pain that reproduce dyspareunia should be noted. A rectovaginal exam is important when DIE is suspected.

During all components of the physical exam, it is important to not only ask the question "Does this hurt?" but also ask the questions "Do you feel pain where I am pressing or somewhere else?" and "Is this the pain you were describing earlier—is this *your* pain?" If a patient answers affirmatively to the final question, it can be helpful to point out what structure you are palpating (e.g., pelvic floor muscle vs. ovary).

Laboratory Tests

Imaging Studies

In the case of CPS, it has already been established that intensity of pain does not correlate well with extent of visible pathology. It follows that if the physical examination is relatively benign and is not severely limited by body habitus, extensive imaging usually adds little to the database needed before laparoscopy is performed. This is especially true in the case of organ-specific studies (intravenous pyelography, barium enema, colonoscopy) in the absence of symptoms or signs pointing to an explicit organ system (e.g., blood in the stools). Ultrasounds, CT scans, and MRIs can, at times, discover unrelated or nonspecific items misinterpreted by the patient and physician. Understandably limited by the setting, many patients have been told by emergency physicians her

pain is due to ovarian cysts. This explanation is supported by an imaging study— either (a) a cyst (physiologic or not) is present or (b) a small amount of fluid is seen, interpreted as cystic rupture. Intervening for CPP on the basis of an imaging study finding alone is unlikely to be fruitful. On the other hand, with a specific question in mind—for example, pelvic sonography to confirm ovarian endometrioma, MRI when adenomyosis is suspected, or lower endoscopic ultrasound to rule out invasive rectal endometriosis—imaging can be quite helpful.

Blood Studies

Relatively few hematologic or chemical measures are of use in diagnosing CPP. An elevated leukocyte count and erythrocyte sedimentation rate may make the clinician suspect chronic pelvic inflammatory disease even when cervical probes are negative for the most common sexually transmitted infections. Serum cancer antigen 125 (CA 125) can confirm suspicions of DIE in those without prior surgical evaluation but is not sufficiently sensitive to detect early-stage disease. In those with advanced endometriosis, anti-müllerian hormone levels can help fertility counseling in a woman considering extirpative surgical treatment for her disease. In patients with post-bilateral oophorectomy with remnant ovarian tissue, FSH and estradiol levels remain in premenopausal ranges. Women using replacement estrogen therapy should stop 3 weeks before these levels are measured.

Anesthetic Blocks

Injection of small volumes of a local anesthetic, 1 to 5 mL of 1% lidocaine or 0.25% to 0.5% bupivacaine, blocks pain from either an entrapped segmental nerve (e.g., ilioinguinal) or an

P.625

abdominal wall trigger point. Such blocks can be therapeutic as well as diagnostic. Many anesthesia pain clinics administer epidural or spinal anesthetics to distinguish pain arising from peripheral organs from pain that has become completely central in origin.

In some instances, it is useful to attempt diagnostic/therapeutic transvaginal blocks with the same local anesthetics for vaginal apex pain, as discussed above. A series of three or four blocks administered 1 to 2 weeks apart may provide durable relief in some instances.

In most cases, a history and careful routine physical examination distinguish central from lateral sources of pelvic pain. When this discrimination is difficult, it may be useful to administer a transvaginal uterosacral block (blocking most uterine innervation) and then repeat the pelvic examination. When this relieves the pain, the pain can be assumed to arise from the uterus. If the pain is not relieved, however, one cannot distinguish a failed block from pain of nonuterine origin.

Psychological Tests and Interviews

To distinguish physical from psychological contributions to pain, many studies of CPP have used traditional psychological instruments that were developed to measure general psychopathology or personality factors. In some studies, more psychological abnormalities are detected in women without visible pathology at laparoscopy. In other studies, women with positive laparoscopy who have had pain for a long time appear equally distressed in their questionnaire responses. These psychometric instruments generally have uncertain face value for chronic pain patients, and their use can support the patient's fears that the health care provider thinks she is "crazy" or that the pain is imagined. Once again, the question of whether the emotional distress identified by these instruments is an antecedent to or a consequence of persistent pain remains unanswered. Psychometric tests are most useful when they are interpreted by a psychologist who has interviewed the patient, and they serve best as a means to better understand the patient's strengths and weaknesses, rather than as a means to decide who has "organic" versus "psychological" pathology or who needs surgery.

Laparoscopy

Great strides have been made in operative laparoscopy in the past three decades. Laparoscopy can be useful diagnostically and therapeutically (even in the face of negative findings), but when a CPS is clinically evident, results of laparoscopic treatment alone, despite comparable pathology, are much less impressive. For a patient with the clinical markers of CPS listed earlier, the complete workup as described should be performed before laparoscopy.

In some puzzling cases, we have performed laparoscopy under local anesthesia to “pain map” the pelvis. A 2-mm laparoscope and a small suprapubic probe are placed with the use of short-acting, reversible intravenous analgesia (e.g., remifentanyl) and local anesthetic. Having been oriented to the procedure beforehand, as each organ is touched, the patient is asked if the site is painful, to rate it on an ordinal scale from 1 to 10, and if the discomfort represents her pain. It is possible in some cases to block the superior hypogastric plexus during pain mapping to better predict benefit from presacral neurectomy. In this approach, mapping is done before and after injecting 10 mL of 1% lidocaine just underneath the peritoneum over the sacrum, using a 7-inch, 22-gauge spinal needle.

Limiting patient characteristics for using pain mapping include high states of anxiety and obesity, where the torque required to move an instrument against a thick abdominal wall can provide distracting nociceptive information. Once thought to be the “holy grail” of CPP diagnostics, better understanding of the central mechanisms of chronic pain and the relationship among various named pain disorders has led to diminished enthusiasm for laparoscopic pain mapping in routine practice.

MANAGEMENT

Relatively straightforward pain problems are not challenging to manage, such as treating isolated dysmenorrhea with hormonal suppression or a chronic tuboovarian abscess with adnexectomy. More often, however, CPP represents a complex and nuanced syndrome where treatment may vary considerably depending on the patient. When pain itself is the disease, the goal of treatment is not necessarily complete eradication of pain, but rather finding strategies that afford more functional living. Neuromodulatory medications (e.g., tricyclic antidepressants, neurotransmitter reuptake inhibitors, neuroleptics), psychological adjuncts (e.g., cognitive-behavioral therapy, pain psychotherapy, sexual counseling), and complementary strategies (e.g., mindfulness-based medication, yoga, acupuncture) can be useful to dampen central hypersensitivity. For the peripheral elements, physical therapy, diet modification, peripheral nerve blocks, and surgery can be helpful depending on the target pain generator. In all cases, good sleep hygiene, exercise, healthy eating, and social support are important foundational elements that improve the effectiveness of CPP treatment.

General Principles

A complete evaluation of CPS often reveals a number of contributing factors, such as bladder irritability, irregular bowel function, poor posture, and emotional and relationship stresses, in addition to laparoscopically visualized pathology. Treating each component sequentially is common practice but often ends in frustration because each treatment addresses only a part of the problem. Simultaneous treatments often begin with disquieting multimodal therapy but allow better relief. Close follow-up at regularly scheduled visits provides support and a coping mechanism for the patient. When the patient is essentially required to feel worse to be seen again, the pain may be tacitly reinforced.

Medication Use

Analgesics

Analgesics such as nonsteroidal anti-inflammatory drugs and opioid narcotics can be quite effective for acute conditions, but their use in chronic pain is marred by a host of adverse outcomes and limited efficacy associated

with long-term use. Dose-related effects of medications such as acetaminophen (liver toxicity) and cyclooxygenase inhibitors (gastric and renal damage) are well known, but they are not major offenders in the realm of tolerance and withdrawal. Opioid narcotics, on the other hand, are notoriously dangerous in regard to these consequences, in addition to problems such as narcotic bowel syndrome and opioid-induced hyperalgesia. Some patients benefit from structured narcotic therapy, but, if they are to be used for CPP, clinicians should screen carefully for factors associated with high risk for misuse and set nonnegotiable ground rules, such as limiting prescriptions to one provider, not entertaining requests for early refills, mandating scheduled urine drug screens, and refraining from uncontrolled dose escalation. Newer opioid medications, such as oxycodone and hydromorphone, are considered less euphoria generating than the more commonly employed narcotics such as hydrocodone, oxycodone, and hydromorphone.

P.626

Antidepressants and Neuroleptics

This class of drugs is commonly employed in the treatment of chronic pain, including CPP, although few controlled trials have been carried out specifically in this population. While no longer first line for mood disorders, tricyclic antidepressants such as amitriptyline, nortriptyline, and desipramine have a long record of being effective in treating chronic pain. Newer-generation neurotransmitter reuptake inhibitors such as duloxetine and desvenlafaxine can also be useful. Neuroleptics such as gabapentin, pregabalin, and lamotrigine are generally employed when symptoms are more specifically neuropathic in nature. It is important to discuss with patients that, although they tend to diminish with continued use, all of these medications have central side effects, some of which are predictable and others quite idiosyncratic. When higher doses or multiple agents are used, it can be helpful to consult with a psychiatrist or psychopharmacologist to avoid complications such as severe mood dysregulation or serotonin syndrome.

Anxiolytics

Anxiolytic drugs are certainly widely prescribed by gynecologists, although it is uncertain how often they are given for pain. In one study, alprazolam, a triazolobenzodiazepine with mixed anxiolytic and antidepressant effects, had a surprising degree of analgesic effect in moderate-to-high doses in patients with chronic pain of malignant origin and concomitant mood changes or anxiety. These patients were already receiving narcotics, which may suggest that alprazolam potentiates the analgesic effect of narcotics. Their role in conjunction with nonnarcotic analgesics is uncertain, and the addiction potential is obvious.

Hormonal Medications

Oral contraceptives are effective in reducing dysmenorrhea and cyclic symptoms associated with endometriosis. It is not uncommon, however, to meet resistance to using these medications in women with CPP—either because they were previously used and did not cure the entirety of the pain syndrome and were thus deemed ineffective or because of sensitivity to side effects such as nausea, an understandable consequence in a viscerally hypersensitive group. Avoiding ultra-lowdose 20-mcg ethinyl estradiol formulations can help reduce unscheduled bleeding, important for women who may closely associate bleeding with pain. Outside of DIE, progestin-only formulations, by enteral or parenteral route, run the risk of exacerbating depressive symptoms in a vulnerable population. A notable exception includes the levonorgestrel intrauterine system (LNG-IUS), which has little systemic absorption and can control dysmenorrhea and pain from endometriosis in a low-risk, reversible, long-acting manner.

The use of GnRH agonists deserves special mention. They have been recommended to distinguish gynecologic from nongynecologic sources of pain; however, these agents also relieve symptoms of other functional conditions. Furthermore, pain thresholds have been shown to be lower premenstrually, even in asymptomatic

women. The impact of the menstrual cycle itself in chronic pain patients has not been well explored, but it seems likely that it may impart some cyclicity even to conditions unrelated to the reproductive tract. Cyclicity of symptoms must therefore be interpreted with caution, and the disappearance of symptoms or of their cyclicity by pharmacologically obliterating the menstrual cycle does not demonstrate a gynecologic cause. To address the most common clinical circumstance, relieving pain with a GnRH agonist does not prove that the pain is due to endometriosis, nor does it prove that pain comes from the reproductive tract, as discussed above. Gonadotropin-releasing hormone agonists can be useful when differential diagnosis includes ovarian remnant syndrome or residual ovary syndrome or in the treatment of DIE, but its utility in treating general CPP is limited by cost and morbidity. Contrary to popular belief, GnRH agonists are not more effective than other more benign hormonal manipulations directed at pelvic pain. For DIE, aromatase inhibitors may work similarly, without as significant hypoestrogenic effects.

Surgery

Two basic surgical approaches have been used to treat CPP: removing pelvic organs and treating visible disease while leaving the pelvic organs in place. The use of both approaches is guided by clinical experience, as scientific data regarding the role of surgery in pelvic pain are sparse. Expansion of literature on the topic, including stratification for characteristics that lead to strong or poor response, would be most welcome.

In the United States, approximately 12% of hysterectomies are performed with pelvic pain as the primary indication. An additional 6.1% are performed for endometriosis or adenomyosis, and 5.1% are performed for pelvic inflammatory disease; no doubt many in these two categories also involve symptoms of pain. In approximately one third of hysterectomies performed for pain, no pathology is found. Despite the frequency of pain as an indication for this procedure, data regarding efficacy are surprisingly sparse. One report notes relief in 78% of women after hysterectomy for pelvic pain of uterine etiology (women with adnexal or other pelvic disease were excluded). Interestingly, the presence or absence of uterine pathology (adenomyosis or leiomyomata) had no bearing on whether pain was relieved.

Others have suggested hysterectomy performed in primary care settings is very effective for the treatment of CPP. In a prospective observational study of private practices in Maine, Carlson and associates reported that at a 1-year follow-up, satisfaction with the outcome of surgical treatment was much higher than satisfaction with the outcome of medical therapy. However, approximately one third of women improved substantially on medical therapy; perhaps, women were more likely to undergo operation when visible pathology was apparent. In the Maryland Women's Health Study, 1,299 women were interviewed at length before hysterectomy for benign disease and at 3, 6, 12, and 24 months after surgery. In more than 90% of cases, the procedure was well tolerated and did not result in postoperative depression or a decline in sexual functioning. In the subset of women with pain as the primary indication for surgery, relief of pain occurred in more than 80%, indicating that the clinicians involved generally used good judgment and technique. In general, women with preoperative depression or sexual dysfunction did not fare as well as their less symptomatic counterparts, although even when hysterectomy is performed in women with both depression and CPP, slightly more than 80% are improved emotionally and in terms of pain at 2-year follow-up.

Rigorous study design is lacking regarding data on adhesiolysis, with reports essentially limited to little more than clinical case series. When treated by laparotomy, 28 of 42 (65%) patients reported cure or improvement of pain. In a sample of mostly primary care patients, 84% of 65 patients had relief of pain after laser laparoscopic adhesiolysis with follow-up intervals of 1 to 5 years. In Sutton's large series, 85% had pain relief at 1 year. Steege and Stout reported that 15 of 20 (75%) patients without a CPS who were undergoing laser laparoscopic adhesiolysis had good relief of pain at a follow-up 6 to 12 months after surgery. However, if a CPS was present, only 4 of 10 (40%) patients with equivalent adhesive disease

obtained relief. The greater the emotional and behavioral disability, the greater the need for combined medical, surgical, and mental health management.

Endometriosis is a more common finding among women undergoing laparoscopy for pelvic pain than those for other indications. Peritoneal disease does not correlate with symptom site or stage of disease with symptom severity. Laparoscopic treatment, even of mild disease, is more effective than diagnostic surgery alone. Some studies suggest superiority of excision to ablation of endometriosis implants, and this approach probably makes good clinical sense, but there is insufficient evidence to conclude one is definitively superior to the other in pain reduction. Specific symptom improvement following DIE (gastrointestinal, urologic, cul-de-sac) resection is best documented in the literature. The benefits of surgical excision may be prolonged by subsequent medical therapy. Numerous studies have been done of postsurgical treatment with hormonal medications. Oral contraceptives, danazol, progestins, and GnRH agonists (with and without add-back estrogen/progestin) have all been shown to be effective. Although the GnRH agonists have become perhaps the most widely used of these, definitive evidence for their superiority is lacking. The more economical and less physiologically intrusive approach would seem to favor sex steroids over GnRH agonists. Most troublesome in reviewing all of these studies is the observation that dyspareunia is the symptom that is most refractory to treatment, testifying to its multifactorial nature.

Presacral neurectomy, as an adjunct to surgical excision of endometriosis, has been evaluated for its effect on pelvic pain. In a retrospective sample of 71 women undergoing conservative resection of endometriosis by way of laparotomy, 35 (50%) who also had presacral neurectomy enjoyed significantly greater improvement in both dysmenorrhea and dyspareunia. Two subsequent retrospective reports noted that similar percentages (approximately 75%) of women obtained pain relief after endometriosis surgery that included presacral neurectomy, compared with approximately 25% who obtained relief without neurectomy. Zullo et al. investigated the question with a double-masked randomized trial and demonstrated a 20% difference in pain improvement when presacral neurectomy was added to endometriosis excision in women with central pain.

An ovarian remnant should be removed if it is persistently symptomatic despite attempts at medical suppression and if menopause cannot be expected in the patient's near future. The dissection should be detailed and should include all the peritoneum surrounding the mass. The pararectal space, and paravesical space if needed, should be opened systematically, and the ureter and pelvic sidewall vessels exposed and carefully freed from the specimen. Usually, there is vascular supply along the tract of the IP, and it is prudent to divide the pedicle well above the pelvic brim. When a GnRH agonist has been used preoperatively for symptom control or to distinguish the relative contributions made by the remnant and other pelvic pathology, such as adhesions, the remnant tissue may become so small as to make it difficult to identify. Hence, if a palpable (or ultrasonically visible) mass disappears after GnRH agonist treatment, it may be wise to allow time for it to regrow before pursuing surgical excision. When the remnant is small, some surgeons have stimulated the remnant with clomiphene citrate to make it easier to find.

Psychological and Alternative Treatments

Psychological disorders should be treated in CPP, whether independently present or the result of a long-standing pain disorder. Some practitioners may find cognitive-behavioral or biofeedback therapy useful in reducing automatic responses to painful stimuli. Sexual counseling, couples counseling, and psychotherapy can be helpful adjuncts. Alternative strategies, such as mindfulness-based meditation, yoga, and acupuncture, all have their appropriate roles in individual cases, but none is so clearly applicable or effective that its automatic use is supported in cases of CPP.

Management Overview

The most effective clinical approach requires simultaneous treatment of as many factors as possible: anatomic, musculoskeletal, functional bowel and bladder, psychological, and so forth. The patient and physician must contract for the long term and work from a rehabilitation perspective, rather than hope that the latest single addition to the treatment will prove to be *the* answer. The physician, to prevent frustration and feelings of defeat, must often play the role of helping to manage and relieve the pain while helping to maximize function, even when pain persists. To the surgically trained gynecologist who prefers a clear-cut single answer to a clinical problem, this can be the most difficult part of dealing with the problem of CPP. It is important to free oneself from the responsibility of needing to “fix” a patient’s CPP. While the compassionate provider can be an invaluable aide, much of the work in improving from pelvic pain is the burden of the patient herself.

THE EVOLUTION OF A CHRONIC PAIN SYNDROME

As is apparent from this discussion, CPP is a heterogeneous problem, not a single diagnosis, and no single etiologic hypothesis is clearly supported. Most of the hypotheses reviewed here have some credible evidence supporting them; none have been sufficiently validated.

Some patients appear to have a pure version of one or the other of the syndromes described, whereas many others present with several or many simultaneously. Psychological and neurologic mechanisms are proposed here to explain how the evolution of chronic pain may occur, regardless of the particular tissue damage or functional disorder that may first have provided nociceptive stimuli. We suggest the following elements ([Fig. 29.1](#)): biologic events sufficient to initiate nociception, alterations of lifestyles and relations over time, recruitment of neighboring organ systems, anxiety and affective disorders, and a circular interaction (vicious cycle) among these elements.

Biologic Events Sufficient to Initiate Nociception

Sexually transmitted diseases, endometriosis, recurrent bladder and vaginal infections, primary or secondary functional dyspareunia, alterations of bowel habit, muscular dysfunction, pelvic congestion, and gynecologic or other abdominal surgeries ([Table 29.1](#)) may contribute individually or in combination.

Alteration of Lifestyle and Relations

Physical activities at home and recreational pursuits can suffer. Believing that rest usually helps in the treatment of most causes of acute pain, the patient may assume that the same applies to chronic pain and may thus restrict herself more than actual discomfort dictates. Family members start to regard the patient as sick and leave her out of many activities, thus reducing her

P.628

roles within the family structure. With time, concern for and discussion of her pain can become the family’s major pattern of communication with the pain victim. If sexual intimacy has been the major means of emotional sharing and smoothing over of differences, and if this intimacy is reduced, then the altered pattern of interactions may take hold more quickly.

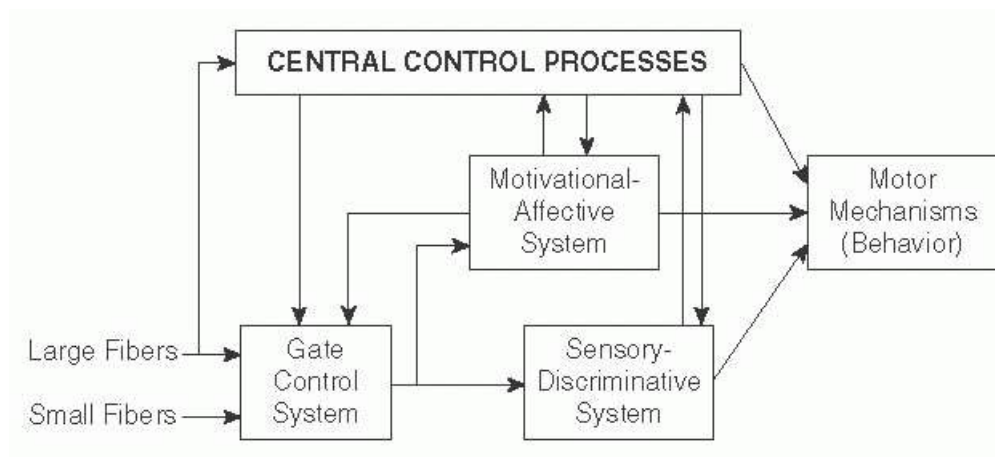

FIGURE 29.1 The gate control theory of pain perception.

Anxiety and Affective Disorders

Depression can occur as a cumulative result of the disability suffered, or the pain can bring on an episode of depression in a patient already biologically vulnerable. The observation most relevant here is that pain patients with a family history of depression can derive the most benefit from antidepressants.

The Vicious Cycle

Diminished activity, altered family roles and social supports, anxiety, and affective disturbances can influence nociception by a variety of central pathways, ultimately altering spinal cord “gating” of nociceptive signals. Cognitions about the pain can play an additional role.

Several important modifying influences can be present in addition to these major pathways ([Fig. 29.2](#)). Incest and other forms of sexual abuse have attracted the most attention as possible forerunners of CPP. However, CPP is clearly not a unique or specific sequel to sexual abuse, and a large proportion of CPP patients have not been abused in this manner. Victims of sexual abuse have many negative emotional sequelae; pain problems often occur after abuse, but they are not necessarily directly caused by the abuse.

A genetic predisposition to depression also allows the vicious cycle to become easily established and strengthened over time. Antidepressant medications play an important role in the overall therapeutic plan in such cases. A relatively new area of research in pain is dealing with possible genetically determined variations in central neurotransmitter processes that may predispose to the development of pain syndromes.

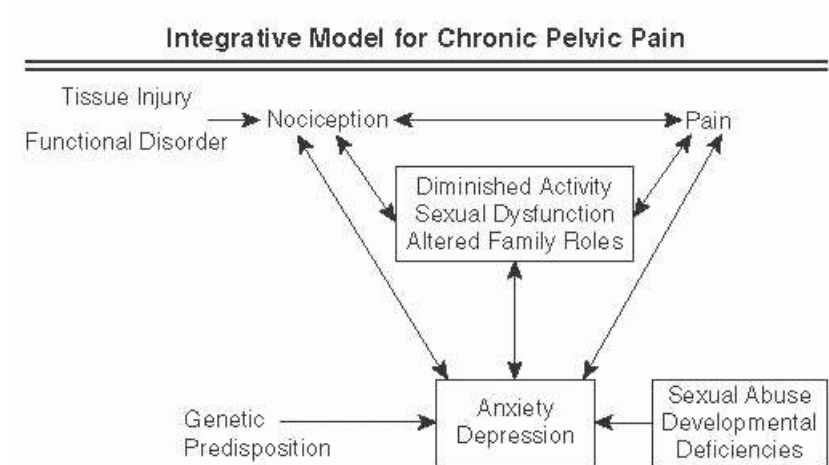

FIGURE 29.2 An integrative model for CPP, including elements of gate control theory, cognitive-behavioral theory, and the operant conditioning model.

Several authors have suggested that the concept of perceived control best explains the development of affective changes accompanying chronic pain, regardless of the location of the pain. The individual who sees herself as having little control over the physical and emotional events affecting her may be most vulnerable to development of a CPS. Another factor thought to influence pelvic pain is a patient's degree of catastrophization, a state of interpreting negative things are far worse than they are. It may be reasonable to consider these variables as a culmination of the effects of affective change, activity, family roles, sexual dysfunction, and previous victimization experiences.

The longer that pain has been a part of the person's life, and the more psychological vulnerabilities she carries forward to the present, the less likely it is that any treatment of the tissue damage itself will be effective in relieving pain and restoring physical and emotional function. However, as treatment studies show, the contribution of peripheral generators to chronic pain can seldom be dismissed entirely. The more difficult task is the selection of an efficient and cost-effective combination of treatment approaches aimed at the most important factors acting in the present.

BEST SURGICAL PRACTICES

- A complete medical and psychosocial history, as well as a pain-oriented physical and pelvic examination, should be completed before diagnostic laparoscopy is performed.
- Neuropathic and musculoskeletal components of CPP often require treatment both before and after appropriate pelvic surgery.
- A minimally invasive (laparoscopic) approach is especially appropriate for chronic pain patients.
- Laparoscopic treatment of endometriosis is more effective than diagnostic surgery alone.
- Presacral neurectomy can be an effective adjunct to endometriosis excision when a central component of pain is present.
- Resection of DIE is effective treatment of organ-specific symptoms.
- Complete skeletonization of the IP vessels, especially in difficult oophorectomy, reduces the risk of adjacent organ injury and ovarian remnant syndrome. Ovarian remnants should be removed with careful opening of avascular spaces and identification of retroperitoneal structures.
- Though not a cure for all components of a woman's CPP, hysterectomy can be an effective treatment, even in women with both depression and pain.

Chapter 30

Pelvic Inflammatory Disease

Mark G. Martens

DEFINITIONS

Bacterial vaginosis (BV)—A vaginal condition demonstrated by a replacement of the normal lactobacillus-predominant vaginal flora with a mixture of facultative and obligate anaerobes, mycoplasma, and other species, resulting in a malodorous discharge. The presence of *Gardnerella vaginalis* without symptoms is not synonymous with BV.

Colpotomy—Incision into and through the vaginal epithelium into a cavity (often abscess or pelvic/abdominal cavity).

Febrile morbidity—Temperature equal to or greater than 100.4°F or 38°C on two separate occasions (>4 hours apart), starting 24 hours after the initiating event.

Fever—Temperature equal to or greater than 99.6°F or 37.5°C.

Lower genital tract infection (LGTI)—An alternative term used to describe infection limited to the cervix and/or vulva and vagina.

Mollicutes—Class of organisms that includes *Chlamydia*, *Mycoplasma*, *Ureaplasma*, and other species.

Outpatient therapy—Previously synonymous with oral therapy; however, the term now includes oral, ambulatory intravenous, or intermittent injectable therapies.

Parenteral therapy—Usually denotes intravenous (antibiotic) therapy, but not necessarily given while hospitalized.

Pelvic inflammatory disease (PID)—A general term used to refer to infection and inflammation of the upper genital tract in women.

Phlegmon—A massive infiltration of inflammatory cells into infected soft tissue resulting not in an abscess, but a “woody induration” sensation upon examination/palpation.

Prevotella—Newly named genus that now includes several species formerly called Bacteroides (e.g., *Bacteroides bivia*).

Salpingitis—Infection/inflammation of one or both of the fallopian tubes (often incorrectly used as an equivalent to all PID).

Tuboovarian abscess (TOA)—A term used to describe an abscess incorporating the fallopian tube and ovary.

Upper genital tract infection (UGTI)—A more descriptive term used alternatively to PID.

FIGURE 30.1 Chlamydia rates by sex, United States, 1991-2011. (Data from the Centers for Disease Control.)

Pelvic inflammatory disease (PID) is one of the most serious infections faced by women today. Also, it is one of the most common gynecologic reasons for hospitalization and emergency department visits in the United States each year.

Untreated or unsuccessfully treated women may suffer lifethreatening consequences, and even adequately treated women are at much higher risk for potentially serious sequelae. PID is a spectrum of diseases initially involving the cervix, uterus, and fallopian tubes. Acute PID, the acute clinical syndrome, is most often attributed to an ascending spread of microorganisms from the vagina and endocervix to the endometrium, fallopian tubes, and contiguous structures. The terms *acute PID* and *acute salpingitis* are often used interchangeably, but PID is not limited to tubal infection only. A more descriptive term to differentiate the severity and extent of various forms of PID was introduced by Hemsell and colleagues: *upper genital tract infection (UGTI)*. This is differentiated from *lower genital tract infection (LGTI)* because response to treatment appears to be different in these two entities. PID has also been categorized into inpatient or outpatient treatment groups. However, this may not accurately reflect the severity of illness, but rather the predictive accuracy of the caregiver for hospitalization.

EPIDEMIOLOGY

Sexually transmitted infections (STIs) have been reported at epidemic proportions in the United States, with the Centers for Disease Control and Prevention (CDC) estimating almost 20 million new infections each year at a cost of \$6 billion each year. The incidence of *Chlamydia trachomatis* infections has increased 8% since 2010, to a rate of 458 per 100,000 people, with a total of 1,412,791 cases reported in 2011 ([Fig. 30.1](#)).

Neisseria gonorrhoeae incidence has also increased to 4% since 2010 with a rate of 104 per 100,000 people, with more than 320,000 cases reported in 2011 in the United States. For women, acute PID is the most common and important complication of STIs. Bell and Holmes in the 1980s estimated that 1 million women a year were treated for acute salpingitis in the United States, but recent estimates by Sutton and colleagues estimated a decrease in cases of PID to approximately 770,000 per year and a 68% decrease in hospitalized PID from 1995 to 2001.

The CDC estimates that of the 750,000 to 1 million women per year who experience an episode of PID, up to 15% will become infertile as a result of the infection. Hospitalization rates have been declining over the past

decade. However, it is uncertain if this is due to decreasing incidence of the disease or a change in clinical management to treat more patients as outpatients. A consequence of the latter scenario is that despite

P.632

the long-term trend of decreased hospitalization, as confirmed by Sørbye and colleagues (35% reduction in hospitalized cases of PID), they also found that there was a 65% increase ($P = 0.013$) of tuboovarian abscesses in these patients.

FIGURE 30.2 PID—Hospitalizations of women aged 15 to 44 years, United States, 2001-2010. (Data from the Centers for Disease Control.)

However, after hitting an all-time low in hospitalizations for PID in 2009, there was a marked increase in 2009 to 2010, and we are anxious to see if this will become a long-term trend ([Fig. 30.2](#)).

In addition to the 200,000 women who are hospitalized each year with a diagnosis of salpingitis or PID, the disease also generates nearly 2.5 million visits to physicians and an estimated 150,000 surgical procedures for complications every year. In terms of overall incidence, acute PID occurs in 10% to 15% of women during their lifetime, with a diagnosis in 1% to 2% of young, sexually active women each year. Therefore, PID is the most common serious bacterial infection in women aged 16 to 25 years, and the resultant morbidity exceeds that produced by all other infections combined for this age group.

ETIOLOGY

Within certain geographic areas or populations, *N. gonorrhoeae* is a common cause of PID. However, most cases of acute PID are the result of a polymicrobial infection caused by organisms ascending from the vagina and cervix to infect the lining of the endometrium and fallopian tubes. Approximately 85% of cases are spontaneous, noniatrogenic infections that occur in sexually active women of reproductive age. The remaining 15% of infections occur after procedures that break the cervical mucous barrier, such as with the placement of an intrauterine device (IUD), endometrial biopsy, or uterine curettage, which allow vaginal flora to infect the upper genital tract.

In the United States, nontuberculous PID was traditionally separated into gonococcal and nongonococcal disease, depending on the isolation of *N. gonorrhoeae* from the endocervix. However, a variety of organisms can be isolated from the endocervix. Therefore, it is difficult to determine which of these organisms cause PID and which are coexistent cervicovaginal flora representing vaginal colonizers in the upper genital tract at time of diagnosis. While upper genital tract organisms are probably more indicative of the causative organisms, they are often difficult to obtain without suspecting endocervical contamination from the diagnostic procedure. However,

studies by Martens and colleagues of transcervical cultures of the infected uterine cavities did not find significant contamination with this approach with either protected catheters or suction curettes. Bacterial organisms cultured directly from tubal fluid may commonly include *N. gonorrhoeae*, *C. trachomatis*, endogenous aerobic and anaerobic bacteria, and genital *Mycoplasma* species. Laparoscopic studies have demonstrated a correlation of no more than 50% between endocervical and tubal cultures, but the presence of *N. gonorrhoeae* is almost always considered an important causative factor. Even in the presence of *N. gonorrhoeae*, direct fallopian tube cultures have demonstrated that tubal infections are often polymicrobial. The type and number of species vary depending on the stage of the disease. Gonorrhea, for example, is often cultured from the cervix during the first 24 to 48 hours of the disease but is often absent later. Similarly, fewer organisms are cultured late in the disease, and anaerobic bacteria such as *Prevotella*, *Bacteroides*, *Peptococcus*, and *Peptostreptococcus* species tend to predominate. Whether these anaerobes play a causative role or increase in number and frequency as a result of the inflammatory response is uncertain. Sweet has summarized the literature by stating that in approximately one third of women with PID, *N. gonorrhoeae* is the only organism recovered by direct tubal or cul-de-sac culture, one third have a culture positive for *N. gonorrhoeae* plus a mixture of endogenous aerobic and anaerobic flora, and the remaining third have only aerobic and anaerobic organisms. Chow and colleagues and Monif and colleagues have postulated that the intense inflammatory nature of gonococcus may initiate acute PID and produce tissue damage. This damage changes the local environment, which in turn allows anaerobic and aerobic organisms from the vaginal and cervical flora to invade the upper genital tract. Both Eschenbach and Sweet have suggested that not all PID follows gonococcal infection and that acute PID initially may also have a polymicrobial etiology.

According to Sweet and Gibbs, approximately 20% of all women with salpingitis have tubal cultures positive for *C. trachomatis*. Also, both *N. gonorrhoeae* and *C. trachomatis* are found in the same individual 25% to 40% of the time. Scandinavian studies by Eilard and coworkers have reported the recovery of *C. trachomatis* from the cervix in 22% to 47% of women with acute PID. *C. trachomatis* by itself produces a mild form of salpingitis with an insidious onset. In contrast to gonorrhea, *Chlamydia* can remain in the fallopian tubes for months or years after initial colonization of the upper genital tract. Svensson and colleagues found that women with *C. trachomatis* infection at laparoscopy had the most severe fallopian tube involvement, probably because of its clinically silent or minimally symptomatic nature, which results in difficult or delayed diagnosis and therefore delayed or absent treatment. The two major sequelae of acute PID are tubal infertility and ectopic pregnancy. These have been strongly associated with prior chlamydial infection as a consequence of intratubal and peritubal adhesions.

P.633

Although *C. trachomatis* is generally believed to be one of the most common causes of PID, its etiologic role is very different when compared to *N. gonorrhoeae*. *N. gonorrhoeae* is a Gram-negative diplococcus with rapid growth that is due to a short reproductive cycle of about 20 to 40 minutes to divide. This results in a logarithmic increase in the number of organisms once *N. gonorrhoeae* reaches a relatively sterile area such as the endometrium or fallopian tube, where growth is relatively unimpeded. This rapid increase in the number of Gram-negative bacteria usually results in a rapid and intense inflammatory response by the woman's host defenses. The response to this rapid bacterial growth is proliferation and aggregation of white blood cells (WBCs) and their inflammatory products. Migration of this bacterial and leukocytic mixture in two directions, both through the fallopian tube to the ovary and peritoneal cavity and back to the cervix and vagina, causes the symptoms that are pathognomonic of acute PID— abdominal/pelvic pain and cervicovaginal discharge.

For years, *N. gonorrhoeae* was thought to be the primary PID pathogen. Its often severe immunologic response, mostly due to its release of lipopolysaccharide, resulted in acute and severe pain, high fevers, and a marked WBC response. This triad resulted in an easily recognized clinical course, a prompt diagnosis and often early

hospitalization, and initiation of antibiotic treatment.

Chlamydia trachomatis, however, is a slow-growing intracellular organism. Its lack of mitochondria results in its obligatory intracellular existence and also causes its growth cycle to be extremely slow compared with *N. gonorrhoeae* and other nonintracellular microorganisms. The growth cycle of *Chlamydia* is 48 to 72 hours; therefore, several weeks to months are required for the growth to reach numbers sufficient to cause clinical symptoms, if at all. Its slow growth does not induce a rapid or violent inflammatory response. This explains the slow and insidious nature of the symptoms of acute *C. trachomatis* infections. However, because of its intracellular growth cycle, the release of elementary bodies (its infectious vehicle) occurs by rupture of the cell that it has invaded. In addition, Linhares and Witkin have eloquently documented the serious immunopathologic consequences of the 60-kDa heat shock protein (hsp60) from *Chlamydia* on the fallopian tube.

Thus, the repeated occurrence of elementary body infection of susceptible cells—and their subsequent destruction by rupture—along with a chronic inflammatory response are the major mechanisms by which *C. trachomatis* causes disease in acute and chronic pelvic infections. Also, because the slow growth and the chronic inflammatory response often result in subtle clinical symptoms, treatment is often delayed or not started at all, adding to the extended tissue destruction and PID sequelae.

The lack of acute symptoms does not lessen the importance of *Chlamydia* as a PID pathogen. Not only does the tissue destruction result in severe complications such as ectopic pregnancy and infertility, but also the tissue damage provides fertile ground for the growth of secondarily infecting aerobic and anaerobic bacteria. This necrotic tissue is an excellent growth medium, and the epithelial damage enhances the breakdown of the surface defense mechanisms. The importance of *Chlamydia* was documented during the 1980s when treatment of acute PID during new antibiotic research trials was initially believed to be successfully accomplished with regimens not active against *C. trachomatis*. However, although success was evident at short-term follow-up, long-term follow-up demonstrated that treatment of *C. trachomatis* was necessary. PID regimens without *Chlamydia* coverage resulted in an increased incidence of recurrent episodes and long-term complications such as abscesses and chronic pelvic pain, with resultant increased surgical intervention. Therefore, current treatment of PID includes *C. trachomatis* coverage, even though this organism may not be the cause of the acute symptoms. Therefore, despite the lack of immediate and acute symptoms, *Chlamydia* remains an important pathogen in PID, as subtle or absent symptoms are more difficult to diagnose and treat early, resulting in much of the serious long-term sequelae found with PID. This is supported by the high incidence of *Chlamydia* antibodies in patients with acute PID, ectopic pregnancy, and infertility in several studies.

Despite the focus on these two STIs, nongonococcal and nonchlamydial pathogens cause more than 60% of PID infections. Besides *N. gonorrhoeae* and *C. trachomatis*, aerobic and anaerobic bacteria and other microorganisms, particularly other mollicutes, have been implicated as etiologic agents in acute salpingitis.

Haggerty et al., Cohen et al., Short et al., and others have all demonstrated the clinical significance of *Mycoplasma genitalium* in PID. Other novel pathogens are certain to be identified as the Human Microbiome Project identifies new, difficult-to-culture organisms found to be associated with PID.

However, *M. genitalium* is the current pathogen generating much attention after recent studies by Clausen et al. and Svenstrup and colleagues have found an association with *M. genitalium* and tubal factor infertility. More importantly, current PID treatment regimens may not adequately treat *M. genitalium*. Since it is a mollicute similar to *Chlamydia*, it lacks a cell wall and thus is resistant to cell wall-inhibiting antibiotics such as the penicillins and cephalosporins.

Also, studies by Björnelius and Falk and their colleagues in men and women with *M. genitalium* have found persistence of the organism despite treatment with levofloxacin and tetracyclines. However, these same researchers have found azithromycin to have better activity against *M. genitalium*. Moxifloxacin, a newer

quinolone, also appears to have good in vitro activity.

In the large National Institutes of Health (NIH) PID study called the PID Evaluation and Clinical Health trial, Haggerty reported that 41% of *M. genitalium*-positive women experience microbiologic failure to eradicate the organism with standard Centers for Disease Control (CDC) PID treatment regimens, and more importantly, 44% experienced clinical failure. These results will most certainly be addressed at the next CDC review of PID treatment guidelines scheduled for 2015.

Bacterial vaginosis (BV)-related organisms such as *Gardnerella*, *Mycoplasma hominis*, and *Ureaplasma urealyticum* have also been suggested as causal agents in acute salpingitis by Ness and colleagues. However, their role remains controversial, as other studies have not found an association with PID. Cervical cultures positive for both *M. hominis* and *U. urealyticum* have been recovered from women with PID. However, the rate of isolation can be as high as 75%, which is not statistically different from that of women who are sexually active but without PID (baseline rate of about 50%), as found by Lemeke and Lsonka. Also, Clarke et al. have published evidence that *Cytomegalovirus* (CMV) may be associated with PID, but additional confirmatory investigations are limited.

Group B streptococcus, *Escherichia coli*, and other facultative anaerobic agents are also associated with PID, but fortunately are generally adequately covered by current CDC guidelines. In light of all the new data, the main point to emphasize is that although *N. gonorrhoeae* and *C. trachomatis* are significant pathogens, they are still only associated with 30% to 40% of all PID episodes. Thus, while current standard of care requires testing for both these organisms, negative results do not mean the patient does not have PID, and treatment should be initiated or completed based on the patient clinical course or additional microbiologic testing if possible.

P.634

RISK FACTORS

Several factors that predispose to the development of acute PID have been identified. Risk factors are important considerations in both the clinical management and prevention of UGTIs. First and foremost, there is a strong correlation between exposure to STIs and PID. In the United States, recent studies have confirmed this association with the recovery of *N. gonorrhoeae* or *C. trachomatis* in 40% to 50% of patients hospitalized with acute PID. Age at first intercourse, frequency of intercourse, number of sexual partners, and marital status are all associated with the frequency of exposure to STIs and thus are associated with PID. Women with multiple partners have an increased risk (four to six times normal) for development of PID, compared with women who have monogamous sexual relations. Additional studies by Ness and colleagues have found significant factors including age at first sex, cervicitis, history of PID, family income, smoking, medroxyprogesterone use, and sex with menses.

The incidence of acute PID decreases with advancing age. Adolescent girls are at significant risk for development of acute salpingitis. Westrom reported that nearly 70% of women with PID were younger than 25 years of age, 33% experienced their first infection before the age of 19, and 75% were nulliparous. The risk for development of acute PID in a sexually active adolescent female patient was 1:8, whereas the risk was 1:80 for a sexually active woman 24 years of age or older. Several reasons have been suggested for this increased risk. The two microorganisms most commonly considered to be the inciting agents in cases of PID, *N. gonorrhoeae* and *C. trachomatis*, have a predilection for columnar epithelium. As suggested by Schaefer and by Sweet and colleagues, cervical columnar epithelium is exposed to a greater extent in younger individuals and recedes into the cervical canal with increasing age.

Clinical and laboratory studies have documented that the use of contraceptives change the relative risk for development of PID. Multiple case-control studies have shown an increased risk of acute PID in women who use an IUD. It has been estimated that IUD users have a threefold to fivefold increased risk for development of acute

PID, with the greatest risk the first 20 days after insertion. The incidence of infection has recently been described by Sufrin and colleagues in over 57,000 IUD insertions in California from 2005 to 2009. They reported an overall rate of approximately 1 in 200 patients.

Barrier methods of contraception (condoms, diaphragms, and spermicidal preparations) are effective both as mechanical obstructive devices and as chemical barriers. A nearly 60% decrease in the risk of PID has been demonstrated among women using a barrier method of contraception. Ness and colleagues found a 30% to 60% decrease in recurrent PID in women using condoms consistently.

Oral contraceptives have also been shown to reduce the risk and severity of acute PID. The mechanism for such protection remains speculative. The thicker cervical mucus produced by the progestin component of oral contraceptives is believed to inhibit sperm and accompanying bacteria penetration into the upper genital tract. The decrease in duration of menstrual flow accompanying oral contraceptive use theoretically creates a shorter interval for bacterial colonization. Svensson and coworkers reported that in addition to protecting against PID, the use of oral contraceptive pills was associated with a better prognosis for future fertility than was seen in women with acute PID using other contraceptive methods or no contraceptive methods. The pill's ability to inhibit ovulation also helps prevent an open nidus for tuboovarian abscess formation.

Surgical procedures of the female genital tract also place the patient at risk for PID. About 15% of pelvic infections occur after procedures that break the cervical mucous barrier, allowing for colonization of the upper genital tract. Eschenbach and Holmes reported that these procedures include endometrial biopsy, curettage, IUD insertion, hysteroscopy, and hysterosalpingography. The incidence of UGTI associated with first-trimester abortions is approximately 1 in 200 cases. Recent practice has emphasized the use of prophylactic antibiotics in high-risk cases to attempt to decrease the incidence of iatrogenic acute PID. A randomized trial by Jackson and a randomized trial by the Luton and Dunstable Hospital Study Group have indicated that the treatment of BV with metronidazole substantially reduced postabortion PID.

Acute salpingitis occurring in a woman with a previous tubal ligation was once believed to be rare. However, Phillips and D'Abling reported that acute PID developed in the proximal stump of previously ligated fallopian tubes in 1 of 450 women hospitalized for acute salpingitis. In addition, it is suspected that many cases may be undiagnosed because of the absence of peritoneal signs from the prevention of retrograde spillage of bacteria and inflammatory exudate in the pelvic cavity.

Previous acute PID is also a risk factor for future episodes of the disease. Another acute tubal infection develops in approximately 25% of women who have had acute PID. The exact mechanism for this increased susceptibility has not been determined, but it may be loss of the natural protective mechanisms of the fallopian tube lining against microorganisms. This increased risk may also be related to the sexual habits of the woman involved, such as reinfection from an untreated male partner. Eschenbach has documented that more than 80% of male contacts are not treated.

Genetic factors for PID have been further delineated recently. Paavonen and Taylor et al. have demonstrated that variants in the genes that regulate toll-like receptors can interfere with the innate immune system and are associated with an increased progression of infection, especially with *C. trachomatis*.

DIAGNOSIS

Acute PID presents with a broad spectrum of clinical symptoms. The differential diagnosis of acute PID includes acute appendicitis, endometriosis, torsion or rupture of an adnexal mass, ectopic pregnancy, and cervicitis.

Common clinical manifestations include lower abdominal pain, cervical motion tenderness, and adnexal

tenderness and may include fever, cervical discharge, and leukocytosis. Historically, the diagnosis of acute PID was not established unless the patient had the triad of lower abdominal and pelvic pain, fever, and leukocytosis.

Jacobson and Westrom have shown that all three criteria are present in only 15% to 30% of documented PID cases. In fact, 50% of patients initially present with a normal temperature and WBC count. Pain in the lower abdomen and pelvis is by far the most common symptom of acute PID. It occurs in more than 90% of patients at initial presentation. The pain is usually described as constant and dull and is accentuated by motion and sexual activity. Generally, the pain is of recent onset, usually less than 7 days. About 75% of patients with PID have an associated endocervical infection and coexistent purulent vaginal discharge. Nausea and vomiting are relatively late symptoms in the course of the disease. Abnormal vaginal bleeding, especially menorrhagia or spotting, is noted in about 40% of patients. The CDC has established the criteria for making the diagnosis of salpingitis based on clinical grounds. They specify that only signs of pelvic and abdominal pain are required for a potential diagnosis of PID and eliminate leukocytosis and fever as essential criteria ([Table 30.1](#)).

TABLE 30.1 Criteria for the Diagnosis of Acute PID

<p>Empirical treatment of PID should be initiated in sexually active young women and other women at risk for STDs if they are experiencing pelvic or lower abdominal pain, if no cause for the illness other than PID can be identified, and if one or more of the following minimum criteria are present on pelvic examination:</p> <ul style="list-style-type: none">• Cervical motion tenderness <i>or</i> uterine tenderness <i>or</i> adnexal tenderness
<p>The requirement that all three minimum criteria be present before the initiation of empiric treatment could result in insufficient sensitivity for the diagnosis of PID. The presence of signs of lower genital tract inflammation (predominance of leukocytes in vaginal secretions, cervical exudates, or cervical friability), in addition to one of the three minimum criteria, increases the specificity of the diagnosis. Upon deciding whether to initiate empiric treatment, clinicians should also consider the risk profile of the patient for STDs.</p>
<p>More elaborate diagnostic evaluation frequently is needed because incorrect diagnosis and management might cause unnecessary morbidity. One or more of the following criteria can be used to enhance the specificity of the minimum criteria. The following additional criteria can be used to enhance the specificity of the minimum criteria and support a diagnosis of PID:</p> <ul style="list-style-type: none">• Oral temperature >101°F (>38.3°C)• Abnormal cervical or vaginal mucopurulent discharge• Presence of abundant numbers of WBC on saline microscopy of vaginal secretions• Elevated erythrocyte sedimentation rate (ESR)• Elevated C-reactive protein• Laboratory documentation of cervical infection with <i>N. gonorrhoeae</i> or <i>C. trachomatis</i>

Most women with PID have either mucopurulent cervical discharge or evidence of WBCs on a microscopic evaluation of a saline preparation of vaginal fluid (i.e., wet prep). If the cervical

discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be considered. A wet prep of vaginal fluid offers the ability to detect the presence of concomitant infections (e.g., BV and trichomoniasis).

The most specific criteria for diagnosing PID include the following:

- Endometrial biopsy with histopathologic evidence of endometritis;
 - Transvaginal sonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tuboovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia); or
 - Laparoscopic abnormalities consistent with PID
-

A diagnostic evaluation that includes some of these more extensive procedures might be warranted in some cases. Endometrial biopsy is warranted in women undergoing laparoscopy who do not have visual evidence of salpingitis, because endometritis is the only sign of PID for some women.

Abdominal pain can also be associated with perihepatic inflammation and adhesions, more commonly known as the Fitz-Hugh-Curtis syndrome. It is believed to develop in 1% to 10% of patients with acute PID. Signs and symptoms include right upper quadrant pain, pleuritic pain, and tenderness in the right upper quadrant when the liver is palpated ([Fig. 30.3](#)). Usually, the symptoms and signs of this syndrome are preceded by the clinical onset of acute PID. Due to the upper abdominal pain, this condition is often mistakenly diagnosed as either acute cholecystitis or pneumonia. Fitz-Hugh-Curtis syndrome is believed to develop from vascular or transperitoneal dissemination of either *N. gonorrhoeae* or *C. trachomatis* to produce the perihepatic inflammation. Other organisms may be involved, but limited data exist on their causality.

Jacobson and Westrom attempted to correlate the clinical diagnosis of acute salpingitis with laparoscopic pelvic findings. Of 814 women in whom laparoscopy was performed for presumed acute PID, 512 (65%) had visual evidence of salpingitis, 184 (23%) had normal visual findings, and 98 (12%) had other pelvic pathology. Because of the positive clinical findings consistent with PID, many of the patients with normal findings were suspected to have early PID with endometritis and endosalpingitis, without the visual evidence of tubal or pelvic damage. Thus, *laparoscopy* is limited as a method of diagnosing the early stages of PID, but it is crucial to rule out the 12% “other” pathology, especially the non-PID surgical emergencies, such as appendicitis, and noninfectious entities requiring different treatment modalities, such as endometriosis or hemorrhagic cyst.

FIGURE 30.3 Violin-string adhesions of chronic Fitz-Hugh-Curtis syndrome. (Image reprinted from Medscape Reference, <http://emedicine.medscape.com/>, 2013, with permission, available at: <http://emedicine.medscape.com/article/256448-overview>)

Despite these shortcomings of early diagnosis, laparoscopic visualization of the pelvis is still important as the most

P.636

accurate method of confirming the diagnosis and assessing the severity of acute PID. However, it is logistically and economically impractical for all patients suspected of having acute PID to undergo diagnostic laparoscopy in the United States. Therefore, the diagnosis of most episodes of acute PID is often made on the basis of clinical history and physical examination. Although it is suggested that laparoscopy be offered to all patients with an uncertain diagnosis, it is strongly indicated for patients who are not responding to therapy, to confirm the diagnosis, to obtain cultures from the cul-de-sac or fallopian tubes, or to drain pus if necessary. In summary, laparoscopic studies have shown the following:

1. The clinical diagnosis of acute PID may be inaccurate.
2. Acute PID is sometimes found in patients undergoing laparoscopy for other causes of pelvic pain.
3. Laparoscopy is a relatively safe method in most cases for making the visual diagnosis of the latter stages of PID and thus assessing future fertility prognosis and planning.
4. Laparoscopy is an excellent means of obtaining cultures directly from the tube and peritoneal cavity.

The appearance of the pelvic organs can vary from erythematous, indurated, edematous oviducts, to pockets of purulent material, to a large pyosalpinx or tuboovarian abscess. However, although no disease may be evident in early stages, it is imperative to render treatment to all stages to avoid long-term sequelae. Other less invasive methods of diagnosis have been suggested for verifying a clinical diagnosis of acute PID.

Because most cases of UGTI are associated with and preceded by LGTI, examination of the endocervix for inflammation, Gram stain, and culture for both *N. gonorrhoeae* and *C. trachomatis* are important for proper evaluation. A negative Gram-stained smear of the endocervix does not absolutely rule out upper tract infection. However, most studies have found that acute PID is rare without a concomitant increase in inflammatory cells in the vagina and the cervix.

Endometrial biopsy is one alternative to laparoscopy. Paavonen and associates reported a 90% correlation between histologic endometritis and laparoscopically confirmed salpingitis. However, results may be

delayed up to 2 to 3 days, making its clinical applicability limited.

Ultrasonography is of limited value for patients with mild or moderate pelvic PID. Thus, the routine use of sonography in patients with early PID is often not helpful. However, ultrasound is indicated in distinguishing an adnexal mass, especially in patients who demonstrate a lack of response to antimicrobial therapy in the initial 48 to 72 hours of therapy. Sonohysterography, an ultrasound examination using the instillation of saline to better define pelvic structures, is not indicated at this time for patients suspected of having PID, because no studies have been performed to demonstrate its safety in the event that pathogens are dispersed into the upper genital tract in the process of instilling the saline.

Culdocentesis, with evidence of purulent peritoneal fluid, is a helpful, but painful, method to help diagnose acute PID. With acute PID, the WBC count of peritoneal fluid is greater than 30,000 cells/mL, compared with a WBC count of 1,000 cells/mL in women without peritoneal inflammation. However, other infections, such as appendicitis and diverticulitis, among others, can also cause purulent pelvic fluid and a false diagnosis of PID.

Laboratory tests can be obtained, but their results lack sufficient sensitivity and specificity to make them an important factor in establishing the diagnosis. Leukocytosis is not a reliable indicator of acute PID, nor does it accurately correlate with the severity of tubal inflammation or need for hospitalization. Less than 50% of women with acute PID have a WBC count greater than 10,000 cells/mL. Similarly, the erythrocyte sedimentation rate (ESR), which for years was a routine laboratory test for women with acute PID, is nonspecific and is a crude indicator of severity of disease. The ESR is elevated higher than 15 mm/hour in about 75% of women with laparoscopically confirmed acute salpingitis. However, 53% of women with pelvic pain and normal-appearing pelvic organs also have an elevated ESR. Plasma proteins, such as C-reactive protein and antichymotrypsin, have been studied to determine whether they help in the diagnosis of acute PID. They have been found to be more sensitive than the ESR. Other investigators have found that *decreased or absent isoamylase in peritoneal fluid* in cases of acute PID is the best nonculture laboratory test for the disease. The major disadvantages of this test are that it requires several hours to complete and that peritoneal fluid must be obtained.

Other evaluations have revealed various inflammatory cytokines to be associated with pelvic infections; however, these tests are not yet commercially available to a useful extent.

SEQUELAE

Infertility

One fourth of all women who have had acute salpingitis experience one or more long-term sequelae. The most common is involuntary infertility, which occurs in about 20% of patients. Thus, PID ranks as one of the major causes of infertility. Before antibiotic therapy, 50% to 70% of women who had experienced UGTIs became sterile. The sequelae of infections vary from a patent oviduct, to peritubular and periovarian adhesions that may interfere with ovum pickup, and/or to complete tubal obstruction. The infertility rate increases directly with the number of episodes of acute pelvic infection. Also, women with mild disease are seven times less likely to suffer tubal obstruction than women with severe PID.

Ectopic Pregnancy

The chance of ectopic pregnancy is increased 6- to 10-fold in patients with a previous episode of acute salpingitis. Pathologic studies estimate that at least 50% of ectopic pregnancies occur in fallopian tubes damaged by previous salpingitis. The mechanism for the increased rate is believed to be interference of ovum transport through the tube or entrapment of the ovum secondary to intraluminal tubal damage.

Chronic Pelvic Pain

The chance that chronic pelvic pain will develop in a woman after acute salpingitis is four times that of control subjects without pelvic infection (20% vs. 5%). Chronic pelvic pain can be caused by a hydrosalpinx. A hydrosalpinx is presumably the end-stage development of a pyosalpinx. The pain can also be related to adhesions surrounding the tube and ovary. All patients with chronic pelvic pain believed to be caused by acute PID should undergo laparoscopy or laparotomy to establish the cause of the chronic pain and rule out other diseases such as endometriosis, which require different treatment, or the presence of pelvic adhesions, which can often be directly resolved.

A tuboovarian complex is a collection of pus within an anatomic space created by adherence to adjacent organs. The incidence of true adnexal abscess is about 10% in women with acute PID. Landers and Sweet noted a 20% rate of early treatment failure (after 48 to 72 hours) of antibiotic therapy as a result of persistent pain or enlargement of a tuboovarian

P.637

abscess or complex. In addition, according to Landers and Sweet, 31% required an operation several weeks to months after their acute infections for persistent disease or pain.

MORTALITY

Before antibiotic therapy, the mortality rate associated with acute PID was 1%. Most of these deaths resulted from rupture of tuboovarian abscesses. Today, death associated with PID is rare, as effective antibiotic treatment is frequently initiated. However, the mortality rate can still be as high as 5% to 10% for ruptured tuboovarian abscesses, if treatment is delayed or inadequate. Death is mostly the result of subsequent development of adult respiratory distress syndrome (ARDS), a condition often associated with serious infection or delayed treatment after intra-abdominal spillage of pus and bacteria.

TREATMENT

The therapeutic goals in the management of acute PID include both elimination of the acute infection and symptoms and prevention of long-term sequelae such as infertility, ectopic pregnancy, and chronic pelvic pain. Antibiotic treatment should be started as soon as cultures have been obtained and diagnosis is confirmed or strongly suspected. Treatment is based on the consensus that PID is polymicrobial in cause. Empirical antibiotic protocols should cover a wide range of bacteria, including *N. gonorrhoeae*, *C. trachomatis*, anaerobic rods and cocci, Gram-negative aerobic rods, Gram-positive aerobes, and *Mycoplasma* species. Despite general agreement that broadspectrum therapy is appropriate, questions persist regarding optimal therapeutic regimens.

Controversy has arisen over the issue of outpatient treatment with oral antibiotics versus inpatient treatment with parenteral antibiotics. There is limited data available to evaluate the efficacy of hospital versus ambulatory management of acute PID, due to the ethics of randomizing seriously ill PID patients to outpatient therapy. However, in the United States, three of four women with acute pelvic infection are treated as outpatients for their disease.

In Scandinavia, which has a different health care system, most women are treated as inpatients. In 2010, the CDC published recommended treatment guidelines for outpatient management of acute PID ([Table 30.2](#)). Some of the treatment regimens are based on the controversial premise that it may be adequate to cover just a few of the major etiologic agents (*N. gonorrhoeae* and *C. trachomatis*) involved in acute PID. As a result, studies have documented a 10% to 20% treatment failure rate for women receiving oral antibiotics as outpatients compared with a 5% to 10% failure rate for women without an abscess receiving intravenous antibiotics as inpatients, where broader coverage is used.

It is important to reevaluate patients within 48 to 72 hours of initiating outpatient therapy to determine the response of the disease. If a poor response has been obtained, the patient should be hospitalized with parenteral antibiotics and possible laparoscopic evaluation in the hope of preventing or limiting the sequelae of PID or discovering a different diagnosis, such as appendicitis or diverticulitis.

Ideally, every woman with acute PID should be hospitalized for the first few days for parenteral antibiotic treatment. Because this may not be practical because of limited economic or physical facility resources, the clinician who diagnoses acute PID in the office or emergency department is faced with the question of which patient to hospitalize. Indications for the hospitalization of patients with acute PID are also defined by the CDC in the 2010 guidelines ([Table 30.3](#)). In the past, the CDC has suggested that all adolescents with PID be hospitalized because of their high noncompliance rate and to optimize treatment to prevent damage to the reproductive tract, which could affect future fertility and/or result in chronic pelvic pain. Recently, Kelly and colleagues found a high incidence of recurrence in adolescents, perhaps related to poor compliance. However, the CDC's new policy is to use the same criteria for hospitalization as for older women. This recommendation is not agreed upon by all infectious disease groups because of the seriousness of inadequately treated PID in a younger, often noncompliant population.

Another indication for hospitalization is the presence of an adnexal or pelvic abscess. Outpatient therapy may not provide antibiotic levels high enough to penetrate an abscess, and rupture of the abscess may have serious consequences.

Also, women in whom the definitive diagnosis of acute PID is in question should also be hospitalized, and additional diagnostic measures should be instituted. As previously stated, at least 10% of all patients have other serious diagnoses, such as acute appendicitis, ectopic pregnancy, or adnexal torsion, and these should be ruled out. Patients with serious illness, patients with nausea and vomiting, patients who are unable to follow or tolerate outpatient therapy, and patients with a previously failed outpatient oral regimen also should be hospitalized and given parenteral antibiotics. A trial by Ness and colleagues investigating the outcomes in patients randomized to inpatient or outpatient did not find differences in short-term outcomes, but difficulties in patient selection and randomization may not permit these results to be applicable to all PID patients.

The 2010 CDC guidelines for inpatient treatment of acute PID describe two regimens ([Table 30.4](#)).

Regimen A is a combination of oral or parenteral doxycycline plus intravenous cefoxitin or cefotetan. Other third-generation cephalosporins can be substituted, such as ceftizoxime (Cefizox) or cefotaxime (Claforan). All of these agents are effective against penicillinase-producing *N. gonorrhoeae*, *Peptostreptococcus*, and other anaerobic species, as well as *E. coli* and other aerobic (facultative) species. Ceftriaxone is recommended by the CDC; however, its poor anaerobic activity and lack of controlled trials in PID patients do not make it an acceptable alternative for several investigators. Doxycycline can be given intravenously if the patient is unable to tolerate oral therapy, but it must be infused very slowly to prevent pain and sclerosis of the vein. Oral doxycycline has been demonstrated to be equally effective as parenteral doxycycline because of the slow growth cycle of *Chlamydia* and the requirement of prolonged treatment.

A recent study by Viberga and colleagues investigating the microbiology of IUD-related infection found an increased recovery of *Fusobacterium* and *Peptostreptococcus* species, which generally are covered by both cephalosporin and clindamycin. A possible disadvantage of the cephalosporin-doxycycline combination is that these two antibiotics may be less than ideal for anaerobic infections such as in a pelvic abscess.

Regimen B is a combination of clindamycin and an aminoglycoside (gentamicin). This combination provides excellent activity against anaerobes, Gram-negative aerobes, and Gram-positive aerobes. Historically, it has been the preferred regimen for patients with an abscess, IUD-related infections, or pelvic infections after a diagnostic or operative procedure. However, there are few data to prove that it is significantly more effective

than the cephalosporin regimens. A possible disadvantage of regimen B is that it may not provide optimal activity against *C. trachomatis* and *N. gonorrhoeae*. Clindamycin in high doses (900 mg in 8 hours) has good activity against *Chlamydia*, and in vitro studies by Martens and colleagues have demonstrated

P.638

effectiveness against 90% of *C. trachomatis* strains. Doxycycline is the most effective chlamydial agent, according to in vitro testing, but needs to be used for at least 7 days to complete treatment when the patient is switched from parenteral to posthospitalization therapy. Also, the CDC recommendation of once-daily dosing for gentamicin is not based on any data on PID patients and should be used only if indicated for renal considerations until more studies are completed.

TABLE 30.2 CDC-Recommended Treatment Regimen for Oral Therapy of Acute PID

Outpatient oral therapy can be considered for women with mild to moderately severe acute PID, because the clinical outcomes among women treated with oral therapy are similar to those treated with parenteral therapy. The following regimens provide coverage against the frequent etiologic agents of PID. Patients who do not respond to oral therapy within 72 h should be reevaluated to confirm the diagnosis and should be administered parenteral therapy on either an outpatient or inpatient basis.

Ceftriaxone 250 mg IM in a single dose

PLUS

Doxycycline 100 mg orally twice a day for 14 d

WITH OR WITHOUT

Metronidazole 500 mg orally twice a day for 14 d

OR

Cefoxitin 2 g IM in a single dose and probenecid, 1 g orally administered concurrently in a single dose

PLUS

Doxycycline 100 mg orally twice a day for 14 d

WITH OR WITHOUT

Metronidazole 500 mg orally twice a day for 14 d

OR

Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime)

PLUS

Doxycycline 100 mg orally twice a day for 14 d

WITH OR WITHOUT

Metronidazole 500 mg orally twice a day for 14 d

The optimal choice of a cephalosporin is unclear; although cefoxitin has better anaerobic coverage, ceftriaxone has better coverage against *N. gonorrhoeae*. A single dose of cefoxitin is effective in obtaining short-term clinical response in women who have PID.

However, the theoretical limitations in its coverage of anaerobes may require the addition of metronidazole to the treatment regimen. Adding metronidazole also will effectively treat BV, which is frequently associated with PID. No data have been published regarding the use of oral cephalosporins for the treatment of PID.

Alternative Oral Regimens

Although information regarding other outpatient regimens is limited, other regimens have undergone at least one clinical trial and have demonstrated broad-spectrum coverage. In a single clinical trial, amoxicillin/clavulanic acid and doxycycline were effective together in obtaining short-term clinical response; however, gastrointestinal symptoms might limit compliance with this regimen.

Azithromycin has demonstrated short-term effectiveness in one randomized trial, and in another study, it was effective when used in combination with ceftriaxone 250 mg IM single dose and azithromycin 1 g orally once a week for 2 wk. When considering alternative regimens, the addition of metronidazole should be considered, because anaerobic organisms are suspected in the etiology of PID and metronidazole will also treat BV.

As a result of the emergence of quinolone-resistant *Neisseria gonorrhoeae*, regimens that include a quinolone agent are no longer recommended for the treatment of PID. If parenteral cephalosporin therapy is not feasible, use of fluoroquinolones (levofloxacin 500 mg orally once daily or ofloxacin 400 mg twice daily for 14 d) with or without metronidazole (500 mg orally twice daily for 14 d) can be considered if the community prevalence and individual risk for gonorrhea are low. Diagnostic tests for gonorrhea must be performed before instituting therapy and the patient managed as follows if the test is positive.

- Laparoscopic abnormalities consistent with PID. If the culture for gonorrhea is positive, treatment should be based on results of antimicrobial susceptibility.
 - If the isolate is determined to be quinolone-resistant *N. gonorrhoeae* or if antimicrobial susceptibility cannot be assessed (e.g., if only nucleic acid amplification testing is available), parenteral cephalosporin is recommended. However, if cephalosporin therapy is not feasible, the addition of azithromycin 2 g orally as a single dose to a quinolone-based PID regimen is recommended.
-

Each regimen stresses two concepts: the polymicrobial etiology of acute pelvic infection and the necessity of protecting against *C. trachomatis* and *N. gonorrhoeae*. With both regimens, the CDC recommends a minimum of at least 24 hours of intravenous treatment after clinical improvement. Both protocols also require completion of a 14-day course of oral antibiotics (doxycycline or clindamycin) to eradicate slow-growing organisms such as *C. trachomatis* and other mollicutes.

P.639

TABLE 30.3 Criteria for Hospitalization of Patients with Acute PID

In women with PID of mild or moderate clinical severity, outpatient therapy yields short- and long-term clinical outcomes similar to inpatient therapy. The decision of whether hospitalization is necessary should be based on the judgment of the provider and whether the patient meets any of the following suggested criteria:

- Surgical emergencies (such as appendicitis) cannot be excluded.
- The patient is pregnant.
- The patient does not respond clinically to oral antimicrobial therapy.
- The patient is unable to follow or tolerate an outpatient oral regimen.
- The patient has severe illness, nausea and vomiting, or high fever.
- The patient has a tuboovarian abscess.

No evidence is available to suggest that adolescents benefit from hospitalization for treatment of PID. The decision to hospitalize adolescents with acute PID should be based on the same criteria used for older women. Younger women with mild-to-moderate acute PID have similar outcomes with either outpatient or inpatient therapy, and clinical response to outpatient treatment is similar among younger and older women.

TABLE 30.4 CDC-Recommended Treatment Regimens for Parenteral Therapy of Acute PID

REGIMEN A

Cefotetan 2 g IV every 12 h

OR

Cefoxitin 2 g IV every 6 h

PLUS

Doxycycline 100 mg orally or IV every 12 h

Because of the pain associated with intravenous infusion, doxycycline should be administered

orally when possible. Oral and IV administration of doxycycline provides similar bioavailability.

Parenteral therapy can be discontinued 24 h after clinical improvement, but oral therapy with doxycycline (100 mg twice a day) should continue to complete 14 d of therapy. When tuboovarian abscess is present, clindamycin or metronidazole with doxycycline can be used for continued therapy rather than doxycycline alone, because this regimen provides more effective anaerobic coverage.

Limited data are available to support the use of other second- or third-generation cephalosporins (e.g., ceftizoxime, cefotaxime, and ceftriaxone), which also might be effective therapy for PID and could potentially replace cefotetan or ceftiofur. However, these cephalosporins are less active than cefotetan or ceftiofur against anaerobic bacteria.

Regimen B

Clindamycin 900 mg IV every 8 h

PLUS

Gentamicin loading dose IV or IM (2 mg/kg of body weight) followed by a maintenance dose (1.5 mg/kg) every 8 h. Single daily dosing (3-5 mg/kg) can be substituted.

Although use of a single daily dose of gentamicin has not been evaluated for the treatment of PID, it is efficacious in analogous situations. Parenteral therapy can be discontinued 24 h after clinical improvement; ongoing oral therapy should consist of doxycycline 100 mg orally twice a day or clindamycin 450 mg orally four times a day to complete a total of 14 d of therapy. When tuboovarian abscess is present, clindamycin should be continued rather than doxycycline, because clindamycin provides more effective anaerobic coverage.

Alternative Parenteral Regimens

Limited data are available to support the use of other parenteral regimens. The following regimen has been investigated in at least one clinical trial and has broad-spectrum coverage.

Ampicillin/sulbactam 3 g IV every 6 h

PLUS

Doxycycline 100 mg orally or IV every 12 h

Ampicillin/sulbactam plus doxycycline is effective against *C. trachomatis*, *N. gonorrhoeae*, and anaerobes in women with tuboovarian abscess. One trial demonstrated high short-term clinical cure rates with azithromycin, either as monotherapy for 1 wk (500 mg IV for one or two doses followed by 250 mg orally for 5-6 d) or combined with a 12-day course of metronidazole.

Alternative inpatient parenteral regimens are included in the 2010 CDC PID guidelines ([Table 30.4](#)). The CDC lists only the β -lactamase inhibitor combination ampicillin-sulbactam (Unasyn), but piperacillin-tazobactam combination has been demonstrated by Hemsell and colleagues, Sweet and colleagues, and others to have excellent in vitro and in vivo activity against PID and its pathogens and does have an FDA-approved indication for the treatment of pelvic infections.

MANAGEMENT OF SEX PARTNERS

According to the CDC:

Male sex partners of women with PID should be examined and treated if they had sexual contact with the patient during the 60 days preceding the patient's onset of symptoms. If a patient's last sexual intercourse was less than 60 days before onset of symptoms or diagnosis, the patient's most recent sex partner should be treated. Patients should be instructed to abstain from sexual intercourse until therapy is completed and until they and their sex partners no longer have symptoms. Evaluation and treatment are imperative because of the risk for reinfection of the patient and the strong likelihood of urethral gonococcal or chlamydial infection in the sex partner. Male partners of women who have PID caused by *C. trachomatis* and/or *N. gonorrhoeae* frequently are asymptomatic.

Sex partners should be treated empirically with regimens effective against both of these infections, regardless of the etiology of PID or pathogens isolated from the infected woman. Even in clinical settings in which only women are treated, arrangements should be made to provide care or appropriate referral for male sex partners of women who have PID. Expedited partner treatment and enhanced patient referral are alternative approaches to treating male partners of women who have chlamydial or gonococcal infections.

HIV INFECTION

Differences in the clinical manifestations of PID between human immunodeficiency virus (HIV)-infected women and HIV-negative women have not been well delineated. In early observational studies, HIV-infected women with PID were more likely to require surgical intervention. In recent, more comprehensive observational and controlled studies, HIV-infected women with PID had similar symptoms when compared with uninfected controls. They were more likely to have a tuboovarian abscess, but responded equally to standard parenteral and oral antibiotic regimens when compared with HIV-negative women. The microbiologic findings for HIV-positive and HIV-negative women were similar, except for (a) higher rates of concomitant *M. hominis*, *Candida*, streptococcal, and HPV infections and (b) HPV-related cytologic abnormalities among those with HIV infection. Regardless of these data, whether the management of immunodeficient HIV-infected women with PID requires more aggressive interventions (e.g., hospitalization or parenteral antimicrobial regimens) had not been determined.

Intrauterine Contraceptive Devices

Also, per CDC guidelines:

IUDs are popular contraceptive choices for women. Both levonorgestrel and copper-containing devices are marketed in the United States. The risk for PID associated with IUD use is primarily confined to the first 3 weeks after insertion and is uncommon thereafter. Given the popularity of IUDs, practitioners might encounter PID in IUD users. Evidence is insufficient to recommend the removal of IUDs in women diagnosed with acute PID. However, caution should be exercised if the IUD remains in place, and close clinical follow-up is mandatory. The rate of treatment failure and recurrent PID in women continuing to use an IUD is unknown, and no data have been collected regarding treatment outcomes by type of IUD (e.g., copper or levonorgestrel).

SURGICAL MANAGEMENT

If the diagnosis is under question, or the patient is responding poorly, surgical evaluation and/or management

are indicated.

Laparotomy should generally be reserved for patients with surgical emergencies such as ruptured abscesses or definitive treatment of failed medical management. Laparoscopy, however, is an underused but usually helpful procedure for diagnosis, prognosis, and possibly treatment of PID. Laparoscopic evaluation should be considered in all patients with a differential diagnosis of PID and without laparoscopic surgery contraindications.

Laparoscopy is important not only to diagnose PID but also to rule out surgical emergencies, such as appendicitis and ruptured abscesses. It also prevents inappropriate management of patients with noninfectious problems, such as endometriosis. These patients need additional surgical and medical management, not antibiotic therapy and delayed diagnosis. In addition, evaluation of the extent of the inflammatory process in confirmed PID is helpful in establishing a prognosis and further management plan if initial treatment fails. Patients with evidence of current or previous abscesses have a higher failure rate with antibiotic therapy. Also, treatment of unilateral abscesses may necessitate surgical management to avoid the spread of the infection to the other tube and ovary.

Cultures obtained from the peritubal region or from the peritoneal cavity can also be helpful for identifying organisms resistant to initial management. This has become increasingly important in light of the increasing rate of clindamycin-resistant anaerobes and the elimination of intravenous metronidazole from the CDC-recommended inpatient guidelines. Laparoscopic management of PID that appears helpful includes copious lavage of the pelvis with normal saline or preferably Ringer solution. Antibiotic inclusion in the lavage fluid has not been demonstrated to be helpful to date.

Laparoscopic manipulation or drainage of documented pelvic abscesses has been attempted by several investigators. Henry-Suchet and associates reported the successful use of laparoscopy to diagnose and drain tuboovarian abscesses in 50 women. Adhesions were lysed, and the abscesses were drained through the laparoscope. All patients received intravenous antibiotics. Forty-five of the fifty (90%) patients were cured. Reich and McGlynn had a similar experience in 25 women with pelvic abscesses treated laparoscopically. Four of seven women desiring pregnancy conceived, and two women had unplanned pregnancies. However, the diagnosis of abscesses was not uniform in these studies. Also, it is of concern that similar results will not necessarily be demonstrated in less experienced hands. Anatomically, drainage of abscesses within the pelvic cavity by laparoscope will not drain the entire abscess contents out of the pelvic cavity, and despite how extensive the lavage or laparoscopic removal is, pus and bacteria will be spilled and exposed to the pelvic cavity. This is contrary to the natural defense mechanism of the body of isolating and containing the inflammation-causing organisms within an abscess. Therefore, laparoscopic drainage of pelvic abscesses should be undertaken only by experienced laparoscopic surgeons and with the patient's full understanding of all other options.

Laparotomy with extensive pelvic surgery was often recommended in the past, before the development of broad-spectrum antibiotics.

If a patient has been hospitalized on several occasions for acute exacerbation of PID with bilateral tuboovarian abscesses to the point where the future surgical risk increases

P.641

significantly, definitive surgical intervention may be indicated. The operation should be done when the infection is quiescent, if possible. The surgery may still be difficult, but there will be fewer complications than when patients are operated on in the acute phase of the infection. The timing of the operative intervention is important. There should be complete absorption of the inflammatory exudate surrounding the focus of the infection, as seen radiologically. Bimanual pelvic examination should be possible without producing a marked or persistent febrile response. It has been suggested that definitive surgery be delayed for 2 to 3 months after the recent

exacerbation for more complete resolution of the infection. Ideally, the patient should have a normal ESR, WBC, and hematocrit, and relatively nontender pelvic organs, except possibly with motion.

Kaplan and associates recommended more aggressive management in patients who exhibit either no clinical response or only partial response after 24 to 72 hours. Their approach included a total abdominal hysterectomy and bilateral salpingo-oophorectomy and was thought to reduce the protracted period of intensive medical therapy in a group of patients who would eventually require surgery. They noted that conservative management of their cases usually resulted in protracted periods of intensive care and repeated hospital admissions, and rarely in subsequent pregnancies. However, the early surgical intervention described above was associated with several incidences of injury to the bowel and additional postoperative complications. Also, patients with acute pelvic abscess are frequently young, and future childbearing is often desired. Even with uterine and ovarian preservation, pregnancy is difficult without intervention such as in vitro fertilization for most patients. Conservation of ovarian function for these young women is an important benefit of medical management for the rest of their adult lives.

Older studies of the management of patients with pelvic abscess, which emphasized the early use of surgery, are no longer pertinent, because modern antibiotic drugs were not available then. Collins and Jansen in 1959 had an early failure rate of 10% for conservative medical therapy. However, 113 of their 174 patients required later surgery, which corresponds to a late failure rate of 65%. Two decades later, Ginsburg and associates reviewed cases of 160 patients treated for tuboovarian abscess during the years 1969 to 1979. The early failure rate with broad-spectrum antibiotics was high at 31%, but the late failure rate was only 21%. Thus, with an average followup period of 25.5 months, 48% did not require later surgery. Subsequent reports by Hager and colleagues and by Landers and Sweet support conservative management, as better antibiotics have been introduced.

POSTERIOR COLPOTOMY

When conservative management fails and a pelvic abscess is noted dissecting the rectovaginal septum, drainage by way of colpotomy may be possible.

In a classic article, Wharton described various techniques of vaginal drainage of pelvic abscess. Today, posterior colpotomy is done to evacuate pus and to establish drainage from a pelvic abscess that presents in the cul-de-sac.

There are three requirements for colpotomy drainage of a pelvic abscess:

1. The abscess must be predominantly midline.
2. The abscess should be adherent to the cul-de-sac peritoneum and should dissect the rectovaginal septum to assure the surgeon that the drainage will be extraperitoneal and that pus will not be disseminated transperitoneally.
3. The abscess should be cystic or fluctuant to ensure adequate drainage.

Occasionally, a cul-de-sac abscess can be successfully drained without dissecting the septum. However, the serosal surface of the abscess should be adherent to the cul-de-sac peritoneum. Ultrasonography may be helpful in locating the pockets of pus.

After adequate anesthesia, the patient is placed in the lithotomy position. It is essential that a thorough examination of the pelvis be performed under anesthesia so that the operator knows the size and position of the mass that is to be drained.

After preparation and draping in the dorsal lithotomy position, the posterior lip of the cervix is grasped with a tenaculum and drawn down and forward. The vaginal epithelium of the posterior vaginal fornix is incised just below the reflection of the vaginal mucosa onto the cervix, and the transverse incision is widened with a pair of

long scissors (**Fig. 30.4A**). The incision must be large enough to allow adequate exploration and drainage of the abscess cavity with the index finger. The cul-de-sac peritoneum and abscess wall are punctured with a long Kelly clamp (**Fig. 30.4B**). As the abscess wall is perforated, there is a definite sensation of puncturing a cystic cavity. If blood or pus is present, this is soon seen coming into the upper vagina. The jaws of the clamp are spread, and the flow

P.642

of liquid from the cul-de-sac is increased. A sample of the purulent exudate is sent to the microbiology laboratory for appropriate culture and sensitivity. Collection of the specimen anaerobically with a capped syringe with rapid transport to the laboratory allows the more fastidious flora to be defined. A direct smear for Gram stain is also made from the pus examined for predominating organisms.

FIGURE 30.4 Posterior colpotomy. **A:** A transverse incision is made through the vaginal mucosa at the junction of the posterior vaginal fornix with the cervix. **B:** A Kelly clamp is thrust through the abscess wall.

FIGURE 30.5 Pus may be contained within the tuboovarian abscess and within other pockets in the pelvic cavity.

There may be more than one compartment in an abscess cavity (**Fig. 30.5**). It is desirable to insert an index finger in the cavity and explore. Fibrous adhesions within the cavity can be gently broken. If another abscess wall is felt, it can often be cautiously and safely punctured under the guidance of a finger. Exploration and manipulation should be done carefully to avoid intraperitoneal rupture of the abscess or perforation of the bowel. To allow adequate drainage, the vaginal incision should be at least 2 cm wide. If pus has been obtained, one or two drains are inserted into the abscess cavity and anchored by balloon or with fine absorbable suture to permit easy removal. Penrose or closed suction drainage systems can be used. These should be left for several days until drainage stops and to allow air to prevent the reaccumulation of anaerobic organisms. Wharton has emphasized the importance of prolonged drainage. A suture or two may be required to control bleeding from the vaginal mucosa. However, if a mushroom (Malecot) catheter is used for drainage, it should be removed in 48 to 72 hours to prevent significant fibrosis that could hinder removal.

Patients in whom the abscess does not meet the criteria for colpotomy drainage often require laparotomy and direct drainage. Transabdominal, transvaginal, and transrectal drainage has been attempted to avoid the expense and complications of laparotomy and for patients in whom laparotomy is contraindicated.

PERCUTANEOUS DRAINAGE

Experience with *percutaneous drainage* of intraabdominal and pelvic abscesses under ultrasonographic or computed tomographic (CT) guidance has been reported by Olak and associates and by others. Worthen and Gunning used percutaneous catheter drainage of 11 abscesses in nine patients and achieved a cure rate of 77%. Two patients required surgical intervention subsequently. In 19 patients, simple percutaneous aspiration of 23 abscesses was successful, with a 94% cure rate. The attempt at aspiration failed in seven patients (**Fig. 30.6**). The Grady Memorial Hospital experience, as reported by Tyrrel and associates, is similar. CT-guided percutaneous drainage in eight patients with tuboovarian abscess resulted in recovery without surgery in seven. One patient had marked clinical improvement but still required a posterior colpotomy. No complications occurred. Loy and associates have reported that the simultaneous use of real-time pelvic ultrasonography can facilitate transvaginal drainage of a pelvic abscess. If patients do not respond to intravenous antibiotics and percutaneous

drainage or aspiration, surgical intervention is required. MR-assisted drainage has been utilized and is helpful when overlying gas patterns from the intestines or abscess cavity obscure ultrasonic imaging for needle placement.

FIGURE 30.6 Transabdominal needle aspiration of a pelvic abscess under guidance of CT. Drainage tube is also placed.

The long-term effects of pus and organisms released into the pelvis from the puncture site are unknown. However, short-term success rates are good, and surgical drainage of acute abscess is the basic principle. Therefore, needle drainage can be considered with proper patient selection and appropriate informed consent, which includes other management options.

EXPLORATORY LAPAROTOMY

If *exploratory laparotomy* is necessary, the patient can be positioned in Allen universal stirrups. A lower abdominal transverse Maylard incision is ideal because it affords good exposure to the lateral adnexal pelvic organs and pelvic side walls. Pelvic adhesions should be released, and the bowel should be packed off before the pelvic dissection commences. During the dissection, free pus is often spilled, and the upper abdomen should be isolated from this, if possible. When a ruptured abscess is encountered, the exudate is collected and sent immediately to the laboratory for Gram stain, anaerobic and aerobic cultures, and antimicrobial sensitivity studies. The easiest way to obtain the material for anaerobic culture is simply to collect it in an airtight syringe and to submit a small piece of the abscess wall in an airtight container. The easiest place to begin the dissection is in the round ligament, which is the most consistently

P.643

available and identifiable landmark. Following the round ligament medially always leads to the uterine corpus. Variations in the usual technique for the operation may be required because of extensive disease, dense adhesions, indurated and edematous tissue, and distorted anatomy. For example, it is sometimes convenient to perform the central dissection first (i.e., a subtotal hysterectomy). This allows more space and adequate exposure to perform the required adnexal surgery. Tuboovarian inflammatory masses may be found densely adherent in the cul-de-sac to the uterus, to the posterior surface of the broad ligament, and to the lateral pelvic sidewall. There is risk of injury to the ureters, sigmoid, rectum, and small intestines. The method of dissection used depends on the nature of the adhesions. Soft, fresh adhesions can be broken gently and easily with finger dissection. Dense fibrotic adhesions must be carefully dissected and cut with scissors. The dissection can be

especially difficult and risky if pelvic tissues are intensely indurated, as in ligneous pelvic cellulitis. If the infundibulopelvic ligament can be clamped, cut, and securely ligated, one can gain access to the lateral retroperitoneal space and identify the ureter. This facilitates a safe dissection of the abscess wall away from the ureter. In cases with extensive disease involving one or both adnexa, the use of preoperative ureteral catheterization may be helpful in identifying the location of the pelvic ureters. With tuboovarian abscess, the anatomic limits of the ovary may be difficult to define. If the ovary is to be removed, it should be removed completely to prevent subsequent development of ovarian remnant syndrome.

When both adnexa must be removed, a hysterectomy should be entertained if extensive uterine involvement is suspected. In some cases, only a subtotal hysterectomy is feasible. However, if the lower uterine segment can be visualized, the cervix can usually be excised after removal of the adnexa and the uterine corpus. The operative field should be copiously irrigated. The vaginal vault should be left open for drainage. A Penrose drain can be inserted and then removed several days later. Suspension of the vaginal vault and reperitonization of the pelvis are accomplished in the usual manner, if possible. A routine closure of the abdominal incision is performed. Jackson-Pratt suction drains are often placed above the fascia and brought out through a separate incision.

Because the patient has been placed in the Allen universal stirrups for laparotomy, ureteral integrity can be confirmed as discussed elsewhere. Five milliliters of indigo carmine is given intravenously, and a cystoscope is placed in the bladder. Blue dye can then be seen flowing from each ureteral orifice.

In the past, it was standard practice to do a bilateral salpingo-oophorectomy in almost all patients who had a laparotomy for acute pelvic abscess. This practice was based on the belief that the disease is almost always severe in both adnexa. Recent studies have suggested that as many as 25% to 50% of patients will have a relatively normal tube and ovary on one side. This may be especially true of patients whose infection is associated with IUD use. Golde and associates reported that 37 of 85 patients (44%) with tuboovarian abscesses confirmed at operation had unilateral abscesses; 20 were using an IUD. The studies of Landers and Sweet, Hager and Majmudar, and Ginsburg and coworkers also found a higher percentage of unilateral adnexal disease than was previously reported. In light of these findings, conservative adnexal surgery may be possible in some patients. We have no hesitation in leaving a relatively normal tube and ovary at the time of hysterectomy with removal of the opposite adnexa for acute pelvic abscess. When the uterus is removed and the continuity between the conserved tube and the lower genital tract is interrupted, there is little risk of a new infection. If a strictly unilateral pelvic abscess is found at laparotomy, removal of the affected tube and ovary only, leaving in the uterus and the opposite adnexa, is acceptable in a patient who wishes to preserve fertility. However, in vitro fertilization techniques may be required to accomplish pregnancy. Such a patient will then still have a risk of recurrent tuboovarian abscess. It is especially important that her sexual partner be examined and receive treatment when indicated.

In recent years, there have been advances in reproductive technology that allow infertile patients to conceive and carry pregnancies to term under the most extraordinary circumstances. It has been possible, for example, to accomplish a successful pregnancy in a woman who has a uterus but no ovaries by instillation of a donated fertilized ovum into a suitably prepared uterus. Such a sophisticated procedure is not available to a large number of patients. However, in light of the recent findings of the risk of estrogen plus progesterone treatment from the Women's Health Initiative Study, the option of leaving in the uterus when bilateral salpingo-oophorectomy is to be performed should be discussed with the patient, especially if she is young and nulliparous.

In summary, patients with an acute pelvic abscess should be hospitalized for treatment with parenteral broad-spectrum antibiotics. Surgery is indicated if the diagnosis is uncertain, if intraperitoneal rupture is diagnosed or suspected, or if the patient fails to respond to medical management.

RUPTURED PELVIC ABSCESS

A tuboovarian or pelvic abscess can rupture spontaneously into the rectum or sigmoid colon, into the bladder, or into the free peritoneal cavity. A pelvic abscess almost never ruptures spontaneously into the vagina unless the patient has previously damaged epithelium such as from a previous posterior colpotomy for drainage of an abscess. Under these circumstances, a recurrent pelvic abscess can dissect along the tract of the previous posterior colpotomy incision and drain spontaneously through the vagina.

Spontaneous drainage through the rectum or sigmoid colon usually occurs in a patient whose abscess is too high to drain with a posterior colpotomy. In other words, although the abscess is fluctuant and midline, it is not yet dissecting the rectovaginal septum. While waiting for the abscess to come down, a sudden unexpected improvement in the patient's condition is noted, and she will confirm that pus has begun to drain through the anus. Further improvement in her condition usually occurs. A posterior colpotomy is not needed and, indeed, is contraindicated because doing so could cause a rectovaginal fistula to form.

Spontaneous drainage through the bladder is rare. It occurs most commonly in elderly women with chronic abscesses developing from ruptured sigmoid diverticula. Only rarely does a chronic tuboovarian or pelvic abscess rupture and drain through the bladder, causing secondary infection of the bladder. When the abscess is removed with laparotomy, a defect in the bladder wall is noted. The indurated tissue around the defect should be removed and the defect closed with 3-0 delayed absorbable suture in two layers. A Foley catheter can be left in place for 10 to 14 days while healing of the bladder wall takes place.

Of all the complications that can result from PID, intraabdominal rupture of a tuboovarian abscess is the most life threatening. Mortality from this complication is due to septic shock and the complications of generalized peritonitis, and the mortality rate can approach up to 10% in patients with warm shock.

P.644

Abscesses can rupture spontaneously or iatrogenically after bimanual examination or accidental trauma. Bacteriologic study of the contents of the abscess has historically been unrewarding; a specific organism has been isolated in less than 50% of cases. The gonococcus is rarely identified in a pelvic abscess. Careful aerobic and anaerobic cultures often demonstrate the presence of a mixed infection that includes anaerobic organisms. McNamara and Mead reviewed the results of three separate studies that demonstrated 31 positive isolates of anaerobes in 30 patients with a pelvic abscess. Landers and Sweet have also confirmed similar findings in their series.

Diagnosis of Ruptured Tuboovarian Abscess

The major clinical symptom of ruptured tuboovarian abscess is acute, progressive pelvic pain that is usually so severe that the patient can accurately identify the time and place of its occurrence. In a classic series from the Johns Hopkins Hospital reported by Vermeeren and Te Linde, the average age of patients with a ruptured tuboovarian abscess was 33 years, which is at least 10 years older than the average age of patients with acute PID. Approximately 2% of these patients are postmenopausal. To our knowledge, only two cases of ruptured tuboovarian abscess in a pregnant patient have been reported. Often, there is a history of recurrent attacks of PID, with a sudden increase in the severity and extent of abdominal pain during a recent exacerbation of infection. On examination, the patient appears seriously ill and dehydrated, with rapid, shallow respirations. The abdomen is distended and quiet, with diminished or absent bowel sounds. Signs of generalized peritonitis, direct and rebound tenderness, muscle rigidity, and shifting dullness may be noted. A pelvic mass is palpable in only approximately 50% of cases. Tachycardia is common. Shock can be present or can develop while the patient is under observation. It is due to accumulation of fluids in peripheral tissues and later failure of compensatory vasoconstrictor mechanisms. The patient's temperature is usually greater than 101°F, but it can also be normal

and even subnormal late in the course. The leukocyte count is likely to be more than 15,000, but it also can be normal, if the neutrophils are being depleted. Severe leukopenia is an ominous sign. A culdocentesis is a valuable diagnostic aid and was positive for purulent material in 70% of the cases in the Mickal and Sellmann series. An abdominal radiograph usually shows a paralytic ileus, sometimes evidence of free fluid in the peritoneal cavity, and atelectasis in the lung bases. A CT scan of the pelvis and abdomen is most helpful and will usually confirm the pelvic abscess with free purulent fluid in the upper abdomen. It may also suggest an alternative diagnosis such as a ruptured appendix or acute cholecystitis.

Treatment of Ruptured Tuboovarian Abscess

The longer the delay in the operative treatment of ruptured tuboovarian abscess, the greater the primary mortality rate. In the series by Vermeeren and Te Linde from the Johns Hopkins Hospital, death occurred less than 90 hours after the time of rupture in 88% of fatal cases, both operative and nonoperative.

As time passes after rupture of a tuboovarian abscess, septic peritonitis becomes more severe and generalized. The passage of time allows the development of septic shock from greater absorption of bacteria and bacterial endotoxins and secretion of great quantities of fluid into the peritoneal cavity across inflamed peritoneal surfaces. Fluid shifts from the intravascular compartment to interstitial spaces as a result of the increased vascular permeability of the inflamed peritoneal membrane. This leads to hypovolemia, decreased cardiac output, decreased central venous pressure, hypotension, vasoconstriction, increased peripheral resistance, decreased tissue perfusion, metabolic acidosis, ARDS, decreased renal glomerular perfusion and filtration with decreased urine flow, severe hypoxemia, multiple organ system failure, and ultimately death. The prompt diagnosis and treatment of intraperitoneal rupture of a tuboovarian abscess is essential to minimize the risk of mortality of generalized peritonitis.

The treatment of patients with ruptured tuboovarian abscess can be divided into three phases: preoperative, operative, and postoperative.

Preoperative Phase

Surgery should be undertaken after rapid but adequate preoperative preparation. The patient should be typed and crossmatched for 2 to 4 units of packed red blood cells. Monitoring of central venous pressure is essential for proper evaluation of the hemodynamics of this condition, because many patients are dehydrated, in shock, and anemic. Swan-Ganz catheter placement may be preferable because it allows pulmonary capillary wedge pressure and pulmonary artery pressure determinations that are helpful in assessing the adequacy of fluid replacement and in detecting fluid overload. Variable amounts of fluid, sometimes tremendous amounts, are lost into the peritoneal cavity and intestinal tract because of peritonitis. Blood chemistry determinations (e.g., serum electrolytes, creatinine, glucose, bilirubin, and alkaline phosphatase) should be obtained and intravenous fluids, preferably Ringer lactate, started immediately. Crystalloid solutions for fluid volume resuscitation are preferred for most patients with septic peritonitis. It may be advantageous to use partial colloid resuscitation in some patients with evidence of cardiopulmonary dysfunction, because a smaller total volume is required. An excess of intravenous crystalloid solution may result in fluid overload.

Vigorous broad-spectrum intravenous antibiotic therapy should be instituted. The most active antimicrobials with FDA approval for female pelvic infections include piperacillin-tazobactam 3.75 g every 6 hours and ertapenem 1 g every 24 hours. Dosage adjustments need to be made due to the patient's renal status. Changes can be made to single or combination therapies once culture results and sensitivities return.

An indwelling urethral catheter is used to monitor fluid intake with hourly urine output. Combating shock is a primary concern throughout treatment. Clinical assessment of respiratory function should be made. A distended tender abdomen may cause rapid, shallow respirations and use of accessory muscles for ventilation. Arterial

blood gases may indicate mild hypoxemia, in which case oxygen should be administered. If anemia is severe, blood transfusion should be started before surgery.

When the patient has been properly prepared, immediate surgery should be undertaken. The results of treatment are better if major metabolic and hemodynamic problems are corrected before operation, but one cannot wait even a short amount of time in treating a critically ill patient with septic peritonitis.

Operative Phase

The anesthetic of choice depends on the preference and experience of the anesthesiologist and the medical condition of the patient.

The operation should be performed as rapidly as possible. Because speed as well as access to the upper abdomen may be required, a lower midline incision should be used. It can be quickly extended above the umbilicus if necessary. The patient

P.645

should not be put in the Trendelenburg position until the abdomen is packed off, and no more of a dependent position should be used than is needed to prevent further dissemination of pus into the upper abdomen. When the abdomen is opened, any odor that is present should be noted. An unpleasant, putrid odor is indicative of infection with anaerobic organisms. Pus from the abdomen should be collected correctly for both aerobic and anaerobic culture and for Gram stain and should be promptly transported to the laboratory. Organisms grown should be tested for sensitivity to various antibiotics.

The operation of choice in a patient with a ruptured abscess is the removal of the free pus. In patients bordering or in shock, removal of the abscess, the uterus, the tubes, and usually the ovaries is often necessary. Occasionally, it is possible to leave an ovary in a patient with a ruptured pelvic abscess. However, reoperation in a seriously ill patient is often not an option, so all tissue suspected to be infected should be removed. If rupture has occurred from a strictly unilateral tuboovarian abscess, with a relatively normal tube and ovary on the opposite side, a unilateral salpingo-oophorectomy can be performed, especially if the patient is young. However, the risk of a recurrent abscess in the opposite tube and ovary is high if the uterus is also left in place. When the uterus is removed along with the tuboovarian abscess, the risk of recurrent abscess in the opposite adnexa is reduced. When hysterectomy is performed, usually a total hysterectomy can be done. However, even in the best surgical hands, a subtotal hysterectomy is faster than a total one and is sometimes justified. Although we believe firmly in total hysterectomy, we do not believe in performing it when the danger of total hysterectomy exceeds the danger from a retained cervix. Except in the young patient, it is often better to remove the corpus than to perform a unilateral adnexectomy alone. Furthermore, the opposite adnexa are significantly involved in most patients, and subsequent operation may be necessary if conservation of one side is practiced, as was required in 35% of Pedowitz and Bloomfield's cases. This is contrary to what has been described earlier in the surgical treatment of an unruptured abscess, because the risk of incomplete eradication of the immediate infection in an acutely ill patient with rupture, peritonitis, and possibly septic shock is much higher. Therefore, definitive surgical treatment is usually recommended in severely ill patients with ruptured abscess.

The technical performance of the procedure may be difficult, but it is similar to that described earlier for laparotomy followed by failed colpotomy drainage or suspected rupture. Anatomy is distorted, dependable landmarks are obscured, and tissues are thick, edematous, friable, and inflamed. Loops of densely adherent intestine must be separated carefully to avoid injury. Injury to the serosa of distended bowel occurs commonly and often requires repair. Any entry into the lumen of the bowel must be recognized and repaired.

Retroperitoneal planes of dissection can be used to advantage in identifying the ureters and removing inflammatory adnexal masses. Otherwise, it is likely that a fragment of ovary will be left behind, which can subsequently cause signs and symptoms of the ovarian remnant syndrome. As much of the remaining abscess

wall as possible should be removed without causing unnecessary additional bleeding. Pieces of the abscess wall can be left adherent to the pelvic sidewall and cul-de-sac.

The upper abdomen should be carefully explored for collections of pus in the subdiaphragmatic and subhepatic regions. If an upper abdominal abscess is found, it may be necessary to place a closed suction drain into the abscess cavity through the upper abdominal wall.

Before the incision is closed, the abdominal cavity should be irrigated with copious quantities of warm sterile saline to remove remaining bacteria and debris. There is always some fear of dissemination of the infection by copious irrigation. However, this disadvantage is far outweighed by the benefit of diluting and removing bacteria and necrotic debris. We do not add antiseptics or antibiotics to the irrigating solution. If hemostasis is poor or if considerable necrotic material is left behind, there may be some benefit from peritoneal drainage with closed suction catheters. Closed suction drains can be placed through a separate stab wound in the abdominal wall, through the cul-de-sac, or through the vaginal vault when a total hysterectomy has been done, but the drainage of free peritoneal exudate in the upper abdomen is of no therapeutic value.

The abdominal incision is closed with a Smead-Jones technique or with a continuous suture taking large bites of tissue. A monofilament suture of polypropylene or nylon should be used. Retention sutures can be placed but are not usually necessary. The incision should be irrigated with warm saline. When there has been gross contamination of the incision, the subcutaneous fat and skin should be left open and packed lightly with gauze soaked in an antibiotic or dilute acetic acid solution. The wound is repacked daily and inspected. In 4 to 5 days, if the tissues are healthy, the incision is closed secondarily with sutures. Alternatively, the edges can be drawn together with sterile adhesive strips.

Postoperative Phase

Postoperative care should consider shock, infection, ileus, and fluid imbalances. Complications of the late postoperative period include undrained or recurrent pelvic and abdominal abscesses, intestinal obstruction, intestinal fistulas, incisional breakdown with or without evisceration, pulmonary embolus, continued sepsis, and disseminated intravascular coagulation. Serious medical problems such as uncontrolled diabetes or renal or pulmonary failure (ARDS) further complicate recovery from this potentially lethal disease.

Septic shock should be combated with blood (when indicated for a hemoglobin less than 7.0 g), Ringer lactate, respiratory support, and, if necessary, vasoactive substances. Infection is controlled by the continued aggressive use of broad-spectrum intravenous antibiotics until the patient can take antibiotics orally. When the results of the antibiotic sensitivity studies on the operative specimen are available, a change to more effective or safer agents should be considered, but only if the patient shows evidence of continued sepsis. Antibiotics should not necessarily be changed on the basis of sensitivity studies if the patient is improving clinically. Sometimes, the patient's condition improves initially, only to show signs of recurring intraabdominal infection the 2nd week after operation. Under these circumstances, it is appropriate to change antibiotics. Antibiotics should be continued until the patient is afebrile with only a mild leukocytosis or mildly elevated C-reactive protein and is able to eat a regular diet. Too long a period of treatment with antibiotics may result in complications such as pseudomembranous enterocolitis or fungal superinfection.

The semi-Fowler position may help prevent subphrenic and subdiaphragmatic abscess formation. Patients with signs of continued intraabdominal sepsis should have CT scans to identify collections of pus. If found, CT-directed drainage may be possible.

Constant intestinal suction by means of a long intestinal tube is a very important feature of postoperative care. A dynamic ileus persists postoperatively for a variable period and is best treated with the long intestinal tube until there is evidence of peristalsis and the patient is passing flatus.

Close attention to fluid balance and blood chemistry determinations is mandatory. Frequently, patients with ruptured tuboovarian abscess may have poor kidney function. The fluid output and serum creatinine should be followed closely.

PRIMARY OVARIAN ABSCESS

A primary ovarian abscess is an entity distinctly different from tuboovarian abscess. A tuboovarian abscess is one in which the abscess wall is composed of fallopian tube and ovarian parenchyma. A primary ovarian abscess, on the other hand, is one in which the infection occurs in the parenchyma of the ovary. Unlike tuboovarian abscess, it is an unusual condition. Interest in primary ovarian abscess was stimulated by the 1964 report of Willson and Black. According to a review by Wetchler and Dunn, 120 cases had been reported by 1985. Its frequency may be increasing, although still rare, as Askenazi and colleagues in 1994 reported a 0.2% to 2.2% rate of ovarian abscesses following transvaginal oocyte retrieval and transcervical embryo transfer.

Although bacteria can gain access to the ovarian parenchyma by hematogenous or lymphatic spread, it is probable that most primary ovarian abscesses occur because bacteria present around the ovary gain access to the parenchyma through a break in the ovarian capsule. This can occur naturally by ovulation, or it can be broken by a surgical procedure. Bacteria come from the fallopian tube, from the vagina during or after hysterectomy or any colpotomy procedure, from intrauterine infection associated with an IUD or another transcervical procedure, or from appendicitis, diverticulitis, or any other condition that is associated with peritonitis. A primary ovarian abscess is usually unilateral. However, its occasional occurrence simultaneously in both ovaries and during pregnancy seems to support the rare hematogenous or lymphatic spread, or both. Primary ovarian abscess has been reported secondary to infections at distant sites (tonsillitis, typhoid, parotitis, and tuberculosis).

Diagnosis of an unruptured primary ovarian abscess can be difficult because of the variable clinical presentation. Lower abdominal pain and fever are usually present. Lower abdominal and pelvic tenderness and an adnexal mass may be present, but the pelvic examination is sometimes not helpful, due to pain and guarding. Although an event predisposing to primary ovarian abscess (e.g., surgery, IUD use, appendicitis, or systemic infection) may be uncovered in the history, the event is sometimes remote. Ultrasonography and CT can be helpful in identifying an abscess cavity. If an ovarian abscess ruptures, the clinical picture is much the same as in ruptured tuboovarian abscess, with abdominal distention, direct and rebound tenderness, ileus, and sometimes shock. The patient appears gravely ill, and the need for immediate surgery is usually obvious.

The management of patients with primary ovarian abscess is similar to the management of patients with acute tuboovarian abscess. If the abscess is not ruptured, medical management with antibiotics for both anaerobic and aerobic organisms plus supportive care is indicated. A failure to respond or deterioration in the patient's condition suggests alteration in antibiotic coverage or possible exploratory surgery, or both, to remove the abscess. Ruptured ovarian abscess requires immediate laparotomy after a brief but intense effort to stabilize the patient and start antibiotic therapy. At operation, only the affected ovary need be removed. The tubes and the uterus can be conserved.

If both ovaries are involved, they should be removed. For a patient who is not interested in conception in the future, the uterus and both tubes can also be removed to decrease the possibility of the need for reoperation. If the patient is interested in pregnancy, the uterus and fallopian tubes can be left in place for possible implantation of a donated egg in the future.

SURGERY FOR CHRONIC PELVIC INFLAMMATORY DISEASE

Although the gonococcus may be responsible for initiating acute salpingitis, which is short-lived, residual chronic

salpingitis is usually due to secondary invaders, both aerobic and anaerobic, or perhaps to an initial infection with *C. trachomatis*. As a result of the initial infection or from subsequent secondary exacerbations, the fimbria can become occluded and the tubes bound to the ovaries with adhesions. In addition, the bowel can become adherent to the broad ligament and the adnexal structures, and the fascia and loose connective tissue of the broad ligament can be converted into an indurated, brawny structure typical of ligneous induration. This can extend to include tissues beneath the peritoneum on the lateral pelvic sidewall, where ligneous pelvic cellulitis can cause ureteral obstruction. If the chronic infection persists, serious effusion from the inflammatory process within the endosalpinx produces a hydrosalpinx that can ignite periodically with secondary subacute pelvic infection or can progress to produce a pyosalpinx and tuboovarian abscess. If the subacute infection is left untreated or is treated inadequately, spontaneous intraabdominal rupture or leakage of an old tuboovarian abscess can occur. In a review of this subject, Heaton and Ledger identified this problem principally in premenopausal women, with only 1.7% of patients with a tuboovarian abscess being postmenopausal. However, when tuboovarian abscess is diagnosed in postmenopausal women, Protopapas et al. found that 47% had a concomitant gynecologic malignancy. They concluded, "Conservative treatment of TOAs has no place during the menopause."

The signs and symptoms of chronic PID that most often require surgical treatment include severe, persistent, progressive pelvic pain, usually bilateral, although occasionally localized in one of the lower abdominal quadrants; repeated exacerbations of PID requiring multiple hospitalizations and recurrent medical treatment; progressive enlargement of a tuboovarian inflammatory mass, especially if it cannot be distinguished from a neoplastic tumor of the ovary; severe dyspareunia related to the chronic pelvic infection; and bilateral ureteral obstruction from ligneous cellulitis. It was formerly accepted that a history of previous colpotomy for drainage of a pelvic abscess was sufficient reason in itself to justify definitive abdominal surgery later for removal of the uterus and adnexa. However, several patients have become pregnant after posterior colpotomy for drainage of a cul-de-sac abscess or have remained relatively free of symptoms for long periods. Today, previous posterior colpotomy for pelvic abscess drainage is not a sufficient indication by itself for definitive abdominal surgery later when the patient is stable.

Selection of Operative Technique

The final decision regarding the proper operation for the surgical management of chronic PID is usually made with the abdomen open. Consideration must be given not only to the pathologic lesions found at operation but also to the patient's age, parity, desire for children, previous history of pelvic disease, and other associated pelvic disease and symptoms. Because a knowledge of all these is essential to the best surgical judgment, the operator should be thoroughly familiar with the patient, her history, and her desires.

In the surgical management of chronic PID, the question of removal or retention of the ovary at the time of hysterectomy

P.647

and salpingectomy has been left open to conjecture and individual surgical opinion in most instances. This question was the subject of a study by Weiner and Wallach of the ovarian histology in ovaries removed from patients with PID. In 40 consecutive women who underwent oophorectomy during surgical treatment of PID, nearly 50% of the removed ovaries were free of inflammatory disease and demonstrated normal follicular activity. The study concluded that ovarian histology was usually normal among patients who gave no history of dysfunctional uterine bleeding. Therefore, the menstrual history of such patients should be helpful in the decision regarding ovarian conservation or ablation. Kirtley and Benigno have reviewed the Emory experience with ovarian conservation at the time of surgery for PID. In this series, 98 (82%) patients who required surgery had a total abdominal hysterectomy and bilateral salpingo-oophorectomy. In 22 patients (18%), either part or all of an ovary was retained. Of these 22 patients, 15 were available for follow-up hormonal assays. The mean follow-up

time was 58 months. Cyclic ovarian function was confirmed in all but two patients. In the two patients with ovarian failure, other significant disease processes were also present. No patient suffered a complication as a result of adnexal conservation. We believe that normal ovarian tissue should be conserved at the time of definitive surgery for PID (**Fig. 30.7**). The release of peritubal adhesions in mild chronic PID is indicated occasionally in women in whom future childbearing is desired, as long as the tubes can be shown to be patent, usually by transfundal chromotubation after the lower uterine isthmus is occluded by a Ziegler clamp. This type of procedure provides the most rewarding pregnancy rate of all types of tubal reconstructive surgery. More often, one tube is hopelessly closed, and the opposite tube is patent after release of adhesions. In such a case, unilateral salpingectomy may be required if reconstructive surgery of the blocked tube is not possible (**Fig. 30.8**).

FIGURE 30.7 Total abdominal hysterectomy and unilateral salpingo-oophorectomy from extensive chronic salpingo-oophoritis. A small hydrosalpinx on the opposite side can be left in to preserve blood supply to the ovary.

In most instances of surgery for chronic PID, total abdominal hysterectomy and bilateral salpingo-oophorectomy are necessary to remove the primary tubal pathology because of inflammatory damage of both tubes and ovaries. Total abdominal hysterectomy and bilateral salpingo-oophorectomy (**Fig. 30.9**) have been performed for severe actinomycosis infection.

If the uterus is removed and an ovary is preserved, it may be preferable to leave the entire adnexa in place in the absence of active tubal infection rather than compromise the venous drainage or the arterial blood supply to the ovary with subsequent cystic changes that may require an additional operative procedure later. Once the continuity of the tubal lumen from the uterine cavity is broken, the chronically inflamed tube does not usually produce subsequent symptoms, as shown by Falk in his series of cases with interstitial tubal resection. A small hydrosalpinx on the same side as the normal ovary can also be left in place so that ovarian blood supply is not disturbed during an attempt to remove the tube. When it is considered advisable to remove both adnexa because of the extent of the tuboovarian disease, a total hysterectomy may also be considered unless the uterus is hopelessly encased in pelvic scar tissue and densely adherent to the pelvic viscera.

In the optimum case, especially in a young woman who wishes to establish or maintain the possibility of future fertility, conservative surgery may be desirable, with the hope that pregnancy can be accomplished through in vitro fertilization techniques. In this situation, the uterus and one adnexa should be conserved, and the ovary should be positioned in the pelvis so an ovum can be harvested later through the laparoscope or through the vagina. As mentioned earlier, if the patient wishes, the uterus can be left in place even though both tubes and ovaries have been removed.

FIGURE 30.8 When significant chronic PID involves only one adnexum and preservation of uterine function is indicated, a unilateral salpingo-oophorectomy can be performed.

FIGURE 30.9 Total abdominal hysterectomy and bilateral salpingo-oophorectomy for severe pelvic actinomycosis.

P.648

Salpingectomy for Chronic Salpingitis

At the time of surgery for the treatment of chronic PID, every effort should be made to retain uninvolved organs. Unilateral salpingectomy should be considered when the oviduct is hopelessly destroyed by the disease process and presents as a large hydrosalpinx.

Once the abdomen has been opened and the extent of disease evaluated, the adhesions binding the tube are cut, and the tube is freed. It is held by a Kelly clamp placed on the mesosalpinx just beneath the fimbriated end. The mesosalpinx is then clamped and cut, with a succession of small bites taken as close to the tube as possible (**Fig. 30.10A**). Removal of a chronic hydrosalpinx can also be done laparoscopically.

FIGURE 30.10 Salpingectomy. **A:** Mesosalpinx is clamped with multiple Kelly clamps and cut. *Dotted lines* indicate cornual excision, which is elective. **B:** Cornual wound is closed with 2-0 delayed absorbable suture. **C:** Mesosalpinx vessels are transfixed. **D:** Mattress suture is placed to cover operative area. **E:** Round ligament and broad ligament cover operative area.

P.649

Keeping the operative trauma as far as possible from the ovary that is to be retained lessens the danger of imperiling its blood supply. Experience has shown that the ovary whose tube has been removed is more apt to become cystic than the ovary whose tube has been left undisturbed.

The tube is excised at the uterine cornu in a wedge-shaped manner, as indicated in **Figure 30.10B**. A wide, figure-of-eight 2-0 delayed absorbable suture is placed in the cornu before the wedge is excised and is tightened as the interstitial portion of the tube is removed. If there is palpable extension of the inflammation at the uterine cornu (so-called salpingitis isthmica nodosa), the wedge may be large.

The wound in the uterus is closed with one or more 2-0 delayed absorbable figure-of-eight sutures (**Fig. 30.10B**). The vessels in the mesosalpinx are ligated with transfixion 3-0 delayed absorbable sutures. The

advantage of the transfixion suture is that it does not slip off the tissue when tied as the clamp is withdrawn (**Fig. 30.10C**).

A mattress suture of 3-0 delayed absorbable material is used to bring the broad and round ligaments over the cornual wound (**Fig. 30.10D**). This suture passes just beneath the round ligament, so that the ligament is not strangulated when the suture is drawn tight. When this suture is tied, the cornual wound is covered with the broad ligament, and the uterus is suspended to some extent in a manner similar to that used in the Coffey suspension. Usually, a second mattress or interrupted suture is necessary to cover the mesosalpinx completely, as shown in **Figure 30.10E**.

Salpingo-Oophorectomy for Chronic Salpingitis

As in salpingectomy, the abdomen is entered through a transverse Maylard incision. The chronic tuboovarian inflammatory mass is first dissected free, and the infundibulopelvic ligament is identified. It is doubly clamped with Ochsner clamps, and a third clamp is applied to control back bleeding (**Fig. 30.11A**). The ureter must be identified before the infundibulopelvic ligament is clamped, cut, and ligated.

FIGURE 30.11 Salpingo-oophorectomy. **A:** The infundibulopelvic ligament is doubly clamped. Another clamp is placed to control back bleeding. *Dotted line* indicates incision. **B:** A suture has been placed to ligate the ascending uterine vessels just below the cornual incision. The cornual incision is closed with a figure-of-eight suture of 2-0 delayed absorbable material.

After the infundibulopelvic ligament is cut and ligated, the remainder of the broad ligament attachment of the tube and the ovary is clamped, cut, and ligated. The uterine end of the tube and the ovarian ligament are excised from the uterus in a wedge-shaped manner. The ascending uterine vessels are ligated just below the cornual wound, and the cornual incision is closed with a 2-0 delayed absorbable figure-of-eight suture (**Fig. 30.11B**).

The infundibulopelvic ligament is doubly ligated with 2-0 delayed absorbable sutures, and the vessels in the broad ligament are ligated with 3-0 delayed absorbable sutures. The cornual wound is peritonized, and the

uterus is suspended to some degree by bringing the round and the broad ligaments over the uterine cornu with a mattress suture of 2-0 delayed absorbable material, as shown in [Figure 30.11C](#). An attempt should be made to remove the tuboovarian inflammatory complex completely. If a fragment of ovary is left attached to the lateral pelvic peritoneum or the broad ligament, the ovarian remnant syndrome may develop later. To prevent this, a retroperitoneal approach may be required.

Identification of the Ureter

Identification of the course of the ureter in a pelvis in which the anatomy has become obliterated as a result of PID is one of the most important techniques for the gynecologic surgeon. In the surgical treatment of this disease, one may find a tuboovarian inflammatory mass that is located between

P.650

the leaves of the broad ligament and extends to the lateral pelvic wall. It is not uncommon for the ligneous induration of the thickened parietal peritoneum to obscure completely the location and course of the pelvic ureter so that dissection of the diseased adnexa produces a surgical risk to the urinary tract, requiring great technical skill to avoid ureteral injury. Knowledge of the normal anatomic location of the pelvic ureters is essential so that these vital structures can be identified before an attempt is made to remove the adnexal masses. Division of the round ligament allows access to the lateral pelvic wall beneath the peritoneum. After the round ligament is divided, the peritoneum is incised inferiorly toward the internal cervical os and superiorly just lateral to the infundibulopelvic ligament. The peritoneum is easily reflected medially away from the pelvic sidewall with finger dissection, and the ureter is identified. It remains attached to the peritoneum. If there is difficulty with this procedure, the ureter can usually be identified as it crosses over the common iliac artery just above its bifurcation, and it can be traced downward.

FIGURE 30.11 (Continued) C: The infundibulopelvic ligament and the rest of the broad ligament vessels have been ligated. The cornual wound is covered with the round and the broad ligament using a mattress suture of 2-

0 delayed absorbable material.

Such patients may have a preoperative ureteral catheterization when there is clinical evidence of large, adherent adnexal masses. However, if such an anatomic problem is encountered at the time of laparotomy, an incision can be made in the dome of the bladder that allows the passage of ureteral catheters. If the patient has been positioned in the Allen universal stirrups for operation, intraoperative cystoscopy with passage of ureteral stents is easily accomplished. At the end of the operation, 5 mL of indigo carmine is given intravenously. With a cystoscope in the bladder, the dye can be seen effusing from both ureteral orifices, confirming that the ureters have not been injured or compromised.

PELVIC TUBERCULOSIS

Tuberculosis of the upper genital tract is a rare disease in the United States. However, it is a frequent cause of chronic PID and infertility in other parts of the world. For various reasons, the incidence of tuberculosis is again increasing in the United States. Therefore, cases of tuberculosis-associated PID may also become more evident. It should always be considered in the differential diagnosis of pelvic pain in immigrants, especially those from Asia, the Middle East, and Latin America, and in patients with HIV. Pelvic tuberculosis is produced primarily by either *Mycobacterium tuberculosis* or *Mycobacterium bovis*. The primary site of infection for tuberculosis is usually the lung, with lymphatic spread from the Ghon complex to regional lymph nodes at the hilum usually occurring within 1 to 2 years. More rapid dissemination is due to hematogenous spread, which results in miliary disease often within the 1st year. The fallopian tubes are the predominant site of pelvic tuberculosis, but the bacilli also spread to the endometrium and occasionally the ovaries.

No location in the body is immune to the development of metastatic foci of infection. Tuberculosis of the bone, meninges, kidney, epididymis, fallopian tubes, and other sites can develop. At some sites of miliary spread, the lesions can remain quiescent for long periods before reactivation and further spread of the disease. Direct extension from one organ or system to an adjacent organ or system can also occur. Organs of the female reproductive tract are usually infected by hematogenous miliary spread from a primary pulmonary lesion, by hematogenous spread from a secondary miliary site, by lymphatic spread from a primary pulmonary site to intestinal lymph nodes and then to the pelvis, or by direct extension from adjacent abdominal organs (small intestines, appendix, rectum, bladder) that are the site of tuberculous infection. Fistulas between the intestinal tract and the fallopian tubes have been reported with pelvic tuberculosis.

A venereal transmission of the disease has been reported, with primary genital infection in the woman occurring after coitus with a sexual partner who had tuberculosis of the genitourinary tract. According to Sutherland and MacFarlane, it is not possible to prove conclusively that genitourinary tuberculosis in the man can be transmitted to the woman through sexual intercourse. Because it has been shown that *M. tuberculosis* is present in the sperm of men with urogenital tuberculosis, the possibility of transmission to the pelvic organs of the woman through intercourse must be accepted. Sutherland presents five cases in which sexual transmission of genitourinary tuberculosis from man to woman presumably occurred. However, of 128 husbands of women with genital tuberculosis, only 5 (3.9%) were found to have active genitourinary tuberculosis. When tuberculosis of the vulva, vagina, and cervix is present without evidence of tuberculosis elsewhere in the body, venereal transmission should be suspected.

Pathology of Pelvic Tuberculosis

Both fallopian tubes are involved in almost all patients with pelvic tuberculosis. About one half of patients with tuberculous salpingitis have tuberculous endometritis. Tuberculosis of the cervix is present in 5% of cases. The vagina and vulva are rarely involved. At operation, one may find evidence of generalized tuberculous peritonitis with small, grayish white tubercles covering all peritoneal surfaces of the abdominal and pelvic organs. The

epithelium of the fallopian tubes may not be involved in generalized serosal tuberculous infection. At a later stage of infection, tuberculous salpingitis may grossly resemble other forms of PID involving the adnexa. Unless tubercles are

P.651

seen, the diagnosis may not be apparent until microscopic sections are examined by the pathologist. A large pyosalpinx may contain the caseous material of a tuberculous infection but may also contain the purulent exudate of a secondary infection with other common organisms. Tubercles form in the lining of the tube. Some have caseation at the center, with giant cells and epithelioid cells. A proliferation of the mucosal lining of the fallopian tube may resemble a primary tubal carcinoma microscopically and may be confusing to the pathologist.

FIGURE 30.12 Typical specimen of tuberculosis of the reproductive organs as part of generalized tuberculous peritonitis.

Tuberculous peritonitis is commonly associated with tuberculosis of the pelvis. Clinically, tuberculous peritonitis can be divided into two groups. In “wet” peritonitis, there is an outpouring of straw-colored fluid into the peritoneal cavity, producing ascites. The peritoneum of the parietal wall and viscera is covered with innumerable small tubercles ([Fig. 30.12](#)). The tubes, in addition to being covered with miliary tubercles on the serosal surface, are usually slightly enlarged and distended. In contrast to other forms of salpingitis, the fimbriae may be patent. Within the tubal wall and tubal mucosa, the histology is typical of tuberculosis, with tubercle formation, multinucleated giant cells, and epithelioid reaction ([Fig. 30.13](#)). In advanced cases, frank caseation is present. This pattern is usually associated with hematogenous spread of the tuberculous organism to the peritoneal surfaces and the pelvic organs.

Another type of tuberculous peritonitis encountered in women is the “dry” or adhesive type. Bowel adheres to bowel by innumerable dense adhesions that blend with the musculature. The muscle of the bowel is often

invaded to some degree by the tuberculous process. Separation of these adhesions is extremely difficult surgically, and accidental injury to the bowel is common. The pelvic organs show evidence of tuberculous salpingitis with enlargement of the tubes and occasionally pyosalpinges and even tuboovarian abscess formation.

Tuberculous involvement of the myometrium is rare. Tuberculous endometritis, however, is common, occurring in 60% to 70% of women with pelvic tuberculosis. Microscopically, tubercles are seen scattered throughout the endometrium, but they may be scanty. Tubercles are often seen in the endometrium removed by curettage in the premenstrual phase and are usually located in the endometrium adjacent to the

P.652

tubal ostia. Apparently, the uterine cavity is protected from advanced tuberculous infection by the cyclic shedding of endometrial tissue in the reproductive years. Even in advanced pelvic tuberculous infections, evidence of caseation, fibrosis, and calcification are rarely seen in the uterine cavity. Occasionally, the endometrial cavity is obliterated by extensive adhesions. Total destruction of the endometrium can result in amenorrhea. Tuberculous pyometra can also develop, especially in postmenopausal women with an occluded internal cervical os.

FIGURE 30.13 Tuberculosis of the fallopian tube. Note the multinucleated giant cells.

Tuberculous lesions of the cervix are rare. They can be either ulcerative or exophytic and can resemble a primary cervical malignancy or granuloma inguinale of the cervix. When there is a tuberculous lesion of the cervix, the cervical biopsy often reveals tubercles.

A tuberculous infection of the ovary usually involves only the surface of the ovary and represents simply an extension of infection from the peritoneal cavity and the adjacent fallopian tubes. The infection is usually limited to a perioophoritis. Tuberculous caseation can be found within the ovarian parenchyma, although this is uncommon. Presumably, it occurs as a result of hematogenous spread to the ovarian parenchyma rather than by

direct extension through the ovarian capsule. However, a break in the ovary caused by ovulation may also allow the tubercular bacilli to gain access to the ovarian parenchyma. The ovaries are involved in about 25% of cases of pelvic tuberculosis.

It is uncommon for tuberculosis to involve the vulva and vagina. It is seen in only 2% of patients with pelvic tuberculosis. The gross appearance may be ulcerative with multiple sinuses, it may be hypertrophic with elephantiasis, or it may be similar to that of carcinoma.

Throughout the pelvic organs, the microscopic picture is similar, with tubercles of granulomatous inflammation, Langhans giant cells, epithelioid cells, and central caseation associated with chronic inflammation. With special stains, acid-fast bacilli (AFB) can be demonstrated on careful microscopic examination of the tubercles.

Clinical Features of Pelvic Tuberculosis

Pelvic tuberculosis occurs most often in patients between the ages of 20 and 40 years. The age of patients with gynecologic tuberculosis has changed in recent years; the proportion of patients older than 40 years of age is now much higher than it was in the past. Falk and associates found that the incidence of pelvic tuberculosis in postmenopausal Swedish women is increasing. This was also the opinion of Sutherland, who reported an investigation from Glasgow in which 26 of 701 patients (3.7%) with proven gynecologic tuberculosis were postmenopausal.

The most common clinical symptoms of pelvic tuberculosis include pelvic pain, general malaise, menstrual irregularity, and infertility. Brown and associates found that menstrual irregularity occurred in nearly 50% of patients, whereas amenorrhea or oligomenorrhea was present in 27%. A low-grade fever that on occasion can produce a fulminating septic course is noted in most cases of active or subacute disease. The failure of fever to subside with high doses of broad-spectrum antibiotics is a classic feature of pelvic tuberculosis. A clinical course that is refractory to antibiotic therapy for the usual PID should alert the clinician to the possibility of tuberculosis in a woman who previously resided in an endemic country.

Among patients with pulmonary tuberculosis, the incidence of pelvic tuberculosis generally varies between 10% and 20%. Falk and associates noted that 38% of women with genital tuberculosis had previously had tuberculosis in other organs, usually the lungs. Often, the patient's clinical course is that of a chronic indolent illness.

Diagnosis of Pelvic Tuberculosis

The clinical symptoms and signs of pelvic tuberculosis should direct the clinician to the diagnosis. However, the disease is so uncommon that it is seldom encountered in the gynecologist's usual practice; therefore, the clinical index of suspicion is generally low. In many cases, the clinical presentation is obscure, and the diagnosis is delayed. Howard Kelly once said that when competent gynecologists disagree about the diagnosis of an obscure pelvic condition, it usually is diagnosed as either an "old ectopic pregnancy or pelvic tuberculosis."

More than two thirds of the cases are diagnosed at the time of laparotomy performed for some other indication or at the time of investigation for infertility or abnormal uterine bleeding. The most common symptom is infertility, and the second most common symptom is lower abdominal and pelvic pain. Some patients are completely asymptomatic and are found to have pelvic tuberculosis during examination for other disorders such as infertility. A dilatation and curettage or endometrial biopsy is diagnostic in some cases, especially if performed in the late premenstrual phase of the menstrual cycle. In addition to standard microscopic sections, the specimen can be examined by fluorescent antibody technique. Acid-fast staining of tissue or culture of menstrual blood is effective in detecting the organism in only about 10% of cases, according to Overbeck. The menstrual blood can be collected in a cervical cap, but culture can be repeated many times before a positive result is obtained. Acid-fast stains of tissue suspected of tuberculous infection are important to confirm the diagnosis. Because some AFB

are not tuberculous bacilli, it is important to obtain a positive culture whenever possible. A negative evaluation of the endometrium does not rule out pelvic tuberculosis, because the disease can be present in the fallopian tubes without tuberculous endometritis in 30% to 40% of cases.

On pelvic examination, bilateral adnexal tenderness is the rule. The tenderness is usually less marked than with acute gonococcal or streptococcal infections. Occasionally, a large tuberculous tuboovarian abscess is palpated on pelvic examination and even felt through the abdominal wall. The classic doughy feel of the broad ligament suggests a tuberculous inflammatory disease that is produced by a combination of thickening of the broad ligament, adherent bowel, and some ascitic fluid. On occasion, cul-de-sac nodules representing tubercles on the serosal surfaces of pelvic organs can be felt. The clinical detection of ascites is the strongest evidence obtainable in favor of pelvic tuberculosis. It was present in one fifth of the cases reported by Brown and associates. However, other causes of ascites must be considered, including ovarian carcinoma and cirrhosis of the liver. In differentiating tuberculous salpingitis from gonococcal infections, the finding of a vaginal outlet in the presence of obvious tubal inflammation should lend strength to the diagnosis of pelvic tuberculosis.

The diagnosis of tuberculosis cannot be made with certainty from a hysterosalpingogram, but it may be helpful. The radiographic criteria for a suspicion of pelvic tuberculosis by hysterosalpingogram have been described by Klein and associates as follows: calcified lymph nodes or smaller, irregular calcifications in the adnexal areas; obstruction of the fallopian tube in the zone of transition between the isthmus and the ampulla; multiple constrictions along the course of the fallopian tube; endometrial adhesions or deformity or obliteration of the endometrial cavity in the absence of a history of curettage or abortion; and vascular or lymphatic extravasation of contrast material. Although a conclusive diagnosis of pelvic tuberculosis can be made only from a positive culture, these authors conclude that hysterosalpingography

P.653

is a useful aid, especially in patients who are asymptomatic except for infertility.

When the diagnosis of pelvic tuberculosis cannot be made in other ways, laparoscopy has been used. Because numerous adhesions may be present, making the introduction of the trocar hazardous, we believe that laparoscopy should be used with particular care. If possible, biopsy specimens of tubal fimbriae or other suspicious areas should be examined histologically or cultured to confirm the diagnosis. In addition to disclosing numerous adhesions, laparoscopy may reveal widespread miliary tubercles involving the omentum and peritoneal surfaces. Matted adnexal masses may be seen. Microscopic examination of peritoneal fluid shows a predominance of lymphocytes.

Vaginal cytology is of limited value in diagnosing tuberculosis. The cytologist must be familiar with the morphology of epithelioid cells in the vaginal smear. Only in cases of tuberculosis of the cervix may cytology be helpful. Patients with pelvic tuberculosis should also have an examination and special diagnostic procedures to rule out tuberculous infections in the upper genital tract. Chest radiograph, tuberculin skin test, pelvic ultrasonography, intravenous pyelogram, and urine, gastric, and sputum cultures for *M. tuberculosis* should be done. In some patients, exploratory laparotomy is needed to make the diagnosis.

Treatment of Pelvic Tuberculosis

Before the advent of antituberculous drug therapy, surgery was often used in the treatment of pelvic tuberculosis. Primary surgical treatment was technically difficult, sometimes ineffective, and associated with a high risk of fistula formation and persistent draining sinuses. With the advent of effective drug therapy, the surgical treatment for genital tuberculosis has been restricted to specific indications. Beginning with streptomycin more than 30 years ago, and later isoniazid and para-aminosalicylic acid, it became evident that many cases of pelvic tuberculosis could be cured or controlled with antituberculous drug therapy. There have been major advances in the antibiotic treatment of this disease, including the use of isoniazid with rifampin, with or without

ethambutol, given sometimes for a period of 2 years or longer. Sutherland analyzed the results obtained with various drug schedules. The drugs that have been used to treat tuberculosis are isoniazid, rifampin, streptomycin, ethambutol, and pyrazinamide. Isoniazid and rifampin are the most effective and have the lowest toxicity. They should be the foundation of most drug regimens. The addition of ethambutol may not be of benefit, at least not in pulmonary tuberculosis. Severe and sometimes fatal hepatitis, which can develop even after months of treatment, has been associated with isoniazid therapy. The risk of developing hepatitis increases with age and with the daily consumption of alcohol. Liver function studies should be done before treatment is started, and patients should be carefully monitored with liver function studies throughout the course of therapy and later. The regimen options and dosage recommendations of the American Thoracic Society, the Infectious Disease Society of America, and the CDC from 2003 for the treatment of tuberculosis can be found at <http://www.cdc.gov> with initial treatment outlines shown in [Table 30.5](#).

TABLE 30.5 Basic Tuberculosis Disease Treatment Regimens

PREFERRED REGIMEN	ALTERNATIVE REGIMEN	ALTERNATIVE REGIMEN
<i>Initial Phase</i>		
Daily INH, RIF, PZA, and EMB ^a for 56 doses (8 wk)	Daily INH, RIF, PZA, and EMB ^a for 14 doses (2 wk), then twice weekly for 12 doses (6 wk)	Thrice-weekly INH, RIF, PZA, and EMB ^a for 24 doses (8 wk)
<i>Continuation Phase</i>		
Daily INH and RIF for 126 doses (18 wk)	Twice-weekly INH and RIF for 36 doses (18 wk)	Thrice-weekly INH and RIF for 54 doses (18 wk)
or		
Twice-weekly INH and RIF for 36 doses (18 wk)		

^aEMB can be discontinued if drug susceptibility studies demonstrate susceptibility to first-line drugs.

Note: A continuation phase of once-weekly INH/rifapentine can be used for HIV-negative patients who do not have cavities on the chest film *and* who have negative AFB smears at the completion of the initial phase of treatment. INH, isoniazid; RIF, rifampin; EMB, ethambutol; PZA, pyrazinamide.

The therapeutic success of modern antituberculous drug treatment regimens in pelvic tuberculosis is difficult to assess in view of the limited number of cases available in the literature. The cure rate varies in the literature from 65% to 95%. Kardos removed the fallopian tubes from 168 patients after medical treatment for 10 months and still found active tuberculosis in 35% of the surgical specimens. The experience of Sutherland suggests, however, that the results of treatment may be improved with newer drugs. The patients under treatment must be

followed up closely for evidence of regression or remission of the pelvic tuberculosis. Only about 50% of patients with genital tuberculosis have the disease in the endometrial cavity; therefore, repeat endometrial biopsies and culture of menstrual egress provide only limited diagnostic information. The progress of the disease can be monitored closely by evaluating the size of adnexal masses with pelvic examinations and ultrasonography as well as tracking the ESR, WBC count, and temperature response. Prolonged follow-up is probably indicated in all cases, because recurrence of the tuberculous pelvic lesion 5 years and even later after the end of drug treatment has occasionally been found.

Surgery in the management of patients with pelvic tuberculosis should be reserved for specific indications, as outlined by Schaefer and by Sutherland. In general, surgery is reserved for

P.654

those patients who have failed to respond to an adequate trial of medical therapy. Our indications for the surgical treatment of pelvic tuberculosis include the following:

1. Persistence or enlargement of an adnexal mass after 4 to 6 months of antituberculous antibiotic therapy. The rare possibility of an ovarian tumor must always be considered, even though pelvic tuberculosis is also present. In a 1980 report by Sutherland, the persistence or development of substantial pelvic masses was the indication for surgery in 36 of 91 women with proven tuberculosis of the genital tract treated by surgery. Pelvic ultrasonography should be useful in following the response of adnexal masses to treatment.
2. Persistence of pelvic pain or recurrence of pelvic pain while on medical therapy. In Sutherland's report, 40 of 91 patients were operated on because of pain.
3. Primary unresponsiveness of the tuberculous infection to antibiotic therapy, as shown by persistent spiking temperature, leukocytosis, elevated ESR, and evidence on biopsy specimens of continued endometrial infection. Of the 91 women in Sutherland's report, 10 were operated on because of persistence of endometrial tuberculosis.
4. Difficulty in obtaining patient cooperation for continued long-term therapy. In these cases, we are accustomed to giving a brief course of streptomycin, 0.5 g every 12 hours intramuscularly for 1 week before surgery, to perform definitive surgery, and then to giving 0.5 g every 24 hours in the postoperative period for 2 weeks. A persistent effort should be made to obtain the patient's cooperation for continued antituberculous therapy postoperatively. It is advisable to continue treatment for a year or longer. Isoniazid and rifampin should be used if possible. A common reason for failure of treatment is a tendency for the physician to discontinue drugs after only a few months because the patient appears well.

The preferred surgical treatment includes total abdominal hysterectomy and bilateral salpingo-oophorectomy. The nature of this inflammatory disease may make this operative procedure technically difficult, with an increased risk of injury to bowel and bladder. Consequently, in the event of a frozen pelvis from pelvic tuberculosis, it is occasionally necessary to perform only a subtotal abdominal hysterectomy and adnexectomy.

Adhesions, which are invariably present and usually widespread, may make the dissection more difficult and injury more likely. However, it is usually possible to do this operation without a high incidence of bowel fistulas and other significant complications. Sutherland reported the results of surgery in 77 patients operated on while antituberculous therapy was administered. There were no deaths, no fistulas, and few late complications.

For young patients who are eager to attempt future childbearing, conservative adnexectomy should be carried out only if it is possible to do so after the extent of the adnexal disease is carefully evaluated and is found to be minimal. It is unwise for the surgeon to be committed to a specific operative procedure before the time of surgery, because conservative pelvic surgery for tuberculosis may constitute poor surgical judgment once the operative findings are known. The patient should be forewarned that conservative surgery will be performed only if the

disease is minimal and such surgery is considered medically advisable and is consented to as such.

Conservation of an ovary at the time of operation for pelvic tuberculosis is occasionally possible if the ovary is involved only on its surface. However, if one finds gross evidence of ovarian enlargement or other gross evidence of infection deep in the ovarian parenchyma, the ovary should be removed. Bisection of ovaries to assess the presence of disease deep in the ovarian parenchyma is not advisable.

Reactivation of silent pelvic tuberculosis after tubal reconstructive surgery has been reported by Ballon and associates and by others. We believe that reconstructive tubal surgery has no place in the management of patients whose infertility is the result of bilateral tubal obstruction from tuberculous salpingitis.

Pregnancy after Pelvic Tuberculosis

It is evident from the literature, including the studies of both Schaefer and Sutherland, that only about 5% of patients with genital tuberculosis are capable of becoming pregnant, and only 2% carry a pregnancy to term. It is also evident that in the presence of tuberculous tuboovarian abscesses, pregnancy is extremely rare, and conservative surgery for the purpose of preserving fertility is unwarranted. Only when there is minimal pelvic disease without adnexal masses should conservative surgery be considered.

BEST SURGICAL PRACTICES

- Laparoscopy should be discussed with all patients suspected of PID to confirm the diagnosis and to rule out other surgical emergencies such as appendicitis, ectopic pregnancy, or ruptured abscess. However, stable patients at high risk for complications or with contraindications to laparoscopy can be started on antimicrobial therapy and followed for 24 to 48 hours for a response. With the advent of very effective antimicrobial therapy, strong consideration should be given for surgical exploration if the patient fails initial therapy or symptomatology changes, suggesting an alternative diagnosis. If laparoscopy is not selected as initial management, an endometrial sampling for detection of inflammatory cells and bacterial culture is usually helpful.
- Sonohysterography is contraindicated in patients suspected of having PID. Culdocentesis with the finding of purulent peritoneal fluid may indicate PID but does not rule out appendicitis or diverticulitis.
- Posterior colpotomy requires a midline abscess, an abscess that is adherent to cul-de-sac peritoneum and dissects the rectovaginal septum, and a cystic or fluctuant abscess.
- Hysterectomy is no longer absolutely necessary if salpingo-oophorectomy is needed for treatment of tuboovarian abscesses. Copious irrigation with lactated Ringer is essential if an abscess has ruptured or if pus is present in the abdomen. Antibiotic irrigation has not demonstrated additional benefit or risk. If hysterectomy is necessary after bilateral salpingo-oophorectomy, the vaginal vault should be left open for drainage (with or without a Penrose drain).
- Swan-Ganz catheter placement is helpful in monitoring central venous pressure in patients undergoing surgery for ruptured tuboovarian abscess.

Chapter 31

Leiomyomata Uteri and Myomectomy

Carla P. Roberts

Jennifer F. Kawwass

DEFINITIONS

Intravenous leiomyomatosis—Smooth muscle tumor that consists of polypoid intravascular projections into the veins of the parametrium and broad ligaments.

Leiomyomatosis peritonealis disseminata—A benign reparative process in which fibroblasts replace soft peritoneal decidua on subperitoneal surfaces of the uterus and other pelvic and abdominal viscera resulting in nodules with a pseudoleiomyomatous pattern.

Menorrhagia—Prolonged (>7 days) or heavy (>80 mL) menstrual bleeding occurring at regular intervals.

P.657

Metrorrhagia—Uterine bleeding occurring at irregular intervals, sometimes of prolonged duration.

Menometrorrhagia—Heavy, prolonged bleeding occurring at irregular intervals.

Submucosal—Present within the uterine myometrium just below the basal layer of the endometrial lining.

Subserosal—Present within the uterine myometrium just below the serosal or peritoneal covering of the uterus.

Leiomyomata are the most common tumors of the uterus and the female pelvis. This chapter discusses the pathologic and clinical features of uterine leiomyomata, the choice of treatment, and the indications and techniques for myomectomy.

Hysterectomy is sometimes required for the management of leiomyomata. It is also performed for many other indications, but leiomyomatous uteri are the most common indication for hysterectomy. Refer to [Chapter 32](#) for a complete discussion of hysterectomy.

Advances in gynecologic surgery in the early 1900s finally brought this common, sometimes fatal, disease of women under reasonable control. Before the 20th century, no effective treatment was available. Uterine leiomyomata often grew to enormous size and caused great suffering from bleeding, pain, and emaciation ([Fig. 31.1](#)). Death from this benign disease was not uncommon. Progress in gynecologic surgery and anesthesia finally allowed the safe removal of these tumors by skilled gynecologic surgeons.

No one played a more important role in this endeavor than Drs. Kelly and Cullen. Working together at Johns Hopkins Hospital, they gradually developed surgical techniques that were successful in preventing and controlling intraoperative hemorrhage. Several illustrations from their magnificent treatise, *Myomata of the Uterus*, published in 1907, are included in this chapter. In the preface, Cullen wrote:

It was my good fortune to come to Baltimore in 1891, shortly after the hospital opened. At that time many cases of myoma were considered inoperable, and even when hysterectomy was undertaken it was only in the cases in which a stout rubber ligature could be temporarily tied around the cervix and when, as happened in some cases, this ligature slipped, alarming hemorrhage followed. Then came the systematic controlling of each of the cardinal vessels; later the bisection, and finally the transverse severance of the cervix as a preliminary feature of the operation in

exceptionally difficult cases, until at present a myomatous uterus that cannot be removed is almost unheard of. I have watched the gradual simplification of the surgical procedures with the greatest interest. Many American surgeons have had much to do with the wonderful advance in this direction, but I know of no other man, either here or abroad, who has done as much toward this advancement as Howard A. Kelly.

FIGURE 31.1 The patient is thin and emaciated, the outline of the ribs being prominent. Such advanced and neglected cases of multiple uterine leiomyomata are rarely seen today.

The mortality rate for 1,373 operations performed for uterine leiomyomata at Johns Hopkins Hospital between 1889 and 1906 was 5.75%; it was less than 1% for 238 operations performed between 1906 and 1909. In 55 patients, no operation was attempted because of patients' refusal or weakened condition. Among these patients, 21 deaths occurred in the hospital. Death from uterine leiomyomata rarely occurs today. The near elimination of mortality secondary to uterine fibroids represents a major milestone in the health care of women.

During the past century, hysterectomy and myomectomy by the traditional and classic techniques have been the main treatment for women with uterine leiomyomata and significant symptoms; they continue to be so today. Each year in the United States, more than 200,000 hysterectomies are performed with uterine leiomyomata as the primary indication. However, this traditional management is currently evolving toward more conservative, less invasive techniques for several reasons:

1. Concern regarding the increasing costs of health care has focused on the need to use effective but less expensive methods of management of uterine leiomyomata.
2. Advances in surgical technology now allow certain patients to be treated with new, minimally invasive techniques, including robotic hysterectomy, laparoscopic hysterectomy, laparoscopic-assisted vaginal hysterectomy, robotic myomectomy, laparoscopic myomectomy, laparoscopic myoma coagulation (myolysis), and hysteroscopic resection of submucous myomata. Under proper circumstances, these procedures can be safe, effective, and less costly.
3. Interest in nonsurgical management also appears to be increasing with more data available regarding minimally invasive procedures, including uterine artery embolization (UAE). This procedure has emerged from an investigational realm to common clinical practice. As more long-term data become available,

outcomes and prognosis are becoming more clearly delineated.

4. A medical approach to the management of patients with leiomyomata is now available. Gonadotropin-releasing hormone (GnRH) analogs, administered for 3 to 6 months, cause most uterine leiomyomata to shrink. However, the myomata regain their original size several months after the GnRH analog is discontinued. This medical regimen has

P.658

been useful as an adjunct to surgical management. Women who become symptomatic with leiomyomata just before menopause can be treated temporarily with GnRH analogs and can possibly avoid surgical therapy.

5. Uterine leiomyoma are a major public health and women's health care problem. Society has a legitimate reason for interest and concern and has questioned the advisability of hysterectomy for the management of most cases of uterine leiomyomata. Many women insist on the preservation of uterine function for future childbearing and sometimes even when future childbearing is not desired or not likely to occur. A greater emphasis has developed on expectant management, medical management, minimally invasive surgical procedures, and conservational management of uterine leiomyomata in the future.

In the future, the traditional and classic techniques of hysterectomy and myomectomy will be required less often for patients with symptomatic leiomyomata. At present, however, these operations are still appropriate in many situations.

ETIOLOGY, PATHOLOGY, AND GROWTH CHARACTERISTICS OF UTERINE LEIOMYOMATA

A leiomyoma is a benign tumor composed mainly of smooth muscle cells but containing varying amounts of fibrous connective tissue. The tumor is well circumscribed but not encapsulated. Various terms are used to refer to the tumor, such as *fibromyoma*, *myofibroma*, *leiomyofibroma*, *fibroleiomyoma*, *myoma*, *fibroma*, and *fibroid*. The latter designation is the one most commonly used, but it is the least accurate and acceptable. The term *leiomyoma* is a reasonably accurate one that emphasizes the origin of this tumor from smooth muscle cells and the predominance of the smooth muscle component. The tissue culture work of Miller and Ludovici suggested an origin from smooth muscle cells, and the studies of Townsend and associates affirm a unicellular origin for leiomyomata.

Leiomyomata are the most common tumors of the uterus and female pelvis. It is impossible to determine their true incidence accurately, although the frequently quoted incidence of 50% found at postmortem examinations seems reasonable. Leiomyomata are responsible for about one third of all hospital admissions to gynecology services. It is well recognized that the incidence is much higher in African American than in Caucasian women. In a careful study of leiomyomata among women in Augusta, Georgia, Torpin and associates found the incidence among African American women to be three and one third times that among Caucasian women. There is no known explanation for this racial difference. Leiomyomata also are larger and occur at a younger age in African Americans. In fact, many African American women develop leiomyomata before 30 years of age. However, development prior to age 20 is extremely rare, regardless of race. Patients with uterine leiomyomata often have a positive family history of uterine leiomyomata. This suggests the presence of a gene, which has yet to be discovered, encoding for their development.

About 40% to 50% of leiomyomas show karyotypically detectable chromosomal abnormalities that are both nonrandom and tumor specific. Identified chromosomal abnormalities include t(12;14) (q15;q23-24), del(7) (q22q32), rearrangements involving 6p21, 10q, trisomy 12, and deletions of 3q. Interestingly, a recent study of 217 myomas found a positive correlation between the presence of a cytogenetic abnormality and the anatomic

location of the myoma. In this study by Brosens and colleagues, submucous myomas were consistently shown to have fewer cytogenetic abnormalities when compared with intramural and subserous lesions (12% vs. 35% and 29%, respectively). An increased prevalence in certain races, twin studies indicating higher correlation with hysterectomy in monozygotic twins, and increased incidence in first-degree relatives all seem to support an inherited predisposition. The true genetic contribution to the development of uterine leiomyoma remains to be defined.

Most of the data concerning the incidence of uterine leiomyomata are based on gross examination of the uterus, routine pathology reports, or the clinical diagnosis of uterine leiomyomata. Cramer and Patel subjected 100 uteri to gross serial sectioning at 2-mm intervals. They found 649 leiomyomata, roughly threefold the number identified by routine pathologic examination. Admittedly, some were only a few millimeters in diameter, but all were grossly visible. In 48 uteri with no mention of leiomyomata in the routine report, 27 were found to have small tumors. The incidence of leiomyomata was the same in premenopausal and postmenopausal uteri, although the average number of leiomyomata and the average size of the largest leiomyoma were greater in the premenopausal women. This work has important implications for future epidemiologic studies. It also suggests that it is almost never possible to surgically remove all leiomyomata when a myomectomy is performed.

The growth of leiomyomata is dependent on estrogen production. The tumors thrive during the years of greatest ovarian activity. Continuous estrogen secretion, especially when uninterrupted by pregnancy and lactation, is thought to be the most important underlying risk factor in the development of myomata. After menopause, with regression of ovarian estrogen secretion, growth of leiomyomata usually ceases. Actual regression in the tumor size may occur. There are rare instances, however, of postmenopausal growth of benign leiomyomata, suggesting the possibility of postmenopausal estrogen production either in the ovary or elsewhere.

Postmenopausal ovarian cortical stromal hyperplasia may be associated with an increase in estrogen secretion by the ovary. The postmenopausal ovarian stroma in a variety of presumably inactive ovarian tumors, including mucinous cysts and Brenner tumors, can also produce estrogen. When a central pelvic tumor presumed to be uterine leiomyomata enlarges after menopause, one should think of the possibility of malignant change in the leiomyoma itself or in the adjacent myometrium, or of the growth of a new pelvic tumor of extrauterine origin.

Older nulliparous women have an increased risk of developing leiomyomata. However, in multiparous women, the relative risk decreases with each pregnancy. A woman who has had five term pregnancies has only one fifth the risk of a nulliparous woman of developing myomata. The risk is reduced in women who smoke and is increased in obese women; this is possibly related to the conversion of androgens to estrogen by fat aromatase.

The observation that leiomyomata may show significant enlargement during pregnancy provides further clinical evidence of the relation of estrogen and progesterone to the growth of these tumors. However, a better blood supply during pregnancy might also encourage their growth. In a prospective ultrasonographic study of 29 pregnant patients with uterine leiomyomata, Aharoni and associates found no evidence of enlargement of the myomata in 78%. Lev-Toaff and colleagues also confirmed that some but not all leiomyomata enlarge during pregnancy in response to estrogen and progesterone.

P.659

In the initial two decades following the introduction of oral contraceptives containing high-dose estrogen, there was a striking increase in the occurrence of large leiomyomata among young women of all racial backgrounds who took these pills. Although the growth of uterine leiomyomata is not invariably stimulated, oral contraceptives containing high-dose estrogen should not be prescribed for women with these tumors. Oral contraceptives with low-dose estrogen are less likely to stimulate growth. According to Parazzini and associates, there is no significant relation between the occurrence or growth of leiomyomata and the newer oral contraceptives that contain much smaller amounts of estrogens and progestins, and some believe that the risk of developing myomata is reduced with these low-dose pills.

Scientific investigators have been intrigued by the observation that leiomyomata develop during the reproductive years, sometimes grow during pregnancy, and regress after menopause. Nelson, Lipschutz, and others have produced multiple leiomyomata artificially on the serosal surface of the uterus and other peritoneal surfaces in guinea pigs given prolonged estrogen injections. Spellacy and coworkers found that levels of plasma estradiol were the same in patients with and without leiomyomata. However, Wilson and associates found a significantly higher concentration of estrogen receptors in leiomyomata than in myometrium. Farber and colleagues reported that these tumors bind about 20% more estradiol per milligram of cytoplasmic protein than does the normal myometrium of the same organ. This observation was not uniformly true for all leiomyomata, suggesting that different cellular components with a leiomyoma may be associated with different biologic activity. Otubu and coworkers found the concentration of estradiol to be significantly higher in leiomyomata than in normal myometrium, especially in the proliferative phase of the menstrual cycle. Soules and McCarty reported that leiomyomata had more estrogen receptors than did normal uterine tissues in the first phase (days 1 through 9) and in the second phase (days 10 through 18) of the menstrual cycle. Gabb and Stone found that the ability to convert estradiol to estrone was similar in leiomyomata and myometrium. However, Pollow and associates found the conversion of estradiol into estrone to be significantly lower in leiomyomata than in myometrium. This difference in conversion rate could result in a relative accumulation of estrogen in a leiomyoma, causing a hyperestrogenic state within the tumor and surrounding tissues. The enzyme 17β -hydroxy dehydrogenase accelerates the conversion of estradiol to estrone. Leiomyomata have a low concentration of 17β -hydroxy dehydrogenase, which results in a relative accumulation of estradiol in leiomyomatous tissue. These findings may explain the myometrial hypertrophy that is invariably present with leiomyomata.

Other abnormalities in endocrine function have also been suggested. Ylikorkala and colleagues found that pituitary function may be abnormal in women with leiomyomata. Patients with leiomyomata had a low follicle-stimulating hormone level and a diminished follicle-stimulating hormone response to pituitary GnRH. There was an excessive prolactin response to thyrotropin-releasing hormone. Spellacy and colleagues found that the peak levels of human growth hormone reached during a hypoglycemic test were twice as high in patients with leiomyomata as in the control group. Reddy and Rose suggested the possibility that 5α -reduced androgens may play a role in the pathophysiology of uterine leiomyomata, because a significant increase in 5α -reductase has been found in leiomyoma tissue as compared with the myometrium and endometrium. Influenced by the experimental investigations of Lipschutz and associates, Goodman in 1946 treated patients with uterine leiomyomata with progesterone and noted a decrease in tumor size in all patients. However, Segaloff and colleagues reported no effect in their study. Goldzieher and coworkers produced histologic evidence of extensive degenerative changes in leiomyomata by administering high-dose progestin therapy (medrogestone in high doses for 21 days). Filicer and associates have reported the regression of a uterine leiomyoma after longterm administration of a long-acting luteinizing hormone-releasing hormone agonist given to suppress ovarian estrogen secretion. Coutinho successfully used a potent 19-norsteroid antiestrogen-antiprogesterone to treat excessive uterine bleeding in 16 patients with uterine leiomyomata. A reduction in the size of the tumors was noted.

Although the exact etiology of uterine leiomyomata is not known, the puzzle may be solved bit by bit by the research of Kornyei and colleagues, Wilson and coworkers, Tamaya and associates, Buchi and Keller, Sadan and colleagues, and others who continue to investigate estrogen and progesterone as possible growth factors. Although some data are conflicting, evidence suggests that both estrogen and progesterone are involved in the growth of uterine leiomyomata. The possibility that progesterone may play a role in the growth of leiomyomata is suggested by the work of Kawaguchi and coworkers, who found a higher mitotic count in leiomyomata obtained in the proliferative phase of the menstrual cycle.

Anderson and associates have shown that medroxyprogesterone acetate, a progestin, causes a decrease in

connexin-43 messenger ribonucleic acid levels in primary cultures of human myometrium and leiomyoma. Connexin-43 is a gap junction protein whose formation is stimulated by 17β -estradiol.

According to the research data of Brandon and colleagues, progesterone receptor messenger ribonucleic acid is overexpressed in uterine leiomyomata, compared with normal adjacent myometrium, suggesting that amplified progesterone-mediated signaling is instrumental in the abnormal growth of these tumors. It is possible that the increased amount of progesterone receptor is caused by an alteration of estrogen or estrogen receptors in leiomyomata. The work of Kastner and coworkers and Nardulli and associates has demonstrated that progesterone receptor expression is regulated by estrogen.

Research in recent years has also focused on polypeptide growth factors in the stimulation of growth of leiomyomata. Polypeptide growth factors that have been investigated include epidermal growth factor, transforming growth factor alpha and beta, insulin-like growth factor (IGF), platelet-derived growth factor, vascular endothelial growth factor, and basic fibroblast growth factor. Other growth factors may also be involved. Polypeptide growth factor research has been performed by Goustin and colleagues, by Hoffmann and coworkers, by Lumsden and associates, and by others. A brief review of this research has been written by Vollenhoven and associates, who have been involved in the study of IGFs in uterine leiomyomata.

Results from a study by Strawn and colleagues demonstrate that IGF-I stimulates leiomyoma growth in a dose-related manner over that of normal myometrial tissue in monolayer culture. This stimulatory effect, in the absence of sex steroid hormones or other growth factors, provides additional support that IGF-I may play an important direct role in the pathogenesis of these tumors, possibly by modulating the response of these tumors to various levels of sex steroids. Dawood and Kahn-Dawood were unable to find any significant elevation in peripheral levels of serum IGF-I in nonpregnant premenopausal women with uterine leiomyomata of 14 weeks gestational size. The authors state, "Nevertheless, the finding does not detract from the potential paracrine or autocrine role that

P.660

IGF-I produced by leiomyoma cells may have either on the growth of its own or adjacent myomas or on the vascular supply and blood flow of the uterus and myomas."

Rein and coworkers have proposed a hypothesis to explain the pathogenesis of myomata. This hypothesis suggests a critical role for progesterone in the growth of myomata. They state:

The initiation and growth of myomas likely involves a multistep cascade of separate tumor initiators and promoters. The initial neoplastic transformation of the normal myocyte involves somatic mutations. Although the initiators of the somatic mutations remain unclear, the mitogenic effect of progesterone may enhance the propagation of somatic mutations. Myoma proliferation is the result of clonal expansion and likely involves the complex interactions of estrogen, progesterone, and local growth factors. Estrogen and progesterone appear equally important as promoters of myoma growth.

To treat patients with uterine leiomyomata properly, the gynecologic surgeon must be familiar with their pathology, growth characteristics, and clinical features. Leiomyomata may be single, but most are multiple. They develop most commonly in the uterine corpus and much less often in the cervix. They may develop in the round ligaments, but this is rare. Because they arise in the myometrium, they are all interstitial or intramural in the beginning. As they enlarge, they can remain intramural, but growth often extends in an internal or external direction. Thus, the tumor can eventually become subserous or submucous in location. A subserous tumor can become pedunculated and occasionally parasitic, receiving its blood supply from another source, usually the omentum. A submucous tumor can also become pedunculated and may gradually dilate the endocervical canal

and protrude through the cervical os. Indeed, a submucous myoma may descend through the vagina. Rarely, chronic uterine inversion results if the prolapsing submucous leiomyoma is attached to the top of the endometrial cavity and pulls the uterine fundus downward through the cervix.

In general, subserous leiomyomata contain more fibrous tissue than submucous leiomyomata. However, submucous leiomyomata contain more smooth muscle tissue than subserous leiomyomata. Sarcomatous change is more common in submucous tumors.

The typical uterine leiomyoma is a firm multinodular structure of variable size. The largest tumor, reported by Hunt in 1888, weighed more than 65 kg. Tumors of 4 to 5 kg are not rare, but most are smaller. In the operating room, leiomyomata appear as nodular tumors of different sizes that distort the uterus in various ways, depending on their size, location, and direction of growth. Growth between the leaves of the broad ligament and origin from the cervix may make surgical removal difficult. Subserous and subserous pedunculated tumors, as well as intraligamentous tumors, may create problems in diagnosis because they are difficult to distinguish from tumors arising from the adnexal organs (**Fig. 31.2**). When tumors cause symmetric enlargement of the uterus, they may be mistaken for a pregnant uterus on bimanual examination.

FIGURE 31.2 The uterine corpus is almost completely replaced by small and large myomas in intramural, subserous, and submucous positions. Some are pedunculated. A pedunculated submucous myoma is dilating the endocervical canal. A pedunculated subserous myoma is adjacent to the left ovary and will interfere with its palpation.

The “normal” intramural leiomyoma on section protrudes from the surrounding compressed myometrium. Ordinarily, there is a clear distinction between the myoma and the myometrium so that dissection between the two is easy to accomplish. Myomata usually can be removed from surrounding myometrium with ease. Although these tumors are not encapsulated, a clear distinction can usually be made between a myoma and the myometrium that surrounds it. The cut surface appears as glistening pinkish white and gray. It is firm, and there is a whorllike arrangement of the muscle and the fibrous tissue. In contrast to this typical appearance, the myometrium may be thickened by a diffuse, ill-defined nodularity of smooth muscle. This so-called diffuse leiomyomatosis usually involves all parts of the myometrium and causes symmetric enlargement of the uterine corpus. The nodules of smooth muscle are not distinct, contain little collagen, and merge with one another and the surrounding hypertrophied myometrium.

The extracellular matrix of leiomyomata is composed mostly of collagen but also contains proteoglycans and fibronectin. According to Fujita, myomata contain 50% more collagen than does normal myometrium, and the ratio of collagen type I to collagen type III is increased in myomata. Proteoglycans provide hydrated spaces between myoma cells. Fibronectin is a glycoprotein that mediates adhesion between myoma cells and extracellular matrix.

The most common change in leiomyomata is hyaline degeneration. The cut surface of a hyalinized area is smooth and homogeneous and does not show the whorllike arrangement of the rest of the leiomyoma. Almost all leiomyomata, except the smallest, have scattered areas of hyaline degeneration. Eventually, these may become liquefied and form cystic cavities filled with clear liquid or gelatinous material

P.661

(**Fig. 31.3**). Sometimes, the cystic change is so great that the leiomyoma becomes a mere shell and is truly a cystic tumor. Softness of a tumor does not necessarily indicate cystic degeneration. Fleishy leiomyomata may be equally soft.

FIGURE 31.3 Multiple leiomyomata are present. A large subserous myoma has undergone partial cystic degeneration.

Over time, with continued diminished blood supply and ischemic necrosis of tissue, calcium phosphates and carbonates are deposited in myomata. Their presence is evidence of a continuum of degenerative changes. The calcium may be deposited in varying amounts. If it is deposited at the periphery of the tumor, the leiomyoma may resemble a calcified cyst. Other calcified leiomyomata may show an irregular or diffuse distribution throughout with a honeycomb or mulberry appearance. When the degenerative change is advanced, the leiomyoma may become solidly calcified. Such calcified tumors have been called “womb stones.” Calcified leiomyomata are seen most often in elderly women, in African American women, and in women who have pedunculated subserous tumors. They are easily seen radiographically (**Fig. 31.4**).

Leiomyomata may undergo changes as a result of infection. Submucous leiomyomata are most commonly infected when they protrude into the uterine cavity, or especially into the vagina (**Fig. 31.5**). The pedunculated submucous leiomyoma thins out the endometrium as it grows inward, and eventually, the surface becomes ulcerated and infected (**Fig. 31.6**). An intramural leiomyoma in an involuting puerperal uterus can also become infected when endometritis is present. Microscopic abscesses can be found, and gross abscesses occasionally occur, particularly if the leiomyoma descends as low as the cervical canal. Such infections are usually streptococcal and may be virulent. *Bacteroides fragilis* infections also occur. Parametritis, peritonitis, and even septicemia may result.

FIGURE 31.4 An abdominal radiograph shows typical calcification in a leiomyoma.

FIGURE 31.5 A large submucous pedunculated myoma has dilated the cervix and is now located in the vagina. Its pedicle is attached inside the uterine cavity. Morcellation of the myoma performed transvaginally allows clamping and ligation of the pedicle.

Necrosis of a leiomyoma is caused by interference with its blood supply. Occasionally, a pedunculated subserous leiomyoma twists, and if an operation is not done immediately, infarction results. Necrosis sometimes occurs in the center of

P.662

a large tumor simply as a result of poor circulation. Necrotic leiomyomata are dark and hemorrhagic in the interior. Eventually, the tissue breaks down completely. So-called red or carneous degeneration is seen occasionally, especially in association with pregnancy. This condition is thought to result from poor circulation of blood through a rapidly growing tumor. Thrombosis and extravasation of blood into the myoma tissue are responsible for the reddish discoloration ([Fig. 31.7](#)).

FIGURE 31.6 Pedunculated submucous myoma showing necrosis and ulceration.

FIGURE 31.7 Degenerating leiomyoma showing carneous discoloration caused by thrombosis and extravasation of blood into the myoma tissue. A Dalkon shield can be seen in the endometrial cavity.

A subserous and especially a subserous pedunculated myoma may gradually outgrow its blood supply ([Fig. 31.8](#)). To keep the myoma tissue from undergoing complete ischemic necrosis, the omentum becomes adherent to the peritoneal surface of a pedunculated subserous myoma and provides whatever blood supply is needed. Eventually, the pedicle may disappear or twist, and the myoma will become completely free from the uterus, wander in the upper abdomen, and receive its “parasitic” blood supply from the omentum and other sources.

On occasion, fat occurs in leiomyomata as true fatty degeneration. The cut surface may have a yellowish discoloration. Infrequently, a deposit of true fat may form a fibrolipoma; however, the presence of fat in a leiomyoma is rare. Indeed, if fat is seen grossly or microscopically in a curettage specimen, one should not assume that it represents fatty degeneration of a leiomyoma. One should assume that the uterus has been perforated and that fragments of fat have been curetted from the mesentery or omentum.

The most important, but rare, change in a leiomyoma is sarcomatous degeneration. There is much variation in the reported incidence of sarcoma in leiomyomata. The incidence given by

P.663

Novak is 0.7%. However, a review of 13,000 myomata by Montague and associates at Johns Hopkins Hospital revealed 38 cases of malignant change, the incidence of sarcoma thus being 0.29%. Corscaden and Singh indicated by their study that the true incidence of sarcoma developing within uterine leiomyomata is no higher than 0.13% and is probably as low as 0.04%. It should be remembered that because most women with uterine leiomyomata do not undergo surgical removal, the true incidence of sarcoma in leiomyomata is probably much lower than 1 per 1,000 (0.1%).

FIGURE 31.8 A subserous pedunculated myoma receives tenuous blood supply through its uterine pedicle. Such a myoma may wander in the upper abdomen and eventually receive its blood supply from other sources. It may also twist on its pedicle and undergo infarction.

After hysterectomy in 1,429 patients with presumed benign leiomyomata, the histologic diagnosis of leiomyosarcoma was made in seven (0.49%), according to a study by Leibsohn and coworkers. There was no evidence of malignancy in the endometrial sampling of any of these seven patients, and the diagnosis was suspected intraoperatively in only three. Uterine weights ranged from 120 to 1,100 g. In a woman between 41 and 50 years of age with presumed symptomatic leiomyomata, there is a 1 in 112 chance of a leiomyosarcoma being present, according to these authors. This information has important implications in the consideration of conservative or delayed treatment for these women. Parker and associates found that the total incidence of uterine sarcomas (leiomyosarcoma, endometrial stromal sarcoma, and mixed mesodermal tumor) among patients operated on for presumed benign uterine leiomyoma is lower (0.23%) than the 0.49% reported by Leibsohn and coworkers.

The difficulty in defining the true incidence of sarcomatous change is understandable if one is familiar with the histology of leiomyomata. Abundantly, cellular leiomyomata are relatively common, and at first glance, they suggest sarcoma; however, they lack a significant number of mitotic figures, and patients from whom such tumors are removed all remain well. Misinterpretation of the histologic picture of this type of cellular leiomyoma undoubtedly accounts for the increased incidence of leiomyosarcoma reported by some. When cutting into leiomyomata in the operating room, the surgeon finds that sarcomatous areas have a somewhat characteristic appearance, although the histologic diagnosis certainly cannot be made by gross examination. A sarcoma is likely to occur in a rather large leiomyoma and toward the center of the tumor, where the blood supply is poorest.

Instead of being firm fibrous tissue that grates when scraped with a knife blade, the tissue is soft and homogeneous and is described as resembling raw pork. Later, as necrosis of the malignant tissue occurs, it becomes more friable and hemorrhagic.

It has been difficult to understand uterine leiomyosarcoma, because pathologists do not agree on the criteria necessary for diagnosis. Some pathologists rely on the mitotic count. All tumors with less than 5 mitotic figures per 10 high-power fields are considered benign. All tumors with more than 10 mitotic figures per 10 high-power fields are called malignant. Those in between can be called smooth muscle tumors of uncertain malignant potential.

Other pathologists believe the mitotic count may have some significance but choose to rely instead on the presence of nuclear hyperchromatism, nuclear pleomorphism, or giant cells and other bizarre cell forms to make the diagnosis. Corscaden and Singh believe that no combination of histologic features is reliable and that only smooth muscle tumors that metastasize or recur are definitely malignant. We believe that all of these features should be taken into consideration for diagnosis and prognosis. When the tumor is confined to the uterus, both mitotic grade and histologic grade are important in the diagnosis and prognosis. A poor prognosis is associated with high mitotic counts and extremely atypical and anaplastic cytologic features. Bell and colleagues at Stanford University Medical Center assessed a variety of histopathologic features of 213 problematic smooth muscle neoplasms for which there were at least 2 years of clinical follow-up data. From the wide variety of light microscopic features assessed, the important predictors that emerged were mitotic index, the degree of cytologic atypia, and the presence or absence of coagulative tumor cell necrosis. Previously, the mitotic index was relied on exclusively to determine whether a uterine smooth muscle tumor was benign or malignant, but currently, an approach is used that incorporates additional histopathologic features.

A normal chromosome complement (46,XX) was observed by Meloni and coworkers in about 50% of leiomyoma cases. About 50% showed clonal abnormalities, such as those of chromosomes 1, 7, and 13, and t(12;14). Interstitial deletions of chromosome 7 were the ones most often involved, suggesting that this abnormality may be of primary importance in the cellular proliferation of leiomyomata. A relation between more aggressive histology and chromosomal abnormalities was also suggested.

Tumors that show obvious evidence of blood vessel invasion or spread to contiguous organs are rarely cured. The extent of the disease at the time of initial diagnosis is of even greater significance. In other words, when the diagnosis is suspected for the first time by the pathologist when he or she examines routine sections from a uterine leiomyoma, the patient almost always survives. However, if the diagnosis is made preoperatively by the gynecologist or is suspected during the operative procedure because of invasion of surrounding organs, the prognosis is grave.

P.664

An unusual atypical smooth muscle tumor was first described in the stomach by Martin and associates in 1960. Various called *bizarre leiomyoma*, *leiomyoblastoma*, *clear cell leiomyoma*, and *plexiform tumorlet*, these atypical smooth tumors probably all belong together. The term *epithelioid leiomyoma* was adopted by the World Health Organization. Kurman and Norris have proposed that this term be used for all atypical leiomyomata. Histologically, the characteristic feature is the mixture of rounded polygonal cells and multinucleated giant cells present in epithelioid clear cell and plexiform patterns. Clinically, in the uterus most of these tumors are benign. They may rarely exhibit malignant potential. Malignancy is difficult to predict from histologic criteria because some metastases occurred from tumors that demonstrated very few mitoses. Kurman and Norris have suggested, however, that epithelioid neoplasms having more than 5 mitotic figures per 10 highpower fields should be called *epithelioid leiomyosarcomas* and that the term *epithelioid leiomyoma* should be applied when there is a lower level of mitotic activity. Although combination therapy (surgery plus radiation therapy or chemotherapy) may not be indicated for a patient with an epithelioid leiomyoma, follow-up should be considered

essential, as emphasized by Klunder and colleagues.

An unusual benign form of leiomyomata uteri, *intravenous leiomyomatosis*, was first recognized at the turn of the 20th century and has been reported sporadically since then. Before 1982, about 50 cases had been reported, according to Bahary and coworkers. Probably, at least that many have been reported since. Marshall and Morris presented the first detailed report of this entity in the American literature in 1959. The characteristic feature of this peculiar smooth muscle tumor is the extension of the polypoid intravascular projections into the veins of the parametrium and broad ligaments. Although there may be some difficulty in distinguishing such lesions from lowgrade sarcoma, they are distinctly different histologically from stromatosis uteri because the intravenous plugs are mainly smooth muscle in origin. In 1966, Edwards and Peacock collected 32 cases of intravenous leiomyomatosis, including two cases of their own, and reviewed the clinical experience with this condition. In approximately 50% of the cases, the intravenous tumor was confined to the parametrium; in 75%, it extended no further than the veins of the broad ligament. The observations of Edwards and Peacock suggest that the severed intravenous extensions are probably incapable of independent parasitic existence and remain dormant after removal of the uterus. However, the cases presented by Bahary and associates tend to refute this idea. Total surgical excision of the tumor should be attempted for successful therapy. Some patients have survived for many years after incomplete resection of the tumor. A review of 14 cases of this rare uterine tumor from the file of the Armed Forces Institute of Pathology has been reported by Norris and Parmley. In this series, two of three patients with incomplete resection had a recurrence; the recurrent tumor was excised surgically, and the patients were alive and free of disease 5 and 11 years after operation. The authors concluded that this tumor behaves clinically like a benign neoplasm, although its wormlike extensions may involve uterine, vaginal, ovarian, and iliac veins. The uterine veins in the broad ligaments are the most common sites of extension. The mitotic index is quite low, with the most active lesions showing only one mitosis per 15 high-power fields. The material from the Armed Forces Institute of Pathology provides histologic evidence consistent with both theories of origin of intravenous leiomyomatosis, namely, that it may be the result of unusual vascular invasion from a leiomyoma or may arise de novo from the wall of veins within the myometrium.

Extension of benign leiomyomatosis up the vena cava and into the right atrium has been reported in several cases, with a fatal outcome in some. Before 1994, approximately 27 cases of intravenous leiomyomatosis extending to the heart were reported. Several recent cases requiring open heart surgery to remove the intracardiac tumor thrombosis have been successful and without recurrence. All reported cases occurred in women. Tierney and colleagues reported that substantial quantities of cytoplasmic estradiol and progesterone receptors were found in the right atrial tumor removed from a patient with intravenous leiomyomatosis. Their patient was treated with the antiestrogen tamoxifen because of residual tumor in the vena cava that could be estrogen dependent. Irey and Norris have presented evidence that female reproductive steroids can produce intimal proliferation of veins in predisposed persons. Interestingly, of the 30 patients with leiomyomata and leiomyosarcomas of the vena cava reviewed by Wray and Dawkins, 80% were female. Both intravenous leiomyomatosis and benign metastasizing leiomyoma have been reported to metastasize to the lung. As suggested by Banner and coworkers, by Horstmann and associates, and by Evans and colleagues, oophorectomy may be indicated in patients with these conditions, again because of the possibility that these tumors may be estrogen dependent or that estrogens may have the ability to stimulate their development, whether in a uterine or extrauterine location and whether they appear to be endothelial or mesenchymal in origin.

The possibility of metastases from a histologically benign uterine leiomyoma has been discussed by Idelson and Davids and by Clark and Weed. When such a case occurs, it is usually settled by finding a sarcomatous component in the leiomyoma or by finding evidence of intravenous leiomyomatosis. However, multiple cases have now been reported in which a benign uterine leiomyoma metastasized. Idelson and Davids' case showed metastases to the aortic lymph nodes. The patient reported by Cramer and associates had metastatic tumor to

the omentum, ovary, periaortic lymph node, and lung. In each location, the histology and estrogen receptor content of the tumor resembled those of a benign leiomyoma. The recommended treatment consists of surgical removal with castration and little or no estrogen replacement.

Leiomyomatosis peritonealis disseminata is sometimes confused with intravenous leiomyomatosis. However, only subperitoneal surfaces of the uterus and other pelvic and abdominal viscera are involved with leiomyomatosis peritonealis disseminata, and invasion of the lumen of blood vessels does not occur. Only about 15 cases have been reported, according to Pearce. All occurred in patients in the reproductive years who often had large uterine leiomyomata and were usually pregnant or taking oral contraceptives. The condition is likely to be confused with a disseminated intraabdominal malignancy, but it is entirely benign histologically and clinically. Parmley and colleagues have demonstrated the histologic similarities between this peritoneal lesion and the decidual change of the mesothelium in the pelvis, and they propose that the condition represents a benign reparative process in which fibroblasts replace soft peritoneal decidua. They suggest that this fibrotic reaction occurs during pregnancy and especially in the postpartum period, resulting in nodules with a pseudoleiomyomatous pattern. Similar findings have been noted in patients with endometriosis treated with prolonged Enovid therapy. These findings indicate that prolonged and continuous stimulation of subperitoneal decidua by either endogenous or exogenous estrogen and progesterone is important in the pathogenesis of this condition. Parmley and coworkers suggest that the condition is more appropriately called *disseminated fibrosing deciduositis*. Goldberg and associates, on the other

P.665

hand, on the basis of electron microscopy studies, believe that the tumors arise from smooth muscles of small blood vessels. This has been confirmed by Ceccacci and colleagues. It has been possible to show a continuum from fibroblastic cells through myofibroblasts to leiomyocytes. Although the cell of origin of this tumor is still controversial, the tumor is benign, and the acceptable treatment to date is total abdominal hysterectomy and bilateral salpingo-oophorectomy. If this tumor occurs in the omentum, an omentectomy should also be performed to define more clearly the histologic nature of the lesion.

In attempting to distinguish between benign and malignant disease in a patient with uterine leiomyomata who also has unusual clinical findings, it is appropriate to keep the entities mentioned earlier (intravenous leiomyomatosis, atypical bizarre leiomyoma, benign metastasizing leiomyoma, and disseminated intraperitoneal leiomyomatosis) in mind. Although they all have features similar to those of malignant disease, they are almost always benign and amenable to treatment. One should also remember that benign uterine leiomyomata have been associated with pseudo-Meigs syndrome in a few cases. Meigs reported five cases in 1954. In these cases, the ascites did not reappear after removal of the uterine leiomyomata.

There is a high frequency of endometrial hyperplasia when the uterus contains leiomyomata. Degligdish and Loewenthal reported that cystic glandular hyperplasia is often found in the endometrium at the margin of the leiomyoma. Yamamoto and coworkers have reported high concentrations of estrone and estrone sulfatase activity in the endometrium overlying a myoma. They suggest that the local hyperestrogenism in the endometrium overlying a leiomyoma may assist in the genesis or enlargement of these tumors.

FIGURE 31.9 Sonographic images of a 48-year-old patient with a history of pelvic pain. Both transabdominal and transvaginal images were obtained on cycle day 8. Longitudinal (**A**) and transversely oriented (**B**) transvaginal images reveal a suspicious endometrial cavity, suggesting a thickened lining, endometrial polyp, or a submucosal myoma. **C and D**: Fluid-enhanced sonohysterographic studies clearly demonstrate a mass lesion and not generalized thickening of the endometrial lining. The patient underwent a hysteroscopy and uterine curettage, which revealed a histologically confirmed endometrial polyp. (Images courtesy of Jeff Dicke, MD.)

Gynecologic surgeons are especially concerned about the vascularity of individual leiomyomata and about the blood flow to the uterus in the presence of multiple and sometimes very large leiomyomata. These considerations are pertinent when surgery, especially myomectomy, is contemplated.

According to Vollenhoven and associates, the vascularization of leiomyomata was studied by Vasserman and colleagues, and the findings were presented to the World Congress of Gynecology and Obstetrics in 1988. Using femoral arteriography, selective intraoperative angiography, radiography, and injection of surgical specimens, these investigators showed that leiomyomata have a rich vascular supply, including blood lakes within tumors. They found more than one nutrient vessel per myoma. Venous channels were predominantly peripheral, whereas the arterial supply was both internal and peripheral. Farrer-Brown and coworkers, using radiologic methods, demonstrated that myomata in various locations within the myometrium can cause congestion and dilatation of endometrial venous plexuses by obstructing venous return. These obstructions can result in ectasia of endometrial and myometrial venules ([Fig. 31.9](#)). The degree of vascularity of leiomyomata was also studied by Karlsson and Persson. Vascularity varied from many, to few, to no intrinsic vessels demonstrable. Generally, the sum of the width of the uterine arteries increases with the size of the uterus, but the diameter of the two sides sometimes differs markedly. A rich vascularity was found in 22 of 34 uteri with leiomyomata, but with increasing size, there is a tendency to less vascularity. In none of five cases with very large (20 cm or more) leiomyomata uteri was the vascularity rich. The intrinsic vessels were few in two cases and absent in three cases.

CLINICAL FEATURES OF UTERINE LEIOMYOMATA

Asymptomatic Leiomyomata

Most leiomyomata are asymptomatic. Untold numbers of such symptomless leiomyomata are removed surgically by either hysterectomy or myomectomy when they would have been better left undisturbed. The incidence of malignancy in leiomyomata is less than 0.1%, which is lower than the operative mortality rate of hysterectomy in the average hospital; therefore, unless there is some reason to suspect malignant change, the risk of the operation for asymptomatic leiomyomata may exceed the danger of malignancy. A history of rapid growth, however, particularly postmenopausal growth, does indicate removal, even when the tumor produces no symptoms. Signs of rapid enlargement are important in all patients but are even more ominous in older patients. In younger patients, the most common reason for rapid enlargement of a uterus with leiomyomata is pregnancy. If pregnancy can be ruled out, a leiomyosarcoma may be suspected but is rarely found.

Small leiomyomata that are asymptomatic need only to be observed from time to time, with pelvic examinations perhaps every 6 to 12 months and pelvic ultrasonography (US) when indicated. In the beginning, frequent examination may be indicated to determine the growth rate. Such tumors may remain remarkably constant in size for years. If small leiomyomata are discovered late in menstrual life, it is unusual for symptoms to appear or for surgical treatment to be required. Larger tumors can also be watched safely, but if a policy of watchful waiting is adopted, one should be very sure of the nature of the tumors. If there is uncertainty of the uterine or ovarian origin of a tumor, as may well be the case when the tumor fills the whole pelvis or when a pedunculated tumor is felt in the adnexal region (**Fig. 31.10**), special diagnostic procedures may be indicated. Pelvic examination by an experienced gynecologist can usually clear up the uncertainty. In difficult cases, an examination under anesthesia may be necessary. Laparoscopy may be of great value in determining the nature of an adnexal mass. Before invasive techniques are used, however, noninvasive diagnostic evaluation should be performed. These include radiographic studies of the abdomen and pelvis, US, and computed tomography (CT). The characteristic calcification in a leiomyoma may be seen on radiographs. The US and CT features of uterine leiomyomata have been well described. However, mistakes in the interpretation can still be made. Tada and associates reported that 5% of patients given the diagnosis of uterine leiomyomata by CT actually had an ovarian tumor at operation. Therefore, if uncertainty about the diagnosis persists, laparoscopy or laparotomy should still be performed.

FIGURE 31.10 Although this central pelvic mass may feel like a multiple leiomyomatous uterus on bimanual

pelvic examination, it is actually a bilateral ovarian malignancy. Differentiation between these two diagnoses may require special diagnostic procedures.

When large asymptomatic leiomyomata occur in premenopausal women who have had their families or in whom future childbearing is not desired, a recommendation for removal may be made. It is impossible to predict which patients will become symptomatic in the remaining years before menopause. However, such tumors, with additional years to grow, are likely to require surgical removal eventually. Therefore, it is better to remove them when the patient is a good operative candidate of relatively low operative risk and when conservation of normal ovaries with a good blood supply can be easily accomplished. Such tumors should usually be 12 to 14 weeks in gestational size or larger. Depending on a variety of factors, either myomectomy or hysterectomy can be recommended to the patient. GnRH agonists may be useful in women approaching menopause to control symptoms or asymptomatic uterine myoma growth until menopause. The regrowth of tumors after the cessation of treatment limits the usefulness of these agents, however. Nakamura and Yoshimura reported their experience with GnRH agonists in the treatment of uterine leiomyomata in perimenopausal women. One third of patients reached menopause after 16 weeks of treatment, thus avoiding the need for surgery.

Reiter and colleagues studied 93 consecutive patients undergoing hysterectomy for leiomyomata. When the uterus was larger than 12 weeks gestational size, there was no increased incidence of surgical complications compared with women with smaller uteri. On the basis of this small series, the authors concluded that hysterectomy need not be recommended to women with large asymptomatic uterine leiomyomata to avoid a possible increased risk of surgical complications.

There is no uniform size of an asymptomatic leiomyomatous uterus that can be used as an indication for hysterectomy or myomectomy. When size is the only significant indication for surgery in an asymptomatic patient, the location of the tumors is more important than the total uterine mass. When the leiomyomata are located in the cornual area or in the lateral wall of the uterus and obscure the anatomy of the adnexa and broad ligament, the risk of error in the early recognition of an ovarian tumor is greater. In such cases, one must carefully weigh the advantages and disadvantages of the conservative approach to the management of uterine leiomyomata. When adnexal tumors are present, it is critical that the origin of these tumors be confirmed. The diagnostic studies mentioned earlier should be performed to establish clearly that the tumors are of uterine origin before a decision is made to follow up the patient rather than operate. It is unacceptable to wait to see whether an adnexal tumor enlarges before identifying the site of origin of the mass as either uterine or ovarian. Ovarian carcinoma remains the most lethal disease of the female reproductive tract and the most difficult to diagnose early. Every diagnostic and therapeutic effort must be made to avoid errors in the clinical evaluation of pelvic neoplasms ([Fig. 31.10](#)). In women who are approaching menopause, relatively large uterine leiomyomata can be kept under observation with the knowledge that after menopause, they will not increase in size and may actually regress somewhat. Still, one must be certain

P.667

that the entire central pelvic mass is a leiomyomatous uterus. Patient management is largely dependent on knowledge of the exact location and size of leiomyomas. Imaging modalities play an important role in determining patient management, especially when differentiating a benign leiomyoma from other pathologic conditions that may require different therapies.

Uterine size as an indication for surgical intervention in women with leiomyomata has been thoughtfully discussed by Friedman and Haas. These authors point out that many gynecologists advocate surgical removal of leiomyomata when the uterus reaches 12 weeks gestational size or greater, regardless of the presence or absence of significant symptoms. Historical reasons given for surgical intervention include the following:

- The inability to accurately assess the ovaries by examination

- The possible malignancy of the pelvic mass
- The potential for compromise of adjacent organ function if the mass continues to enlarge
- The greater risk of surgical complications if the mass grows to a larger size
- The potential for better fertility if myomectomy is performed when the uterus is smaller
- The possibility of continued growth of uterine leiomyomata if hormone replacement therapy is given after menopause

Friedman and Haas find very little in the literature to support these indications for surgical intervention and believe the availability of modern high-resolution US and magnetic resonance imaging (MRI) allows for expectant management in many patients with large asymptomatic uterine leiomyomata. They prefer to give primary consideration to the presence and severity of myoma-related symptoms in deciding whether surgical intervention is indicated. We believe that such a course of expectant management is appropriate only when there is relative certainty regarding the benign nature of the central pelvic mass and all of its components and when it is possible to get the patient to return for periodic assessment of gynecologic symptoms and findings on pelvic examination. Repeat MRI may also be required occasionally.

If one elects to observe a patient with a relatively large asymptomatic uterine leiomyoma, it is a good rule to obtain an excretory urogram or renal ultrasound. Everett and Sturgis showed many years ago that ureteral compression at the pelvic brim may occur so that hydroureter and hydronephrosis develop ([Fig. 31.11](#)). It is usually the symmetrically enlarged uterus with intramural leiomyomata that extends near or above the umbilicus and rests on the pelvic brim that compresses the ureters, in the same way as a symmetrically enlarged gravid uterus. The process is usually slow and painless even when moderate to severe hydronephrosis has occurred. Pyelographic evidence of kidney damage may be the determining factor in a decision to operate on a patient with an entirely asymptomatic leiomyoma. The irregularly and asymmetrically enlarged uterus with subserous tumors usually does not produce pressure on the ureters.

After menopause, asymptomatic leiomyomata generally should be left undisturbed. Again, the gynecologist must be absolutely certain that an ovarian neoplasm can be ruled out. In the postmenopausal years, shrinkage of myomata and the myometrium occurs. However, the myometrial shrinkage may be disproportionately greater than the myoma shrinkage. Therefore, a myoma in an intramural location before menopause may become a submucous myoma after menopause and then become symptomatic for the first time, usually with postmenopausal bleeding.

FIGURE 31.11 Bilateral ureteral obstruction and dilatation from pressure of large leiomyomata.

In menopausal women, the appearance of even the slightest trace of vaginal bleeding should make one suspect cervical or endometrial malignancy or the possibility of sarcomatous change in the leiomyoma (**Figs. 31.12** and **31.13**). Careful pelvic examination, Papanicolaou smear, and evaluation of the cervix by colposcopy or biopsy, pelvic US, fractional curettage, and perhaps hysteroscopy should be done. If the bleeding remains unexplained and the presence of atrophic vaginitis or the use of exogenous estrogens has been excluded, the leiomyomatous uterus should be removed because of the risk of sarcomatous change.

FIGURE 31.12 Adenocarcinoma of the endometrium is present in a symmetrically enlarged leiomyomatous uterus.

P.668

FIGURE 31.13 This specimen shows multiple uterine leiomyomata but also shows chronic pelvic inflammatory disease and cervical carcinoma. Patients with uterine leiomyomata may have abnormal bleeding, but a coexisting cervical carcinoma may also cause bleeding.

Transabdominal and endovaginal US are the standard imaging modalities for the detection of leiomyomas. Pelvic US by transvaginal and transabdominal techniques is most useful because of good patient tolerance, relatively low cost, availability, and accuracy when performed by well-trained and experienced ultrasonographers ([Fig. 31.14](#)). Ultrasonography is the most cost-effective screening mechanism for uterine masses suggestive of myomata. Sonographic criteria for diagnosis have been well described. Generally, abdominal US is unable to detect myomas less than 2 cm in diameter. Transvaginal probes have allowed for improved visualization of both the uterus and adnexa. With higher frequencies, sensitivity in the detection of small myomas has substantially increased. In a series evaluated by Fedele and colleagues using endovaginal ultrasound before hysterectomy, submucous leiomyomas were identified with a sensitivity of 100%. Difficulties may arise, however, if myomas are small or pedunculated, patients are obese, or the uterus is retroverted.

FIGURE 31.14 An US study shows a cervical myoma and a very early intrauterine pregnancy.

Transvaginal fluid-enhanced vaginal probe sonography (sonohysterography) is a useful technique to assess myomata that distort the endometrial cavity. This technique has little to no complications and is generally well tolerated with only mild cramping described by patients. The limitation of detection of leiomyomas with this modality is 0.5 cm diameter. In a study by Hoetzing, the majority of intrauterine myomata (14 of 16, or 88%) were detected by sonohysterography. Ultrasound transducing catheters have been suggested as a potential tool to supplement abdominal and endovaginal sonography. Threedimensional data display has recently undergone development and application in sonography; however, the role in evaluation and management of leiomyoma remains unclear ([Fig. 31.9](#)).

There is no technique that reliably identifies a leiomyosarcoma. Plain abdominal or pelvic radiographs and hysterosalpingography are older, standard techniques that are still useful in assessing uterine size, calcification in myomata, intrauterine filling defects caused by submucous myomata, and tubal patency. These techniques, combined with US, are the most useful for assessing patients with a central pelvic mass thought to be a leiomyomatous uterus. CA-125 levels may be elevated in women with uterine leiomyomata, but the levels are generally lower than those in patients with ovarian cancer.

Symptomatic Leiomyomata

Less than 50% of patients with uterine leiomyomata have symptoms. Symptoms may be single or multiple and depend on the location, size, and number of tumors present. A clinical and pathologic study of 298 patients with uterine leiomyomata by Persaud and Arjoon revealed no significant relation between the presenting symptoms and the presence of degenerative changes in the tumors. Some form of degeneration was demonstrated in 65% of the specimens, with hyaline degeneration accounting for 63% of all types of degeneration. Hyaline degeneration produces no characteristic symptoms. Symptoms, especially pain and fever, may be present in some patients with red degeneration of a leiomyoma during pregnancy, with torsion and infarction of a subserous pedunculated leiomyoma, or with an infected leiomyoma. A discussion of the signs and symptoms caused by uterine leiomyomata follows.

Abnormal Bleeding

It is surprising but not unusual that even patients with large uterine leiomyomata may have a history of normal menstruation. Such patients should be questioned carefully about recent slight increases in the amount, duration, and frequency of menstruation. Some patients with a history of normal menstruation are found to have iron deficiency anemia from a gradual increase in menstrual blood loss that even the patient has not recognized. If a case of uterine leiomyomata is to be followed, the patient should be asked to monitor her menstrual blood loss carefully and should be given instructions to keep a menstrual calendar and monthly record of the number of

pads or tampons used each day. A more objective measurement of the amount of menstrual blood loss using the method of Hallberg and Nilsson may be helpful in doubtful cases. Iron depletion may not be evident by laboratory determination unless one checks serum ferritin levels. In the early months of increased menstrual blood loss, the hemoglobin and hematocrit values are normal. Heavy menstruation does not cause anemia until iron stores are first depleted.

Abnormal bleeding occurs in about one third of patients with symptomatic uterine leiomyomata and commonly indicates that treatment is necessary. The menstrual flow is usually heavy (menorrhagia) but can also occur for prolonged periods

P.669

of time at irregular intervals (metrorrhagia). It may also be both heavy and prolonged (menometrorrhagia). Abnormal bleeding may be associated with submucous, intramural, and subserous tumors, but there is a distinct clinical impression that bleeding is more common and more severe in the presence of submucous tumors. The submucous leiomyoma bleeds freely at menstruation and may also bleed between periods as a result of passive congestion, necrosis, and ulceration of the endometrial surface over the tumor and ulceration of the contralateral uterine surface. If the submucous myoma is pedunculated, there is usually a constant, thin, blood-tinged discharge in addition to the menorrhagia. An intramural tumor that is just beginning to encroach on the uterine cavity can also be responsible for menorrhagia. Intramural leiomyomata near the serosal surface and pedunculated subserous tumors can also be associated with abnormal bleeding. When bleeding occurs with such tumors, however, one should search for some other lesions to account for it. The mere presence of leiomyomata in a woman who has abnormal uterine bleeding is not proof that the leiomyomata are causing the bleeding. This fact is important, particularly when there is intermenstrual bleeding. When a patient with leiomyomata has intermenstrual bleeding, it is a rule in our practice to examine and study the cervix carefully with special diagnostic procedures and to sample and evaluate the uterine cavity before we proceed with treatment of the leiomyomata. If an endometrial or cervical malignancy is detected, the treatment of the leiomyomata may need to be altered.

There are several mechanisms by which leiomyomata can cause abnormal bleeding, although a single specific mechanism may not be apparent in a particular patient. According to Sehgal and Haskins, the surface area of the endometrial cavity in a normal uterus is 15 cm². The surface area of the endometrial cavity in the presence of leiomyomata may exceed 200 cm². These authors demonstrated a correlation between the severity of the bleeding and the area of endometrial surface. In addition to an increased surface area from which to bleed, the endometrium may demonstrate local hyperestrogenism in areas immediately adjacent to submucous tumors, and endometrial hyperplasia and endometrial polyps are commonly found. Deglisdish and Loewenthal noted a broad spectrum of histologic abnormalities in the endometrium associated with leiomyomata, ranging from atrophy to hyperplasia. Thinning and ulceration of the endometrial surface may be present over large submucous tumors; smaller ones may show slight thinning without ulceration. The presence of leiomyomata may interfere with myometrial contractility as well as contractility of the spiral arterioles in the basalis portion of the endometrium. Miller and Ludovici suggested that anovulation and dysfunctional uterine bleeding are more common in the presence of uterine leiomyomata.

Sampson in 1913 was the first to study the blood supply of uterine leiomyomata and its effect on uterine bleeding. More recent studies have been performed by Faulkner and by Farrer-Brown and associates. The most prominent and important change is the presence of endometrial venule ectasia. Tumors that are strategically located in the myometrium may cause obstruction and proximal congestion of veins in the myometrium and endometrium. Thrombosis and sloughing of these large dilated venous channels within the endometrium produce heavy bleeding ([Fig. 31.15](#)).

Makarainen and Ylikorkala have presented evidence that further supports the concept that prostanoids play a

role in primary menorrhagia. They found that the production of 6-keto-prostaglandin F1 alpha (6-keto-PGF_{1α}), a metabolite of prostacyclin (PGI₂), and thromboxane B₂ (TXB₂), a metabolite of thromboxane A₂ (TXA₂), was normal in menorrhagic endometrium. However, the balance between TXA₂ and PGI₂ shifted to a relative TXA₂ deficiency and was negatively related to blood loss in patients with menorrhagia. Although ibuprofen decreased the blood loss in patients with primary menorrhagia, it failed to reduce myoma-associated menorrhagia. The authors suggest that uterine factors other than prostanoids are more important in causing menorrhagia associated with uterine leiomyomata.

FIGURE 31.15 Dilated endometrial venous space communicating with a grossly enlarged vessel in the inner myometrium of a uterus with submucous leiomyomata. (Reprinted from Farrer-Brown G, Beilby JO, Tarbit MH. Venous changes in the endometrium of myomatous uteri. *Obstet Gynecol* 1971;83:743, with permission. Copyright 1971, The American College of Obstetricians and Gynecologists.)

In most cases, when bleeding occurs postmenopausally and leiomyomata are discovered on bimanual examination, the bleeding is due to some other factors, such as cervical or endometrial abnormalities, atrophic vaginitis, or exogenous estrogen, and the leiomyomata are purely incidental. Occasionally, however, the postmenopausal leiomyoma can be responsible for the bleeding. As stated earlier, leiomyomata that do not bleed during the menstrual life of the patient have been found to migrate to a submucous position in later years. This occurs because after menopause, the myometrium atrophies and the uterine wall becomes thinner. Leiomyomata also shrink somewhat, but not as much as the surrounding myometrium. Thus, a leiomyoma that was intramural before menopause may work itself into a submucous position after menopause, become ulcerated, and bleed. Postmenopausal growth of uterine leiomyomata may indicate malignant change, especially if associated with postmenopausal bleeding. We have rarely observed postmenopausal growth in a leiomyoma without finding malignancy in the tumor; whenever there is enlargement of the leiomyoma after menopause, one should seriously consider the possibility of sarcomatous change and remove the leiomyoma.

Patients with heavy menstruation and uterine leiomyomata should be evaluated for the presence of submucous myomata. Even patients without palpable evidence of uterine leiomyomata or uterine enlargement who have

should be evaluated for the presence of submucous myomata. When endometrial curettage is performed, irregularity of the uterine cavity may suggest the presence of a submucous myoma. However, a submucous myoma may not be detected with the curette. An accurate diagnosis is more likely to be made by hysterosalpingography, conventional transvaginal or transabdominal US, sonohysterography, MRI, or hysteroscopy. Cincinelli and colleagues reported their experience with transabdominal sonohysterography, a technique that involves transabdominal ultrasonographic scanning while 30 mL of sterile isotonic saline is slowly injected into the uterine cavity. According to these investigators, this technique provided the most accurate evaluation of the size of submucous myomata, intracavitary and intramural growth, and location within the uterine cavity, with sensitivity, specificity, and predictive values of 100%.

Pressure

Evidence of pressure on nearby pelvic viscera may be an indication for treatment. The urinary bladder suffers most often from such pressure, giving rise to urgency and frequency of urination and sometimes even urinary incontinence ([Fig. 31.16](#)). Although this symptom is common with large leiomyomata, one frequently finds the pelvis filled with leiomyomata when there is no urinary frequency. Occasionally, acute retention of urine or overflow incontinence results from a leiomyoma and necessitates surgical intervention. These effects can occur as a result of rapid interior growth of the leiomyoma with compression of the urethra and bladder neck against the pubic bone. More often, a tumor the size of a 3-month pregnancy may become incarcerated in the cul-de-sac, wedging the cervix forward against the urethra and obstructing the flow of urine through the urethra. A large pedunculated submucous tumor may fill and distend the vagina and press the urethra against the symphysis, causing urinary retention.

FIGURE 31.16 Cystogram and intravenous pyelogram showing distortion of the bladder by pressure from a leiomyoma.

As pointed out by Mattingly, one can expect to encounter women who have uterine leiomyomata of significant size and in addition have protrusion of the bladder base and posterior urethra through a widened levator muscle hiatus and a weakened urogenital diaphragm. Both conditions are relatively common. In addition to the usual symptoms produced by the leiomyomata, socially disabling stress urinary incontinence may be present. When the anterior wall of the uterus is greatly distorted by the presence of these tumors, pressure against the bladder can cause urinary frequency. If anatomic pressure equalization incontinence is also present, it may be aggravated by the increased intravesical pressure caused by the leiomyomata. However, the presence of anatomic stress urinary incontinence has no etiologic relation to the uterine enlargement caused by the leiomyomata.

Silent ureteral obstruction from pressure against the pelvic brim is an uncommon complication of uterine enlargement caused by multiple large leiomyomata. Such an asymptomatic anatomic change occurs more often with a symmetrically enlarged leiomyomatous uterus that becomes large enough to fill the pelvis and compress the ureter against the pelvic sidewalls (**Fig. 31.11**). Although an infrequent complication, the obstruction can occur in either ureter, depending on the location of the uterine tumors. If there has been no infection or parenchymal damage to the kidney, this anatomic alteration is completely reversible with removal of the uterus and relief of the pressure against the ureter. However, if urinary tract obstruction from leiomyomata has been neglected, uremia may result. Removal of the tumor and relief of obstruction are necessary to restore kidney function. Chronic bladder neck obstruction from uterine leiomyomata can be so severe as to cause a remarkable increase in the thickness of the bladder wall and enlargement of the bladder resembling that seen in men with urethral obstruction from prostatic enlargement. Indeed, in these neglected cases, the bladder may fill the entire lower abdominal wall so that an incision above the umbilicus is required to enter the peritoneal cavity to remove the tumor without injury to the bladder.

The bowel is less apt to show symptoms from pressure than is the bladder, but constipation can be caused and aggravated by pressure of leiomyomata against the rectum. The small intestines can become entwined with subserous pedunculated tumors, causing intermittent intestinal obstruction.

Pain

Abdominal and pelvic pain or discomfort, a feeling of heaviness in the pelvis, and dyspareunia are present in about one third of patients with symptomatic uterine leiomyomata and may be an appropriate reason for intervention. There are several causes of pain with leiomyomata. However, the usual hyaline or cystic degeneration of these tumors does not produce symptoms. In rare instances, pedunculated subserous leiomyomata twist and give rise to a clinical picture of acute abdominal pain, much like that seen with a torsed ovarian tumor. These pedunculated tumors twist more often during pregnancy and after menopause. Acute carneous or red degeneration of a leiomyoma can occur at any period of reproductive life, although pain from this form of degeneration is more common during pregnancy. Dysmenorrhea, acquired in the fourth or fifth decade, may be the outstanding symptom of the growth of leiomyomata. A common symptom complex resulting from leiomyomata at this time of life is menstrual pain coupled with increased menstrual flow. Diffuse adenomyosis can also

P.671

cause these symptoms, and the differentiation of this condition from a symmetrically enlarged intramural leiomyoma may be extremely difficult and may require MRI. The differentiation may be academic when surgery is planned; however, in cases when UAE is considered, this distinction is important because it may be less effective in cases of adenomyosis.

Patients who have uterine leiomyomata and pain may have concomitant pelvic disease such as ovarian pathology, pelvic inflammatory disease, tubal pregnancy, endometriosis, or urinary tract or intestinal pathology, including appendicitis. One must be careful to rule out other pathologies that may be obscured by uterine leiomyomata.

Abdominal Distortion

Distortion of the normal abdominal wall contour because of large tumors may justify their removal. Tumors of such size often give rise to other symptoms also, so there is ample reason for surgical interference. However, when no other symptoms are present, one may recommend removal of the tumors if the abdominal distortion is of such a magnitude as to be embarrassing to the patient.

Rapid Growth

Evidence of rapid growth of uterine leiomyomata, as observed by the same examiner over time or as confirmed by US, is an indication for surgical intervention. Such rapid growth in a premenopausal patient is only rarely due to sarcoma. Parker and others reviewed the medical records of 1,332 women admitted for surgical management of uterine leiomyoma. They found no correlation between rapid growth and the presence of uterine sarcoma. It may be due to pregnancy or to the use of oral contraceptives containing large amounts of estrogens. In the latter case, these drugs should be discontinued and an alternative method of contraception prescribed. In the postmenopausal patient, however, growth of a uterine leiomyoma is highly suggestive of a malignancy. The malignancy may be a sarcomatous change in the leiomyoma itself, a sarcoma or carcinoma in the endometrium causing uterine enlargement, or an ovarian neoplasm whose estrogen secretion is stimulating enlargement of the leiomyoma or whose growth may be mistaken for rapid enlargement of uterine leiomyomata. Although malignancy is not invariably found, the chances in its favor are so great that one must proceed on the assumption that it exists and should perform dilatation and curettage followed by removal of the enlarged uterus.

Rapid growth of a leiomyomatous uterus is difficult to define in exact terms. Buttram and Reiter have arbitrarily defined it as a gain of 6 weeks or more in gestational size within a year or less. Although this definition could apply in premenopausal women, it might be disastrous to wait for this amount of growth in a postmenopausal woman. It is important to have a definite method of documenting uterine size at periodic intervals. Repeated sounding of the uterine cavity may be of some benefit, although leiomyomatous growth is not always accompanied by concomitant enlargement of the uterine cavity. It is important to document the size of specific leiomyomata or the total uterine size in terms of centimeters or grams of uterine weight rather than in terms of gestational size of the uterus, although the latter method has become quite popular. Changes in a patient's weight can make evaluation of growth more difficult. Ultrasonography is a much more objective way of establishing the size of a uterine leiomyoma in the beginning and, when indicated, of evaluating its rate of growth. There is a need for more information about the natural growth patterns of myomata before and after menopause.

Although leiomyomata can increase dramatically in size during pregnancy, usually there is no appreciable growth. Winer-Muram and coworkers studied 89 pregnant women with uterine leiomyomata documented by US examination. In 83 of the patients, there was no demonstrable increase in the size of the leiomyomata. In 6 patients, there was an increase in size of up to 4 cm. Those myomata that increase in size during pregnancy will decrease in size a few weeks after the pregnancy is over.

Spontaneous Abortion and Other Pregnancy-Related Problems

Fibroid size and location affect the type and degree of patient symptoms and may also have reproductive consequences including pregnancy loss and infertility. The extent of uterine fibroids' effect on pregnancy rates and outcomes remains controversial.

Various mechanisms have been proposed to explain the occurrence of spontaneous abortion from uteri with leiomyomata. These include disturbances in uterine blood flow, alterations in blood supply to the endometrium, uterine irritability, rapid growth or degeneration of leiomyomata during pregnancy, difficulty in enlargement of the uterine cavity to accommodate for the growth of the fetus and placenta, and interference with proper implantation and placental growth by poorly developed endometrium or by subjacent leiomyomata. Implantation in a thin, poorly vascularized endometrium over a submucous leiomyoma is doomed to failure, because proper growth and development of the embryo and placenta are impossible (Fig. 31.17). Matsunaga and Shiota found a twofold increase in the number of malformed embryos recovered from patients with uterine leiomyomata having artificial termination of pregnancy.

Uterine leiomyomata may also be associated with other obstetrical concerns, including premature delivery, stillbirth, and interstitial pregnancy, as in the case reported by Starks. In a retrospective population-based study by Sheiner and colleagues, obstetrical outcomes appeared to be compromised by uterine leiomyoma. Compared with controls, women with myomata during pregnancy had an increase in intrauterine growth restriction (6.8% vs. 1.9%), placental abruption (2.8% vs. 0.7%), abnormal presentation (16.9% vs. 2.4%), cesarean section rate (57.7% vs. 10.8%), premature rupture of membranes (9.6% vs. 5.5%), and likelihood to receive a blood transfusion (4.2% vs. 1.4%). All of these outcomes were statistically significant ($P < 0.001$). Muram and associates have followed patients with leiomyomata through pregnancy with US. When a leiomyoma was in close proximity to the placental site, an increased incidence of pregnancy-related complications was seen. These were mainly bleeding complications, but pain, premature delivery, and postpartum hemorrhage also occurred. Exacoustos and Rosati reviewed the US scans of 12,708 pregnant patients. Four hundred ninety-two patients had myomata. A statistically significant increased incidence of threatened abortion, threatened preterm delivery, abruptio placentae, and pelvic pain was observed in patients with myomata. Abruptio placentae was particularly evident in women with myoma volumes greater than 200 cm³, submucosal location, or superimposition of the placenta. The authors suggest that US findings make it possible to identify women at risk for myoma-related complications of pregnancy. Factors responsible for spontaneous abortion in patients without uterine leiomyomata may also be responsible for spontaneous abortion in patients with leiomyomata.

Occasionally, pregnancy causes a remarkable growth of leiomyomata in the same way that the myometrium undergoes hypertrophy in pregnancy. Red or carneous degeneration of

P.672

leiomyomata during pregnancy is associated with pain, tenderness over the tumor, low-grade fever, and leukocytosis. Management should be expectant with analgesic medications and bed rest. If premature uterine contractions occur, tocolytics may be given. Pain usually subsides within a few days. Operation is not indicated unless it is necessary to rule out other problems that require surgery for relief, because differentiation from appendicitis, placental abruption, torsed adnexa, and other problems may be difficult. After delivery, leiomyomata involute and generally return to their prepregnancy size by the third postpartum month.

FIGURE 31.17 When the placenta is implanted over a myoma in the uterine wall, the blood supply to the fetus may be tenuous.

Torsion with infarction of subserous pedunculated leiomyomata is more common in pregnancy. A leiomyoma may interfere with labor and delivery by causing an abnormal presentation, by causing dysfunctional labor, or by obstructing the pelvis. A submucous leiomyoma in the lower uterine segment may entrap the placenta, necessitating manual removal. Indeed, furious postpartum hemorrhage can result if a submucous leiomyoma is disturbed at delivery or during exploration of the uterine cavity. Immediate hysterectomy may be necessary to control the bleeding.

Most patients with uterine leiomyomata have no difficulty conceiving and carry their pregnancies to term without complications. The only problem encountered may be a difficulty in estimating gestational age from uterine size because of the presence of leiomyomata.

Infertility

When asymptomatic leiomyomata are discovered in young women, the question of how these tumors relate to sterility and pregnancy usually arises. A number of factors may be responsible for infertility in a patient with uterine leiomyomata. Anovulatory cycles may occur more commonly. There may be interference with sperm transport caused by distortion and an increased surface area within the uterine cavity, impingement of leiomyomata on the endocervical canal or interstitial portion of the fallopian tube, or interference with prostaglandin-induced uterine contractions, which are thought to enhance sperm migration. Endometrial changes (atrophy, ulceration, focal hyperplasia, and polyps), vascular alterations (venous congestion, venule ectasia, impaired blood flow), and enlargement of the uterine cavity may be present. Because uterine leiomyomata occur in later reproductive years, relatively greater difficulty accomplishing conception can be expected in older couples.

The finding of small leiomyomata in sterile women is not an indication for immediate myomectomy. Quite often, an infertile patient with uterine leiomyomata is found to have some other causes of infertility. Tubal inflammatory disease with associated pelvic adhesions is especially common in patients with uterine leiomyomata. Both marital partners should have a complete infertility investigation, and the leiomyomata should initially be disregarded if it is asymptomatic. The ultimate decision regarding disposal of the tumors depends on their size and location.

Usually, small subserous leiomyomata are not considered a factor in infertility. Even if the woman fails to become pregnant, removal of small subserous leiomyomata is not justified. When leiomyomata are intramural or submucous and of significant size, they may well be factors causing the infertility, and a myomectomy may be rewarded with a subsequent pregnancy.

When an unsuspected asymptomatic leiomyomatous uterus of significant size is found in a woman who is planning to become pregnant in the future, great tact is required in describing the problem to the patient. The best surgical and obstetric judgment is needed to make a proper recommendation. Should the patient be discouraged from attempting pregnancy because the risk of complications may be increased? Should a myomectomy be advised before pregnancy is attempted, with the knowledge that postmyomectomy adhesions may cause infertility? Such questions cannot be answered in a stereotypical manner. Each case presents its own problems, and the answers depend on the patient's age, her general physical health, her pelvic findings, and, most important, her own desires. All must be considered before a final recommendation can be made. In general terms, under these circumstances, an attempt to become pregnant will be rewarded with a satisfactory outcome in most cases. If pregnancy does not occur or is not successful, a myomectomy may be advised, but one must keep in mind that all causes of infertility, spontaneous abortion, and other pregnancy-related problems must also be investigated in patients with uterine leiomyomata; uterine leiomyomata represent an infrequent cause of infertility.

Eldar-Geva and colleagues performed a retrospective review of the treatment outcome of 106 assisted reproductive technology cycles in 88 patients with uterine myomata (subserosal,

P.673

intramuscular without cavity distortion, and submucosal). Patients underwent controlled ovarian hyperstimulation and advanced reproductive technology. Not surprisingly, pregnancy (30.1%) and implantation (15.7%) rates were significantly lower in women with submucosal myomas; however, both pregnancy (16.4%) and implantation (6.4%) rates were also significantly lower in women with intramural myomas. In some advanced assisted reproductive technology patients, this information may influence the decision for surgical intervention regardless of menstrual pattern. A study by Olive et al. suggests that submucosal myomas that significantly distort or encroach on the uterine cavity may lower implantation and pregnancy rates in infertile women undergoing IVF. Several recent studies evaluated the effect of fibroids on in vitro fertilization cycles; the balance of data from independent studies by Farhi, Ramzy Jun, and Surrey suggests that pregnancy outcomes and implantation rates are adversely affected by submucosal myomas that enter the uterine cavity but not by subserosal or intramural fibroids that are less than 5 to 7 cm in size. Resection of submucosal fibroids clearly within the uterine cavity is likely warranted in patients with dysfunctional uterine bleeding, infertility, or pregnancy loss who desire to optimize future fertility.

A review of information about infertility and uterine leiomyomata was published by Wallach and Vu, by Vercellini and colleagues, and by Verkauf.

Miscellaneous Signs and Symptoms

A variety of other unusual problems may be associated with uterine leiomyomata and may require treatment. Ascites and uterine inversion have already been mentioned. Sudden intraperitoneal hemorrhage can result from rupture of a dilated vein beneath the serosal surface of a subserous leiomyoma. Although leiomyomata are more often associated with iron deficiency anemia from chronic uterine blood loss, occasionally, patients present with polycythemia. Islands of extramedullary erythropoiesis have been found in leiomyomata. Arteriovenous shunts within the tumors have been found and may be etiologically important in polycythemia. If the tumor obstructs the ureters and causes back pressure on the renal parenchyma, erythropoiesis can be stimulated. Weiss and coworkers and other investigators have found marked erythropoietin activity within uterine leiomyomata. The

polycythemia in these cases is cured by hysterectomy.

CHOICE OF TREATMENT FOR UTERINE LEIOMYOMATA

According to statistics from the Centers for Disease Control, 600,000 hysterectomies are performed annually in the United States. Approximately 33% are performed with uterine leiomyomata as the primary indication. Nearly 35,000 myomectomies were reportedly performed annually in 2001, and it is believed that this number is increasing substantially. There are no statistics to indicate the number of hysteroscopic and laparoscopic myomectomies performed each year. Effective medical therapies are available to use as adjuncts to surgical treatment. Additional radiologic procedures may also be desirable in patients who may not be suitable surgical candidates. However, surgery is the preferred method of therapy in many circumstances.

Hysterectomy (abdominal, vaginal, and laparoscopic or robot assisted) is discussed in [Chapter 32](#). In this chapter, surgical techniques that allow conservation of uterine function are discussed, as are medical therapies that can be used as adjuncts to surgical therapy.

Medical Management of Uterine Leiomyomata

Most (70% to 80%) uterine leiomyomata are asymptomatic and are discovered incidentally during a routine pelvic examination. Such patients require an explanation and reassurance and reexamination at periodic intervals. An initial baseline pelvic US examination or MRI study may be indicated for comparison with future examinations and to evaluate the adnexa if the ovaries cannot be felt on pelvic examination. An experienced pelvic examiner can be fairly certain that a central pelvic mass is a leiomyomatous uterus. However, pelvic US examinations and repeat pelvic examinations can add to the certainty of the diagnosis. If the diagnosis remains doubtful, however, visualization of the mass, usually by laparoscopy, may be indicated. Patients with an asymptomatic central pelvic mass should be followed up with periodic pelvic examination only when the mass is benign, usually a leiomyomatous uterus. Otherwise, expectant management is not appropriate.

Effective medical treatment that is likely to result in the permanent cure of uterine leiomyomata is not yet available. Surgical excision by a variety of techniques remains the most effective and widely used method of management for patients with significant symptoms. Medical therapies are available as an adjunct to surgical treatment or as a temporary substitute for definitive surgical treatment. The role of radiologic intervention continues to expand with UAE and recently U.S. Food and Drug Administration (FDA)-approved, MRI-guided, high-frequency focused ultrasonography.

Hormonal therapy for the management of uterine leiomyomata has been the subject of investigation for many years. There is no support for the use of danazol or progestins in view of the disappointing results reported. Antiprogestin therapy with mifepristone (RU-486) for 3 months has been shown by Murphy and colleagues to decrease leiomyoma volume by an average of 49%, with a variation of 0% to 87%. The immunoreactivity of progesterone, but not estrogen, receptors in the myoma and myometrial tissue was decreased significantly by RU-486 treatment, suggesting that regression of these tumors may be attained through a direct antiprogesterone effect. All patients became amenorrheic. Side effects were mild, and bone density was not diminished. An effective dose to cause a clinically significant (50%) decrease in leiomyoma volume appears to be 25 mg daily. Additional experience is needed to further evaluate these promising results. Reinsch and associates have demonstrated that RU-486 and leuprolide acetate are both effective in decreasing blood flow to the uterus. It is suggested that a decrease in uterine artery blood flow may provide a mechanism for a decrease in uterine size.

Gestrinone, a synthetic derivative of ethinyl-nortestosterone with antiestrogen and antiprogesterone properties, has been shown by Coutinho and associates to induce regression of leiomyomata. The treatment lasted 6 months to 1 year. The best results were obtained when the drug was administered intravaginally. Even the regression of large leiomyomata lasted up to a year after treatment. Side effects, though mildly androgenic, were

well tolerated.

Many studies have been performed to investigate the treatment of patients with uterine leiomyomata with GnRH analogs. GnRH analogs bind to GnRH receptors, resulting in a biphasic response: a temporary increase in the levels of gonadotropins and gonadal steroids (agonist phase) is followed by chronic suppression of gonadotropin and gonadal steroid secretion (desensitization phase). In 1 to 3 weeks, a profound hypogonadotropic hypogonadal state begins and exists as long as the treatment lasts, but it is promptly reversed when treatment is discontinued. GnRH agonist treatment results in

P.674

“medical oophorectomy” and “medical menopause” and is associated with the usual symptoms of a profound hypogonadal state (e.g., hot flashes, insomnia, mood lability, headaches, vaginal dryness, arthralgias, and myalgias). According to Friedman and associates, these adverse effects of treatment are self-limited and disappear within 3 to 6 months of cessation of GnRH agonist treatment. Dawood and colleagues describe a significant reduction in trabecular bone density after 24 weeks of GnRH agonist treatment that may not be completely reversible when treatment is discontinued. A mean reduction in trabecular bone density of 1% per month occurs in women treated for 6 months. Some of this bone loss may be permanent, but some is reversible.

Friedman and colleagues state that the average reduction in uterine and myoma volume is 40% to 50% after 3 to 6 months of GnRH agonist treatment; this is generally confirmed by others. Most of the response occurs in the first 12 weeks, and it is variable and unpredictable.

According to the analysis by these investigators, 4% of patients had an increase in uterine volume ranging from 0.1% to 25%, 24% had decreases in uterine volume ranging from 0.1% to 25%, 51% had decreases in uterine volume ranging from 25.1% to 50%, and 21% had decreases in uterine volume greater than 50%. No factors were found to predict the degree of uterine shrinkage. There were negative correlations with body weight, pretreatment uterine volume, age, height, and serum estradiol concentration.

It is commonly thought that GnRH analogs affect leiomyomata by reducing vascularity and the individual cell size within the tumor. The biochemical changes in leiomyomata obtained from women treated with the GnRH agonist leuprolide acetate depot for 3 months were studied by Rein and coworkers. The concentrations of amino acids contained in collagen were significantly greater in uterine myomata from treated patients than in myomata from placebo-treated controls. These investigators suggest that the reduction in uterine myoma volume associated with GnRH agonist therapy is due primarily to alterations in the extracellular matrix rather than to a reduction in the number or volume of cells in the myoma. Di Lieto and colleagues evaluated the clinical response; immunohistologic expression of the angiogenetic growth factors β FGF, VEGF, and PDGF; and vascular changes in uterine leiomyomas from women treated with GnRH agonist. They demonstrated that the GnRH agonist therapy caused a reduction in the synthesis of the three considered growth factors in leiomyomatous cells (β FGF, VEGF, and PDGF). The total number of vessels and angiogenetic vessels was also decreased after treatment with leuprolide acetate for 3 months.

Because uterine leiomyomata are hormone-sensitive neoplasms that can be stimulated to grow by estrogen, some clinicians have been reluctant to prescribe oral contraceptive pills in patients with leiomyomata. However, Friedman and Thomas and others have demonstrated conclusively that oral contraceptives containing 30 to 35 mg of ethinyl estradiol do not cause uterine leiomyomata to increase in size. Therefore, low-dose contraceptives can be used to manage menorrhagia in patients with uterine leiomyomata. Friedman and Thomas demonstrated a significant decrease in the mean duration of menstrual flow and a significant increase in hematocrit values in response to low-dose oral contraceptives in patients with uterine leiomyomata.

When myoma-associated menorrhagia is more severe, GnRH agonist and iron treatment may be more effective than oral contraceptives. In about two thirds of patients, GnRH agonist treatment induces amenorrhea. Most of

the remaining patients experience very light, irregular vaginal bleeding or spotting, according to Friedman. A combination of menstrual suppression and iron therapy allows correction of iron deficiency and iron deficiency anemia during a 6-month treatment period. Ovulatory menses resume 3 to 24 weeks after the last depot GnRH agonist injection. Stovall and associates reported that a GnRH agonist plus iron was more effective than iron alone in treating anemia in patients with leiomyomata and in alleviating menorrhagia. With such effective treatment now available, there is rarely a need to use blood transfusions to correct anemia caused by myoma-associated menorrhagia. Only patients with significant symptoms from severe anemia may require transfusion.

Medical therapy may also be used transiently before surgery. By initiating the medication preoperatively, the maximum decrease in myoma volume may play a role in determining the route of surgery. If a hysterectomy is planned, the pharmacologic effect may facilitate a vaginal hysterectomy when the uterus is of borderline size. Vercellini and colleagues performed a multicenter, prospective, randomized, controlled study to assess if this shrinkage may increase the likelihood of a vaginal procedure. One hundred and twenty-seven premenopausal women with uterine volumes of 12 to 16 weeks were enrolled. After examination and disposition for an abdominal or vaginal hysterectomy, patients were randomized for GnRH therapy. Clinical assessment after the treatment course showed that abdominal hysterectomy was no longer indicated in 25 of 53 (47%) patients. No appreciable difference was found between the groups in postoperative complications. These findings are consistent with previously published studies, as well.

GnRH agonist treatment alone should not be given for periods longer than 6 months. A prolonged hypoestrogenic state is undesirable for a number of reasons, the most important being the loss of trabecular bone. If there are circumstances that require that GnRH treatment be extended beyond 6 months, consideration should be given to adding low-dose steroids after 3 months of GnRH therapy. The usual postmenopausal estrogen-progestin replacement regimen can be prescribed without interfering with the reduction in uterine volume anticipated. Loss of trabecular bone may not be as great. By adding estrogen-progestin replacement to GnRH agonist therapy, the adverse effects of a prolonged hypoestrogenic state may be prevented, and treatment with GnRH agonists may be prolonged. Friedman and colleagues treated 51 premenopausal women with large, symptomatic myomata with leuprolide acetate depot for 104 weeks. After the first 12 weeks, 0.75 mg of estropipate plus 0.7 mg of norethindrone was added on days 1 through 14 each month. Menorrhagia and other symptoms of uterine leiomyomata were controlled successfully. Hemoglobin and hematocrit levels increased. Symptoms of hypoestrogenism (hot flashes, vaginal dryness) were decreased significantly. Bone density decreased in the first 12 weeks, but only a small additional decrease occurred between weeks 12 and 52.

The use of GnRH analogs in the medical management of uterine leiomyomata is an emerging issue. How valuable it will be remains to be seen. Additional information and experience will define its use more exactly. For example, it may be possible for patients with symptomatic uterine leiomyomata who are approaching menopause to be managed medically through menopause without having a hysterectomy. It may be possible to improve fertility in some patients with uterine leiomyomata by treatment with GnRH analogs without myomectomy. With additional data, these and other questions can be answered.

Vaginal Myomectomy

In 1845, Atlee performed the first successful vaginal myomectomy on a patient with a submucous pedunculated myoma.

When a submucous myoma becomes pedunculated within the uterine cavity, there is a natural tendency for the uterus to try to expel it through the endocervical canal. Eventually, the cervix dilates. Even very large submucous pedunculated myomata can be delivered gradually through a markedly dilated cervix. Because adequate blood

circulation through a long pedicle is difficult to maintain, the myoma becomes necrotic and infected (**Figs. 31.5** and **31.6**).

Patients report cramping lower abdominal pain; pressure and heaviness in the pelvis; a thin, bloody, foul discharge; difficulty with urination; and other symptoms. Episodes of profuse vaginal hemorrhage can occur. Such large submucous myomata may resemble a fetal head.

After satisfactory preoperative preparation, including broad-spectrum antibiotics and correction of anemia, vaginal myomectomy should be performed in the operating room. Morcellation may be required to remove very large tumors in many small pieces. Usually, there is very little bleeding. One should avoid too much downward traction on the tumor because the uterine fundus may invert. Eventually, the pedicle is identified. It should be clamped and ligated as high as possible within the uterine cavity. The use of a laparoscopic instrumentation, such as the Endoloop, can be advantageous to facilitate safe, secure ligation of the pedicle as high as possible. If ligation of the pedicle is not possible, the clamps can be left in place and safely removed 48 hours later.

Smaller submucous pedunculated myomata can be diagnosed by hysteroscopy, by hysterosalpingography, by sonohysterogram, or at the time of dilation and curettage. They can also be felt on digital exploration through a slightly dilated external cervical os. If the myoma can be grasped with an instrument (ring forceps or Allis clamp), it can be removed by twisting it free of its attachment. A tonsil snare can also be used. Bleeding is usually minimal. If brisk bleeding does occur, a 26-French, 30-mL Foley catheter can be inserted through the cervix and inflated for tamponade. If necessary, the cervix can be sutured around the catheter to hold it in place.

FIGURE 31.18 Transvaginal removal of a pedunculated submucous myoma that presents itself at the external cervical os. **A:** Sagittal view of uterus, demonstrating the location of the myoma originating on the posterior wall of the fundus just above the cervix. **B:** A transverse incision made anteriorly through the vaginal mucosa at the cervicovaginal junction.

To gain access to submucous pedunculated myomata that are higher in the endocervical canal or uterine cavity,

special procedures are required. An attempt at hysteroscopic removal may be successful. Alternatively, the cervix can be dilated with instruments or with *Laminaria japonica*, as described by Goldrath. Dührssen incisions can be made in the cervix. Also, the cervix can be incised by having the surgeon perform a vaginal hysterotomy (**Fig. 31.18A, B**). After the bladder is advanced, the cervix is dilated, and an anterior midline incision is made in the cervix high enough to identify the myoma. The pedicle of the myoma is ligated as high as possible (**Figs. 31.18C, D**). The incision in the cervix is repaired with 2-0 interrupted delayed absorbable sutures. The vaginal mucosa is reapproximated with 3-0 delayed absorbable sutures (**Figs. 31.18E, F**).

A submucous pedunculated myoma may be solitary, and there may not be other myomata in the uterus. In fact, many patients exhibit no evidence of uterine enlargement. After a successful vaginal myomectomy, most patients are asymptomatic and menstruate normally. A few even become pregnant and deliver vaginally without difficulty. Cervical incompetence has been reported. Hysterectomy or myomectomy is required only for those few patients who have multiple leiomyomata and continue to have significant symptoms.

Excellent results of vaginal removal of submucous pedunculated myomata in 151 patients were reported by Goldrath. Ben-Baruch and coworkers also achieved excellent results in 43 of 46 women in whom vaginal myomectomy was attempted. Vaginal myomectomy is recommended as the most appropriate initial treatment for pedunculated submucous myomata.

Vaginal myomectomy is traditionally used for submucosal myomata; however, it has been described for other myomata. Davies and colleagues reported a prospective study regarding the safety and efficacy of excision of intramural and subserosal leiomyoma by a vaginal route. Preoperative criteria included (a) uterine size less than or equal to 16 weeks gestation, (b) good uterine mobility, (c) adequate vaginal access, (d) the presence of intramural or subserosal myomata, and (e) the

P.676

absence of adnexal pathology. Essentially, an open abdominal myomectomy technique was performed through an anterior or posterior colpotomy. The uterus was manipulated to bring the myoma into the colpotomy. The management of 35 women was described. The mean number of myomas removed was 2.5 per patient with mean mass of 113.8 g. Three patients (8.6%) required conversion to a laparotomy. Neither mean blood loss nor length of hospital stay was improved. Additionally, four (11.4%) patients developed pelvic hematomas postoperatively. At this time, this procedure does not seem to provide inherent benefits over an open abdominal myomectomy or a laparoscopic approach. With further review, better outcome data may demonstrate the advantages of this technique.

FIGURE 31.18 (Continued) **C:** After the bladder is advanced bluntly, the cervix is incised anteriorly in the midline. **D:** The myoma and its pedicle are exposed, and the pedicle is suture ligated for hemostasis. **E:** After the myoma is excised, the cervix is reapproximated with interrupted 2-0 absorbable, nonreactive sutures. **F:** The overlying vaginal mucosa is sutured with interrupted 3-0 absorbable sutures.

The tissue removed at vaginal myomectomy must be submitted for pathologic examination to rule out malignancy.

Hysteroscopic Resection of Submucous Myomata

Hysteroscopic resection of submucous myomata was first reported by Neuwirth and Amin in 1976 and was reported again by Neuwirth in 1978. A urologic resectoscope was used. In 1981, Goldrath and associates used "photocoagulation" of the endometrium with the neodymium-doped:yttrium-aluminum-garnet (Nd:YAG) laser to treat patients with menorrhagia. Many subsequent reports by Derman and associates, Donnez and colleagues, Goldenberg and coworkers, Corson, Indman, Hallez, Baggish and associates, Wamsteker and colleagues, and others have confirmed the advantages of hysteroscopic treatment of menorrhagia in women with and without submucous leiomyomata. The menorrhagia associated with submucous myomata can sometimes be managed with oral contraceptives as long as the bleeding is not too severe. A favorable response can also be expected with GnRH analogs, but the menorrhagia usually reappears when the treatment is discontinued. Friedman has reported three cases of severe menorrhagia with resultant anemia requiring transfusions in women with submucous leiomyomata treated with leuprolide acetate. Both oral contraceptives and GnRH analogs are counterproductive in women who are seeking relief from infertility. The uterine cavity can be curetted several

times, but the benefit of this procedure is temporary at best.

When hysteroscopic resection of submucous myomata is performed, menorrhagia can be controlled in more than 90% of patients. According to Indman, the mean number of pads used during the heaviest day of menses decreased from 17.8 before treatment to 6.8 after treatment in women undergoing myoma resection only and from 21.4 to 1.7 pads per day in women whose treatment also included endometrial ablation. Dysmenorrhea was also reduced significantly. Forty-eight of fifty-one women (94%) with uterine leiomyomata who were seen with menorrhagia were able to avoid major gynecologic surgery for up to 5 years of follow-up. In the report of 156 patients by Derman and associates, 91.3% of patients did not require further surgery after 6 years of follow-up, and 83.9% did not require further surgery after 9 years of follow-up. Further review in recent papers supports Derman's results. Magos and colleagues performed a prospective observational study to identify factors that influence outcomes of hysteroscopic myomectomies by following up patients for almost 8 years. One hundred twenty-two patients enrolled in the study, and results suggest that hysteroscopic myomectomy is successful in treating menstrual symptoms in four of five cases. In addition, statistical analysis demonstrated that outcome is significantly better when the uterus is only slightly enlarged and if the myoma is mainly submucous in nature.

If endometrial ablation is performed with myoma resection, pregnancy is not likely to occur subsequently. Without

P.677

simultaneous endometrial ablation, 21 patients became pregnant after myoma resection only, with 18 infants delivered in the series reported by Derman and colleagues. The pregnancy rates among women who wished to conceive varied between 47% and 66% in several reports. These rates are comparable to those reported for abdominal myomectomy.

Donnez and coworkers used a biodegradable GnRH agonist (Zoladex Implant ICI) preoperatively in a series of 60 women with large submucous myomata. Submucous myomectomy by hysteroscopy and Nd:YAG laser was easily performed. In 12 patients, the procedure was accomplished in two stages. Perino and associates used GnRH agonists in 58 women with submucous leiomyomata diagnosed during investigation for infertility or menstrual disorder. There was a significant reduction in operating time, intraoperative bleeding, infusion volume, and failure rate in the treated group compared with the control subjects. Myoma size is reduced and hemoglobin concentration is restored to normal preoperatively. Campo and colleagues collected data on 80 consecutive resectoscopic myomectomies performed on premenopausal women. Forty-two patients did not receive any preoperative medical therapy, whereas 38 patients received 2 months of intramuscular GnRH analog therapy. Perioperative results were recorded, followed by a 24-month follow-up period when recurrent symptoms, myoma recurrence, and the need for repeat surgery were collected. Surgical time for the pretreated group was significantly longer than that of the untreated patients. Although GnRH analog pretreatment may be beneficial in improving anemia in some patients, Campo and colleagues did not demonstrate any improvement in short- or long-term outcomes.

A hysteroscopic approach is reasonable if the majority of the fibroid is within the cavity or if subtotal hysteroscopic myomectomy is deemed preferable to total abdominal myomectomy. Hysteroscopic resection may be performed using a hysteroscopic morcellator or resectoscope. A resectoscope allows for the use of electrocautery at the time of resection but, as a result, requires electrolyte-poor distending media such as mannitol, sorbitol, or glycine. Morcellating devices resect using a rotating blade rather than electrocautery and allow for use of isotonic distending media such as normal saline or lactated Ringer, which have lower risk for fluid overload and subsequent electrolyte imbalance. The avoidance of electrocautery also has a theoretical benefit of avoiding thermal damage to the myometrium and decreasing the chance of future uterine rupture at time of pregnancy. Both methods incur a risk of procedure abortion secondary to bleeding. Prior to starting the hysteroscopy, injection of vasopressin into the cervical stroma can be used to help decrease myoma bleeding. If bleeding is encountered intraoperatively, conversion from morcellator to electrocautery or use of uterine balloon

for tamponade and uterine compression can be used to help achieve hemostasis.

When submucous myomata extend deeply into the myometrium, it may not be possible to perform a complete resection for obvious technical reasons. However, it should be possible to remove most irregularities in the uterine cavity and to restore the contour of the cavity to almost normal in most cases. According to Wamsteker and colleagues, hysteroscopic resection of submucous myomata with more than 50% intramural extension should be performed only in selected cases. Repeat procedures may be needed in cases of initial incomplete resection.

To avoid the possibility of inadvertent uterine perforation or to allow its prompt diagnosis if it occurs, hysteroscopic resection is usually performed under laparoscopic guidance. However, as reported by Sullivan and coworkers, laparoscopy may be insufficient to evaluate fully the possible sequelae of uterine perforation. Laparotomy may be necessary to assess the pelvic viscera fully. Letterie and Kramer were able to safely substitute intraoperative transabdominal ultrasonographic guidance for laparoscopy. In their opinion, operative hysteroscopy with intraoperative ultrasonographic guidance provides an accurate and precise method to monitor intrauterine surgery, and it can be used to enhance the performance of hysteroscopic myomectomy and endometrial resection. Intraoperative US guidance provided sufficient details of the relation between the hysteroscope and the myoma and uterine walls to gauge the depth of resection and prevent uterine perforation. Lin et al. resected six submucous myomas under ultrasonographic guidance. All cases were completed in under 1 hour without any complications and resulted in improvement in menorrhagia and metrorrhagia. Postoperative hysteroscopy revealed no intrauterine adhesions, and the endometrium at the operative site appeared normal. Wortman and Dagget used ultrasonographic control to remove large submucous myomas and claimed that US may help prevent perforation and obviate laparoscopy.

The success and safety of the procedure depend on the experience and skill of the operator. During hysteroscopic resection, vascular spaces are opened in the endometrium and myometrium. Large volumes of fluid are instilled into the uterine cavity. Fluid balance must be monitored carefully by the surgeon and the anesthesiologist to avoid fluid overload.

All tissue must be submitted for pathologic examination. Among 92 patients undergoing hysteroscopic resection in the series reported by Corson and Brooks, two cases of leiomyosarcoma were diagnosed. Leiomyosarcoma is said to be more common in submucous leiomyomata than in intramural or subserous leiomyomata.

As time passes after hysteroscopic resection of submucous myomata, the possibility of recurrent problems increases because of regrowth of myomata. However, this is no more likely to occur than it is with standard abdominal myomectomy. The experience of many investigators has demonstrated that hysteroscopic management of menorrhagia in patients with submucous leiomyomata is a reasonable alternative to classic surgical hysterectomy or myomectomy. The occasional psychological problems and complications of hysterectomy are avoided. An abdominal incision is avoided, there is less discomfort, the procedure can often be performed in an outpatient setting, and the patient can usually resume normal activity after a very brief recovery period.

Hysteroscopic resection of a small submucous myoma is illustrated in [Figure 31.19](#). Details of the indications, technique, complications, and results of hysteroscopic resection are also provided in [Chapter 18](#).

Laparoscopic and Robotic-Assisted Myomectomy

When abdominal myomectomy is indicated, the laparoscopic or robotic-assisted approach can be offered as an alternative to the standard “open” abdominal myomectomy in selected patients. However, this procedure is appropriate in very few patients for several reasons. First, myomectomy is indicated in infertility patients only if there is significant distortion of the uterine wall or endometrial cavity or if there is obstruction or distortion of the

fallopian tubes by myomata. Second, myomectomy is indicated in patients who wish to retain their uterus only if the myomata are significantly symptomatic. In both circumstances, the myomata are likely to be multiple and large, and laparoscopic/robotic-assisted myomectomy should only be considered if the uterine repair is comparable, or superior, to the uterine closure of an abdominal myomectomy.

P.678

FIGURE 31.19 Hysteroscopic removal of a submucous myoma. **A:** After insertion of the resectoscope, the submucous myoma is removed by progressive shaving. The loop of the resectoscope is placed at the most distant portion of the myoma, and the current is applied as the resectoscope is drawn toward the surgeon. Pressure is exerted by the loop against the myoma with each stroke. **B:** A grasping forceps is used to twist off the remaining tissue once the size has been appreciably reduced.

There are limitations to both laparoscopic and robotic-assisted myomectomies, and these are mostly technical. Myomata in certain locations are difficult to remove. When myomata are large or multiple, or both, operative time and blood loss may be unacceptable. When myomata are embedded deeply in the myometrium, proper repair of the uterine wall may be difficult or impossible, and uterine rupture may occur in a subsequent pregnancy. Retrieval of the resected myomata from the peritoneal cavity can also pose problems. Large myomata must be morcellated into smaller pieces for retrieval. Retrieval through the posterior vaginal fornix or through the abdominal wall requires separate additional incisions, which somewhat defeats the idea of a minimally invasive procedure. Only very skillful laparoscopists or trained robotic surgeons should attempt extensive myomectomy through the laparoscope. According to Mais and colleagues, operation time for myomectomy was significantly longer for laparoscopy than for laparotomy when more than four myomata had to be removed and the largest myoma was greater than 6 cm. Dubuisson and coworkers also reinforce the difficulty of the technique by reporting conversion to laparotomy at a rate of 7.5% (93.7% due to operative difficulties) and a complication rate of 3.8%. These authors echo similar intraoperative concerns: (a) the location of the hysterotomy, (b) the type of hysterotomy, (c) the uterine suture, and (d) removal of the myoma. In addition, they report that one third of patients developed adhesions at the uterine scar.

The robot, which provides additional degrees of freedom as compared to laparoscopy, was first approved by the

U.S. FDA for use in gynecologic surgery in 2005. It improves potential surgical dexterity and allows for 3-dimensional visualization of the tissue. Several technical innovations have been developed to facilitate laparoscopic and robotic-assisted myomectomy. Electrosurgical and laser techniques are used in ingenious ways. Special traction devices, including corkscrews of various sizes, are required. The operator must be able to provide hemostasis using monopolar cutting current and bipolar forceps. The role of the Harmonic scalpel has also expanded for clean dissection and the potential for less blood loss. Aquadissection can be used to establish planes for dissection between myomata and the surrounding myometrium. Special techniques of approximating myometrium with larger curved needles are used with either intracorporeal or extracorporeal suture tying, depending on the surgeon's expertise. Knowledge of available laparoscopic instrumentation is essential to maximize surgical outcome. Autologous blood donation with intraoperative transfusion when necessary reduces the risk of homologous transfusion. Larger myomata can be removed vaginally with morcellation through a posterior colpotomy incision. In cases of myomas of extreme size, Pelosi and colleagues proposed the use of hand-assisted laparoscopy to avoid a laparotomy. This technique allows the insertion of a hand into the abdomen to assist in dissection. This is accomplished through a glove-sized incision at laparoscopy while preserving the pneumoperitoneum. A cylindrical serrated morcellator can also be used to convert smaller myomata to small strips of tissue, which can then be removed abdominally through the trocar sleeve or through a minilaparotomy incision. Retrieval of all bits and pieces of myoma tissue from the peritoneal cavity can be a tedious challenge. Hirai and colleagues from Japan described a microwave coagulator and electromechanical tissue borer to minimize invasion of the myometrium and abdominal wall. The proposed advantage of this technique is that by morcellating the tissue before removal from the uterus, less myometrial trauma is sustained. Horizontal and perpendicular blades at the tip rotate and hollow out the myoma, allowing large myomas to be removed through a small uterine incision. The authors described the use in five patients with four of the five having myomas weighing less than 170 g. The blood loss and operating time were not substantially different than with conventional abdominal procedures. Long-term data regarding myometrial strength over time and pregnancy outcomes are not yet available. More experience with this procedure is necessary to determine its role in myomectomy. A recent review of robotic-assisted technique was published by Quaas and colleagues.

Another technical innovation called myolysis has been described by Goldfarb and is based on earlier experience in Europe. Either Nd:YAG laser or bipolar needles are used laparoscopically to penetrate the myomata at multiple sites at a 90-degree angle to the uterus. In response to treatment,

P.679

the myomata ultimately atrophy. The technique is based on the theory that the coagulating effects of lasers or the bipolar needle can necrose myometrial stroma, denature protein, destroy vascularity, and result in substantial shrinkage of myomas when deprived of their blood supply. Goldfarb advises treatment with GnRH agonists before surgery. The ideal candidates for myolysis are perimenopausal women who have symptomatic leiomyomata measuring 3 to 10 cm or uterine size less than 14 weeks gestation. Goldfarb combines myolysis with endometrial ablation in patients with symptomatic myomas with persistent uterine bleeding. The addition of myolysis to endometrial ablation increased the rate of postsurgical amenorrhea from 36.5% to 57%, and second procedures, including hysterectomy, were reduced from 38% to 12.5%. Goldfarb described significant adhesions at follow-up laparoscopy in patients treated with the Nd:YAG laser technique because of excessive serosal injury from multiple punctures. A circumferential technique was later developed to destroy vasculature instead of the myomatous tissue. The devascularized myoma becomes cyanotic, loses viability, and fibroses. Phillips reported on women who underwent elective diagnostic laparoscopy to evaluate adhesions associated with previously performed myolysis. Mean adhesion score was only 1.15 ± 0.6 on a scale of 10.

Zreik and colleagues at Yale University modified the myolysis procedure to include cryotechnology to "freeze" uterine leiomyomas. The technique, *cryomyolysis*, was described in a prospective pilot study of 14 patients. All patients were pretreated with GnRH agonist therapy for 3 months. Thirteen of the fourteen endoscopic

procedures were performed by laparoscopy and the remaining one by hysteroscopic visualization. Cryoprobe placement was verified, and freezing was performed at an internal probe temperature of -180°C until the ice ball encompassed the entire fibroid or reached maximum size. A thaw cycle was then performed, followed by one more freeze-thaw cycle. A hollow track remained within the frozen myoma after removal of the cryoprobe. MRI studies were used to assess uterine and myoma size. The uterus enlarged by 22% after discontinuation of the GnRH therapy. Myoma volume decreased by 6% over 4 months postoperatively, with some patients having a decrease of more than 50%. Four of six women who underwent second-look office laparoscopy had adhesion formation at freezing sites. The authors attributed risk and severity of adhesion formation to the number of punctures with the cryoprobe. The role of this therapy in conservative treatment of uterine myomata remains to be defined.

Hysteroscopic myomectomy and endometrial resection can be performed simultaneously if submucous myomata are present. In more than 300 myolysis procedures, the author reported minimal morbidity with a 30% to 50% reduction in myoma size beyond the reduction achieved with GnRH agonist treatment. No regrowth occurred after several years of follow-up, even after estrogen replacement therapy. Bipolar coagulation myolysis may be less likely to cause damage to the uterine serosa and less likely to cause adhesion formation postoperatively. According to Goldfarb, "As a same-day procedure, myoma coagulation appears to be an extremely safe alternative to hysterectomy, allowing the patient to avoid major surgery and its subsequent recovery time, while providing an alternative solution for patients with symptomatic leiomyomas."

Nezhat and coworkers used a combination of laparoscopy and minilaparotomy to perform myomectomy in 57 women with uteri at 8 to 26 weeks in gestational size. In this laparoscopically assisted myomectomy procedure, the myomata were removed and the uterus repaired through the minilaparotomy incision. It was technically less difficult than laparoscopic myomectomy and allowed better closure of the uterine defects. This technique may be preferable in the case of large myomas in that it is easier to achieve conventional multilayer suturing and easier to extract myomas.

A recent retrospective review by Pitter et al. included 872 women who underwent robotic-assisted myomectomy and evaluated pregnancy outcomes among 127 of the women who conceived (92 of whom delivered) postoperatively. They found rates of miscarriage, preterm delivery, and uterine rupture to be comparable to those reported for laparoscopic myomectomy. A similar but smaller study by Göçmen including 38 patients noted comparable operative time, hospital stay, and estimated blood loss between patients undergoing laparoscopic and robot-assisted myomectomy. Moreover, several independent studies by Ranisavljevic, Mansour, and Nash suggest that robotic-assisted myomectomy appears to have similar advantages as laparoscopic myomectomy when compared to abdominal myomectomy. Behera, however, contends that, currently, robotic-assisted cases are less cost-efficient than laparoscopic or abdominal cases. This cost discrepancy may improve over time.

A significant disadvantage of myomectomy is the risk of postoperative pelvic adhesions. The adhesions may adversely affect fertility, give rise to pain, and increase the risk of ectopic pregnancy or even intestinal obstruction. Several studies have demonstrated that the risk of postoperative adhesions decreases when a laparoscopic approach is used in lieu of an open abdominal approach. Literature review demonstrates that the average rate of postoperative adhesions after laparoscopic myomectomy is 41% versus more than 90% after a myomectomy via laparotomy. Dubuisson and colleagues assessed adhesion formation after laparoscopic myomectomy in a prospective manner. Forty-five patients underwent a second look after laparoscopic myomectomy. Seventy-two sites were evaluated. The overall rate of postoperative adhesions was 35.6% per patient. The rate of adhesions per myomectomy site was 16.7%. The rate of adhesions on the adnexa was 24.4%. Associations with the occurrence of adnexal adhesions included an additional surgical procedure carried out at the same time, the existence of adhesions before the operation, and posterior location of the myoma. Several factors may increase the risk of postoperative adhesion formation after a laparoscopic myomectomy.

Recognition of these factors may be helpful in limiting adhesion formation.

The use of uterine suture appears to increase the risk of uterine adhesions. In some studies, the frequency doubled after suturing. The suture induces local tissue ischemia with inflammatory changes, which slow the healing process and induce the formation of adhesions. Contradictory data have been published regarding adhesion formation and the use of bipolar coagulation during a laparoscopic procedure.

The location of the myoma also affects adhesion formation. Adhesions are more likely to form when the myomectomy site is located on the posterior uterine wall. During laparoscopy, a uterine incision must be made over each individual myoma. With laparotomy, a single anterior uterine incision may be used for polomyomectomy, even when posterior myomas are present.

The prior existence of pelvic adhesions significantly increases the risk of postoperative adnexal adhesions but has not been shown to affect adhesions at the myomectomy site.

Two prospective, randomized controlled studies have evaluated the efficacy of adhesion barriers during laparoscopic myomectomy, and both found intervention to be beneficial. Mais and colleagues evaluated the efficacy of oxidized regenerated cellulose, Interceed, on adhesion formation in a prospective

P.680

randomized study of 50 women after laparoscopic myomectomy. Interceed was placed over all incisions and suture material with a 1 cm margin, and the barrier was then moistened with saline. During the second-look laparoscopy, 60% of the Interceed group was free of adhesions, compared with only 12% of patients in the control group. Interceed appeared to substantially reduce, but not prevent, adhesions after laparoscopic myomectomy. Pellicano and collaborators showed that hyaluronic acid gel reduced adhesions after laparoscopic myomectomy in a prospective randomized study of 36 infertile women. During second look, 72% of patients were adhesion free, with hyaluronic acid gel treatment versus an adhesion-free rate of only 22% in the control group.

Multiple published studies (Seracchioli et al., Bulletti et al., Stringer et al., and Campo et al.) suggest that laparoscopic myomectomy may be a viable option for women with leiomyomata and infertility. The best prognosis is for young women with otherwise unexplained infertility and myomas that distort the endometrial cavity. Pregnancy rates and spontaneous abortion rates are comparable to abdominal myomectomy. Data are currently insufficient to determine the appropriate recommendation regarding mode of delivery.

Laparoscopic myomectomy is further discussed in [Chapter 17](#).

Abdominal Myomectomy

The first successful abdominal myomectomy was performed in the United States by the Atlee brothers, Washington and John, in 1844. The first abdominal multiple myomectomy was performed by W. Alexander of Liverpool in 1898. In the early part of the 20th century, the technique of abdominal myomectomy was refined by many notable gynecologic surgeons, including Kelly, Cullen, Mayo, Rubin, Bonney, and others. The procedure did not gain popularity until the middle of the 20th century. The incidence of complications, including hemorrhage, infection, and postoperative intestinal obstruction from adhesions, was considered to be too high. Advances in surgical techniques to control intraoperative bleeding during myomectomy, along with advances in anesthesia, blood transfusion therapy, and GnRH analogs, have made myomectomy a safe alternative to hysterectomy in women with symptomatic leiomyomata. The number of myomectomies performed in the United States is increasing.

Because myomectomy is rarely an emergency, time is available to prepare the patient for surgery. It is important that she be properly informed of the reasons myomectomy has been recommended. She should understand the nature of the procedure so she can know what to expect and what is expected of her. It is especially important that she be informed of the possibility that intraoperative findings may contraindicate myomectomy and require

that hysterectomy be performed instead. For example, myomectomy may not be technically feasible if diffuse leiomyomatosis is found. The technical challenge of removing a large cervical myoma can also preclude myomectomy.

A preoperative hysterosalpingogram may indicate distortion of the fallopian tubes or uterine cavity, findings that are important in planning the technique of myomectomy. An assessment of fallopian tube patency is helpful in predicting fertility. If the tubes are occluded, however, myomectomy is not necessarily contraindicated. According to Seoud and associates, myomectomy does not interfere with in vitro fertilization performance in relation to overall and ongoing pregnancy rates. The patient whose tubes are occluded should understand that fertility may not be established by myomectomy, and assisted reproductive technologies may still be required after myomectomy. Tubal reconstruction procedures are uniformly unrewarding when performed at the same time multiple myomectomy is done. Indeed, tubal reconstruction may not always be necessary to establish tubal patency. In a report by Lev-Toaff and associates, nonfilling of the fallopian tubes was present on the preoperative hysterosalpingogram unilaterally in two patients and bilaterally in another two. In all four patients, tubal patency was shown after myomectomy. In the experience of these authors, hysterosalpingography before myomectomy can assist the gynecologic surgeon in planning the surgical approach by showing the presence, size, and location of submucous leiomyomata and concomitant tubal disease.

Imaging modalities such as transabdominal, transvaginal US and MRI play an important role in the management of patients with leiomyomata, especially those patients who are being prepared for myomectomy. As explained by Mayer and Shipilov, US is the preferred method for screening and initial evaluation of the pelvis. In many cases, it is the only imaging study necessary. There are special cases for which US cannot provide all the diagnostic information required. In a study by Schwartz and colleagues, US results were inconclusive in 20% of cases and did not yield a definitive diagnosis in 59% of cases. MRI was more definitive in all cases ([Fig. 31.20](#)).

P.681

The preoperative diagnosis of submucous leiomyomata by MRI may allow hysteroscopic resection and avoid abdominal myomectomy in some cases. Differentiation between uterine leiomyomata and adnexal pathology is more accurate with MRI and thus avoids the need for laparoscopy or laparotomy in some cases ([Fig. 31.21](#)). MRI studies can differentiate between uterine leiomyomata, diffuse and localized adenomyosis, and diffuse leiomyomatosis. MRI is the most accurate imaging technique for the detection and localization of leiomyomata ([Fig. 31.22](#)). Hricak and coworkers were able to identify accurately by MRI all subserosal (9 of 9), all intramural (37), and 10 of 11 submucosal leiomyomata. Leiomyomata as small as 0.3 cm can be detected. Various degrees of cellularity, degeneration, necrosis, and calcification can be identified by MRI, and sarcomatous change can be suspected. MRI provides imaging planes that are not available on transabdominal or transvaginal US, a feature that permits better visualization of the more lateral and posterior areas of the pelvis. MRI is the most accurate method for preoperative localization of leiomyomata and surgical planning for myomectomy. Given the greater costs of MRI, it should be used judiciously. However, as noted by Mayer and Shipilov, the effective cost differential between MRI and US is decreasing.

FIGURE 31.20 A: The ultrasound evaluation of this patient with a very large leiomyoma was not helpful in delineating the leiomyoma from the adnexa. **B:** The MRI study demonstrated multiple leiomyomas distinctly separate from the adnexa bilaterally. The ovaries are seen bilaterally with multiple cysts. (Image courtesy of Deborah Baumgarten, MD.)

As discussed by Wiskind and Thompson, one of the most serious risks of surgical bleeding during myomectomy is the risk associated with homologous blood transfusion. The first rule in reducing or eliminating the need for transfusion is to bring the patient to the operating room with the highest possible hemoglobin and hematocrit level. About 30% of myomectomy patients have associated menorrhagia. These small, repeated menstrual hemorrhages deplete the body's iron stores over time and eventually result in iron deficiency anemia of various degrees of severity. Patients scheduled for myomectomy benefit from oral iron supplementation. In a study by Thompson, the liberal use of oral iron therapy preoperatively was shown to decrease the number of blood transfusions on the gynecologic surgical service at the Johns Hopkins Hospital. A blood transfusion is seldom necessary to correct iron deficiency anemia in a gynecologic patient. Blood transfusions should generally be reserved for patients with hypovolemic shock or aregenerative forms of anemia. In most other circumstances, elective surgery should be delayed until the anemia has been corrected by oral iron supplementation.

FIGURE 31.21 On MRI, a large anterior, pedunculated leiomyoma is shown as a separate entity from the ovary in this patient. The ovary is displaced superiorly. (Image courtesy of Deborah Baumgarten, MD.)

FIGURE 31.22 The location of this small posterior intramural leiomyoma is clearly delineated in this magnetic resonance image. The cervical canal is also easily visible. (Image courtesy of Deborah Baumgarten, MD.)

Occasionally, patients with a myomatous uterus have iron deficiency anemia because of menstrual bleeding that

is too heavy or too continuous to allow a response to oral iron therapy. In this situation, it may be beneficial to induce amenorrhea with hormonal therapy to allow the anemia to be corrected more expeditiously. Amenorrhea can be induced with progestational agents such as norethindrone or medroxyprogesterone acetate, with danazol, or with GnRH agonists. Several studies have demonstrated a significant increase in hemoglobin and hematocrit values in patients with leiomyomata treated preoperatively for 8 to 24 weeks with GnRH analogs compared with matched control groups. Friedman and colleagues also found a significant increase in serum iron and total iron-binding capacity in a study group treated with the GnRH agonist leuprolide acetate. In some patients, oral iron was also given. In an evaluation of 265 patients, GnRH agonists plus iron were more effective than iron alone in treating the anemia of patients with uterine leiomyomata, according to Stovall and coworkers. In a double-blind, placebo-controlled, multicenter study, Friedman and associates reported resolution of menorrhagia in 97% of uterine leiomyomata patients treated with GnRH agonists.

Preoperative treatment with GnRH analogs can actually reduce the operative blood loss during myomectomy, according to studies by Friedman and colleagues, Andreyko and coworkers, Moghissi, and others. In a prospective randomized study of 50 patients undergoing hysterectomy for symptomatic leiomyomata, Stovall and colleagues found a significant decrease in operative blood loss between those patients who

P.682

received 2 months of leuprolide acetate treatment preoperatively and matched control subjects. An elegant study by Friedman and associates demonstrated a significant decrease in operative blood loss during myomectomy between patients with pretreatment uterine volumes greater than 600 cm³ who were treated with depot leuprolide acetate for 12 weeks preoperatively and a matched control group. However, there was no significant difference in blood loss between the two groups when patients with smaller uterine volumes (150 to 600 cm³) were included in the analysis. It has been suggested that the hypoestrogenic environment caused by GnRH analog therapy reduces the vascular supply to uterine leiomyomata. However, even in patients not treated with GnRH agonists, blood flow has been observed to be lower in myomata and adjacent tissue.

Intraoperative autotransfusion and normovolemic hemodilution are also discussed. These techniques of reducing or avoiding the risk of homologous blood transfusion are discussed in detail by Wiskind and Thompson.

Perioperative antimicrobial prophylaxis is indicated with myomectomy. It is preferable to perform the operation in the follicular phase of the menstrual cycle. This avoids the chance of encountering an unknown or unsuspected pregnancy and reduces the problems encountered when a fresh corpus luteum is inadvertently traumatized.

Surgical Technique: Abdominal Myomectomy

After induction of anesthesia, the patient is placed in Allen universal stirrups, the bladder is emptied, and a careful pelvic examination, including a rectovaginal-abdominal bimanual examination, is performed under anesthesia. Preparation and draping are done to allow access to the vagina and cervix in case it is necessary to place an instrument through the cervix and into the endometrial cavity during the procedure. Cervical dilatation should be done to facilitate postoperative drainage from the endometrial cavity, especially for cases in which the endometrial cavity has been entered during the myomectomy.

Many of the general principles of pelvic surgery are applicable to myomectomy. Perhaps the most important of these is optimum exposure at the operative site. This is accomplished primarily by an adequate incision, but there must also be proper retraction, good lighting, and able assistants. Although a Pfannenstiel incision is considered adequate for myomectomy on a small uterus, we prefer the Maylard incision for larger uteri, even those that exceed a size equivalent to a 12-week pregnancy. A Maylard incision provides excellent exposure throughout the pelvis. Because it is a transverse incision, it is stronger and provides better cosmesis than a vertical midline incision. A Bookwalter retractor optimizes exposure of the operative site. A Pfannenstiel incision can be used for removal of a small, solitary myoma.

The importance of adequate exposure cannot be overemphasized. With proper exposure, operative time can be shortened and surgical bleeding can be more easily identified and controlled. Limited exposure may lengthen operative time, increase the risk of inadvertent injury to other pelvic structures, and force abandonment of a myomectomy in favor of a hysterectomy in especially difficult cases.

After the peritoneal cavity is entered, the abdomen is explored as usual. Adhesions in the pelvis must be carefully released or excised so that the intestines can be placed in the upper abdomen and held there with packs. The operation is performed according to microsurgical techniques and principles. For example, the laparotomy packs that are used to hold the intestines in the upper abdomen are placed in plastic bags to reduce the microscopic trauma to peritoneal surfaces caused by regular laparotomy packs. Lintless laparotomy packs are preferred. Several laparotomy packs in plastic bags can be used to fill the cul-de-sac, thus elevating and stabilizing the uterus for easier access. Visualization of the operative site can be improved by the liberal use of suction to remove blood from the field. Suction should be used instead of sponges because it allows for a more accurate determination of blood loss and is less traumatic to tissues.

The operative field is kept moist and free of clots with a solution of lactated Ringer containing heparin. Very fine instruments and sutures are used when possible, and tissue is handled gently to avoid unnecessary trauma to serosal surfaces. Traumatic instrumentation (e.g., uterine elevators with teeth, Kocher clamps, or any instrument on the uterine serosa) must be avoided. Sutures on serosal surfaces should be of a fine absorbable nonreactive material. Running suture lines are preferable to avoid extra knot volume, which may contribute to adhesion formation. If pelvic adhesions develop after myomectomy, future fertility may be adversely affected. Performing the operation in a way that minimizes adhesion formation greatly improves the possibility of a successful result.

At this point in the operative procedure, one should pause and evaluate the size, location, and number of myomata present. Special note should be made of their proximity to the endocervical canal, uterine vessels, and fallopian tubes. One must decide if myomectomy is still feasible, how the leiomyomata will be removed (and in what sequence), and how the uterus will be reconstructed.

The conservation of uterine function with myomectomy requires control of bleeding from uterine incisions and myoma beds. Contrary to hysterectomy for leiomyomata, conservation of the uterus requires that the blood supply to the uterus through the uterine and ovarian vessels remains intact. Removing multiple myomata embedded deeply in a vascular myometrium can result in considerable blood loss. Proper application of special techniques to limit blood loss can allow multiple myomectomies even in uteri up to 20 weeks pregnancy size if satisfactory reconstruction is possible.

Controlled hypotensive anesthesia has become a useful adjunct to decrease surgical bleeding in selected patients. The main mechanism in the control of operative field bleeding with hypotensive anesthesia is the reduction of venous tone. This can be accomplished by specific vasodilating agents—such as nitroglycerin or sodium nitroprusside, epidural or spinal anesthesia, some inhalation anesthetic agents, and ganglionic blockade—to achieve and maintain a target mean blood pressure of 60 mm Hg. Our experience with this technique has been favorable. Venous bleeding can be further reduced if the patient is placed in a moderate Trendelenburg position. This facilitates venous drainage from the lower extremities and pelvis by gravity and may further reduce the blood pressure at the operative site.

Induced hypotension is contraindicated in patients with cerebrovascular disease, myocardial ischemia, peripheral vascular disease, severe renal or hepatic disease, and hypovolemia. None of these contraindications is seen very often in myomectomy patients. An anesthesiologist experienced with the technique is an essential requirement. The decision to use hypotension should be made jointly by the surgeon and the anesthesiologist. It is essential that the blood pressure be returned to normal before closure of the incision to ensure that adequate surgical hemostasis has been established.

Early proponents of myomectomy focused on methods to temporarily occlude uterine blood flow to control hemorrhage and provide a bloodless operative field. One of the earliest methods was simply to have an assistant grasp the broad ligaments firmly with each hand during myomectomy to impede blood flow through the uterine vessels. In the 1920s, Victor Bonney

P.683

introduced a specially designed clamp that was placed around the uterine vessels and the round ligaments. The ovarian vessels were occluded with ring forceps. Using this technique, he was able on one occasion to remove more than 200 myomata from a single uterus. Rubin, in 1938, was the first to use an elastic rubber tourniquet through the broad ligament, encircling the cervix and occluding the uterine vessels during myomectomy. Rubbershod clamps applied to the broad ligaments have also been used to occlude the uterine vessels and control bleeding.

Gynecologic surgeons do not often have the opportunity to use tourniquets to control bleeding; however, a myomectomy is particularly suited to their use. We prefer to use tourniquets fashioned in the manner of a Rumel-type tourniquet, which is used by vascular, thoracic, and trauma surgeons to occlude major vessels. Initially, a small hole is made in an avascular space in the broad ligament on either side of the uterine isthmus just lateral to the uterine vessels. A 5-French pediatric feeding tube is looped around the upper cervix through the holes in the broad ligament, and the two ends of the tube are then threaded through a 4-inch length of 35-French Malecot catheter and held with a clamp. A loop tourniquet can then be placed around each infundibulopelvic ligament through the same holes in the broad ligaments ([Fig. 31.23A](#)).

As the tourniquets are being placed, controlled hypotension is induced by the anesthesiology staff. Before the tourniquets are tightened, the location of the uterine arterial blood flow is identified with a sterile Doptone. When everything is in readiness and the plan of operation has been selected by the surgical team, the tourniquets are snugged down and tightened progressively until the uterine arterial flow is no longer audible with the Doptone ([Fig. 31.23B](#)). It is very important that the arterial blood flow be occluded. If the venous flow is occluded while the arterial flow remains intact, blood loss could actually be increased with the tourniquets. The mean blood pressure should be reduced to the target hypotensive level (about 60 mm Hg) before the tourniquets are tightened. The higher the blood pressure, the tighter the tourniquets must be to occlude the uterine circulation.

FIGURE 31.23 A: Through a small hole in the broad ligament on each side of the uterus, a Rumel tourniquet is placed around the lower uterus and around each infundibulopelvic ligament. **B:** When the tourniquets are tightened sufficiently, the blood flow to the uterus stops. The absence of arterial pulsations can be determined with the sterile Doptone.

FIGURE 31.24 With tourniquets properly secured, myomectomy can be performed with minimal blood loss.

With the combination of properly applied tourniquets and controlled hypotensive anesthesia, the entire circulation to the uterus can be occluded. The myomectomy can then be performed in a bloodless field, greatly facilitating complete removal of all tumors and a neat reconstruction of the uterus ([Figs. 31.24](#) and [31.25](#)). Occasionally, a large cervical or broad ligament myoma prevents placement of the tourniquets. In this situation, the offending tumor should be removed first, the defects repaired when feasible, and the tourniquets applied for the remainder of the multiple myomectomy.

Once the tourniquets are tightened in place, the myomectomy should proceed expeditiously to prevent ischemic damage to the uterus, tubes, and ovaries. The length of time the pelvic structures can be without blood flow before irreversible damage occurs is unknown. We generally do not release the tourniquets until the myomectomy is complete (usually within an hour) and have not experienced any adverse events. Lock also agrees that intermittent release of the tourniquets is unnecessary. However, because the potential for injury does exist, tourniquet time should be monitored and kept to a minimum. The tourniquets should not be tightened until the surgical team is ready to perform the myomectomy. Intermittent release of the tourniquets should be considered if the operating time becomes excessive. We usually release the tourniquets around the ovarian vessels as the uterine serosa is being closed to restore circulation to the tubes and ovaries and to restore some collateral flow to the uterus. After reconstruction of the uterus is complete, the determination of adequate hemostasis in the uterus cannot be made until all the tourniquets are released and the blood pressure has returned to normal. Sometimes, additional sutures are required for hemostasis. Before the abdomen is closed, the small holes in the broad ligament are repaired with figure-of-eight sutures.

FIGURE 31.25 The use of tourniquets to control bleeding facilitates closure of the myoma bed and uterine incision.

Tourniquets are not necessary for every myomectomy, especially when the tumors are small or pedunculated. However, they are safe and inexpensive to use and can be of great benefit when large or multiple intramural myomata must be removed. A criticism of uterine tourniquets is that they are traumatic to pelvic structures. Our experience, to the contrary, is that soft plastic tubes used as tourniquets are quite atraumatic. No injuries attributable to these tourniquets have occurred in several hundred cases.

An alternative to the use of tourniquets to control bleeding during myomectomy is the local injection of vasoconstrictive agents. Perhaps, the most commonly used agent is vasopressin, a synthetic derivative of the antidiuretic hormone from the posterior lobe of the pituitary gland. In addition to this antidiuretic effect, vasopressin induces smooth muscle contraction of the gastrointestinal tract and the vascular bed. In particular, it has been found to have a potent vasoconstrictor effect on the nonpregnant uterus when injected locally. It has a plasma half-life of 10 to 20 minutes and has been used effectively as a hemostatic agent during myomectomy. Pharmacologic vasoconstriction can be accomplished with vasopressin (antidiuretic hormone), 20 U (Pitressin). Twenty units of vasopressin are diluted in 20 mL of normal saline and injected into the superficial myometrium and serosa overlying the myoma. The effect usually lasts for 30 minutes.

Dillon reported that with the use of vasopressin, 72% of patients requiring myomectomy did not need blood replacement compared with control subjects. Frederick and coworkers noted significantly less blood loss compared with an untreated group. Ginsberg and associates compared vasopressin with mechanical vascular occlusion and found that there were no demonstrable

P.685

differences in blood loss, morbidity, or transfusion requirements between the two techniques. A favorable experience with vasopressin has also been reported by Semm and Mettler.

The weight of evidence in current clinical investigation indicates that vasopressin is as effective as mechanical vascular occlusion in controlling blood loss with myomectomy. Nevertheless, careful dissection around myomata and prompt suturing with exertion of direct pressure to bleeding vessels by the operative assistant are necessary to minimize blood loss. Care should be taken to avoid injecting the solution directly into a vascular channel, and no more than 30 mL per patient is recommended because of potential side effects. Vasopressin should not be used in patients with vascular disease, especially disease of the coronary arteries. Inadvertent intravascular

injection can cause anginal pain; larger doses can cause myocardial infarction. Water intoxication can also occur as a result of the antidiuretic effect of vasopressin. This effect is potentiated in patients taking tricyclic antidepressants.

Although late postoperative bleeding does occur with the use of vasopressin, it is not a common complication. Arterial bleeding masked by vasopressin still requires suture ligation. Because of the short half-life of vasopressin, the hemostatic effect is observed only for 20 to 30 minutes and should be over before the incisional closure is started. However, some do claim that vasopressin simply delays bleeding, gives a false sense of security, and is not particularly effective for larger myomata and very extensive myomectomies.

For a variety of reasons, epinephrine as a vasoconstrictive agent is not recommended for use in gynecologic surgery.

Since its introduction into clinical practice in 1972, the CO₂ laser has been touted as a tool that increases surgical precision and decreases bleeding, tissue injury, and adhesion formation. The laser can be used to make a single uterine incision through which multiple myomata are removed. An elliptical incision can also be made around the base of larger myomata to facilitate their removal. Myomata less than 1 cm in diameter can be vaporized directly with the laser, which destroys tissue by vaporizing cellular water. Despite the favorable results reported by Weather, Reyniak and Corenthal, McLaughlin, and Starks, we believe that there is no clear advantage to using the CO₂ laser for abdominal myomectomy, especially considering the added cost to the patient.

Although the methods described earlier to control bleeding during myomectomy are helpful, they cannot substitute for good surgical techniques. Adherence to basic principles is essential for good results. Perhaps the most important of these is careful planning of the uterine incisions. Only a minimal number of incisions should be made. If possible, removal of all leiomyomata should be accomplished through a single incision in the anterior uterine corpus and in the midline, when feasible, to avoid the vascular areas of the uterus and broad ligaments laterally. Even intramural leiomyomata in the posterior uterine wall can be removed through anterior incisions. Incisions in the posterior uterine wall may be necessary, however, if posterior subserous tumors are being removed. If posterior uterine incisions are made, adhesions are more likely to develop and will likely involve the tubes and ovaries as well.

As many tumors as possible should be removed through a single incision. Methods of removing myomata through a single anterior incision have been described by Bonney. The linear or elliptic incision should usually be over the largest myoma. It should be carried through the superficial myometrium directly into the underlying myoma. The myoma is then grasped with a double-tooth tenaculum or a large Lahey thyroid clamp for traction. The plane of cleavage between the myoma and the surrounding myometrium is easily identified. Sometimes in patients who have been treated with GnRH analogs, the plane of cleavage may seem less distinct. Sharp dissection with the scalpel or Metzenbaum scissors, or blunt dissection with the finger or knife handle, is required to enucleate the myoma from its bed. Sometimes, the myoma is larger than expected. It may then be necessary to enlarge the incision or to remove the tumor by morcellation. Other adjacent tumors should be removed through the same incision. Any entry in the endometrial cavity should be noted, and a special attempt should be made to close it with sutures placed in the underlying supporting myometrium. Examples of the step-by-step planning and performance of a multiple myomectomy are illustrated in [Figures 31.26](#) and [31.27](#).

FIGURE 31.26 The sequence of steps in a multiple myomectomy is shown in these illustrations. **A:** Through a transverse Maylard incision, tourniquets are placed to occlude the uterine and ovarian artery flow. Through a single incision in the anterior myometrium, a large anterior myoma is removed first. All other myomas are removed through this incision. **B:** A smaller intramural myoma is removed through the same incision.

FIGURE 31.26 (Continued) C: To avoid making a separate incision in the posterior uterine wall, a large posterior myoma is removed through the uterine cavity. After an incision has been made through the anterior endometrium, an incision is made in the posterior endometrium directly over the posterior myoma. **D:** The myoma in the posterior uterine wall is dissected from its bed and removed through the uterine cavity. An incision in the posterior uterine serosa is thus avoided. **E:** Multiple sutures (2-0 delayed absorbable) are used to close the defect in the posterior uterine wall first. Incisions in the uterine cavity are closed. Then, the defects in the anterior uterine wall are closed. **F:** Trimming excess myometrium from the anterior uterine wall allows a better approximation of the myometrium. The edges of the serosa are closed with a continuous "baseball" stitch with 4-0 delayed absorbable sutures.

FIGURE 31.27 Techniques of multiple myomectomy. **A:** A vertical incision is made over a myoma on the anterior surface of the fundus as close to the midline as possible. Many myomas can be removed through this single incision. **B:** The incision is extended into the substance of the myoma.

FIGURE 31.27 (Continued) C: By incising progressively deeper into the myoma, the surgeon can identify and bluntly dissect the plane between myoma capsule and myometrium. **D:** Sharp dissection may be necessary to separate the myoma from its capsule at its base. **E:** After the removal of as many myomas as possible, the remaining cavity is obliterated and hemostasis secured. **F:** Multiple rows of nonreactive interrupted absorbable suture material are used to close the cavity. **G:** When the “dead space” has been obliterated, the serosa is closed with a continuous “baseball” suture of 5-0 or 6-0 nonreactive absorbable material. **H:** This type of closure approximates the serosal edges.

The muscle fibers and blood vessels surrounding a myoma are compressed by its growth. This compression of surrounding tissue forms a pseudocapsule around the myoma. No large blood vessels enter the myoma, and there is no vascular pedicle. If the dissection can be carried out between the myoma and the pseudocapsule, blood loss can be minimized. If blood vessels are cut or left on the surface of the myoma, it usually means that the dissection has been carried out in an improper plane. Dissection in the proper plane may be more difficult if the patient received GnRH analog therapy preoperatively.

Several ingenious techniques for removing leiomyomata and for repairing defects have been described. For

example, Bonney hood can be used to remove a large leiomyoma in the uterine fundus. The myoma is first exposed through an elliptic incision made transversely across the anterior fundus, taking care to avoid the interstitial portion of the fallopian tube on each side (**Fig. 31.28A, B**). After the primary tumor is removed (**Fig. 31.28C**), other leiomyomata can also be removed through the same incision. Excess myometrium can be trimmed away (**Fig. 31.28D**). Interrupted sutures obliterate the dead space, approximate the myometrium, and accomplish satisfactory hemostasis. The sutures are placed in such a way that the posterior flap of myometrium is folded over the anterior uterine wall and sutured in place, thus fashioning Bonney hood (**Fig. 31.28D**).

P.688

FIGURE 31.28 Technique of myomectomy using an anterior hood incision as described by Bonney. **A:** A transverse incision is made in the anterior fundal wall over the myoma. **B:** Sagittal view of the location of the incision. **C and D:** Using blunt and sharp dissection, the surgeon enucleates the myoma from its bed. Excess hypertrophied myometrium may be trimmed and removed before closure of myometrium and serosa.

Meticulous closure of defects from the enucleated myomata is essential to maintain hemostasis postoperatively, but this should be deferred until all the tumors are removed. Hypertrophy of the normal myometrium is always

present with uterine leiomyomata. Some of this hypertrophied myometrium is considered excess and can be trimmed to facilitate a more normal reconstruction of the uterus. Involution of the myometrial hypertrophy is expected to occur in the first few months after myomectomy. Therefore, only a small amount of normal myometrial tissue should be removed. In reconstructing the uterus, the surgeon should refer to fixed points such as the attachments of the round ligaments and fallopian tubes on each side of the corpus. Symmetric reconstruction is preferred but is not always possible. The myoma beds are usually closed with interrupted figure-of-eight or mattress 2-0 delayed absorbable sutures. Large defects can be closed initially with a purse-string suture to obliterate the dead space. Several layers of sutures may be required. One must be careful to avoid occlusion of the uterine vessels, the endocervical canal, or the interstitial portion of the fallopian tubes. Transfundal or transcervical chromotubation to test fallopian tube patency after uterine reconstruction is complete is not usually possible because of leakage of the dye through the myometrial incisions.

In closing a myomectomy incision, the security of the closure comes from sutures placed in the myometrium. If possible, these sutures and knots must not be exposed. In [Figure 31.26E](#) and [F](#), several techniques of closing myometrial defects are illustrated. The serosal edge of the uterine incision should be carefully approximated with a continuous 5-0 or 4-0 delayed absorbable “baseball” stitch.

The tourniquets are removed, the hypotensive anesthesia is reversed, and the uterus is carefully inspected for evidence of bleeding. Additional sutures are sometimes required. If a uterine suspension is needed, a modified Coffey or modified Gilliam technique along with uterosacral ligament plication is used.

Adhesion prevention can also be achieved by the use of absorbable or nonabsorbable barriers. The absorbable barrier Interceed (oxidized regenerated cellulose) can be placed over the uterine corpus to protect the tubes and ovaries from denuded peritoneal surfaces and uterine incision. Alternatively, a nonabsorbable barrier, Gore-Tex (polytetrafluoroethylene

P.689

surgical membrane), can be sutured over the uterine incisions with 7-0 absorbable minimal reactive sutures. The use of Gore-Tex has been associated with a reduction in new adhesion formation. Diamond and the Seprafilm Adhesion Study Group assessed the efficacy of Seprafilm (HAL-F) bioresorbable membrane (sodium hyaluronate and carboxymethylcellulose) in reducing the incidence, severity, extent, and area of uterine adhesions after myomectomy. This prospective, randomized, blinded, multicenter study involved an independent gynecologic surgeon's review of each patient's second-look laparoscopy. One hundred twenty-seven women undergoing uterine myomectomy with at least one posterior uterine incision were randomized to treatment with Seprafilm or to no treatment at the completion of the myomectomy. All indices, including incidence, severity, and extent of adhesions, were decreased in the treatment group. This suggests that newer barriers may also have a role in adhesion prevention. Free grafts of peritoneum or omentum should not be used to cover uterine incisions.

In a randomized controlled trial, Imai found fewer adhesions with GnRH analogue pretreatment compared with no treatment after both laparoscopic and abdominal myomectomy. The utility of GnRH analogues in reducing adhesions has also been demonstrated in other clinical and animal studies.

Second-look laparoscopy may be indicated in patients with multiple incisions or in those with posteriorly located incisions adjacent to the adnexa. Early adhesions can be easily lysed, and an additional barrier membrane can be placed. The clinical role of second-look laparoscopy, outside of research, is not well defined, and conflicting studies can be found in the literature regarding the efficacy of this procedure.

A comprehensive review of methods to prevent adhesion formation in gynecologic surgery has been published by Damario and Rock and by diZerega.

Results of Myomectomy

An extensive multiple myomectomy is a major operation with the potential for a higher morbidity than that found with hysterectomy. The major immediate postoperative complications after myomectomy are febrile morbidity and intraperitoneal bleeding.

Postoperative febrile morbidity may be related to extensive tissue trauma or to infection for a variety of reasons. Perioperative antibiotics are routinely given, but antibiotics are not usually continued beyond the day of operation. Any evidence of infection in the recovery period should be treated vigorously and promptly because infection in the operative site may be adhesiogenic and may have devastating effects on future fertility. Unfortunately, subclinical infection in the operative site may not be recognized and therefore may not be treated, but it can also have adverse effects on fertility because of de novo adhesion formation. For these reasons, meticulous and sterile surgical technique during myomectomy must be impeccable.

Intraperitoneal bleeding after myomectomy is usually due to failure to achieve hemostasis of the myometrial vessels during closure of the myoma beds and uterine incisions. Although we do use a heparin solution (5,000 U of heparin per 1,000 mL of lactated Ringer solution) for irrigation during myomectomy, there is no evidence to suggest that this contributes to occult intraperitoneal bleeding.

The diagnosis of intraperitoneal bleeding in the postoperative patient may be difficult. The vital signs can remain stable for several hours before rapidly deteriorating. Peritoneal signs are often subtle and may be masked by incisional pain and analgesic medications. In addition, the peritoneal cavity has an enormous capacity for accommodating occult blood loss. Indeed, as much as 3,000 mL of blood can be shed into the peritoneal cavity with only a 1-cm increase in the abdominal radius.

Therefore, patients must be carefully monitored for the first 24 hours after myomectomy. Vital signs are routinely checked every 15 minutes for the first 2 hours after surgery, then every 30 minutes until stable. Subsequently, they are monitored every 2 to 4 hours for the first 24 hours postoperatively. A hematocrit is usually performed 6 hours after the operation is completed and again on the first postoperative morning. It can also be performed whenever there is a suspicion of intraperitoneal bleeding, anemia, or hypovolemia. Any sign of restlessness, tachycardia, or tachypnea may be an indication of blood loss, especially when associated with hypotension.

When occult postoperative intraperitoneal bleeding is suspected, peritoneal lavage can be a valuable diagnostic tool. If the lavage solution yields a red blood cell count of $100,000/\text{mm}^3$, intraperitoneal bleeding is likely, and reexploration is indicated without delay. Lavage is unnecessary when the diagnosis of intraperitoneal bleeding is unequivocal and associated with definite hypovolemia. In this situation, immediate return to the operating room for reexploration is indicated.

Postoperative bleeding after myomectomy can be devastating. Intraoperative control of bleeding during an extensive multiple myomectomy often requires that the uterine blood flow be impeded with tourniquets, clamps, or the local injection of vasoconstrictive agents. However, the demonstration of adequate surgical hemostasis in the uterus cannot be made until the uterine circulation has been fully restored. Assiduous attention to this principle intraoperatively prevents postmyomectomy bleeding in almost all cases.

Reports by Smith and Uhlir, Rosenfield, and LaMorte and associates indicate that the morbidity of myomectomy is no greater than the morbidity of hysterectomy. Verkauf reviewed current published reports and found that the operative risk of myomectomy does not exceed that of hysterectomy. One case of disseminated intravascular coagulation, hemolytic anemia, and acute renal failure associated with extensive multiple myomectomy was reported by Sacks and Hoyne.

Myomectomy has an excellent record in reducing heavy menstruation in patients reporting menorrhagia. In more than 80% of patients, menorrhagia is cured or significantly improved. Pelvic pain and discomfort and dysmenorrhea can also be relieved, but the results are not as dramatic because leiomyomata are often

associated with other gynecologic diseases (e.g., endometriosis and pelvic inflammatory disease) that can also cause pelvic pain.

The impact of abdominal myomectomy on infertility is difficult to assess. Other factors besides leiomyomata may be present to a varying degree. The extent to which the uterine cavity or the fallopian tubes are distorted also varies. The percentage of patients in each series who wish to conceive after myomectomy is not the same. There is also considerable variation in the surgical technique and skill of the gynecologic surgeon. Prospective, randomized, controlled studies are lacking. These and other factors make it difficult to assess the impact of abdominal myomectomy on infertility.

There are a number of published reports regarding women who experience recurrent pregnancy wastage or prior infertility with another cause and who undergo myomectomy. According to Verkauf's review, conception occurs in more than half of such women who were not previously pregnant. A comprehensive review of 23 studies by Vercellini and colleagues regarding leiomyomas and reproduction reported an overall conception rate of 57% after myomectomy among prospective studies. Among women with otherwise unexplained infertility,

P.690

the conception rate was 61% after myomectomy. The conception rate is approximately 53% to 70% after myomectomy for submucous myomas and 58% to 65% after myomectomy with intramural or subserosal leiomyomas. The conception rate among women older than age 35 may not be as good. Also, the postmyomectomy conception rate may be lower when the uterus is greater than 12 weeks gestational size and when more than four myomata are removed. When abdominal myomectomy includes removal of submucous myomata, Garcia and Tureck report that 53% of patients attempting to establish a pregnancy conceive. Both Li and colleagues and Vercellini and coworkers published retrospective reviews supporting excellent conception and pregnancy rates following abdominal myomectomies. Vercellini's work suggests that certainly age at the time of the procedure is important, as it was one of three independent variables (age, duration of infertility before surgery, and the presence of other infertility factors) associated with postoperative cumulative conception rate.

An ultrasonographic study of uterine remodeling after conservative myomectomy was reported by Beyth and associates. There was a gradual decrease in uterine volume in all patients during the 6 months after myomectomy, with the most remarkable decrease occurring in the first 2 to 3 months. Presumably, this represents an involution of myometrial hypertrophy and postoperative healing of uterine incisions. We recommend that all patients use local methods of contraception (diaphragm, condoms, and spermicidal jelly or foam) for at least 3 months to avoid conception until the myomectomy incisions are healed.

Finally, there is the matter of recurrence of myomata after myomectomy. In Verkauf's review, leiomyomata recurred in 7.5% of patients, and 6.8% required reoperation. Most recurrences appeared more than 3 years after myomectomy, thus allowing sufficient time for conception to occur before recurrence. Friedman and associates investigated a concern that GnRH agonist-induced myoma shrinkage would make some small intramural and submucosal tumors "invisible" at myomectomy, causing early "recurrence" of leiomyomata once gonadal suppression ceased and estrogen production returned. In their study, there was no difference in myoma recurrence between women pretreated with GnRH agonists (67%) and those treated with placebo (56%) 27 to 38 months after myomectomy. Their myoma recurrence rate of 61% is much higher than that previously reported in combined myomectomy series. The authors believe that this discrepancy is most likely due to the use of high-resolution US to diagnose small myomata that would otherwise be missed on bimanual examination. Rosetti and colleagues reported long-term followup of 81 patients randomized to abdominal or laparoscopic myomectomy plus 84 nonrandomized patients and found similar recurrence rates, 23% and 27% respectively, between the laparoscopic and abdominal myomectomy, with most recurrences seen within 24 months of surgery.

Matta and colleagues reported that after GnRH analog treatment, the US outline of some myomata was lost or obscured. Such myomata are probably more difficult to identify and remove with myomectomy and may be more

likely to reappear when GnRH analog treatment is discontinued after myomectomy.

Embolotherapy

With current technology progressing toward less invasive therapies, the minimally invasive procedure of UAE is gaining popularity. This procedure can potentially obviate the need for surgical procedures in patients who suffer from symptomatic leiomyomas.

In the female genital tract, embolotherapy for control of hemorrhage from malignancy was first reported in the late 1970s. In 1980, Pais and colleagues described successful embolization for postpartum hemorrhage. Many more reports followed in the mid-1980s. In the early 1990s, Ravina and coworkers began using embolotherapy as a preoperative maneuver to decrease intraoperative blood loss during surgery for myomas. The protocol generally included embolization about 24 hours before the surgery; however, some occurred a few days or weeks before surgery. Such an improvement in symptoms occurred that many surgeries were canceled altogether. This serendipitous discovery led to the performance of UAE as a primary procedure. UAE for leiomyomas was first performed in the United States by Goodwin and colleagues in 1995. Since then, several large series have been reported, and experience continues to grow.

UAE is appropriate for patients with symptomatic leiomyomata and a preference for treatment other than surgical. Clinical findings, therapeutic goals, and overall medical conditions factor into the decision making. Several concerns have developed in treating patients who may desire future conception. Hypotheses include reduced fertility as a consequence of injury to the uterus or ovaries, placental insufficiency resulting from inadequate blood flow through the uterus, or uterine rupture during pregnancy from UAE-induced myoma necrosis. A limited number of deliveries have been reported after UAE for uterine myomata. Reports of obstetric outcomes following embolization are mixed. Although previous studies have suggested that embolization therapy may increase the risk of miscarriage, postpartum hemorrhage, preterm delivery, and malpresentation compared with laparoscopic myomectomy, a recent retrospective review by McLucas including 28 pregnancies following UAE found no significant difference in preterm delivery or miscarriage as compared to the general population. Nonetheless, desire for future pregnancy remains a contraindication for UAE until more comprehensive long-term outcome data are available.

Interestingly, amenorrhea has been reported in 1% to 2% of patients after UAE; however, some authors have attributed this to the coincidental onset of menopause. Contraindications to this procedure include pregnancy, active pelvic infection, severe contrast medium allergy, arteriovenous malformations, desire for future pregnancy, a strong suspicion of adenomyosis or pedunculated leiomyoma, and undiagnosed pelvic mass. The technique is generally preceded by preprocedural testing, and patients are pretreated with intravenous antibiotics. Many perform preliminary arteriographic mapping of the pelvis. A review by Hutchins and Worthington-Kirsch provides an excellent description of the procedure.

The technical success rate is consistently reported in the 96% to 98% range with experienced teams. Eighty percent to ninety percent of embolized patients have reported improvements in menorrhagia, bulk-related symptoms, or both. Reduction in overall uterine volume peaks at more than 60% by 6 to 9 months after the procedure because of the gradual nature of the process. Individual myomas show average volume reductions of 60% to 65%.

The Fibroid Registry for Outcomes Data was established by the Society of Interventional Radiology and includes 25 core sites and 50 to 60 other participating sites. This clinical registry has enrolled more than 3,300 patients in an effort to obtain rapid and reliable data regarding patient outcomes. Based on 30-day and 1-year data, near 90% of patients responded favorably to UAE. Recurrence of symptoms and repeat procedures occur in about 10% of patients by 3 years. Worthington-Kirsch, a leading member of the steering committee, estimates that by 5 years

postprocedure, as many as 20% of patients will have another procedure. Approximately 1,300 to 1,500 patients continue to provide annual data through self-reported questionnaires, permitting continued long-term follow-up of the UAE procedure.

Forty percent of patients develop a syndrome of fever and malaise in the first 10 to 14 days after UAE. This is also associated with leukocytosis. This entity is well described as postembolization syndrome. It is typically self-limited and resolves in 3 to 5 days and rarely requires treatment except antipyretics. Other complications include those that may be attributed to the angiographic component and target or nontarget organ embolization. Groin infections, groin bleeding or hematoma, contrast-induced renal damage, and vascular damage may be attributed to the angiographic component. Uterine infection or perforation, sexual dysfunction, and myoma sloughing may be attributed to the target organ effects. Reported nontarget organ embolization complications include ovarian sequelae, sciatic nerve effects, and gluteal muscle pain. Current experience confirms a major complication rate of less than 1%.

BEST SURGICAL PRACTICES

- Women with symptomatic or problematic uterine leiomyomata should be considered candidates for surgical or radiologic intervention.
- Management options, including medical, radiologic, and surgical, should be discussed with patients, emphasizing risks and benefits of each option.
- Careful preoperative evaluation for women who undergo surgical treatment of leiomyomata should include radiographic evaluation to determine the extent, location, and size of leiomyomata.
- In patients with infertility, myomectomy—performed by either an abdominal or a laparoscopic approach—should only be performed after complete evaluation of other potential causes of infertility.
- Adhesion barriers are advantageous in reducing adhesions during both abdominal and laparoscopic myomectomies.
- Pregnancy rates and outcomes after laparoscopic myomectomy compare favorably with those after abdominal myomectomy.
- Meticulous repair of the uterine myometrium is essential for patients desiring pregnancy after a myomectomy.
- Hysteroscopic myomectomy is an effective surgical alternative to relieve symptoms associated with submucosal myomas.
- Current information regarding UAE is promising, but patients should be made aware that limited long-term data are available regarding outcomes, especially relating to fertility and pregnancy.

ABDOMINAL MYOMECTOMY CHECKLIST

- Position the patient in Allen stirrups.
- Perform exam under anesthesia, paying careful attention to uterine size and mobility.
- Prep and drape the patient.
- Place Foley.
- Perform cervical dilation, and consider staining the endometrial cavity.
- Make an abdominal incision (consider Maylard for uteri >12-week size), and enter the abdominal cavity.
- Optimize exposure (incision type and size, lighting, packing of intestines, retractors).

- Evaluate number, size, and location of fibroids.
- Minimize blood loss.
 - Make use of delicate surgical technique (avoid traumatic instruments).
 - Consider hypotensive anesthesia.
 - Consider use of a tourniquet.
 - Consider use of dilute Pitressin.
- Make a linear uterine incision over the largest myoma.
 - Dissect along the natural tissue plane, and excise the myoma.
- Meticulously close all uterine defects.
- Confirm hemostasis.
- Close abdominal cavity, fascial, and skin incisions.

Chapter 32A

Abdominal Hysterectomy

Howard W. Jones III

DEFINITIONS

Incidental oophorectomy—When clinically normal ovaries are removed at the time of a hysterectomy. This is an older term. *Prophylactic oophorectomy* is now preferred.

Prophylactic oophorectomy—The preferred term for removing clinically normal ovaries at the time of hysterectomy. This terminology emphasizes the risk reduction of ovarian and possibly breast cancer as a result of oophorectomy.

Supracervical hysterectomy—Also referred to as a *subtotal hysterectomy*. This operation removes the uterine fundus, transecting the upper portion of the cervix below the level of the uterine vessels. The cervix is left in situ.

Trendelenburg position—With the patient on the operating table in the supine position, the head is lowered below the level of the pelvis.

Hysterectomy is the most common operation performed by the gynecologist, and it is the second most common major surgical procedure done in the United States. Only cesarean section is more common. There are many indications for hysterectomy, and the uterus can be removed using any of a variety of techniques and approaches, including abdominal, vaginal, laparoscopic, and, more recently, robotic hysterectomy. In most cases, a total hysterectomy with removal of the uterine corpus and cervix is done; but in recent years, there has been a resurgence in the popularity of supracervical hysterectomy. The ovaries and tubes may or may not be removed along with the uterus, depending on the patient's age and a variety of other factors. The gynecologic surgeon not only should be technically adept at these various procedures but also should use history, physical examination, and discussion with the patient to match the surgical procedure to the patient to obtain the most satisfactory outcome.

The three sections of this chapter discuss abdominal, vaginal, and laparoscopic hysterectomy. Robotically assisted hysterectomy or robotic hysterectomy is discussed in [Chapter 17](#) on Robotic Surgery.

HISTORY

The history of hysterectomy is long and varied. Although significant advances in the technique of hysterectomy did not occur until the 19th century, earlier attempts are known. Some references to hysterectomy even date to the fifth century bc, in the time of Hippocrates. The earliest attempts at removal of the uterus were made vaginally for indications of uterine prolapse or uterine inversion. By the 16th century, a number of hysterectomies already had been done in Europe, including Italy, Germany, and Spain. In 1600, Schenck of Grabenberg cataloged 26 cases of vaginal hysterectomy.

Vaginal hysterectomies were done sporadically through the 17th and 18th centuries. In 1810, Wrisberg presented a paper to the Vienna Royal Academy of Medicine recommending vaginal hysterectomy for uterine cancer. Three years later, the German surgeon Langenbeck successfully performed a vaginal hysterectomy for uterine cancer. The first vaginal hysterectomy performed in the United States was in 1829 by John Collins Warren at Harvard University; however, the patient expired on the fourth postoperative day. Three years following Warren's attempt, Herman and Werneberg in Pittsburgh successfully performed a vaginal hysterectomy

for uterine cancer. By the late 19th century, techniques for vaginal hysterectomy were systematically studied and developed by Czerny, Billroth, Mikulicz, Schroeder, Kocher, Teuffel, and Spencer Wells.

The earliest abdominal hysterectomy attempts usually involved uterine leiomyomata that had been misdiagnosed as ovarian cysts. In the early 19th century, laparotomy for ovarian cysts still was considered dangerous, despite initial successes by McDowell in the United States and Emiliami in Europe in 1815. Abdominal hysterectomy for any reason was considered impossible to accomplish successfully. Many of the earliest myomectomies involved pedunculated tumors. Washington L. Atlee of Lancaster, Pennsylvania, performed the first successful abdominal myomectomy in 1844; although in a series of 125 surgeries, he did not attempt to remove the uterus.

The first reported abdominal hysterectomy was attempted by Langenbeck in 1825. The 7-minute operation for advanced cervical cancer resulted in the patient's demise several hours later. Abdominal surgery was commonly complicated by postoperative hemorrhage that was often lethal. In the mid-19th century, an English surgeon, A.M. Heath from Manchester, was the first to ligate the uterine arteries, but it would be nearly 50 years before his technique became common practice.

P.698

Successful surgery depends on control of bleeding, infection, and pain. Ligatures were known to be used to tie off bleeding vessels as early as 1090, and artery forceps were invented in the mid-16th century by Ambroise Pare. However, information regarding the pathophysiology of hemorrhage, shock, and blood transfusions was not available until the 20th century. The importance of infection control was first recognized by Austrian Ignaz Semmelweiss in his work with childbed fever. His 1840s work was furthered by Joseph Lister in the 1860s and aided by notable discoveries by Louis Pasteur and Robert Koch.

It was not until 1864 that the Frenchman Koeberle introduced his method of securing the large vascular pedicle of the lower uterus with his tool, the serrenoeud. This ligature en masse around the lower uterus with the corpus amputated above was the usual technique of controlling bleeding with hysterectomy in the earliest years. The stump thus formed was such a large mass of tissue that it could not always be safely returned to the peritoneal cavity owing to risk of intraperitoneal bleeding; often, the stump was fixed extraperitoneally in the incision so that it could be clamped later if necessary.

American Crawford W. Long first used ether as anesthesia in 1842, and Scotsman Sir James Y. Simpson initiated the use of chloroform in his obstetric practice. W.A. Freund of Germany further refined hysterectomy techniques in 1878 using anesthesia, antiseptic technique, Trendelenburg position, and ligature around ligaments and major vessels. The bladder was dissected from the uterus, and the cardinal and uterosacral ligaments were detached; the pelvic peritoneum then was closed. Late in the 19th century, further refinements were made to abdominal hysterectomy techniques by the surgeons of the Johns Hopkins Hospital, where they reduced their mortality to 5.9%.

In the early decades of the 20th century, hysterectomy became more commonly used as treatment for gynecologic disease and symptoms. Gynecology as a specialty was developing, and little else but surgery was available to gynecologists to help their patients. Major discoveries and concepts of reproductive organ physiology and pathology were just beginning. Estrogen and progesterone were not discovered until the late 1920s and early 1930s.

As gynecology matured as a specialty, knowledge of reproductive organ function and disease became more complete. Special and more accurate diagnostic techniques were developed, and effective nonsurgical methods of therapy were discovered. In the modern practice of gynecology, appropriate use of this knowledge and advanced modern diagnostic technologies allow more accurate diagnosis, and conditions such as uterine fibroids or abnormal uterine bleeding, which used to be treated primarily by surgery, can now often be managed with hormones or other medications. In addition, surgical techniques have evolved and minimally invasive or

even noninvasive approaches to uterine pathology have been developed. Focused ultrasound destruction of uterine fibroids and vascular embolization of fibroids are two examples of modern techniques (done primarily by radiologists) that have replaced traditional gynecologic surgical procedures.

Advances in anesthetic techniques, blood transfusions and fluid management, and the use of prophylactic antibiotics have made surgery safer and appropriate for more women with medical comorbidities. But the gynecologic surgical procedures themselves have changed significantly in the modern era. Laparoscopy, hysteroscopy, and robotically assisted techniques have added new technology to manage gynecology pathology and new platforms to accomplish a hysterectomy.

INCIDENCE

Hysterectomy is a very common surgical procedure. In the United States, more than half a million women undergo hysterectomy each year, and it is estimated that by age 65, one third of women in this country will have had their uterus surgically removed. Annual medical costs related to hysterectomy exceed \$5 billion in the United States. However, there are significant variations in hysterectomy rates within the United States and throughout the world. In a study from the Kaiser health care plan in California, Jacobson and colleagues reported an overall hysterectomy rate of 3.41 per 1,000 women older than age 20 in 2003. This is similar to but somewhat lower than the rate of 4.7 per 1,000 women reported from Olmsted County, Minnesota, from 1995 to 2002. In a nationwide sample, Farquhar and Steiner reported an overall hysterectomy rate of 5.6 per 1,000 women in the United States in 1997. In Western Australia, Spilsbury and colleagues recently reported an agestandardized rate of 4.8 per 1,000 women. In Italy, Mataria has reported a rate of 3.7, and a very low rate of 1.2 per 1,000 eligible women was reported from Norway.

This variation in rates from one location to another is due to several factors, including patient expectations and availability of medical care. But it is primarily related to the training and practice patterns of the local gynecologic surgeons. In some areas, abnormal uterine bleeding may be managed primarily by hormonal therapy, whereas in other locations, hysterectomy may be quickly recommended. Alternatives to hysterectomy have decreased the rate of hysterectomy in recent years. Systemic hormonal therapies have been effective for managing menorrhagia; recently, a progestational intrauterine system has been shown to be similarly effective. Intrauterine thermal balloons, microwave, and electrical instruments are all effective outpatient techniques for endometrial ablation as an alternative to hysterectomy for symptomatic uterine bleeding. Leiomyomata can now be treated with transcervical hysteroscopic resection and also by transcatheter uterine artery embolization. These new management techniques, together with an overall desire to decrease the use of major surgery, have decreased the use of hysterectomy in recent years.

In addition, today's gynecologic surgeon has several techniques for hysterectomy from which to choose. Although abdominal hysterectomy is still the most commonly used approach, there has been a definite increase in the use of both vaginal and laparoscopic hysterectomy in recent years. [Table 32A.1](#) shows

P.699

the frequency of the various techniques in recent reports from around the world. For the first time, this edition of the hysterectomy chapter is subdivided into sections on abdominal, vaginal, and laparoscopic hysterectomy. In this section, we concentrate on the abdominal approach to hysterectomy.

TABLE 32A.1 Worldwide Comparison of Hysterectomy Technique

ABDOMINAL (%)	VAGINAL (%)	LAPAROSCOPIC (%)

Finland	58	18	24

INDICATIONS FOR HYSTERECTOMY

Table 32A.2 lists commonly accepted indications for hysterectomy. As discussed above, a variety of new surgical and nonsurgical techniques or treatments are now available to manage many of the symptoms or conditions for which hysterectomy has been required in the past. These approaches are often a compromise. Alternative management approaches may be less invasive, less morbid, and possibly less expensive, but symptoms, although improved, may persist. Eventually, hysterectomy may be elected as a secondary management option for some patients, such as those who continue to have more bleeding than they are willing to tolerate after transcervical endometrial ablation.

In some cases, hysterectomy may be done in conjunction with other abdominal procedures, such as removal of a benign or malignant ovarian tumor or treatment of chronic pelvic inflammatory disease or endometriosis. There may be no pathologic changes in such a uterus, and some have contended that these are examples of an “unnecessary hysterectomy.” This is certainly not true, but it is important that the surgeon clearly explain why the uterus is being removed as a part of the surgical procedure. Because abdominal hysterectomy is the most common major gynecologic operation done in the United States, it is under careful scrutiny by a variety of regulatory agencies and public health care policy groups. The surgeon should carefully evaluate each patient and consider the diagnosis and management options before recommending hysterectomy and, specifically, abdominal hysterectomy. Numerous studies have shown that women who have undergone hysterectomy show a significant improvement in their quality-of-life indices. But care must be taken to make the correct diagnosis, be sure that the patient's condition will benefit from hysterectomy, and recommend the most appropriate type of hysterectomy for that specific patient.

TABLE 32A.2 Indications for Hysterectomy	
BENIGN DISEASE	MALIGNANT DISEASE
Abnormal bleeding	Cervical intraepithelial neoplasm
Leiomyoma	

Adenomyosis	Invasive cervical cancer
Endometriosis	Atypical endometrial hyperplasia
Pelvic organ prolapse	Endometrial cancer
Pelvic inflammatory disease	Ovarian cancer
	Fallopian tube cancer
Chronic pelvic pain	Gestational trophoblastic tumors
Pregnancy-related conditions	

The late Richard W. Te Linde, professor of gynecology at the Johns Hopkins University and the original author of this text, wrote:

The ease with which the average hysterectomy may be done has proven both a blessing and a curse to womankind. There is no doubt that a hysterectomy done with proper indications may restore a woman to health and even save her life. However, in the practice of gynecology, one has ample opportunity to observe countless women who have been advised to have hysterectomies without proper indications ... I am inclined to believe that the greatest single factor in promoting unnecessary hysterectomies is a lack of understanding of gynecologic pathology. The greatest need today among those who are performing pelvic surgery is a better knowledge of gynecologic pathology.

CHOICE OF APPROACH: ABDOMINAL, VAGINAL, OR LAPAROSCOPIC

Today, there are many different approaches to hysterectomy. The uterus can be removed via the abdominal route, transvaginally, or laparoscopically. Combinations of several techniques can be selected, such as a laparoscopically assisted vaginal hysterectomy. Although abdominal hysterectomy continues to be the most common approach used worldwide, there is good evidence from multiple randomized, prospective trials that vaginal and laparoscopic hysterectomies are associated with fewer complications, a shorter hospital stay, a more rapid recovery, and lower overall costs ([Table 32A.3](#)). In addition, Kovac and others have shown that most patients who require hysterectomy can have it performed vaginally. Who, then, is a proper candidate for an abdominal hysterectomy? Most patients with gynecologic malignancy are still operated on with an abdominal incision. Although this will undoubtedly continue to be true for women with ovarian cancer who frequently have extensive pelvic and upper abdominal metastases, laparoscopic techniques and more recently robotic surgical techniques are being used more and more frequently in women with endometrial and cervical cancer.

Another indication for abdominal hysterectomy is a large uterus that prevents safe and reasonable vaginal hysterectomy. This is obviously very dependent on the skills and experience of the surgeon, because there are various techniques that allow a very large benign uterus to be removed from below. Nevertheless, most gynecologists would agree that a uterus larger than 12 weeks' gestational size is a reasonable size to qualify for an abdominal approach. The shape and size of the pelvic outlet are also key factors. Although the degree of prolapse is not an absolute factor, patients with limited uterine prolapse are more difficult to do transvaginally. Cervical fibroids or cervical enlargement for any reason may compromise vaginal exposure and make it difficult to

place clamps laterally.

An unknown adnexal mass, extensive pelvic endometriosis, or adhesions from prior surgery or pelvic infection may also be an indication for an open abdominal approach including a hysterectomy. In some cases, a diagnostic laparoscopy will clarify the situation and may allow the procedure to be converted to a laparoscopically assisted vaginal hysterectomy. A careful preoperative evaluation—starting with a thoughtful history and physical examination and supplemented, where indicated, by imaging studies such as a pelvic ultrasound or computerized tomography scan of the pelvis and abdomen—will usually enable the gynecologist to decide on the most appropriate type of hysterectomy. The diagnosis and reason for the approach selected should be thoroughly explained and discussed with the patient and any appropriate family or friends. In rare cases, the final decision concerning the type of hysterectomy will depend on the findings of the exam under

P.700

anesthesia or the findings at laparoscopy. In those cases, all the “what ifs ...” should be carefully reviewed with the patient before the surgery and the family kept informed as decisions are made during the operation.

TABLE 32A.3 Characteristics of Hysterectomy by Different Approaches

	ABDOMINAL	VAGINAL	LAPAROSCOPICALLY ASSISTED VAGINAL
Number of patients	1,184	530	839
Uterine weight (average)	216 g	113 g	129 g
Operative time (average)	82 min	63 min	102 min
Blood loss ^a (average)	5.35%	5.19%	6.0%
Complications			
Fever 101 °F	9.1%	3.2%	2.0%
Transfused	2.5%	0.9%	0.6%
Bowel, bladder, or ureteral injury	1.0%	0.9%	0.7%
Death	0	1	0
Hospital stay	60 h	40 h	40 h
Hospital charges	\$6,552	\$5,879	\$6,431

From Johns DA, Carrera B, Jones J, et al. The medical and economic impact of laparoscopically

Subtotal versus Total Hysterectomy for Benign Conditions

In the United States, and throughout most of the world, hysterectomy—whether done transvaginally or through an abdominal incision—usually includes removal of the cervix. Over the past 50 years, subtotal or supracervical hysterectomy has come to be viewed as a suboptimal procedure reserved for those rare instances when concern over blood loss or anatomic distortion dictates limiting the extent of dissection.

More recently, however, the routine practice of removing the cervix at the time of hysterectomy for benign disease is now being challenged as many traditional surgical procedures are being modified to accommodate minimally invasive techniques. Total laparoscopic hysterectomy has been associated with an increased risk of ureteral and bladder injury so that laparoscopic supracervical hysterectomy has been introduced to avoid these complications. The introduction of a powered laparoscopic tissue morcellator has allowed gynecologic surgeons to perform a supracervical hysterectomy rapidly and efficiently, even on an enlarged uterus. The rapidity of the procedure, the quick postoperative recovery, and the popularity of cervical preservation among the lay public have now resulted in an increased use of abdominal supracervical hysterectomy.

In a study from California involving almost 650,000 women who underwent hysterectomy between 1991 and 2004, Smith et al. reported that the incidence of subtotal, supracervical hysterectomy increased from negligible to 21% of all hysterectomies in 2004. It is doubtful that this technique is as common in other regions of the United States and throughout the world, but the advantages of speed and a low complication rate plus the reduced risk of cervical cancer in the retained cervix due to improved screening and conservative management of cervical intraepithelial neoplasia make supracervical hysterectomy attractive to many patients and surgeons.

There is clearly a market for this procedure, but all of the recent prospective, randomized trials have not found any longterm advantage of supracervical abdominal hysterectomy compared with total abdominal hysterectomy. However, several recent prospective, randomized studies in the United States and abroad have shown no difference in sexual satisfaction, bowel or bladder function, or vaginal prolapse after simple total hysterectomy compared with supracervical hysterectomy for benign disease. My own clinical experience over 30 years also confirms this impression.

Management of Normal Ovaries

Should normal ovaries be removed at the time of hysterectomy for benign disease? The term *prophylactic oophorectomy* is preferred when referring to the removal of clinical normal ovaries at the time of hysterectomy. The use of *incidental oophorectomy* is not recommended because it suggests that an oophorectomy is done without planning or consideration and has no consequences. There is no doubt that bilateral oophorectomy reduces the risk of ovarian cancer and the need for future surgery for benign conditions of the ovaries. However, the ovaries continue to produce low levels of androgens even after the menopause, and although the benefits, if any, of this hormone production are unknown, the psychological effect of oophorectomy on some women is significant.

Prophylactic oophorectomy is done in 50% to 66% of women aged 40 to 65 who undergo hysterectomy in the United States. Averette and Nguyen have estimated that 1,000 of the approximately 24,000 new cases of ovarian cancer in the United States would be prevented if prophylactic bilateral salpingo-oophorectomy was done at the time of hysterectomy on all women older than age 40. In a more recent prospective cohort study of 30,117 women in the Nurses' Health Study, Parker et al. confirmed a very significant risk reduction in death from ovarian cancer and death from breast cancer for those women who underwent bilateral oophorectomy before age 47.5

years. However, they also observed that there was a significant (1.15 hazard ratio) increased risk of death from all causes in those women who underwent bilateral oophorectomy before age 50. This increased risk of death from all causes (especially cardiovascular disease and lung cancer) was not observed in those women who used estrogen replacement therapy. The significance and implications of these findings have been discussed and questioned, but it is clear that while removing the ovaries and fallopian tubes will decrease the subsequent risk of

P.701

cancer of these organs, the hormonal effects of premenopausal oophorectomy have implications more life threatening than hot flashes or night sweats. It behooves the gynecologic surgeon to keep up with this ongoing controversy so that we can counsel our patients based on the most recent facts and concepts.

Clearly, there are some significant potential benefits to oophorectomy at the time of any pelvic surgery in women with a known BRCA1 or BRCA2 gene mutation, a strong family history of ovarian or breast cancer, or women of Eastern European Jewish heritage. Recent studies also have clearly shown a decrease in the risk of breast cancer in women who have undergone bilateral oophorectomy. This is of particular importance in women from families with a history of ovarian or breast cancer and those with known BRCA gene mutations. In a series of 177 women with BRCA1 or BRCA2 mutations who were enrolled prospectively and followed for up to 6 years, Kauf and associates reported a 4% incidence of breast cancer among the 69 women who underwent prophylactic oophorectomy compared with a 13% incidence among those who elected follow-up surveillance only. In a similar retrospective review of 259 women compared with matched controls, the risk of breast cancer was reduced by 50% in the women who had bilateral oophorectomy. In both series, the risk of peritoneal or ovarian cancer was decreased by 95%. In a follow-up study of 4,931 women who underwent hysterectomy without oophorectomy at 10, 20, and 30 years with a control group of women who had not had hysterectomy, the risk of additional surgery to remove the ovaries was 3.5% (1.9% rate of oophorectomy in the women who had not has a hysterectomy). By 20 years, 6.2% of the women who had previously undergone hysterectomy had required oophorectomy, and by 30 years, 9.2% had undergone oophorectomy. Removing one ovary at the time of hysterectomy did reduce the risk of subsequent surgery for oophorectomy, but even without any pelvic surgery, 7.3% of the age-matched control group required oophorectomy during 30 years of follow-up.

Four case-control studies that found a lower risk of ovarian cancer among women who had a history of previous hysterectomy with ovarian conservation have been analyzed by Weiss and Harlow. The authors felt the reduction in ovarian cancer risk was explained by incidental screening for visible ovarian malignancy at the time of hysterectomy in those women in whom the ovaries are not removed. Those women with grossly normal ovaries have a reduced risk of developing symptomatic ovarian cancer over the next few years. In a large, prospective cohort study of 238,130 married, female nurses in the United States, Rice et al. found that hysterectomy was associated with a 20% reduction in the rate of subsequent ovarian cancer. Tubal ligation resulted in a 24% decreased risk of ovarian cancer. Unilateral oophorectomy was found to reduce the risk of ovarian cancer by 30%. The mechanism by which hysterectomy and tubal ligation reduce ovarian cancer is not known, but it is possible that the interruption of the pathway of unknown pathogens from the vagina to the ovary may be involved.

Traditionally, many gynecologists have recommended against prophylactic oophorectomy in women younger than the age of 40 and offered oophorectomy to postmenopausal women. There is no consensus for the management of women between 40 and 50. There are no data to support these approaches. It seems reasonable to discuss the possibility of oophorectomy before planned hysterectomy for benign disease in women older than age 45. However, it should be made clear to those women that there are some definite disadvantages to oophorectomy, especially if they will not or cannot use estrogen replacement therapy postoperatively. Each patient brings her own ideas and experiences to this discussion, and the surgeon should try to counsel the

patient and her family so she will be happy with her decision about oophorectomy.

PREOPERATIVE COUNSELING

The gynecologist needs to talk with the patient while trying to decide whether a hysterectomy is indicated. Fortunately for the patient and the gynecologist, time for talking is available in almost every instance. A hysterectomy is rarely an emergency. Unfortunately, the time may not be used properly. In a survey of women who underwent hysterectomy, Neefus and Taylor found that there is an urgent need for patient education on the physical, psychological, and sexual aspects of hysterectomy.

Often, the need for hysterectomy is obvious. There is a complete prolapse, or a large and symptomatic leiomyomatous uterus, or a pelvic cancer. However, under all circumstances, the indications for hysterectomy should be carefully explained. It is important that whenever possible, not only the patient but, in addition, her family and/or those who will support her during the perioperative period be involved in these discussions. The “informed consent” should be explained clearly and in language that the patient and her family can understand. Treatment alternatives should be discussed and the reasons for recommending one approach over another should be explained. The risks, benefits, and side effects, specifically including the possibility of transfusion, must be reviewed, but in such a way that the patient is not unduly alarmed. Then, the patient and the physician should spend the time necessary to discuss any questions that the patient or family may have. Additionally, the patient should be encouraged to ask questions about the operation: how long it will take, the recuperation period in the hospital and at home, whether ovarian function should be conserved, and possible hormone replacement therapy. Patient information pamphlets and videos also are useful for preoperative education. The expectations of the patient and her family are very important in her postoperative view of the success (or failure) of the operation.

Because the uterus is the main organ associated with reproduction, it is an important part of a woman's self-image; in some cultures, a woman's sexuality and reproductive potential are viewed as important parts of her value or status in her family or society as a whole. For these reasons, it is absolutely necessary for the gynecologic surgeon to understand and help patients cope with the emotional turmoil that may accompany hysterectomy. For some women who have had their children and need a hysterectomy for prolonged heavy bleeding and cramping associated with uterine fibroids or those with a diagnosis of endometrial cancer, the indications are clear, the benefits are obvious, and the loss of reproductive capacity often is not of great concern. The emotional stress of hysterectomy on these women is usually minimal, and psychological adjustment often is rapid and complete. However, the young woman needing a hysterectomy for cervical cancer or a complication of pregnancy may have considerable difficulty adjusting to the loss of her uterus. Even the 32-year-old woman with three children and severe uterovaginal prolapse may not be comfortable with the idea of hysterectomy. The gynecologist must be sensitive to these possible concerns and anxiety. Even when the patient does not express any emotional distress, the gynecologist can provide an opening for the patient to discuss her feelings by statements such as “Most studies have shown no change in sexuality and sexual function after hysterectomy, but I know many patients have concerns about this. Do you have any questions?” The support of the patient's husband or partner and her family and friends are very useful elements to prevent and manage depression and the emotional stress of hysterectomy. The wise surgeon includes members of this support group in preoperative discussions and encourages them to

P.702

ask questions or express opinions that actually may be questions or opinions of the patient that she may be hesitant to express.

Despite improvements in preoperative counseling in recent years, some women are depressed after hysterectomy. In most instances, this depression is short-lived and self-limiting, but the gynecologist should be

alert for severe or prolonged symptoms of continued lack of energy, inability to return to normal activities of daily living, sleep difficulties, or other indicators of depression following surgery. Occasionally, antidepressants and/or psychiatric consultation may be necessary. The psychological aspects of pelvic surgery are extensively reviewed in [Chapter 3](#).

PREPARATION FOR HYSTERECTOMY

A complete history and physical examination is indicated before any operative procedure. This evaluation is detailed in [Chapter 8](#), but a few points deserve emphasis. Although it is appropriate to ensure that all gynecologic symptoms have been evaluated carefully and a pelvic examination performed, a complete physical evaluation is necessary to be sure the patient can safely tolerate anesthesia and major surgery. Appropriate consultation should be sought where indicated to assure safe anesthesia administration and anticipation of any perioperative medical problems. In addition to a preoperative hematocrit or hemoglobin and other laboratory tests as indicated by the patient's medical condition, it is important to have a recent Pap or HPV test to rule out cervical neoplasia. A pregnancy test in reproductive-age women is recommended before surgery.

Preoperative chest x-rays are no longer routinely recommended but may be indicated in women with a history of cardiorespiratory disease or malignancy. An intravenous pyelogram, ultrasound, or computed tomography scan of the abdomen and pelvis may be useful in women with uterine or extrauterine pelvic masses, but these are not indicated routinely.

Mechanical bowel preparation before simple hysterectomy has been largely abandoned in recent years. However, when the uterus is large or extensive adhesiolysis is anticipated, we prefer to have the colon evacuated before pelvic surgery to facilitate exposure and reduce trauma to the bowel caused by retraction and packing. In these patients, we recommend a clear liquid diet on the day before surgery, and 250 mL of oral magnesium citrate is an effective laxative on the afternoon before surgery. A bisacodyl suppository immediately on arising on the morning of surgery will evacuate any residual feces or fluid in the sigmoid and prevent contamination of the field during surgery. A complete mechanical or antibiotic bowel preparation is indicated only when intestinal surgery is a possibility (see [Chapter 47](#)).

Surgical site infection risk is decreased by routine use of prophylactic intravenous antibiotics given approximately 30 minutes before the skin incision. First- or second-generation cephalosporins, such as cefazolin or cefoxitin, are commonly used. Recommended antibiotic regimens are shown in [Table 32A.4](#). Prospective, randomized trials have shown a significant reduction in the risk of febrile morbidity and infection in both abdominal and vaginal hysterectomy. Studies have shown no benefit of continuing antibiotics postoperatively, although a second dose of antibiotics generally should be given during hysterectomy procedures that last longer than 3 hours. Some have suggested that bacterial vaginosis increases the risk of postoperative infections after vaginal hysterectomy, but preoperative evaluation and treatment remain controversial. Although povidone-iodine douches and antibiotic scrubs before surgery have been widely used in the past, studies have shown no added benefit when perioperative intravenous antibiotics are employed.

TABLE 32A.4 Recommended Prophylactic Antibiotic Regimens for Hysterectomy

ANTIBIOTIC	DOSAGE	HALF-LIFE
Cefoxitin	2 g IV	0.5-1.1 h
Cefazolin	1-2 g IV	1.2-2.5 h

Cefotetan	1-2 g IV	2.8-4.6 h
For patients with an immediate sensitivity to penicillin		
Metronidazole ^a	1 g IV	6-14 h
OR		
Metronidazole ^b + gentamicin or a quinolone	1 g IV 1.5 mg/kg or 500 mg	
OR		
Clindamycin ^b	900 mg IV	2-5 h
IV, intravenously.

If necessary, the pubic and/or vulvar hair should be clipped with an electric clipper or even scissors rather than shaved. The patient should be instructed not to shave the operative site before surgery because it has been shown to increase the risk of wound infection and cellulitis.

TOTAL ABDOMINAL HYSTERECTOMY: SURGICAL TECHNIQUE

Previous editions of Te Linde's text have described gradually evolving modifications of Edward H. Richardson's technique for abdominal hysterectomy with which thousands of gynecologic surgeons have been trained over the years. The operative technique was first published in 1929, and because Te Linde felt it was a classic, he quoted it word for word in the fourth edition of this textbook with two added "modifications." This was the edition on my bedside table when I was a resident. I have had the good fortune to operate with many fine surgeons, including E. Stewart Taylor and Felix Rutledge, and have been challenged by many young residents over the years. These experiences have been further enhanced by discussions of surgical technique with gynecologists from around the world, who have suggested changes or ideas that I have tried and sometimes incorporated into my basic technique for abdominal hysterectomy. Although it is important

P.703

to learn a basic technique for standard abdominal hysterectomy, every surgeon should be interested in observing new and different techniques or modifications to be tried from time to time when appropriate. As a resident, you should try all of the different techniques used by the different attending physicians, always asking why this clamp is used or that suture or needle is selected or why the cuff is left open or closed. Having tried many different ideas, each gynecologic surgeon gradually evolves her or his own basic techniques that feel comfortable, work for him or her, and make sense. Because each patient is unique, it also is useful to have experience with different techniques and various modifications of the basic operation so that when the occasion calls for it, an alternative technique that is more suitable for the particular situation can be employed. Our basic

technique for abdominal hysterectomy and several modifications are described in the following.

On the day of surgery, the surgeon always attempts to see the patient and her family and supporters before she is brought into the operating room. Although surgery may be routine to the gynecologist, major surgery is often a once-in-a-lifetime, frightening experience for the patient. The calm reassurance of the surgeon and the professional and caring nature of the entire operative team are very helpful to the patient and her family at this point. The focus of attention should be on the patient and her surgery. A certain amount of relaxed chatter about someone's birthday or hospital gossip is reasonable, but the patient should feel that the concentration of the surgical team is focused on the surgery at hand. Remarks about other patients or how the surgeon had to stay up all night with a difficult patient in labor are not appropriate. An equipment problem or technical difficulties that affect the operation certainly should be discussed with the surgeon before starting the procedure; however, it is inappropriate to talk about these in front of the patient. Remarks such as "The table is broken and won't go down" or "We weren't able to get your favorite retractor today" may not affect the performance of the operation, but such statements just before a patient is ready to be anesthetized may raise serious doubts as to whether the operative team is optimally prepared for this operation and may raise uncomfortable questions later if complications or unexpected results occur.

Positioning

The patient is brought into the operating room and placed in the supine position on the operating table. It is nice to place a warm blanket on the bed immediately before the patient's arrival and to cover the patient with a blanket from the warmer or use a warm air circulating blanket when she is positioned on the operating table because most operating rooms are somewhat cool and the patient is only lightly clothed.

When the patient has been anesthetized, a careful examination under anesthesia is done. At this point, the surgeon should concentrate on potential problems affecting resectability. Is there nodularity from endometriosis in the cul-de-sac that may make dissection of the rectum off of the posterior cervix difficult? Is the myoma in the broad ligament really wedged into the pelvic sidewall or does it move freely with the uterus? The mobility and descent of the uterus under anesthesia are particularly important when a vaginal hysterectomy is being considered. These potential problems and possible solutions should be considered and possibly discussed with the operative team while the surgeon scrubs. By consideration and discussion of potential problems and possible solutions, difficulties that arise during surgery may have already been contemplated and plans and solutions already developed.

The vagina and perineum are prepped with antiseptic solutions, and a Foley catheter is inserted. I prefer to position the patient supine on the operative table with a soft pillow under her knees to provide gentle flexion. The patient's legs provide a table on which instruments can be placed. These days, it is common for the patient to be positioned in the low Allen stirrups with her legs slightly apart. This allows an assistant to stand between the legs and provides ready access to the vagina for examination or manipulation and the urethra for cystoscopy, which is routine in most pelvic surgery.

The abdomen then is prepped from the anterior thighs to the xiphoid, and sterile drapes are applied. In most instances, abdominal hysterectomy for benign disease can be done through a low transverse incision; most gynecologists prefer a Pfannenstiel incision, which is cosmetically appealing and strong. If more exposure is required, a Cherney or Maylard incision can be used. A midline incision is usually done if malignant disease is present or exposure to the upper abdomen may be required. The choice of abdominal incision is discussed in [Chapter 14](#).

Once the abdomen is opened, the pelvic pathology is carefully evaluated and the abdomen explored. The operating surgeon should examine the appendix and palpate the upper abdominal organs, including the kidneys, liver, gallbladder, stomach, spleen, diaphragm, bowel, and omentum. The retroperitoneal nodes in the pelvic and

paraortic area should be palpated and the area of the pancreas gently examined to identify any abnormalities. The status of these organs should be recorded in the operative note, and an intraoperative consultation may be indicated if abnormalities are identified.

After the abdomen has been explored, a slight Trendelenburg position should be requested, a self-retaining retractor placed, and the bowel packed superiorly to afford good exposure of the pelvis. Any adhesions of the small bowel or rectosigmoid may need to be divided at this time so that the bowel can be mobilized out of the operative field. In relatively thin patients with benign disease, I prefer to use a Kirschner retractor, which is light and simple and provides a choice of several fairly wide, shallow blades that fit on a square frame, allowing adjustable retraction laterally, inferiorly, and superiorly. The cecum and sigmoid are packed first with separate packs, and a third rolled or folded pack is placed in the center behind the superior retractor blade to hold back the small bowel. In larger patients, or patients with a longer midline incision, a Bookwalter or Omni-Tract retractor, with many options of blades and variable positioning, is invaluable. These large retractor systems are screwed onto the operating table and provide excellent retraction in almost any situation. They are particularly useful in obese patients.

Hysterectomy

When the bowel has been packed away and exposure to the pelvis is satisfactory, the round ligaments and uteroovarian ligaments are grasped on each side with a Kocher clamp, elevating the uterus out of the pelvis. In some cases of extensive inflammatory disease, endometriosis, malignancy, or very large fibroids, uterine mobility is limited; but in most benign conditions, uterine mobility is satisfactory. The operator is generally on the patient's left side so that the right-handed surgeon can use her or his dominant hand to extend down into the pelvis. The first assistant is on the opposite side. The uterus is retracted to the patient's left side, and the right round ligament is stretched taut. A 0 delayed absorbable suture is placed under the round ligament approximately halfway

P.704

between the uterus and the pelvic sidewall. The small artery of Sampson runs just under the round ligament and, in many cases, transilluminating this area allows the surgeon to easily visualize the artery and be sure that the suture is passed under it so that the artery will be ligated. A second suture is placed approximately 1 cm medial to the first suture; these two sutures are now tied simultaneously by the surgeon and first assistant. Clamping the round ligament is an extra step that is rarely necessary.

With traction on these sutures, the round ligament is held taut and divided with Metzenbaum scissors between the two suture ligatures ([Fig. 32A.1](#)). This opens the retroperitoneal space, which is almost always a free space for blunt dissection, even in the patient with extensive tumor, inflammatory disease, or endometriosis. *If the ovaries are to be removed at the time of hysterectomy*, the peritoneal incision then is extended superiorly, lateral to the ovary and parallel with the infundibulopelvic ligament. The peritoneal incision also can be extended anteriorly down to the bladder reflection, but the peritoneum over the anterior cervix does not need to be divided at this time because exposure of this area is not yet required and bleeding may be encountered. With the index finger and the tip of the suction or the back of a tissue forceps, the surgeon gently divides the loose areolar tissue of the retroperitoneum, identifying the external iliac artery on the medial surface of the psoas muscle. In most cases, the artery can be identified very easily, and blunt dissection is used to extend the exposure superiorly to the level of the bifurcation of the common iliac artery. The ureter always crosses the pelvic brim at this location and should be identified easily on the inside of the medial leaf of the peritoneum at this point. The internal iliac or hypogastric artery dives into the pelvis at this location parallel to the ureter, and it should be identified also. This retroperitoneal exploration may seem awkward at first, but with practice, the external and internal iliac arteries and ureter can be visualized easily in 10 to 20 seconds.

FIGURE 32A.1 The technique of abdominal hysterectomy begins with the round ligament. The ligament is ligated with transfixion sutures and cut. The broad ligament is opened.

If the ovary is to be removed, a hole in the peritoneum between the ureter and the ovarian vessels superior to the ovary can be made under direct vision. We use a fairly fine sharp-pointed 9-inch clamp that can be passed gently through the peritoneum from lateral to medial against and between two fingers, supporting the medial side of the peritoneum. Alternatively, the peritoneum may be divided sharply or with the electrosurgical blade. We prefer to use a fairly delicate tonsil clamp on the infundibulopelvic ligament because it reminds us to isolate the vessels and take a fairly small pedicle. If there is significant inflammation or edema, a larger clamp, such as a Heaney clamp, may be used on the infundibulopelvic ligament pedicle ([Fig. 32A.2](#)). A second back clamp then is placed distally and the ovarian vessels divided between the two clamps. This pedicle then is ligated with a free tie, and then, a second transfixion suture ligature is placed for safety between the free tie and the clamp. Zero-gauge delayed absorbable sutures and ties are used throughout. The suture ligature is placed distal to the free tie so that if the needle happens to puncture one of the ovarian vessels, the vessel has already been ligated by the more proximal free tie. The back clamp is ligated with a single free tie, and the posterior peritoneum then is torn or cut above the ureter toward the back of the uterus, mobilizing the ovary, which is then tied to the clamp on the right side of the uterus to keep it from flopping around and obscuring the operative field. The sutures on the round ligaments and infundibulopelvic

ligament then are cut. The procedure is repeated on the patient's left side.

FIGURE 32A.2 A: The infundibulopelvic ligament is doubly clamped, and the ovarian vessels are cut between the clamps. Care is taken to be sure the ureter is clear as the clamps are applied. **B:** The proximal pedicle is ligated with a free tie followed by a transfixion suture ligature.

If the ovary and tube are to be left in situ at the time of hysterectomy, a window in the peritoneum beneath the fallopian tube between the uterus and ovary is made sharply or bluntly, and a heavy clamp—such as a Heaney, Kocher, or similar clamp—is used to clamp the uteroovarian pedicle (Fig. 32A.3). The round ligament should not be included in this clamp. The clamp that was initially placed on the round ligament and fallopian tube just lateral to the uterine fundus at the beginning of the procedure serves as the back clamp for this pedicle. The tube and uteroovarian ligament are divided and the pedicle ligated as previously noted with a free tie followed by a suture ligature. The ovary and tube may be left in the posterior pelvis if exposure is adequate or gently packed in the paracolic gutter, with care being taken to ensure that the blood supply is not compromised.

The next step is the dissection of the bladder from the anterior cervix. With the uterus elevated out of the pelvis by traction on the clamps on the tube and round ligament, the bladder peritoneum is divided just inferior to its attachment to the lower uterine segment. If the peritoneum is divided 5 to 10 mm below its uterine attachment, it is usually mobile, and an avascular plane of loose areolar tissue can be identified between the posterior bladder wall and the anterior cervix. We begin this dissection sharply using the Metzenbaum scissors. With upward traction on the bladder peritoneum and the uterine fundus stretched tightly out of the pelvis, the tips of the Metzenbaum scissors should rest lightly on the fascia overlying the cervix and small bites used to develop this

tissue plane, dissecting the bladder from the anterior cervix (**Fig. 32A.4**). This dissection should take place over the cervix, because if it is carried too far laterally, bleeding may be encountered, and the uterine vessels or ureters could be injured. Except in patients with a previous cesarean section or an adherent bladder for other reasons, this bladder dissection often can be done bluntly, but it is good practice to do it sharply from time to time so that in those patients in whom the bladder is adherent and sharp dissection is required, the technique will be familiar. Blunt dissection of the bladder can be accomplished easily by

P.706

grasping the uterus and lower uterine segment between both hands and gently using the first one or two fingers to advance the bladder, as illustrated in Richardson's classic paper (**Fig. 32A.5**). It also is possible to grasp the uterus with your dominant hand, placing the thumb in front on the anterior cervix and the fingers behind the uterus. The thumb is gently pushed downward toward the cervix and inferiorly toward the vagina, gently dissecting the bladder off of the cervix and lower uterine segment. With this technique, the pressure is against the cervix rather than against the bladder, which should minimize

P.707

the risk of bladder injury. Excessive force should not be used. As the bladder is dissected below the cervix, the thumb in front and the fingers behind come into closer opposition because they now have only the vaginal wall between them. The dissection is extended laterally to encompass the full cervix. Usually, it is not necessary to dissect the rectum off of the posterior cul-de-sac; but if adherent rectum prevents good posterior exposure, it should be dissected free after the uterine vessels have been divided.

FIGURE 32A.3 When the ovary is to be conserved, a peritoneal window is made above the ureter and the tube and utero-ovarian ligament are clamped. This pedicle is divided and doubly ligated.

FIGURE 32A.4 The bladder is mobilized inferiorly by sharp dissection away from the cervix. To avoid unnecessary bleeding, this step may be done in stages as necessary.

FIGURE 32A.5 The bladder and, if necessary, the rectum can be gently advanced with blunt dissection. The depth of this dissection can be checked by squeezing the anterior and posterior fingers together below the cervix. (From Richardson EH. A simplified technique for abdominal panhysterectomy. *Surg Gynecol Obstet* 1929;48:248, with permission.)

Once the bladder has been freed from the anterior cervix, the uterine artery and vein are skeletonized ([Fig. 32A.6A](#)). The uterus is pulled sharply to the patient's left side, and the surgeon gently dissects the loose fatty tissue adjacent to the lateral lower uterine segment on the right. The uterine artery is usually found immediately adjacent to the uterus at the level of the internal cervical os. In most patients, the uterine artery is easily exposed by holding the tissue laterally and gently "raking" with the Metzenbaum scissors slightly opened from medial to lateral. "Skeletonizing" the uterine artery and vein allows them to be clamped more accurately, with less adjacent tissue, and a smaller vascular pedicle, which allows more precise and more secure ligation. However, good surgical judgment should be used so that excessive attempts to isolate the vessels do not produce unnecessary bleeding. When the vessels are exposed, a fairly heavy, slightly curved clamp then is used to clamp the vessels just adjacent to the uterus ([Fig. 32A.6B](#)). We prefer to use a Heaney, Zeppelin, or Masterson clamp for these pedicles. The tip of the clamp should be around the vessels, and the clamp should come across the pedicle as close to a right angle as possible, rather than at the diagonal, so that the least amount of tissue will be incorporated in the pedicle. The tip of the clamp should not include too much cervical or uterine tissue because this makes application of subsequent clamps more difficult. A second clamp can be placed above the first for added safety, if desired, and a third or back clamp used to prevent annoying back bleeding from the uterus after the vessels have been cut if the uterus is enlarged or the other vascular pedicles to the uterus have not been secured.

If exposure is satisfactory after a single clamp has been placed on the right uterine artery and vein, we skeletonize the uterine vessels on the patient's left side and place a clamp on these vessels as well. If the uterus

is small, no back clamp is required because the four major vessels supplying the uterus have now been clamped or ligated. Next, the uterine vessels are cut with scissors or a knife and the pedicle doubly ligated with 0 delayed absorbed sutures. We prefer to use a small tapered point needle (CT-2, Ethicon) for these pedicles because we feel that large needles are more difficult to place in the small confines of the deep pelvis. If a back clamp has been used, it is now ligated and removed so that the field is not obscured by an excessive number of clamps. The technique illustrated here starts with the right side, but the patient's anatomy and surgical preference should guide which side is skeletonized and clamped first.

Hemostasis should be good at this point. If not, any bleeding should be controlled. The bladder is again checked to ensure it is well below the cervix. If the rectum needs to be dissected from the posterior cervix, this should be done now. This is usually not necessary for a simple abdominal hysterectomy for benign disease. The peritoneum of the posterior cul-de-sac between the uterosacral ligaments can be divided easily, and blunt dissection of the posterior vaginal wall from the anterior rectum usually is easy, although the rectosigmoid occasionally may be densely adherent to the posterior uterine segment or cervix by endometriosis or pelvic inflammatory disease. If the bladder and/or rectum is too densely adherent and there is concern that further attempts at dissection may damage them or cause troublesome bleeding, a supracervical hysterectomy should be considered.

Once the bladder has been freed from the cervix anteriorly and the rectum posteriorly, the uterus is placed on tension, exposing the deeper portions of the broad ligament and

P.708

pulling the lower uterine segment away from the ureter. A medium-width malleable retractor may be useful to retract the bladder anteriorly; if necessary, a wide malleable retractor in the posterior cul-de-sac will provide deep exposure posteriorly. In most cases, a series of straight Heaney or Zeppelin clamps can now be used to successfully clamp the remaining portion of the broad ligament ([Fig. 32A.7](#)). The tips of these clamps should be placed on the lateral portion of the cervix, and the upper portion of the jaw should lie immediately adjacent to the previous pedicle. As the clamp is gently squeezed closed, the tip slides off of the firm cervix, finally closing snugly against the lateral wall of the muscular cervix. By staying close to the cervix in this way, the risk of damaging the ureter, which is not too far away laterally, is minimized. The pedicle then is cut with heavy scissors or a knife. A millimeter or two of tissue may be left medial to the clamp as insurance, but this is not necessary. The tip of the transfixion suture needle is placed at the lateral tip of the clamp jaw; if the pedicle is longer than 1 cm, we recommend using a Heaney suture ligature so that the upper end of the pedicle is secondarily transfixed to prevent it from slipping out of the ligature. While good exposure is maintained, one or two pedicles are tied on each side, and then the procedure is repeated on the opposite side until the level of the cervical-vaginal junction has been reached. Once again, the bladder and rectum are checked and advanced if necessary to be sure that they are well clear and the anterior and posterior vaginal walls exposed.

FIGURE 32A.6 A: The uterine vessels are skeletonized. **B:** A curved Heaney clamp is used to clamp the uterine vessels immediately adjacent to the uterus. They are ligated by two suture ligatures.

Sharply angled large Zeppelin clamps are used to clamp across the vagina below the cervix. These clamps include the base of the cardinal ligaments laterally, the uterosacral ligament posteriorly, and the vaginal wall anteriorly and posteriorly. A clamp is applied from each side; in most cases, the

P.709

tips of these clamps meet in the middle just below the cervix ([Fig. 32A.8](#)). A knife or heavy, sharply angled Jorgenson scissors is used to divide the vagina above these clamps and below the cervix. The uterus is removed and placed in a pan on the back table for later examination. Care is taken not to contaminate the surgical field by touching the vagina or vaginal portion of the cervix or dripping vaginal fluid in the pelvis. A single figure-of-eight suture is placed between the tips of the two clamps to close the midportion of the vagina. The ends of this suture are held initially and not tied. A Heaney suture ligature is placed on each of the lateral clamps with the second bite going through the uterosacral ligament posteriorly. Inclusion of the uterosacral and cardinal ligament in this pedicle provides excellent support of the vaginal apex. When these lateral sutures have been tied, the figure-of-eight suture in the middle then is tied also. The lateral sutures are cut and the figure-of-eight in the middle of the cuff is held to provide traction on the vaginal apex. With this closed cuff technique, the vagina is never exposed, which reduces contamination of the pelvis. However, there may be instances, such as a large cervical myoma, when there is a very deep vaginal fornix, and a closed technique would remove too much vagina. Entry into the vagina with the electrosurgical blade and then carefully opening the vagina circumferentially under direct vision is an option in such cases. As the vagina is opened, the full-thickness vaginal edges are grasped with Kocher clamps as the dissection proceeds. In this instance, we generally close the vaginal cuff with a series of figure-of-eight stitches of 0 delayed absorbable suture, taking care to incorporate the uterosacral and cardinal ligaments into the cuff for support. Since the advent of prophylactic antibiotics for hysterectomy many years ago, we have not run the vaginal wall with a locking stitch for hemostasis and left the cuff open for drainage (closing the pelvic peritoneum over the open cuff).

FIGURE 32A.7 After the uterine artery and vein have been ligated, the remaining lower portion of the broad ligament is clamped with a series of straight clamps. The tips are placed on the edge of the cervix and the back of the jaw immediately adjacent to the previous pedicle.

FIGURE 32A.8 A: After checking to be sure the bladder and rectum are clear, the vagina is cross clamped with long, sharply curved Zeppelin clamps just below the cervix (*dotted line*). The vagina is divided just above the

clamps with a knife or angled scissors. **B:** The vaginal cuff then is closed with a figure-of-eight suture in the middle and Heaney suture ligatures on the angles, including the uterosacral and cardinal ligaments for support.

In the classic Richardson technique, the peritoneum over the posterior cervix is divided, the peritoneum is dissected off the cul-de-sac, and the rectovaginal septum is entered to reflect the rectum posteriorly. In our experience, this has not been necessary in the vast majority of patients with benign disease. In contrast to the anterior bladder dissection, this posterior peritoneum is much more adherent. There is usually some bleeding associated with this dissection, making it both bloody and time-consuming. With the Richardson technique, the uterosacral ligaments also are clamped separately and subsequently attached to the vaginal cuff for support. In the technique described above, this is accomplished in a single step.

STEPS IN THE PROCEDURE

Abdominal Hysterectomy

1. Open the abdomen and visualize and/or palpate the pelvis, abdomen, and retroperitoneal area to evaluate the presence of normal or abnormal findings and anatomy.
2. Place a retractor if needed to provide adequate exposure for safe pelvic surgery.
3. Grasp the round ligament, utero-ovarian ligament, and fallopian tube with a large bite of a straight clamp (Kocher) where they arise from each side of the uterus. One clamp on each side will provide an easy way to manipulate the uterus.
4. Elevating the uterus out of the pelvis, the anatomy is reevaluated and any adhesions to adjacent bowel or omentum are freed.
5. The round ligament on one side is ligated and divided, opening the retroperitoneal space.
6. If the ovaries are to be preserved, the utero-ovarian pedicle is clamped, divided, and ligated.
7. If the ovary is to be removed, the retroperitoneal space is opened, the ureter is identified, and the infundibulopelvic ligament (containing the ovarian artery and vein) is isolated, clamped, divided, and ligated.
8. Steps 5, 6, and 7 are then repeated on the opposite side.
9. The bladder is then dissected free from the anterior wall of the lower uterine segment and cervix so that the anterior vaginal wall is exposed.
10. The uterine vessels are skeletonized on both sides at the level of the lower uterine segment.
11. The uterine vessels are clamped bilaterally. The uterine vessels are then divided and suture ligated (usually with two sutures on each side).
12. The exposure of the anterior and posterior vaginal wall just below the cervix is again checked, and the bladder and rectum are dissected still more if additional exposure is needed to safely clamp across the vagina below the cervix.
13. The remaining portion of the broad ligament on each side of the cervix is then clamped, divided, and ligated using a series of clamps until the cervix is reached, and the broad ligament on each side has been detached from the lateral cervix and upper vagina is well exposed.
14. With the uterus strongly elevated out of the pelvis, large right angle clamps are placed across the vagina just below the cervix—one from each side with the tips meeting the middle.
15. The vagina is divided with a knife or long heavy curved scissors above the clamps, and the uterus and cervix are passed off the operative field.
16. The vaginal apex is closed. Heaney suture ligatures can be used on each side incorporating the uterosacral and cardinal ligaments into the cuff for support.
17. The pelvis is irrigated with warm, sterile saline and hemostasis is checked. The packs and retractors are removed, and the sigmoid colon is carefully replaced in the pelvis.

Closure

After the pelvis has been copiously irrigated with warm saline, the pedicles are inspected carefully to be sure that hemostasis is present. Electrocautery or suture ligatures with 3-0 absorbable sutures on fine needles are used to control small bleeders. The location of the ureters, bladder, and major vessels should be known when placing these sutures. Common sites of ureteral injury during abdominal hysterectomy include the infundibulopelvic ligament where the ovarian vessels are ligated, the area of the uterine artery ligation, and the bladder base. Distorted anatomy associated with fibroids, endometriosis, and malignancy is a signal for special care to avoid ureteral injury. The pelvis is not reoperitonealized, but the rectosigmoid colon is gently laid over the vaginal cuff to cover this raw surface and minimize the risk of small bowel adhesions. The packs and retractor are removed, the abdomen checked again for hemostasis, and the omentum placed anteriorly to minimize the risk of intestinal adhesions to the abdominal incision. The anterior peritoneum is closed with delayed absorbable suture, although some surgeons today feel that it is unnecessary to close the abdominal peritoneum. The fascial closure should be commensurate with the patient's risk of infection and hernia. Generally, a running monofilament delayed absorbable suture such as PDS (Ethicon) on a larger, curved, tapered needle (CT-1, Ethicon) can be used. If there is a significant risk of dehiscence secondary to infection, obesity, or other medical problems, interrupted sutures or a mass closure technique may be used. Closure techniques are illustrated in [Chapter 14](#). Because patients are often discharged by the third or fourth postoperative day, we generally prefer to close the skin with a subcuticular absorbable suture, which eliminates the necessity for a return to the office for suture or staple removal.

After the patient has been taken to the recovery room, the surgeon should speak with the family, preferably face to face, to assure them that the patient is doing well and to review the operative findings with them. We also strongly recommend that the surgeon ask the circulating nurse to contact the family about once an hour to update them on the progress of the operation during the surgical procedure. This especially is helpful if there were any unknown questions going into the operation (Did the ovaries look normal? Was the endometriosis involving the ureter?). A brief operative note must be immediately recorded in the patient's chart describing the procedure, blood loss, fluid replacement, and if any packs or drains were left in the patient. Postoperative orders are written. A full and complete operative note should be prepared with emphasis on any unusual findings or variations from standard techniques.

SUBTOTAL ABDOMINAL HYSTERECTOMY

The technique of subtotal or supracervical abdominal hysterectomy is similar to the technique for abdominal hysterectomy as described, until the uterine vessels have been clamped and ligated. At this point, care should be taken to be sure that the bladder and rectum have been advanced at least far enough so that the cervix can be clearly visualized both anteriorly and posteriorly. The uterine fundus is strongly retracted out of the pelvis, and electrocautery is used to cut the cervix anteriorly just above the level of the ligated uterine vessels ([Fig. 32A.9](#)). A shallow V-shaped incision is used both anteriorly and posteriorly until the uterine fundus is excised. The "coagulate" mode of the electrosurgical unit is used, and hemostasis usually is excellent. An attempt to cut across the upper cervix should not be made until the uterine vessels have been ligated bilaterally. Bleeding will be prohibitive. Once the fundus has been amputated, several generous figure-of-eight sutures on a large needle then are used to close the upper endocervix in a hemostatic fashion. The top of the cervix is checked for bleeding, and the bladder peritoneum may be used to cover this cervical stump to minimize the risk of adhesions.

POSTOPERATIVE CARE

Although routine postoperative care is thoroughly reviewed in [Chapter 9](#), there are several facets that should be emphasized following hysterectomy.

Studies over the past few years have indicated that early feeding after hysterectomy is safe and actually results in earlier discharge. In many cases, patients are able to tolerate solid food on the first postoperative day following abdominal hysterectomy. The surgeon should nevertheless take into account the amount of dissection and bowel trauma that occurred during the operative procedure and be conservative with the diet orders if a postoperative ileus is anticipated. Patients and their caregivers always should be cautioned not to eat or drink if they feel nauseous or are vomiting. Having a bowel movement or even the passage of flatus are no longer requirements for hospital discharge as long as the patient has normal, active bowel sounds, is tolerating solid food, and is not distended.

P.711

FIGURE 32A.9 Subtotal or supracervical hysterectomy. **A:** After the uterine vessels have been ligated, the fundus is amputated using the electrocautery in a shallow cone-shaped technique. **B:** The cervix or lower uterine segment then is closed with several large figure-of-eight sutures.

Most patients have a Foley catheter for bladder drainage overnight following abdominal hysterectomy, although Richardson and many gynecologic surgeons have shown it is possible to avoid this in many patients with the help of a good, enthusiastic nursing staff. In most situations, however, a catheter is inserted before hysterectomy

and removed on the first postoperative day. In patients with bladder injury or continuous epidural for postoperative pain relief, more prolonged catheter drainage may be indicated.

The length of postoperative hospitalization has decreased dramatically in the last 20 years. Although it was common in the past for women to remain in the hospital for 7 to 10 days after abdominal hysterectomy, most patients are now discharged home in 3 or 4 days. This trend toward a shorter hospital stay requires better patient education and a reasonable home environment to which the patient can be safely and comfortably discharged. The surgeon must also carefully evaluate the patient before discharge and resist pressure from insurance companies and hospital administrators when the patient's condition indicates that she is not suitable for an early discharge. The patient and her family must be instructed on proper care. Can she take a bath? Can she go up and down the stairs? Can she pick up her grandchild? How soon can she drive a car? A printed set of instructions for home care as well as answers to frequently asked questions are good ideas. Liberal use of home visiting nurses is also recommended, especially in older or more debilitated patients or in those whose home situation may be less than ideal.

COMPLICATIONS

Complications from hysterectomy can be diagnosed intraoperatively or postoperatively. In a thorough review, Harris found an overall complication rate of up to 50% associated with abdominal hysterectomy, but serious complications requiring reoperation or long-term disability are relatively uncommon. Reoperation rates of 4% to 4.3% have been reported by Gambone and associates and Browne and Frazer. The most common complications include infection, hemorrhage, and injuries to adjacent organs ([Table 32A.5](#)). Prevention and management of hemorrhage, infection, and operative injury complications are extensively discussed in several chapters of this text. Good surgical training, proper patient selection, knowledge of the anatomy, and good surgical judgment—which includes knowing your personal skills and limits—are all keys to minimizing complications.

Several factors have been consistently shown to be associated with an increased risk of complications related to hysterectomy. These are increasing age, medical illness, obesity, and malignancy. These conditions are beyond the control of the gynecologic surgeon, but they should be considered in the risk:benefit ratio when considering surgery, and every effort

P.712

should be made to have the patient in the best possible condition at the time of surgery.

TABLE 32A.5 Complications of Hysterectomy

COMPLICATION	ABDOMINAL	VAGINAL	LAPAROSCOPICALLY ASSISTED VAGINAL
<i>Bleeding</i>			
Hemorrhage	1%-2%	1%-5%	1%
Transfusion	2%-12%	2%-8.3%	1.58%
<i>Infection</i>			

Unexplained fever	10%-20%	5%-8%	2.14%
Operative site	6.6%-24.7%	3.9%-10%	0.54%
Wound	4%-8%	NA	NA
Pelvic	3.2%-10%	3.9%-10%	1.27%
Urinary tract	1.1%-5%	1.7%-5%	0.81%
Pneumonia	0.4%-2.6%	0.29%-2%	0.11%
<i>Injuries</i>			
Bladder	1%-2%	0.5%-1.5%	1%
Bowel	0.1%-1%	0.1%-0.8%	0.1%-1%
Ureter	0.1%-0.5%	0.05%-0.1%	0.19%

BEST SURGICAL PRACTICES

- Hysterectomy is one of the most common major operations performed in the United States. The most common indications are uterine leiomyoma, endometriosis, abnormal uterine bleeding, and malignancy. There are many techniques to perform a hysterectomy, including abdominal, vaginal, laparoscopic and laparoscopically assisted, total, and subtotal. Before surgery, the surgeon should discuss the indications, other management options, choice of surgical approach, risks and potential complications of surgery, and expected outcomes with the patient and her supporters and obtain a fully informed operative consent.
- Numerous prospective randomized studies have shown that total abdominal hysterectomy results in the same or better postoperative sexual function, urinary tract and bowel function, and pelvic support as does supracervical hysterectomy.
- Prophylactic antibiotics administered within 1 hour before the initial incision significantly reduce the risk of a surgical site infection. There is no advantage to continuing antibiotics after surgery in an uninfected patient.
- The surgeon and the surgical team should be completely focused on the operation. Thoughtful preoperative

preparation, careful surgical technique, well-reasoned judgment intraoperatively, and attentive postoperative care by a well-trained and interactive team will result in the best outcomes. Good communication between all members of the team is of great importance.

- We have found that the surgical techniques described in this chapter have been highly effective, but each surgeon should be familiar with a number of variations of standard hysterectomy technique and use appropriate variations that might suit the anatomy or pathology of a specific patient.

Chapter 32B

Vaginal Hysterectomy

Carl W. Zimmerman

DEFINITIONS

Endopelvic fascia—The layer of fibroelastic connective endopelvic tissue surrounding the bladder, vagina, and rectum. By investing the central pelvic organs in a continuous fashion from the vaginal introitus to the axial skeleton (sacrum), this tissue furnishes suspension to the entire uterovaginal complex and surrounding organs. Division of the paracolpium portion of this continuum is necessary for the completion of a vaginal hysterectomy.

Enterocoele—Formed from a separation of the rectovaginal fascia or the pubocervical fascia from the posterior cervix or anterior cervix, respectively. An enterocoele is a pelvic hernia that descends through the posterior vaginal fornix or anterior vaginal fornix. The most common location for an enterocoele is the posterior superior vaginal segment.

Intramymetrial coring—A surgical technique useful for removal of a large uterus during vaginal hysterectomy. After the uterine vessels have been divided, the myometrium can be circumferentially incised with a scalpel placed parallel to the long axis of the uterus and beneath the serosal covering of the uterus. In effect, coring converts the normal spherical shape of the uterus into an elongated cylindrical or rod shape, enhancing the surgeon's ability to facilitate uterine removal.

Morcellation—A surgical technique that is useful in reducing the size of an enlarged uterus after the paracolpium and uterine vasculature are ligated. The cervix is divided in a vertical fashion until the enlarged fundus is encountered. At that point, leiomyomata or myometrial segments can be removed using various types of sharp and blunt dissection until the fundus is sufficiently reduced in size to allow completion of extirpation of the organ.

McCall culdoplasty—The most commonly employed technique to reattach the uterosacral ligaments to the posterior vaginal cuff. This technique is useful in posterior enterocoele prophylaxis.

The technique of operating through the vagina is a prerogative of the gynecologic surgeon. Vaginal surgery is an essential prerequisite in the cultural and surgical training of a qualified gynecologist. However, in the United States, the most common operation gynecologists perform, the hysterectomy, is predominantly done abdominally or with one of the various endoscopic techniques.

Vaginal hysterectomy is the signature operation of the gynecologic profession. Ample evidence shows that the vaginal approach results in lower morbidity, less pain, more rapid recovery, more rapid return to normal activities, consumption of fewer health care dollars and resources, and a host of other benefits. A gynecologic surgeon should have the ability to perform abdominal, endoscopic, and vaginal hysterectomies. However, vaginal hysterectomy is, and should remain, the hallmark of gynecologic extirpative hysterectomy surgery, and the ability to perform hysterectomy via the vaginal route is a measure of surgical excellence. Vaginal hysterectomy is the “gold standard” for the surgical removal of the uterus because it is minimally invasive when compared to all other routes and techniques. The vaginal route should be considered primary unless a specific contraindication to that approach is recognized. Surgeons' preference of route is not an indication for avoiding the vaginal approach.

INDICATIONS

With the advent of evidence-based research and outcome studies, several randomized controlled trials have documented the advantages of the vaginal approach to hysterectomy. A 2010 Cochrane review concluded that vaginal hysterectomy, rather than abdominal, should be performed whenever technically feasible to reduce complications, shorten hospital stays, and accelerate the patient's return to normal activities. Endoscopic approaches were recommended only in those cases where the vaginal approach was not practical. Unfortunately, these clear evidence-based recommendations have not stimulated a change in physician practice patterns. Several authors have addressed the reasons for the continued dominance of the abdominal route for hysterectomy. Johns and colleagues suggested that the route of hysterectomy is usually determined by the skill, experience, and preference of the operating gynecologist. Unfortunately, few other parameters really matter in day-to-day practice. Dorsey and associates stated that the hysterectomy patient is best served by a surgeon who selects the route with which he or she is most confident and comfortable; however, ideal surgical care remains the responsibility of the surgeon. With that in mind, training programs should do whatever is necessary to provide graduates with skill sets that give patients access to evidence-based care. Julian has addressed this concept in detail.

Suggesting that the competency and comfort of the surgeon to perform a vaginal hysterectomy is a requisite to selection of that route may restrict its implementation as a primary technique. Surgeons who prefer to use abdominal or laparoscopic techniques may therefore not choose the route that is most minimally invasive to the patient. Hysterectomy guidelines have been developed in order to identify when abdominal hysterectomy is truly mandated ([Fig. 32B.1](#)). Using these guidelines, expert gynecologic surgeons have achieved vaginal hysterectomy rates in excess of 90% without sacrificing quality of care. In contrast, the overall US average for the vaginal approach is approximately 30%, with that figure including laparoscopically assisted vaginal hysterectomy. More recent data indicate that the advent of robotic techniques will further complicate the selection of hysterectomy route in a way that does not rely on outcome data. In an era of pressure to consume fewer health care dollars, the more expensive abdominal, laparoscopic, and robotic approaches continue to flourish despite incontrovertible evidence that vaginal hysterectomy provides as good or better outcomes at less cost.

Vaginal hysterectomy traditionally has been indicated for women with uterine or pelvic organ prolapse, and traditional indications for abdominal hysterectomy have included an

P.716

enlarged uterus, prior pelvic surgery, malignancy, and extrauterine disease, such as endometriosis or pelvic inflammatory disease. We now know that successful vaginal hysterectomy can be done in most of these patients; however, special techniques, such as uterine coring or morcellation, are often helpful, and such ancillary techniques as laparoscopic lymphadenectomy may be required in women with cervical or endometrial cancer. Laparoscopy may also be useful to help evaluate an adnexal mass prior to removal or the extent of endometriosis before completing the surgery with a vaginal hysterectomy and oophorectomy. Laparoscopy may also be used as an aid to reassure and give confidence to the less experienced vaginal surgeon to objectify the pelvic anatomy so that vaginal hysterectomy, in many cases, can be accomplished. With increasing confidence and skill that comes from experience, there are very few patients with indications for hysterectomy in whom the procedure cannot be performed vaginally.

PREOPERATIVE PREPARATION

If the surgeon is concerned about unintentionally injuring the rectum, it may be important for the patient to cleanse the rectum with an electrolyte purgative or a Phospho soda enema given the evening before surgery. Bowel cleansing evacuates solid stool from the rectum, reduces the bacterial load of the intestinal tract, and reduces the incidence of postoperative ileus and constipation.

A single-dose antibiotic as a prophylactic measure, usually a first-generation cephalosporin, should be given within 1 hour before the operation is started. Prophylactic antibiotics have been documented to reduce the risk of postoperative infections. The vaginal pH may be checked at a preoperative visit and prior to prepping the patient. If the pH is elevated above normal (3.8 to 4.2), the normal vaginal ecosystem has been altered. A vaginal pH in the range of 5.0 or greater suggests the potential for bacterial vaginosis and the likelihood that the facultative bacteria normally present in the vagina at concentrations of 10^3 have reached concentrations of 10^8 . This finding strongly suggests that the vagina is infected before the start of the operation. These patients may not be protected by routine prophylactic antibiotics but may benefit from postoperative therapeutic antibiotics and ideally correction prior to arrival in the operating room. In such patients, consider administration of 500 mg of metronidazole orally twice daily from the second to the seventh postoperative day. This practice reduces the postoperative infection rate following vaginal hysterectomy.

Gynecologists have long believed that a Betadine solution used as a preoperative vaginal scrub will remove most potential pathogens in the vagina, but this has recently been questioned. Some surgeons prep patients with

70% ethanol, even in the vagina, and use a self-adherent surgical drape that covers the rectum and conveniently keeps pubic hair and the labia from interfering with the operative field. Shaving of the pubic hair

P.717

is unnecessary, and shaven patients are more uncomfortable postoperatively. Clipping of pubic hair is preferred if hair removal is desired.

Copious lavage of the vaginal vault before, during, and after vaginal hysterectomy may also help to prevent postoperative infections by removing nonadherent bacteria from the vaginal epithelium. Lavage is not used as frequently in the vaginal approach as in other surgical approaches despite the fact that the vagina is a clean contaminated operative field.

The type of stirrups used for the lithotomy position is solely at the discretion of the surgeon. No matter what type is used, careful attention is required to protect vulnerable vascular, bony, and neurologic points in the lower extremities. Some surgeons prefer candy cane-type stirrups. The patient should be positioned with the buttocks at the end of the surgical table or just beyond. The table is placed at a zero horizontal position without Trendelenburg. In this manner, the surgeon can look directly into the vagina without having to look over the weighted speculum. Boot-type stirrups have achieved popularity and may also be used with the patient in the standard lithotomy position. Here, the femur is vertical, and the tibia/ fibula horizontal and oriented toward the contralateral shoulder. Hyperflexion of the femur is discouraged with either type of stirrup. If a procedure lasts more than 4 hours, the risk of neurovascular injury increases. For that reason, every 90 minutes to 2 hours, lowering the legs from the standard lithotomy position into a low lithotomy position for a period of approximately 10 minutes should be considered. Also, final positioning of the patient should protect the patient, allowing the surgeon to operate comfortably, and provide adequate room for surgical assistants to be effective. Assistants need to stand inside the stirrups to see the operative field to both observe and learn the operation. Pneumatic compression stockings are also recommended.

OPERATIVE TECHNIQUE

An examination under anesthesia before initiating the operation to confirm the preoperative findings is recommended in all cases. Undetected pathology may be appreciated during an anesthetized exam along with a more complete assessment of the subtleties of the patient's anatomy. Placement of a tenaculum for applying traction on the cervix can document the degree of descensus. If more descensus is desired, strong traction on the cervix with vigorous massage of the uterosacral ligaments, especially the left uterosacral ligament, for approximately 30 seconds results in a further descensus of the cervix of approximately 2 to 3 cm.

Although some surgeons prefer to stand during vaginal hysterectomy, others prefer to sit. Assistants to the surgeon should be as comfortable as possible during the operation. The height of the operating table and the surgeon's chair should be adjusted accordingly. If sitting, an instrument tray may be placed on the surgeon's lap, making it easier to have access to the desired instruments during the operation. The number of instruments used during vaginal surgery should be kept at a minimum to prevent instruments from obscuring the surgeon's vision.

Catheterization of the bladder before the initiation of vaginal hysterectomy is performed at the preference of the surgeon. Sometimes, it is easier to identify unintentional cystotomy when the bladder is moderately distended (approximately 200 mL) with urine, dyed fluid, or sterile infant milk. If the bladder becomes too distended, catheter drainage of the bladder may improve the visibility within the restricted operative space. If a cystotomy occurs, it is usually best to complete the vaginal hysterectomy before proceeding with repair of the bladder. In many cases, the cystotomy may make the bladder dissection easier because now, the location of the bladder is clear and the correct plane of dissection is more easily visualized. Sometimes, a finger in the bladder may also facilitate a difficult vesicocervical or vesicouterine dissection. The bladder must be mobilized adequately around the area of operative injury so that the surgeon can completely evaluate the extent of the cystotomy and be

certain that the repair is completed without excess tension on the injured site.

The initial anterior vaginal incision should be made through the full thickness of the vaginal epithelium at the border of the vaginal rugae and the smooth epithelium covering the cervix (**Fig. 32B.2**). An initial circumscribing cervical incision made on the cervix at the junction of rugae and smooth epithelium preserves vaginal length and helps avoid unintentional entry into the bladder anteriorly and rectum posteriorly. In addition, an incision at the point where the vaginal rugae begin to reflect away from the smooth epithelium of the cervix appropriately places the epithelial incision closer to the point of entry into the posterior and anterior peritoneum (**Fig. 32B.3**). An incision in this location allows the surgeon to avoid excessive dissection of the connective tissues between the vagina and the peritoneum, reduces blood loss from cervical artery branches, shortens operative time, and facilitates identification of the peritoneal entry points.

Julian has reported on the benefit of infiltrating the vaginal wall with a mixture of 1:200,000 epinephrine diluted in normal saline to control small blood vessel bleeding from the vagina. However, in our experience, oozing from the incised

P.718

vaginal epithelium rarely results in significant blood loss when the incision is made where the vaginal rugae start. If oozing from the incised edges of the vagina becomes a problem, it is easy to control with electrocautery.

FIGURE 32B.2 Initial incision should be a full-thickness incision at the border where the vaginal rugae begin and the smooth cervical epithelium on the cervix ends. FIGURE 32B.3 Relationship between the vaginal rugae and the anterior and posterior peritoneum. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

FIGURE 32B.4 A: When the cervix remains within the vagina when traction is applied with a tenaculum, the anterior full-thickness vaginal incision needs only to be performed between 10 and 2 o'clock. **B:** Initial full-thickness vaginal incision needs only to be performed between the 8- and 4-o'clock position. Note this incision is placed posteriorly where the vaginal rugae begin and where the uterosacral ligaments attach to the cervix. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA:

At the beginning of the operation, when the cervix is still within the vagina, a circumscribing incision around the cervix is difficult to perform with a scalpel or electrocautery instrument because it is difficult to maintain either device perpendicular to the circumscribing vaginal incision. This issue is not a concern when the cervix protrudes from the vagina. However, when the cervix cannot be brought out of the vagina with traction, the initial incision should be made on the anterior vaginal wall from approximately the 10- to 2-o'clock position and on the posterior vaginal wall between the 8- and 4-o'clock positions. These incisions provide adequate space for transection of the paracolpium allowing the cervix to descend for subsequent entry into the posterior and anterior peritoneum and ligation of the uterine vasculature at the appropriate time (**Fig. 32B.4A, B**).

After completing the vaginal incisions, the cervical tenaculum is replaced on the posterior lip of the cervix with taut traction of the cervix achieved by elevating the tenaculum anteriorly. If the posterior incision in the vagina is placed at the appropriate level where rugae are not present and at the point where the uterosacral ligaments join the cervix, the posterior cul-de-sac and peritoneum can readily be identified with an Allis clamp or tissue forceps. This step is facilitated by putting the vaginal epithelium and accompanying peritoneum on stretch as the peritoneum bulges outward

P.719

toward the surgeon (**Fig. 32B.5**). The importance of properly performing this step cannot be overstated. Entry into the posterior peritoneum is best accomplished by an incision directly above the tissue forceps that grasps the outward U-shaped bulge of the peritoneal fold (**Fig. 32B.6**). If the incision is placed closer to the cervix in an attempt to prevent injury to the rectum, the dissection often proceeds into the posterior cervical stroma. Unfortunately, an incision placed nearer to the cervix frequently results in a retroperitoneal dissection, which continues in this plane and ultimately pushes the peritoneum superiorly and posteriorly, obscuring identification of the peritoneum and frustrating the surgeon. Should this occur, the posterior lip of the cervix and vagina can be cut in a vertical direction that exposes the peritoneum at a higher level so it can be recognized and entered directly. This procedure is a cervicocolpotomy (**Fig. 32B.7**).

FIGURE 32B.5 With traction on the cervix anteriorly, the posterior peritoneal fold is grasped with tissue forceps, and the peritoneum is entered by incising with scissors the peritoneal fold directly above the tissue forceps. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:107, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

The posterior peritoneum is then opened with curved scissors, and a long-bladed Steiner Auvard weighted speculum is introduced into the posterior peritoneal cavity. Examination of the cul-de-sac can reveal further pathology, for example, endometriosis, leiomyomata, or adnexal pathology—that may need to be addressed later in the operation. Identification of the uterosacral ligaments by palpation can be accomplished during examination of the cul-de-sac by placing a digit medial to the ligament and identifying the rectouterine fold through the posterior colpotomy incision.

Oozing of blood from the posterior incision between the vagina and peritoneum may occur. Placement of a weighted speculum into the posterior peritoneal cavity will compress

P.720

most bleeding points in this area until completion of the surgery and cuff closure. If the vaginal epithelium has not been completely circumscribed, once posterior dissection has been developed, the vaginal epithelial incision should be completed by connecting the previous anterior and posterior incisions before the supportive ligaments of the uterus can be clamped.

FIGURE 32B.6 Transverse view of entering the peritoneal cavity. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:107, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

FIGURE 32B.7 Cervical colpotomy for entry into the posterior peritoneum. The posterior cervix is grasped with Allis clamps approximately at 4- and 8-o'clock positions. The cervix is incised starting at the 6-o'clock position and incising the cervix and posterior wall of the uterus until the posterior peritoneum is entered. Once the peritoneum is entered, a weighted speculum is placed into the posterior peritoneal cavity. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams &

FIGURE 32B.8 The uterosacral ligament is clamped, cut and ligated. Note that the tip of the clamp closely approximates the cervix. The suture ligature is initially placed with the clamp in an almost vertical orientation for maximum exposure to the anterior blade of the clamp but as the needle comes through the pedicle, the clamp is rotated more horizontally to provide better exposure to the underside of the pedicle for easy retrieval of the needle. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:109, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

Transection of the uterosacral ligaments is the single most important step in successfully completing a vaginal hysterectomy. The uterosacral ligament pedicle should be completed by placing the medial jaw of the clamp within the rectouterine fold while holding the clamp vertical and not try to swing around the cervix in a more horizontal plane. The medial tip of each clamp should be placed within the peritoneal cavity in the rectouterine fold and the lateral tip around the outside of the ligament. Special hysterectomy clamps have been developed to improve on the traditional Heaney clamp ([Fig. 32B.8A-C](#)). After transection of the pedicle, rotating the handles of the clamp laterally and superiorly facilitates suturing at the tip of the clamp. This rotation brings the tip of the clamp into full view and exposes a triangular area beneath the clamp for easier retrieval of the needle. Placement of a double clamp for uterine supportive or vascular structures is not necessary. Each uterosacral ligament should be secured by a transfixation suture to the posterolateral surface of the vagina and tied behind the clamp at about the 4- and 8-o'clock positions. Lateral traction on this suture provides the best exposure to the remaining structures that need to be transected to complete hysterectomy ([Fig. 32B.9](#)). This traction and the use of large hysterectomy clamps largely replace the need for lateral retractors in the vagina. Clamping and tagging the uterosacral ligaments separately allows for their identification, later use in cuff repair, and, if desired, a McCall culdoplasty at the end of the procedure. The uterosacral ligament pedicle is the only one that needs to be tagged during a vaginal hysterectomy and the only one that may safely be placed under traction.

After making sure the tips of the clamps are within the posterior peritoneal cavity, the cardinal and pubocervical

and clamping from the apex of the uterosacral pedicle to a point on the anterior cervix medial to the bladder pillar encompassing all the remaining connective tissue of the paracolpium (**Fig. 32B.10**). If already entered, the anterior peritoneum should not be pulled into this clamp at this point of the operation. A complete anterior dissection is needed to safely complete this pedicle. Bringing the anterior and posterior peritoneal edges together should only be accomplished with the uterine artery pedicle as this maneuver serves to seal off the broad ligament and effectively prevents bleeding from the vascular plexus located within the leaves of the broad ligament. Because the anterior peritoneum usually begins at the level of the uterine vessels, there is not enough peritoneal mobility to bring both the anterior and posterior peritoneal surfaces together at the level of the cardinal ligaments. Therefore, to be certain that the surgeon can seal both leaves of the broad ligament together with the uterine artery, it is best to avoid any attempt to bring the peritoneal edges together when the uterosacral or cardinal ligament is clamped. A simple suture ligature first at the tip and then around the end of the clamp is usually sufficient for hemostasis of the cardinal ligament without the need for transfixation. This suture ligature is not tagged or held.

FIGURE 32B.9 Traction on the uterosacral ligament suture laterally exposes the cardinal ligament. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:116, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

FIGURE 32B.10 With traction on the uterosacral pedicle, the cardinal ligament is exposed and can be clamped with the posterior jaw of the clamp in the posterior peritoneal cavity and the tip of the anterior jaw at the edge of the cervix. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:110, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

If exposure is good, the uterine arteries may be clamped, divided, and ligated at the point before entering the peritoneum anteriorly under the bladder. They are best clamped in their entirety and under direct visualization. In contrast to the uterosacral and cardinal/pubocervical clamps that are placed perpendicular to the body of the cervix, the uterine artery clamp is placed parallel to the long axis of the uterus as the tip of the clamp secures the uterine artery as it bifurcates into ascending and descending branches ([Fig. 32B.11](#)). As traction is placed on the uterus when the artery is cut, there is a definite sensation that the uterus descends signifying that the entire uterine vascular bundle has been transected, including the ascending and descending branches. If descent of the uterus is not noted, often an additional portion of the uterine artery remains and must be secured with another clamp. A single well-tied suture is all that is required for the uterine artery pedicle. Limiting the tissue within the clamp to the vascular bundle helps to make the pedicle manageable and the suture ligature more secure. Many surgeons try to include middle portions of the broad ligament with the uterine artery because they feel a need to place clamps on the remaining portions of the broad ligament as they proceed up on each side of the uterus.

FIGURE 32B.11 If exposure is good after the cardinal ligaments have been divided, the uterine vessels may be clamped before the anterior peritoneum is entered. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:136, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

Complete development by dissection of the vesicocervical and vesicouterine spaces is a prerequisite to identifying and opening the anterior peritoneum. This step is perceived to be the most difficult portion of the vaginal hysterectomy procedure. Adequate exposure, by division of the paracolpium and full dissection of the anterior avascular spaces, makes this key step of hysterectomy much easier to complete.

The cervix should then be retracted downward and inferiorly, and the anterior subvaginal tissue, including the supravaginal septum and the bladder, elevated in the midline and placed on a small amount of tension with an Allis clamp or tissue forceps and elevated. The supravaginal septum is part of the pericervical ring and is identified and incised using curved scissors with the tips pointing downward toward the body of the cervix. The handles of the scissors are not elevated above the horizontal axis because that maneuver would increase the likelihood of dissection into the body of the cervix (**Fig. 32B.12**). Dissection in the proper plane using gentle traction and countertraction exposes the vesicouterine space, the proper avascular cleavage plane to bloodlessly elevate the bladder away from the anterior uterus and thereby gain access to the anterior peritoneum. Gentle push and spread of the blades of the scissors will allow identification of the proper plane of dissection. Bleeding is a warning sign of deviation anteriorly toward the bladder, posteriorly toward the cervix, or laterally toward the bladder pillars. After the vesicouterine

P.722

plane is fully developed, a lightweight right-angled retractor can be placed into this space to elevate the bladder and expose the anterior peritoneal fold.

FIGURE 32B.12 Entry into the anterior peritoneum involves incising the supravaginal septum to gain entry into the vesicouterine space. Once the vesicouterine space has been entered, the space is developed by spreading the dissecting scissors for placement of a retractor to elevate the bladder. (From Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia: Lippincott Williams & Wilkins; 2006:109.)

If the patient had a previous cesarean section, the scar of this procedure can be readily visualized and identified separately from the bladder ([Fig. 32B.13](#)). Controlled dissection of a cesarean section scar is easier and more directly visible from the vaginal than from the abdominal or endoscopic approach. A low transverse cervical cesarean section incision is made in the portion of the cervix near the isthmus of the uterus. For that reason, in the nonpregnant state, the scar is close to the anterior vaginal incision used to develop the vesicocervical and vesicouterine avascular spaces in vaginal hysterectomy and can be readily identified and dissected. A cesarean section scar distorts the anatomy by occluding the vesicouterine space between the scar and the urinary bladder. Further dissection above the scar can be performed by identifying the scar, the bladder, and the peritoneum as independent structures. On occasion, it is also possible to dissect under the scar, which keeps the dissection even further from the urinary bladder ([Fig. 32B.14](#)). Sheth has described the utility of the broad ligament space in the presence of cesarean scar. Gentle lateral pressure along the side of the cervix and uterine body will allow the anterior leaf of the broad ligament to separate lateral to the cesarean scar. At that point, digital or instrument dissection can proceed medially above the scar and often allow complete isolation of the scar. Classical and low vertical cesarean and myomectomy scars present further

challenges that must be individualized based on case-by-case findings.

FIGURE 32B.13 Relationship between the supravaginal septum, vesicouterine space, cesarean section scar, and anterior peritoneal fold. (From Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:109. Copyright © 2007 Lippincott Williams & Wilkins.)

FIGURE 32B.14 Sometimes it is possible to dissect beneath the cesarean section scar to gain entry into the superior part of the vesicouterine space to identify the anterior peritoneal fold. (From Kovac SR, Zimmerman CW,

After dissection of the vesicouterine space, the anterior peritoneum is grasped under direct vision and entered via a 1-cm opening with the scissors. The shining surface of the peritoneum is recognizable after all adventitial tissue is dissected away and may be identified visually or with the so-called silk sac sign prior to incision. Upon confirmation of entry into the peritoneal cavity by seeing intraperitoneal fat, the opening is further stretched by spreading of the scissors into this space to allow insertion of the right-angle retractor into the anterior cul-de-sac. This retractor should remain in this position for the remainder of the hysterectomy in order to safely elevate the bladder out of the operative field. Proper dissection and peritoneal entry reduce the risk of operative injury to the bladder and ureters (**Fig. 32B.15A, B**). Because of the surgeon's desire to avoid injury to the bladder, there is the tendency to dissect as far as possible from the bladder. This move may cause the surgeon to enter into the connective tissue capsule of the cervix and myometrium of the lower uterine segment. Further retroperitoneal dissection in this area will cause bleeding and further delay anterior peritoneal entry. Similar to the posterior dissection, this problem is more likely when the initial incision into the vagina is made too close to the cervix. Further dissection beneath the peritoneum covering of the anterior uterine segment results in failure to enter the anatomic vesicouterine space between the bladder and uterus. Excessive bleeding, frustration, and a lack of progress will occur. Failure to identify the correct tissue plane or a lack of caution results in either further retroperitoneal dissection or unintentional bladder penetration. Cystoscopy may be performed at any point in the process of anterior dissection to confirm integrity or injury to the bladder and ureters.

FIGURE 32B.15 Entry into the anterior peritoneum. Peritoneal fold is grasped with tissue forceps and pulled downward. Scissors incise peritoneal fold just above tissue forceps. **A:** Lateral view demonstrating the method for entering the anterior peritoneum. **B:** Retroperitoneal dissection with elevation of the peritoneal fold. (From Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia: Lippincott Williams & Wilkins; 2006:110.)

If an injury to the bladder results, it will likely occur well above the trigone of the bladder and not near the ureteral orifices. Cystoscopy will reveal the exact location. This injury is simple to repair after the uterus has been removed. Unintentional operative cystotomy is a risk of any type of hysterectomy with any technique or approach. The overall incidence of operative cystotomy while performing and teaching this technique has resulted in a cystotomy rate of 1.2% with vaginal hysterectomies. Gilmour and others have documented the value of cystoscopy at the time of hysterectomy in recognizing urinary tract injury during the operation rather than later after the patient has left the operating room. Additionally, the overall rate of urinary tract injury was lower for the vaginal approach than in any other route of hysterectomy.

The use of a sponge on the surgeon's finger to push through the supravaginal septum and bluntly dissect the vesicouterine space superiorly to expose the anterior peritoneum is frequently taught. This technique could be considered as more of a technique of *accomplir forcee* (i.e., to accomplish with force) than a surgical dissection, as the cleavage plane becomes indistinguishable from the supravaginal septum up to the anterior peritoneal fold. No effort is made to visually or surgically identify any of the involved planes or tissues. The risk of tearing the bladder with this technique is potentially increased, especially if the patient had a previous cesarean section. Furthermore, the risk of not recognizing the injury is likely increased. The anterior peritoneum should always be opened under direct vision, never blindly, as unintentional entry into the bladder frequently results from an attempt to enter the peritoneum blindly.

Persistent attempts to open the anterior peritoneum if there is doubt that the peritoneal fold is clearly identified are unnecessary. Transecting the uterosacral and cardinal ligaments and perhaps the uterine vascular bundle prior to entering the anterior peritoneum will bring the uterus and peritoneal fold closer to the surgeon providing better exposure, thus simplifying this step of the procedure. Eventually, during this sequence of steps, the peritoneum will be identified and entry will be possible at some later point in the operation than is customary. Anterior peritoneal entry can also be safely facilitated, especially when the uterus is enlarged by adenomyosis or leiomyomata, with a vertical incision in the vaginal epithelium similar to the one used in an anterior colporrhaphy (**Fig. 32B.16**). This additional room for dissection of the bladder away from the cervix allows accurate identification of the bladder from the peritoneal fold. The surgeon may use a finger or a malleable uterine sound or retractor inserted through the posterior cul-de-sac and bent over the fundus of the uterus into the anterior cul-de-sac to help identify the exact location of the peritoneal fold. This step is especially useful in difficult cases or those in which the proper plane of dissection has not developed.

After both the posterior and anterior peritonea have been successfully entered, detachment of the uterus from its supportive ligaments can be accomplished if they have not already been surgically transected. As stated earlier, we prefer to secure and divide the uterosacral and cardinal ligaments before attempts to enter the anterior peritoneum. This extraperitoneal approach provides significant additional exposure for anterior peritoneal entry.

Separating the cervix

P.724

from the paracolpium, along with the resulting descent of the uterus, increases visibility. This exposure is significant and makes the peritoneal identification/entry process less troublesome. The uterine artery can also be divided before anterior peritoneal entry, allowing even greater exposure. The key to successful vaginal hysterectomy is not to proceed in lock step through a draconian set of tasks but to identify structures and manipulate them surgically in the order that they present.

The exact location of the ureter during abdominal, laparoscopic, and vaginal hysterectomy is always a concern. Nichols and Randall suggested that the risk of ureteral injury during a vaginal hysterectomy is greater because the ureters may be pulled downward and medially by the tethering effect of the uterine artery. By studying the surgical anatomy of the ureter during vaginal hysterectomy, it has been determined with the use of imaging that the uterine artery is not the primary factor drawing the ureter closer to the uterus. Instead, traction on the cardinal ligament is the chief factor affecting movement of the ureter, suggesting there is a margin of safety during each step of a vaginal hysterectomy. This concept was confirmed by magnetic resonance imaging studies with a brass tenaculum placed on the cervix in a resting state and under traction. When traction was applied to the cervix, the ureter's position was displaced upward and lateral to the position of the ureter at rest (**Fig. 32B.17A, B**). This movement confirmed radiographically that the ureters were displaced further laterally and superiorly from the cervix to a position of surgical safety. When bladder retraction was used, this effect was more pronounced. During surgical identification of the ureter at the time of radical vaginal hysterectomy, it can be observed that once the uterosacral and cardinal ligament complex has been cut, the ureter actually moves further out of harm's way. If the ureters have not been dissected and identified before the cutting of uterosacral and cardinal ligaments, it is difficult to dissect and visualize them vaginally once the ligaments have been cut during a vaginal hysterectomy because of this movement. Thus, it is evident that the uterosacral and cardinal ligaments, not the uterine artery, play a major role in determining the ureter's position during vaginal hysterectomy. Once these ligaments have been divided, the ureter will retract out of the operative field and make division of the uterine artery safer (**Fig. 32B.18A, B**).

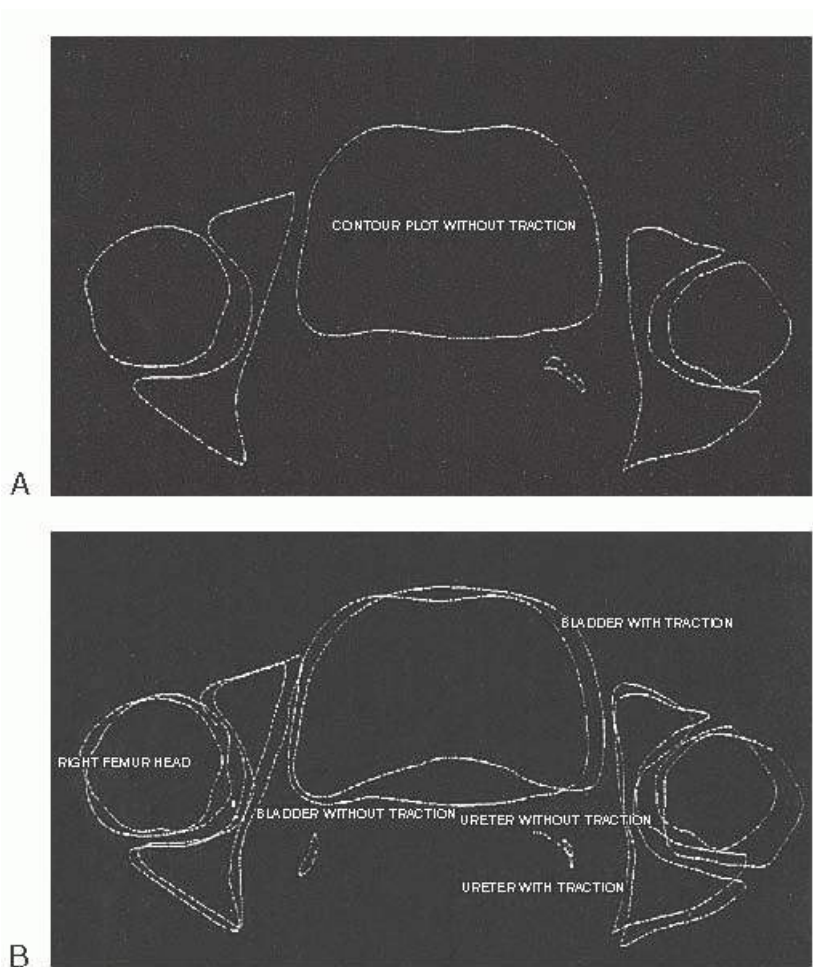

FIGURE 32B.17 **A:** Magnetic resonance imaging (MRI) studies of ureteral movement when downward traction is placed on the uterus. Ureter position is seen on the right. **B:** Overlay of MRI films. Traction on the uterus with a brass tenaculum is applied to the cervix. Note indentation to the bladder from the uterus and lateral and upward displacement of the ureter compared with the position of the ureter without traction to the uterus. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:112, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

Entry into the posterior peritoneum before clamping the uterosacral and cardinal ligaments is desirable. Anterior cervical and uterine plane dissection and placement of a retractor under the bladder also elevate the ureter out of the operative field (**Fig. 32B.19A, B**). Once the retractor is placed under the bladder, it should not be removed during any stage of the vaginal hysterectomy. During vaginal hysterectomy, if forceful traction is applied to the uterus with no retraction of the bladder, the ureter can be pulled medially and potentially placed in harm's way.

After posterior and anterior entry into the peritoneum and completely ligating the vascular pedicle, the remainder of the broad ligament may be dissected in the same manner familiar to the abdominal or endoscopic surgeon. Continued clamping up each side of the remaining broad ligament is not usually required for successful uterine removal. When the vaginal surgeon continues to place clamps above the uterine artery, the space to place each clamp becomes more restrictive, and placing sutures around these clamps becomes more difficult. This is

P.725

P.726

the type of problem that can create the conception that vaginal hysterectomy is a more difficult operation because of restrictive access and visibility. Clamping and suturing of the broad ligament above the uterine artery are unnecessary because there are only occasional significant blood vessels within the leaves of the broad ligament. There is no need to place clamps above the uterine artery until the round ligaments, fallopian tubes, and utero-ovarian pedicles are encountered, visualized, and prepared for ligation. Once the entire vascular

bundle has been transected, a sufficient amount of tissue has been transected to allow rotation of the uterus posteriorly.

FIGURE 32B.18 A: Transection of the uterosacral ligament returns this structure to its original position. **B:** After both uterosacral and cardinal ligaments have been transected, ureters are displaced upward and lateral out of harm's way. Copyright © 2007 Lippincott Williams & Wilkins.)

If the uterus is small and the uterine artery has been secured, the next step in uterine removal is to deliver the fundus through the posterior or occasionally the anterior colpotomy (Döderlein technique). With a small, mobile uterus, simple traction may result in delivery of the uterus without the need for rotating the fundus one way or the other. If delivery of the uterus (regardless of the size) is challenging, the organ may be brought closer to the surgeon and out of the vagina by using the alternate technique of *intramyometrial coring*. This technique was introduced by Lash in 1941 and reintroduced in 1986 by Kovac for removal of large uteri; however, it may be used on uteri of any size. In this simple technique, the myometrium can be circumferentially incised with a scalpel placed parallel to the long axis of the uterus and beneath the serosal covering of the uterus with continuous traction on the cervix and direct

vision at all times (**Fig. 32B.20A, B**). This maneuver removes a core inside the uterus without violating the integrity of the endometrial cavity or uterine serosa. Ligation of the uterine artery is absolutely necessary prior to coring. The Lash or coring incision reduces the size of the uterus by decreasing its width, thereby increasing its length, similar to the way a baby's head becomes more cylindrical and less spherical as it becomes molded during childbirth. In effect, coring converts a spherical structure into an elongated cylindrical or rod shape, enhancing the surgeon's ability to facilitate transvaginal removal of a wide uterine fundus (**Fig. 32B.21A-C**). This process is a surprisingly bloodless maneuver once the uterine arteries have been secured. Strong traction is placed on the uterus during the coring, which restricts blood flow from the ovarian pedicles.

FIGURE 32B.20 A: Coring incision is started just below the serosal covering of the uterus anteriorly. **B:** Coring of a small uterus to facilitate exposure and clamping of the upper pedicle. No sutures were placed above the uterine artery to bring the uterus closer to the surgeon for removal of the uterus. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:118, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

During the coring procedure, the uterus will begin to descend through the vagina, allowing the surgeon to visualize the cornual portion of the uterus and exposing the utero-ovarian ligament, round ligament, and fallopian tube. Once these structures become visible, the surgeon is assured that the uterus can be removed vaginally.

Some surgeons prefer bivalving the uterus with *morcellation*. Morcellation is especially useful if multiple leiomyomata are present. A thyroid vulsellum clamp may be placed on either side of the cervix, and with strong downward traction, the cervix may be incised with a knife vertically until the fundus of the uterus is reached. Once the fundus is reached, wedges of myometrium or specific leiomyomata may be removed in a nearly bloodless field until the uterine size is sufficiently reduced to allow removal. Individual selection of technique for each case is needed. Coring is most useful in the presence of adenomyosis while morcellation is most useful in the presence of leiomyomata although neither technique is restricted to those respective clinical situations. No effort should be made to use either morcellation or coring until the uterine artery pedicles are secure.

Once the cornual pedicles are visualized, they can either be clamped individually. Depending on the surgeon's preference and experience, the clamp may be left on the pedicle or a suture may be placed around the tip of the clamp and tied or transfixed behind is appropriate. This suture may be tagged. The clamp or suture may be used to provide gentle traction on the pedicle and expose the ovary for evaluation or removal.

Once the uterus has been removed, it is appropriate to evaluate each pedicle to confirm hemostasis. If the ovaries are removed before confirmation that all pedicles are hemostatic, the surgeon may spend considerable operative time finding the source of such bleeding, as it frequently appears to be from a higher point but may actually be from one of the uterine pedicles. Each pedicle can be evaluated by starting at the 12-o'clock position within the peritoneal cavity and proceeding in a clockwise manner. The use of a surgical sponge folded longitudinally on sponge forceps may be very helpful as is an auxiliary light source. If brisk bleeding is noted, most often it can be found by placing traction on the uterosacral tag and looking between the uteroovarian and uterine artery pedicles. Bleeding from this area of the broad ligament is usually a result of the anastomosis of vessels between the ovarian and uterine artery. Because this is the most frequent site of this type of bleeding, the surgeon should direct his or her search to this area first. Placement of a long Kelly or Allis clamp at the site of bleeding without undue traction may be followed by a helical suture or a figure-of-eight suture passed through the vagina into the peritoneum from outward to inward will rapidly control this bleeding ([Fig. 32B.22](#)). Care should be taken to specifically identify sites of bleeding, to not suture blindly, and to control the depth of suturing in this area due to the proximity of the ureters.

If no bleeding points are discovered from any of the hysterectomy pedicles, the posterior vaginal epithelium will most likely be determined to be the source of bleeding. Posterior cuff bleeding may sometimes be rather brisk from the separation of the vagina and the peritoneal edge. It is likely to be more brisk in premenopausal patients especially those younger than 40 years of age. Before proceeding with any concurrent procedure, blood loss from this area should be controlled with electrosurgery or absorbable suture. Once hysterectomy pedicle and posterior cuff hemostasis is complete, further examination of the peritoneal cavity should reveal complete hemostasis from all potential bleeding sites. The anterior cuff is rarely a source of troublesome bleeding.

If only the uterus is to be removed, support of the vaginal apex becomes the next most important decision. If a salpingo-oophorectomy is planned in conjunction with the hysterectomy, it should be performed at this point.

VAGINAL OOPHORECTOMY

There appears to be some reluctance to combine vaginal hysterectomy with oophorectomy because vaginal oophorectomy is thought to be a risky and difficult procedure. Factors that seem to foster this perception are fear of restricted access to the ovaries and the belief that there is inadequate visibility of the adnexa along with safe access to the infundibulopelvic ligament during conventional vaginal surgery.

To obtain objective evidence regarding these perceptions, a prospective study was designed by Baden and Walker to determine whether there is adequate visibility and accessibility for transvaginal oophorectomy in most patients undergoing vaginal hysterectomy. After the uterus was removed, accessibility of the ovaries for transvaginal removal was assessed by stretching the infundibulopelvic ligament, placing traction on the suture tag used to ligate the uteroovarian ligament, round ligament, and fallopian tube and grading the position of the ovaries in relation to the long axis of the vagina. The degree of ovarian descent and visibility was graded with a system used to grade pelvic organ prolapse ([Fig. 32B.23](#); [Table 32B.1](#)). The grade corresponded to the minimal degree of descent of either ovary.

To determine what grade would be considered accessible and visible for transvaginal oophorectomy by most gynecologic surgeons, the experience of other surgical specialties was considered. For example, the distance from the hymenal ring to the ischial spine is approximately 8 cm. In dentistry, the distance from the front teeth to the last molar is 6 cm; in otolaryngology, the distance from the front teeth to the tonsil for tonsillectomy is 10 cm. Therefore, it was postulated that any ovary that was positioned at grade I or lower in the vagina should be visible and accessible for transvaginal removal by most gynecologic surgeons. Of the 875 patients between 29 and 69 years of age who were evaluated for ovarian descent after hysterectomy, 92.9% had ovarian mobility to at least the midportion of the vagina (grade II). In another 4.6%, the ovary could be pulled down outside the hymenal ring (grade II). Only 2.5% of these patients had very little ovarian mobility, which would have made vaginal oophorectomy very difficult (2.4% grade I and 0.1% grade 0). Although this study provided objective evidence that the ovaries may be more visible and accessible for transvaginal removal than previously perceived, there may be times that the ovary may be inaccessible for transvaginal removal as a result of adhesive disease, endometriosis, suspected significant pathology, or other conditions. However, the ovary should not be presumed to be inaccessible at the start of any vaginal hysterectomy. Smale and colleagues, Davies and associates, and Sheth have reported

P.729

P.730

that planned vaginal salpingo-oophorectomy is successful in 94% to 97% of women undergoing vaginal hysterectomy. The routine use of the laparoscope to perform an oophorectomy before a vaginal hysterectomy has been heralded as safe and comfortable and therefore has become commonplace. “To be sure we can get the ovaries” is a phrase too often heard worldwide to justify the use of abdominal, laparoscopic, or even robotic approaches to hysterectomy. For too many years, the belief that the ovaries were inaccessible because they are “too high” for transvaginal removal has been prevalent. This misconception has erroneously guided the selection of abdominal or endoscopic hysterectomy.

FIGURE 32B.21 A: The cervix has been circumscribed through the full thickness of the vagina around the cervix, the posterior and anterior peritoneum entered, and the uterosacral and cardinal ligaments secured. B: After ligation of the uterine arteries, an incision is made in a circumferential fashion parallel to the endometrial cavity and into the outer superficial myometrium in the same plane. Constant traction on the tenaculum while coring assists in developing the proper plane. C: Continued coring and traction reduce the size of the uterus by exteriorizing the inside of the uterus with an intact endometrial cavity through the introitus. Intramural myomas are sometimes transected during the coring process. (Reprinted from Kovac SR. Intramyometrial coring as an adjunct to vaginal hysterectomy. *Obstet Gynecol* 1986;76:131, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

FIGURE 32B.22 The most common source of bleeding after removal of the uterus is the anastomosis between uterine and ovarian arteries. Suture placed through the lateral vagina into the lateral peritoneum in a figure-of-eight fashion and tied resolves most, if not all, bleeding from this area. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:120, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

FIGURE 32B.23 Grading ovarian descent after vaginal hysterectomy with Baden-Walker Halfway System. Grade corresponds to the position of the ovary at the ischial spine superiorly and the hymenal ring inferiorly. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:120, with permission. TABLE 32B.1 The Baden-Walker Halfway System for Grading the Degrees of Ovarian Descent After Hysterectomy

GRADE	FINDINGS
0	No descent was defined. The infundibulopelvic ligament has little or no stretchability, and the ovaries are positioned at the lateral pelvic wall at or above the ischial spines and cannot, with traction, be brought into the long-axis plane of the vagina.
I	Infundibulopelvic ligament stretchability brings the descent of the ovaries into the long axis of the vagina with traction halfway between the ischial spines and the mid-vagina.
II	Infundibulopelvic ligament stretchability brings the descent of the ovaries into the long axis of the vagina with traction between the midportion of the vagina and the hymenal ring.
III	Infundibulopelvic ligament stretchability brings the descent of the ovaries into the longitudinal plane of the vagina with traction past the hymenal ring.

Good surgical practice dictates that objective determination of the visibility and accessibility of the ovaries is the primary criteria for selecting a particular route of oophorectomy. Thus, if the ovaries are found to be inaccessible at the time of vaginal hysterectomy, ovarian removal can be performed with the laparoscope or by a simple laparotomy once the initial vaginal operation is complete. The correct paradigm substantiated by clinical evidence is to first attempt ovarian removal by the minimally invasive transvaginal approach. If that is not possible, the surgeon should proceed with laparoscopy or laparotomy after completion of a vaginal hysterectomy for removal of the adnexa. Indications for salpingo-oophorectomy should not change regardless of the route of surgery.

Surgical Technique of Vaginal Salpingo-Oophorectomy

STEPS IN THE PROCEDURE
<p>Vaginal Hysterectomy Bilateral Salpingo-Oophorectomy</p> <ol style="list-style-type: none"> 1. History and physical exam for assessment of indications for surgery and appropriateness of patient for surgery, including medical and anesthesia clearance as needed. 2. Preoperative and examination under anesthesia to document adequate access to the cervix and apical vaginal structures, especially the uterosacral ligaments. 3. Careful positioning of the patient in the standard lithotomy position with the femur vertical and tibia/fibula close to the horizontal plane and oriented toward the opposite shoulder. 4. Debate and variation exist among experts regarding preparation of the bladder for surgery. Some surgeons, including the author, prefer catheter placement prior to surgery. Others prefer leaving fluid in the bladder in order to alert the surgeon of the presence of bladder injury.¹ 5. Grasp the cervix firmly, and in cases that do not include an adequate degree of prolapse, firmly massage the uterosacral ligaments to establish maximum descent prior to proceeding. 6. Grasp the posterior cul-de-sac. With downward traction on the vaginal epithelium and upward traction on the cervix, incise the posterior cul-de-sac and document peritoneal entry. 7. Complete circumscription of the vaginal epithelium around the cervix. 8. Dissect the vesicocervical space, transect the pericervical ring/supravaginal septum, and dissect the vesicouterine space. Place a retractor in the anterior dissection to elevate the bladder. Note

that there is no compelling reason to complete entry into the anterior cul-de-sac at this point unless specifically desired.

9. Identify, clamp, transect, and ligate the uterosacral ligament pedicle separately. This pedicle will be used in cuff closure.
10. Identify, clamp, transect, and ligate the cardinal/pubocervical ligament pedicle.
11. Identify, clamp, transect, and ligate the uterine vasculature.
12. Identify and enter the anterior cul-de-sac if not already accomplished.
13. Clamp and ligate the lower portion of the broad ligament (often including the ascending portion of the uterine vasculature) including the anterior and posterior peritoneum.
14. Deliver the fundus of the uterus posteriorly. An alternative is to deliver the fundus of the uterus anteriorly; however, posterior delivery is usually the more efficient method.
15. If uterine size does not permit fundal delivery, uteroreductive techniques (e.g., morcellation, coring, cervicectomy, or bivalving) may be helpful at this stage of the procedure.
16. Identify, clamp, and transect the adnexal pedicle (fallopian tube, round ligament, and utero-ovarian ligament) to remove the uterus.
17. If adnexectomy is desired, identify and divide the round ligament to begin the process. Then identify, clamp, divide, and ligate the mesovarium.
18. Identify, clamp, divide, and ligate the infundibulopelvic ligament to complete the removal of the adnexa.
19. Carefully inspect all pedicles for hemostasis.
20. Irrigate the surgical field.
21. If appropriate, perform one of the variations of culdoplasty (e.g., McCall) incorporating the uterosacral ligaments into the cuff to help prevent future prolapse.
22. Perform cystourethroscopy to document bladder and ureteral integrity.
23. Perform cuff closure. Several variations exist. Most surgeons prefer interrupted sutures rather than a running closure because of potential hematoma or abscess formation.
24. Vaginal packing is optional. It is not necessary in the absence of concomitant pelvic reconstructive surgery.

¹Author's note: The specific steps of vaginal hysterectomy do not necessarily proceed in a predetermined order, they all must be accomplished; however, the exact order is somewhat variable from case to case and from surgeon to surgeon. For example, some surgeons prefer anterior dissection first and others prefer posterior dissection initially. No evidence clearly favors one approach over the others; therefore, surgeon discretion is paramount. The steps outlined below are the ones favored by the author.

Vaginal salpingo-oophorectomy may be accomplished if sufficient descent is found in the following manner. Downward traction is applied to the surgical clamp or suture ligating the uteroovarian ligament, round ligament, and fallopian tube or the clamp securing that pedicle. The initial step in vaginal adnexal removal is a digital and visual exam of the structures in order to assess size and eliminate any adhesions that may be present. After those tasks have been accomplished, the end of the fallopian tube is directed toward the ovary with tissue forceps and a long, sharply angled clamp is placed between the round ligament, the uteroovarian ligament, and tube across the infundibulopelvic ligament. Under direct vision, the tube and ovary may be excised. A suture is placed approximately 2 cm from the tip of the clamp, and a single throw tie is tightened around the tip, which usually secures the ovarian artery (**Fig. 32B.24**). The suture is then placed behind the clamp for suture transfixation and firmly tied with several throws. As the suture is tied, the surgeon can appreciate the security of this suture around the infundibulopelvic ligament. Alternatively, some surgeons have used an Endoloop (Ethicon

Endo-Surgery, Cincinnati, OH) to secure the infundibulopelvic pedicle. If the Endoloop is used, at least the round ligament should be divided to debulk the pedicle prior to application of the suture.

An alternative method of salpingo-oophorectomy is the three-step technique described by Zimmerman and others. This technique is especially useful when descent of the adnexa is not pronounced; however, routine use of these steps makes difficult cases more manageable when they are encountered. The surgical steps mimic the same maneuvers that are used to remove the adnexa abdominally. After removal of the uterus, the utero-ovarian pedicle is held with a clamp, and the handle is rotated laterally and the tip pointed medially. This maneuver exposes the round ligament that can be clamped, transected, and ligated or divided with electrocautery. Division of the round ligament gives the surgeon access to the retroperitoneal

P.732

space between the leaves of the broad ligament. Gentle dissection of this space makes it possible to isolate, clamp, and ligate the mesovarium as a separate pedicle. Elimination from the adnexal complex of these two structures results in an additional and significant amount of descent of the tube and ovary. After division of the mesovarium, the only remaining tissue connected to the adnexa is the infundibulopelvic ligament. This ligament can be clamped and suture ligated or secured with an Endoloop. Division of the adnexectomy into three manageable steps increases surgical control, decreases the bulk of attachment, and decreases the likelihood of a complication during suture application. Transection of the round ligament and mesovarium as separate pedicles significantly increases descent of the adnexa, resulting in increased visibility of the infundibulopelvic ligament.

FIGURE 32B.24 The infundibulopelvic ligament has been clamped and the ovary and the tube removed. There is a single penetration of the infundibulopelvic ligament and its midpoint and tied around the end of the clamp. This transfixation suture usually occludes the ovarian artery. The suture is then passed around the end of the clamp and transfixed into the tissues behind the heel of the clamp and tied again. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:122, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

Consideration of salpingectomy only has recently become more prevalent. This idea is based on the emerging

idea that many malignancies that have been labeled as ovarian in the past are now suspected to have a salpingeal origin. Obviously, if the ovary was left in place, the surgery would be easier to accomplish. At this time, there is no definitive evidence to either support or refute this idea.

CLOSURE AND SUPPORT OF THE VAGINAL CUFF

Closure of the peritoneum with vaginal hysterectomy is not routinely necessary for healing and rarely is indicated as a part of the procedure. Leaving the peritoneum open may help to expose any immediate intraperitoneal postoperative bleeding.

The remaining part of the vaginal hysterectomy is to support the vaginal cuff so that the chance that an enterocele or vaginal vault prolapse will develop later in life is reduced. Compensation for the connective tissue defect and disruption of the vaginal suspensory axis created by the removal of the cervix is best accomplished at the time of hysterectomy. Failure to adequately compensate for the cervical defect may expose the patient to an increased risk for posthysterectomy vaginal vault prolapse in the form of a posterior enterocele or apical anterior vaginal wall prolapse (anterior enterocele). Enterocele repair and suspension of the prolapsed posthysterectomy vagina are among the most technically demanding of all pelvic surgery procedures. Closure of the cervical defect along with reestablishment of the suspensory axis of the vagina by incorporating the uterosacral ligaments into the cuff is effective prophylaxis reducing the risk of future prolapse. As a general rule, closure of the cuff and correction of the cervical defect should consume approximately as much time as extirpation of the uterus.

The incidence of enterocele after hysterectomy can range between 0.1% and 16%. Nichols and Randall described a technique of excising excess peritoneum in the cul-de-sac to prevent future development of an anterior enterocele ([Fig. 32B.25](#)). Because this technique only removes excess peritoneum and does not address the cause of an enterocele after hysterectomy, subsequent enterocele formation has not been prevented because no musculofascial defect has been corrected or reinforced.

Several other methods to repair the posterior vaginal cuff for prolapse prophylaxis have been described. These procedures emphasize the use of the uterosacral ligaments in any repair. Inclusion of the uterosacral ligaments in cuff repair is very important because of their role as the primary suspensory elements in

P.733

the uterovaginal continuum of structures. Connecting the uterosacral ligaments to the cuff reestablishes the posterior arm of the suspensory axis of the vagina and should be considered during all hysterectomies regardless of route. The most commonly employed technique to close the posterior vaginal cuff is the McCall culdoplasty. This technique is designed to obliterate the cul-de-sac while it suspends the posterior superior vagina and its fascial attachments to the uterosacral ligaments. Bringing these supporting ligaments together in the midline is common; however, it is no longer believed to be necessary. Care should be taken to document ureteral patency after this procedure. The risk of ureteral occlusion is directly proportional to the number of uterosacral plication sutures placed. This type of prolapse prophylaxis technique is a marked improvement over previous beliefs that the only thing necessary after the uterus was removed was to close the vagina. Simple closure of the vagina resulted in a high incidence of vaginal vault prolapse and associated enterocele formation. More recently, simple closures such as those used by abdominal, laparoscopic, and robotic surgeons have resulted in an unacceptably high incidence of vaginal cuff dehiscence. Some form of McCall culdoplasty after all vaginal hysterectomies should be considered routine. Some modification of this step should also be considered if another approach to hysterectomy is used.

FIGURE 32B.25 Identification of excess peritoneum in cul-de-sac. Excision of excess peritoneum will not prevent future enterocele formation, as the cause of the enterocele is not determined. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. Philadelphia, PA: Lippincott Williams & Wilkins, 2007:122, with permission. Copyright © 2007 Lippincott Williams & Wilkins.)

Recent advancements in pelvic reconstructive techniques, as well as an understanding of the cause of enteroceles, have brought us to a new method of preventing enteroceles and vault prolapse at the time of hysterectomy, especially with those patients who have a rectocele. Rectoceles and enteroceles result from an apical separation of the rectovaginal septum from the uterosacral ligaments. This distal displacement of the rectovaginal septum allows both of these vaginal defects to develop contiguously through the same fascial defect. Because enteroceles are routinely associated with rectoceles, they may not both be suspected during the vaginal hysterectomy. This idea suggests that failure to identify and manage the presence of an enterocele at the time of vaginal hysterectomy might be the cause of the increased incidence of rectocele and enterocele formation in later years.

Enteroceles may also form as a result of the separation of the rectovaginal fascia from the pubocervical fascia (**Fig. 32B.26**). As a result of hysterectomy and removal of the cervix, there is an iatrogenic separation of the rectovaginal septum and the fibers that normally connect this structure to the anterior vaginal fascia through the connective tissue that forms the pericervical ring. This separation widens the cul-de-sac and separates the normal fascial attachments thus allowing the peritoneum and accompanying intra-abdominal structures, to potentially protrude through this weakness with any increase in intra-abdominal pressure. This concept likely explains the fact that most posthysterectomy vaginal vault prolapse is located apically or on the apical anterior segment of the vagina (cervical defect). Proper cuff closure reduces this possibility by reconnection of all connective tissue elements by incorporation within the suture lines.

FIGURE 32B.26 Separation of the pubocervical and rectovaginal fascia with enterocele formation. (Reprinted from Kovac SR, Zimmerman CW, eds. *Advances in reconstructive vaginal surgery*. An effort to restore normal anatomy from the disruption of these support and suspensory structures created by hysterectomy is the obligation of the hysterectomy surgeon regardless of route. McCall culdoplasty is intended to prevent incipient recto-enteroceles. If a true rectoenterocele is identified at hysterectomy, a repair should be considered.

Surgical Techniques

Cuff repair is as much a part of hysterectomy as removal of the uterus and adnexa. If a rectocele has not been identified, management of the vaginal cuff is performed by reducing the defect left by the absence of the cervix. Options include incorporation of the cardinal ligament pedicles in the repair particularly in the presence of a sizeable cervical defect. The cardinal ligament pedicles may actually be tied together across the midline with safety. Traditional McCall culdoplasty incorporates suture(s) in each uterosacral ligament accessed intraperitoneally and sutured into the posterior cuff. In the traditional technique, one or more sutures are placed and tied across the midline in order to occlude the posterior cul-de-sac. With recognition of the importance of the integrated suspensory axes, it is sufficient to incorporate the intraperitoneal portion of the uterosacral ligaments into the vaginal cuff ipsilaterally without plication into the midline. Simply securing this attachment is enough to allow the apex of the vaginal vault to remain suspended over the sacrococcygeal raphe. An effort should also be made to incorporate both the anterior and posterior fasciae into the repair of the cuff by suturing through the full thickness of the vaginal epithelium. Apical attachment of the anterior pubocervical fascia and the rectovaginal fascia posteriorly to the cuff is critical to successful cuff closure. Those two attachments close the space vacated by the absence of the cervix. The difference between the shorter anterior pubocervical fascia and the longer posterior rectovaginal fascia is resolved with soft tissue occlusion. Permanent suture may be used on the uterosacral sutures so long as they are not exposed intravaginally.

P.734

Debate exists regarding specific techniques of cuff closure. Some surgeons prefer running suture, others interrupted. Some prefer vertical closure, others horizontal. No definitive data exist to resolve these issues. Much more important are the concepts of reintegration of the suspensory axes of the vagina.

The presence of a rectocele requires the posterior vaginal wall be opened in the midline up to the level of the

newly formed cul-de-sac. The defect from separation of the rectovaginal fascia from the uterosacral ligaments is identified. If an enterocele sac is identified, opening of the sac with high ligation of the sac is unnecessary, as the mesothelial lining of the peritoneal sac has little supportive value. The sac is simply pushed upward by reattachment of the uterosacral ligaments to the posterior cuff and the rectovaginal septum. The vagina can be closed vertically or horizontally, as neither is superior in preserving vaginal length. Cruikshank and Pixley demonstrated that vaginal length depended on the support of the vaginal cuff, not any specific method of epithelial closure. They concluded that as long as there is good restoration of vault suspension, vaginal length is not affected by the vertical versus horizontal orientation of the vaginal epithelial closure. If the cuff has been adequately suspended, the cuff closure is positioned toward the anterior vagina wall, leaving more depth to the posterior vaginal wall for accommodation of coitus.

Some investigators have recommended that the vaginal cuff be left open or a drain placed within the vaginal (closure) incision to reduce the morbidity of vaginal cuff cellulitis or abscess formation. With the widespread use of prophylactic antibiotics and the recognition that irrigation during a vaginal procedure is required, there is no longer any need for those techniques. In addition, leaving the cuff open may lead to an increased incidence of enterocele formation and vaginal vault prolapse.

The decision to place packing into the vagina postoperatively is an optional one. A vaginal pack need not be used after vaginal hysterectomy unless concomitant pelvic reconstructive surgery is performed. Complete hemostasis should be achieved after vaginal hysterectomy and prior to cuff closure. Significant postoperative bleeding will rarely occur from the single vascular pedicle on each side of a hysterectomy bed. If that type of bleeding does occur, it is important to become aware of this problem as soon as possible and vaginal packing will only delay the diagnosis and not prevent the problem. Vaginal packing compresses the vaginal walls much more effectively than the apex of the vagina where there is no structure against which packing may compress the vaginal tissues. It is important to be aware of postoperative bleeding sooner rather than later while the patient is still hemodynamically stable, so a pelvic arteriogram or surgical intervention can be performed early in the course of any such bleeding. The arteriogram may demonstrate the bleeding site and allow arterial occlusion, thus preventing the need for a return to the operating room or laparotomy.

For some surgeons, it is not routine practice to insert an indwelling transurethral catheter following the removal of a normal-size uterus. Removal of an enlarged uterus may cause occasional transient insult to the bladder and transient postoperative voiding problems; therefore, in such patients, bladder drainage is usually suggested, at least overnight.

Routine cystoscopy following vaginal hysterectomy significantly increases the incidence of recognition of both bladder and ureteral injury. Before cystoscopy, 5 mL of indigo carmine is administered intravenously by the anesthesiologist. Alternatively, a single tablet of Pyridium 200 mg can be administered prior to the start of the procedure. The strong efflux of blue or ochre dye through each ureteral orifice following hysterectomy with or without pelvic reconstruction implies the integrity of the ureters. Although this routine may not be absolutely necessary with each vaginal hysterectomy, it certainly makes the surgeon more comfortable and helps protect the patient from unacceptable consequences.

BEST SURGICAL PRACTICES

- Randomized controlled trials have demonstrated that women treated by vaginal hysterectomy experience lower morbidity, less pain, more rapid recovery, and a more rapid return to normal activities compared with abdominal, endoscopic, or laparoscopically assisted vaginal hysterectomy. They also consume fewer health care dollars and resources. Little evidence is available to compare robotic and vaginal surgeries.
- Using guidelines to determine the route of hysterectomy adopted by the National Guideline Clearinghouse, and with maximum development of surgical technique, it is feasible to perform 90% of hysterectomies for

benign disease indications via the vaginal route.

- Following the National Guideline Clearinghouse guidelines for selecting the route of hysterectomy, even for a resident training environment, has been shown to decrease the number of abdominal and consequently endoscopic hysterectomies.
- To minimize bladder and rectal injuries, the anterior and posterior peritoneum should always be entered under direct vision.
- The risk of ureteral injury can be minimized by retracting the bladder anteriorly at all times after completion of the dissection of the vesicocervical and vesicouterine spaces and dividing the cardinal ligament before cutting, clamping, or suturing in the anterolateral area above the cervix.
- The only vascular pedicle above the uterine vessels contains the round ligament, utero-ovarian ligament, and fallopian tube. These structures can generally be clamped in a single pedicle.
- Transvaginal removal of the ovaries at the time of vaginal hysterectomy should be technically feasible in more than 90% of patients.
- Following vaginal hysterectomy, the presence of preexisting pelvic support defects should be carefully evaluated and repaired if present. The vaginal vault should always be resuspended to the uterosacral ligaments.
